Superior detection of faces in male infants at 2 months

1   **Abstract**

2   Females generally attend more to social information than males; however, little is known about

3   the early development of these sex differences. With eye tracking, we measured 2-month-olds'

4   (N=101) social orienting to faces within 4-item image arrays. Infants, overall, were more likely

5   to detect human faces compared to objects, suggesting a functional face detection system.

6   Unexpectedly, males looked longer at human faces than females, and only males looked faster

7   and longer at human faces compared to objects. Females, in contrast, looked less at human faces

8   relative to animal faces and objects, appearing socially disinterested. Notably, this is the first

9   report of a male face detection advantage at any age. These findings suggest a unique stage in

10   early infant social development.

11

12   Sex differences in social interest and sensitivity appear across multiple levels, including

13   the brain, cognition, and behavior (Hines, 2011). Adult females are generally more socially

14   attentive (Cárdenas, Harris, & Becker, 2013; Hall, Hutton, & Morgan, 2010), better at

15   remembering faces (Rehnman & Helitz, 2007), and more empathetic than adult males (Christov-

16   Moore et al., 2014). Compared to adult males, adult females are also faster, more accurate, and

17   more automatic in their recognition of facial, vocal, and other nonverbal expressions (Kirkland,

18   Peterson, Baker, Miller, & Pulos, 2013; McClure, 2000; Schirmer, Simpson, & Escoffier, 2007;

19   Sokolov, Krüger, Enck, Krägeloh-Mann, & Pavlova, 2011).

20   Social competencies, like the ones listed above, are important from a young age. Such

21   competencies are positively associated with children's interpersonal successes in both personal

22   relationships and educational settings (Agostin & Bain, 1997; Connell & Prinz, 2002; Huitt &

23   Dawson, 2011). Children with poor social skills often struggle with peer rejection, low levels of

24   behavioral regulation, learning disabilities, and low achievement (Alexander, Entwisle, &

25   Dauber, 1993; Kavale & Forness, 1996; McClelland, Morrison, & Holmes, 2000). These studies

26   underscore the need to understand the genesis of individual differences in social abilities.

27   Many sex differences in sociability are present early in development. Within the first 3

28   days after birth, female neonates, compared to males, appear cuddlier (Benenson, Philippoussis,

29   & Leeb, 1999), maintain eye contact longer (Hittelman & Dickes, 1979), and orient more to

30   faces and voices (Connellan, Baron-Cohen, Wheelwright, Batki, & Ahluwalia, 2000). In the

31   first week after birth, female neonates also display more contagious crying, possibly an early

32   marker of empathy (Sagi & Hoffman, 1976), and higher rates of neonatal imitation, a purported

33   early social skill (Nagy, Kompagne, Orvos, & Pal, 2007). In later infancy, females continue to

34   look longer at faces at 6 and 12 months of age (Gluckman & Johnson, 2013; Lutchmaya &

Male infants' superior detection of faces   3

35   Baron-Cohen, 2002), and maintain eye contact longer at 3 and 12 months (Leeb & Rejskind,

36   2004; Lutchmaya, Baron-Cohen, & Ragatt, 2002). Infants' early preferences for and engagement

37   with social stimuli, such as faces, are theorized to be precursors for more complex social skills.

38   For instance, looking at faces, eye contact, and imitation are proposed to lay the groundwork for

39   the later development of joint attention, theory of mind, and more advanced communication

40   (Charman et al., 2000).

41   Despite a large body of convergent evidence that reports a female advantage in social

42   sensitivity in infancy (Simpson et al., 2016), a handful of studies report that, in some contexts,

43   males exhibit greater social sensitivity than females. For example, a study of mother-infant

44   interaction (i.e., face-to-face still-face paradigm) in 6-month-old infants reported that males,

45   compared to females, displayed more positive expressions and vocalizations, spent more time in

46   synchronous interactions, and looked longer towards their mothers; in contrast, females spent

47   more time engaging with novel objects (Weinberg, Tronick, Cohn, & Olson, 1999). Another

48   study reported that 6- to 8-month-old male infants looked longer at images of social groups than

49   females, which suggests that males may be more attentive to social complexity (Benenson,

50   Markovits, Muller, Challen, & Carder, 2007). In sum, these studies challenge the assumption that

51   females consistently show advantages in social interest and sensitivity and highlight the need for

52   further research on sex differences in early infancy, when social skills are swiftly emerging.

53   The first months after birth are a critical time in development. Infants at 2 months of age

54   experience rapid developments in their visual attention (i.e., looking behaviors, typically defined

55   by eye tracking measures or behaviorally coded live or from videos, based on where infants'

56   eyes are oriented), including the onset of smooth pursuit tracking (i.e., continuously following an

57   object without corrective saccades), attention towards internal features of patterns, and the ability

58   to detect stimuli in the nasal visual field (Johnson, 1990). As infants' visual systems mature, their

59   processing shifts from being primarily subcortical to more cortical (Morton & Johnson, 1991),

60   accompanied by improvements in visual acuity and attentional control. In addition to

61   developments in visual perception, at 2 months of age, faces are taking on new meaning, as

62   social interactions are becoming more complex (Lavelli & Fogel, 2005). New social skills are

63   forming, such as the emergence of social smiles (Wörmann, Holodynski, Kärtner, & Keller,

64   2012), growing sensitivity to social contingencies (Bigelow & Rochat, 2006; Soussignan, Nadel,

65   Canet, & Gerardin, 2006), and increasing attention to the eye-region of faces (Jones & Klin,

66   2013). Already by 2 months of age, infants are faster to orient to and attend longer to silent

67   dynamic social videos (e.g., people interacting), compared to nonsocial videos (e.g., high-

68   contrast spinning shapes), potentially reflecting greater attention capture and holding for social,

69   relative to nonsocial, stimuli (Maylott, Paukner, Ahn, & Simpson, 2020). At 2 months, infants

70   also display improvements in facial identity recognition (Johnson, 1990), facial expression

71   discrimination (Nelson, 1987), and face-voice cross-modal matching (Patterson & Werker,

72   2003). Additionally, 2-month-olds exhibit some adult-like face preferences (e.g., relying more on

73   structural than contrast information; Kleiner & Banks, 1987), and display experience-driven face

74   specialization (e.g., preferences for own-species' faces; Heron-Delaney, Wirth, & Pascalis, 2011;

75   Simpson, Maylott, Mitsven, Zeng, & Jakobsen, 2020), as well as brain activation in core face

76   perception regions, including the fusiform face area (Tzourio-Mazoyer et al., 2002). The wide-

77   ranging physical, cognitive, and psychosocial advances at 2 months underscore the importance of

78   studying this period of development.

79   Despite these remarkable perceptual and social changes at 2 months, infants' attention to

80   social stimuli at this age is relatively unexplored (Shultz, Klin, & Jones, 2018). To our

Male infants' superior detection of faces   5

81   knowledge, few studies have examined 2-month-olds' social attention to faces (for a review of

82   studies to date, see Table 1). The capacity to orient to a face in a complex visual environment is a

83   critical early social skill, enabling infants to learn from socially relevant information in their

84   environment (Capozzi & Ristic, 2018). With recent innovations, researchers can accurately track

85   young infants' eye gaze with remote infrared eye tracking, allowing for more spatial and

86   temporal precision than other methods (Oakes, 2012). Notably, 2 months is the earliest age, to

87   date, in which modern eye tracking has been used (Jones & Klin, 2013; Sifre et al., 2018); thus,

88   we are only beginning to understand infants' early visual abilities. Additionally, previous studies

89   typically present only one or two images at a time, which may not approximate real-world

90   demands on attention (Di Giorgio, et al., 2013; Gliga, Elsabbagh, Andravizou, & Johnson, 2009;

91   Gluckman & Johnson, 2013; Jakobsen, et al., 2016). However, with modern eye tracking, it is

92   now possible to present a greater number of stimuli at once, which enables researchers to

93   examine how infants allocate their attention when confronted with numerous items. Therefore,

94   contemporary eye tracking widens opportunities to further detect the nuances of infants' early

95   skills. Detailing infants' looking behavior in these ways will provide a baseline of healthy social

96   attention from which divergent trajectories may be identified (Telford et al., 2016), particularly

97   in the first 2-3 months after birth, a period of rapid and significant neurodevelopment (Bradshaw

98   et al., 2019).

99   Thus, we examined whether male and female 2-month-old infants demonstrate visual

100   biases—privileged capture and holding of eye gaze—to human faces. In a free-viewing eye

101   tracking task, infants observed a series of 4-item visual arrays (Figure 1), including our target of

102   interest, human faces, and control images of non-face objects and chimpanzee faces. We

103   predicted that 2-month-old infants would display overall attentional efficiency to human faces—

104   faster orienting to and longer looking at human faces than non-face objects—and that these

105   abilities would be modulated by infant sex (Gluckman & Johnson, 2013). Given that few studies

106   have examined sex differences in social attention during the first year after birth, and no previous

107   well-powered studies have examined sex differences in social attention at this age (2 months),

108   we based our hypothesis on studies in older infants. Therefore, we predicted that females would

109   be more socially attentive than males. In addition, although there's limited evidence of own-

110   species bias (i.e., privileged processing of conspecifics relative to heterospecifics) before 6

111   months of age (Jakobsen et al., 2016; Scott & Fava, 2013), we hypothesized that a subtle own-

112   species bias might be detectable using eye tracking, given its greater accuracy than manual

113   coding (Gredebäck, Johnson, & von Hofsten, 2009; Oakes, 2012). We, therefore, predicted

114   infants' greater attentional efficiency to human faces relative to chimpanzee faces.

115

116   **Methods**

117   The Institutional Review Board for Human Subject Research [Blinded for review]

118   approved this study.

119   *Participants*

120   We recruited families with 2-month-old infants ($N = 101$; 44 females) from [Blinded for

121   review] through community events (e.g., baby fairs, maternity centers) and advertisements (e.g.,

122   Facebook, flyers in public libraries). One or both parents spoke English. Families were invited to

123   participate when their infant was 2 months (51-69 days) of age ($M = 61.13$ days, $SD = 6.40$

124   days). Infants were healthy, full-term ($\geq$37 weeks of gestation, with the exception of two sets of

125   twins, who were given a more lenient gestation of >35 weeks because twins are often born

126   sooner than singletons), and had normal vision (see Supplementary Methods for detailed

Male infants' superior detection of faces　　　　　　　　　　　　　　　7

127　　participant demographics). Data from a subsample of these infants ($n = 55$) were previously

128　　published as part of a larger longitudinal study, examining the influence of head and eye

129　　orientations on infants' face detection (Simpson, Maylott, Mitsven, Zeng, & Jakobsen, 2020).

130　　The additional infants in our current sample enabled us to move beyond group level effects to

131　　focus on individual differences in infancy, an underexplored area (Pérez-Edgar, Vallorani, Buss,

132　　& LoBue, 2020).

133　　*Materials*

134　　　　　　Infants viewed a series of 16 circular arrays, each with 4 images (see examples in Figure

135　　1), in one of two semi-random orders, on a remote 58.4 cm monitor (51 cm in width by 28 cm in

136　　height) with integrated dark pupil eye tracking technology and a sampling rate of 300 Hz. We

137　　remotely tracked infants' eye gaze via corneal reflection using a Tobii TX300 eye tracker. Each

138　　array contained either a human face ($n = 8$ arrays) or a chimpanzee face ($n = 8$ arrays), and all

139　　arrays included three non-face objects.

140　　　　　　Faces were upright with neutral expressions and visible, open eyes, as well as visible

141　　noses and mouths. Faces included males and females and were of various ages (e.g., young and

142　　old adults) and ancestries. The faces systematically varied in their attentional states, with half of

143　　the faces (8 arrays) oriented with direct-gaze (i.e., eye-contact) and half (8 arrays) with averted

144　　gaze (i.e., eyes/head oriented away at approximately 45°) to examine infants' attention to

145　　specific head and eye orientations (Simpson et al., 2020). While the inclusion of faces with

146　　averted gaze likely made the task more challenging, given infants' early preferences for eye-

147　　contact (Gliga & Csibra, 2007; Guellaï et al., 2020), it also made the faces more naturalistic, as

148　　infants often encounter people in their everyday lives who are not looking at them. We balanced

149　　these orientations across chimpanzee and human faces, such that half of each species oriented

150   towards and half oriented away. Faces had little makeup or accessories. We counter-balanced

151   face locations across conditions (species, orientation), to ensure each face type was equally likely

152   to appear in all locations. The non-face images were common manufactured objects (i.e., chairs,

153   cars) and natural items (i.e., flowers).

154   Each colored image was 180×180 pixels (4.76×4.76 cm; $6.48 \times 6.48°$) and was equally

155   spaced in circular arrays, equidistant from the center. We collected images through internet

156   searches and positioned them into arrays using GNU Image Manipulation Program (GIMP;

157   https://www.gimp.org/) and Microsoft PowerPoint. To ensure novelty, each image appeared only

158   once. For all arrays, we chose heterogeneous images, instead of matching images on low-level

159   features, to retain the natural details of each stimulus (e.g., keeping images in color instead of

160   converting to grayscale; Hershler & Hochstein, 2005; Jakobsen et al., 2016). Additionally, we

161   used the Saliency Toolbox to analyze the arrays for differences in low-level salience—low-level

162   features, such as contrast or brightness—that may cause an image to stand out from the rest

163   (Gluckman & Johnson, 2013; Ho-Phuoc, Guyader, & Guérin-Dugué, 2010). This analysis

164   revealed that the non-face objects, not the faces, were the most salient images within each array,

165   for both human arrays ($t(15) = 5.61$, $p < .001$, $d = 2.12$) and chimpanzee arrays ($t(15) = 6.76$, $p <$

166   .001, $d = 2.75$). There were also no differences in low-level salience between the human and

167   chimpanzee faces, ($t(15) = .212$, $p = .835$). A binomial test indicated that the proportion of trials

168   in which the faces were the most salient images within the arrays (.03) was lower than the

169   expected proportion of observing a face (.25, since ¼ of images were faces; $p = .001$), indicating

170   that faces were the most salient images within the arrays significantly less often than chance.

171   Together, these finding suggest that any human face detection efficiency found with these stimuli

172   is unlikely to be due to low-level features of the images. However, we should interpret these

173   findings cautiously given that the Saliency Toolbox is based on adult, and not infant, vision and

174   low-level features may be particularly salient for young infants, especially newborns (Simion et

175   al. 2007).

176   *Procedure*

177   We obtained caregivers' informed consent for infants' participation. We followed infant

178   eye tracking best practices (Hessels, Andersson, Hooge, Nyström, & Kemner, 2015; Wass,

179   Forssman, & Leppänen, 2014). Lighting was kept constant across infants, with overhead lights

180   turned on, and all people (i.e., experimenters or additional family members) in the room were

181   quiet and hidden from infants' view. We instructed caregivers not to speak or point to the screen

182   during testing, and all test sessions were videotaped with two Sony HDR-PJ540 Full HD

183   Handycam Camcorders to ensure these instructions were followed.

184   Testing took place when the infants were awake, alert, and calm. Infants who were sleepy

185   or fussy were given a break to nap, feed, or be changed as needed. Infants sat on their caregiver's

186   lap approximately 60 cm from the screen on which we presented the arrays (Figure 2A).

187   Before displaying the arrays, we calibrated each infant using five or more calibration

188   points in Tobii Studio's preset locations. There were no sex differences in calibrations (for more

189   information, see Supplementary Methods and Supplementary Results). After the calibration, a

190   central cartoon (from Tobii Studio's standard set; e.g., bird, cat, school bus) and music attracted

191   the infant's attention to the center of the screen for about 3 to 5 seconds before each array.

192   Because we were interested in infants' initial looking behaviors, each array was displayed for

193   only 10 seconds. Also, because of our interest in which images selectively captured infants' gaze

194   compared to other images in the array, we chose this length of time to ensure that infants had

195   enough time to look at some, but not all the images. In this passive-viewing task, infants were

196   free to look anywhere on or off the screen while the arrays were displayed. Infants viewed up to

197   16 arrays in each test session. We considered a trial complete if an infant produced at least one

198   fixation on one of the images in the array. A fixation was defined as occurring within a window

199   of 35 pixels for at least 100 ms; the end of a fixation was marked by a saccade (either within the

200   same AOI, to a different AOI, offscreen, or lost data). All fixations within each image were

201   counted towards the total look duration measure. Beyond this requirement, there was no

202   minimum fixation duration. An additional five infants were excluded from the sample due to no

203   fixations ($n = 3$; 1 female), fussiness ($n = 1$; female), or inability to track gaze ($n = 1$; male).

204   Infants completed an average of 12.38 trials ($SD = 3.67$, range 3-16).

205   In total, each test session lasted just under 4 minutes (without breaks, including

206   calibration). Parents completed demographic questionnaires, including information on infants'

207   date of birth, gestational age, and sex, as well as parents' education level, family income, and

208   ethnicity. Families were compensated $50.

209   *Measures*

210   We measured three independent but related types of looking behavior (Cohen, 1972): (1)

211   *Look latency* (eye gaze capture): the time from the start of the trial until the infants' first fixation

212   on each image, theorized to reflect attention capture (Kosinski, 2008), (2) *Look duration* (eye

213   gaze holding): the total time fixating on a stimulus, theorized to reflect both attention capture and

214   holding (Bronson, 1991; Simpson et al., 2014a; 2014b), and (3) *Detection*: proportion of trials

215   with at least one fixation on a stimulus, theorized to reflect attentional efficiency (Jakobsen et al.,

216   2016). We created areas of interest (AOIs) around each individual picture (faces and objects) and

217   extracted our measures from these regions (Figure 2B). The AOIs were 220 × 220 pixels (5.82 ×

218   5.82 cm; 7.80 × 7.80°), drawn slightly larger than the image to account for measurement error,

Male infants' superior detection of faces   11

219   based on a previous study of Tobii TX300 accuracy ([Blinded for review]; for method, see

220   Morgante et al., 2012). Our measures were extracted using Tobii Studio software (Tobii

221   Technology, Sweden) with the Tobii (default) filter, which defines fixations as occurring within

222   a window of 35 pixels for at least 100 ms. For look duration, if the infants looked at the array

223   but not at a specific image, they were assigned a zero for look duration to that specific image;

224   however, if there were no fixations on the array at all, we treated that trial as missing data. For

225   look latency, an infant had to produce a fixation to the AOI, otherwise it was treated as missing

226   data. Within each array, we computed an average for the non-face objects, as each array

227   contained three objects.

228   *Preliminary Analyses*

229   Preliminary analyses revealed no sex differences in data quality, calibration, overall

230   infant attentiveness, or infant/parent demographic variables (see Supplementary Materials).

231   There were no statistically significant interaction effects between infant sex and eye/head

232   orientations (direct vs. averted gaze) across the three dependent variables ($ps > .05$; for full

233   results see Supplementary Results).

234   *Analysis*

235   We conducted two 2×2 mixed-design analyses of variance (ANOVAs) for each

236   dependent variable—look latency, look duration, and detection—for six total ANOVAS. Each

237   ANOVA included the between-subjects variable of infant sex (male, female). The first set of

238   ANOVAs explored the repeated measures variable of image type (human faces, non-face

239   objects) and the second set of ANOVAs explored the repeated measures variable of species

240   (humans, chimpanzees). We used non-face objects from the chimpanzee arrays as the control

241   objects when comparing objects to human faces, as to not violate the assumption of

242 independence in the ANOVA (see Primary Data Analysis section in Supplementary Material for

243 more information). We conducted *t*-tests to explore statistically significant interactions.

244 *Data Availability*

245   The datasets analyzed during the current study are available from the corresponding

246 author on reasonable request.

247

248 **Results**

249 *Look Latency*

250   We measured how quickly infants looked at each type of image. We found no main

251 effects of stimulus type (human face, non-face object; $F(1, 92) = .03$, $p = .859$) or infant sex

252 $(F(1, 92) = .61$, $p = .633)$. However, there was a stimulus type × infant sex interaction (Figure

253 3A; $F(1, 92) = 9.59$, $p = .003$, $\eta_p^2 = .09$). While female infants looked faster at non-face objects

254 $(M = 2.85$ sec, $SD = 1.25)$ than human faces $(M = 3.40$ sec, $SD = 1.95$; $t(40) = 2.03$, $p = .049$, $d =$

255 .45), male infants looked faster at human faces $(M = 2.92$ sec, $SD = 1.68)$ than non-face objects

256 $(M = 3.58$ sec, $SD = 1.51$; $t(52) = 1.97$, $p = .022$, $d = .42)$. We detected no difference in male and

257 female look latency within human faces $(t(93) = 1.30$, $p = .196)$; however, we did find that

258 females were faster to look at non-face objects than males $(t(97) = 2.58$, $p = .011$, $d = .53)$. There

259 were no other statistically significant effects, $ps > .10$. See Supplementary Table 2 for details.

260   We found no main effect of species (human face, chimpanzee face; $ps > .05$) nor did we

261 detect a species × infant sex interaction $(ps > .05$; Supplementary Table 1).

262 *Look Duration*

263   We measured how long infants looked at each type of image. We found no main effects

264 of stimulus type (human face, non-face object; $F(1, 93) = .19$, $p = .664$) or infant sex $(F(1, 93) =$

Male infants' superior detection of faces   13

265   3.14, p = .080); however, there was a stimulus type × infant sex interaction (Figure 3B; $F(1,93)$ =

266   16.26, p < .001, η_p^2 = .15). Male infants looked longer at human faces (M = 1.05 sec, SD = .88)

267   than female infants (M = .56 sec, SD = .51; $t(95)$ = 3.19, p = .002, d = .68). Further, male infants

268   looked longer at human faces than non-face objects (M = .73 sec, SD = .49; $t(53)$ = 3.08, p =

269   .003, d = .41). In contrast, female infants looked longer at non-face objects (M = .86 sec, SD =

270   .65) than human faces ($t(40)$ = 2.83, p = .007, d = .40). There were no other statistically

271   significant differences (see Supplementary Table 2 for details).

272   While we found no main effect of species (human face, chimpanzee face; ps > .05;

273   Supplementary Table 1), there was a species × infant sex interaction ($F(1, 93)$ = 7.32, p = .008,

274   η_p^2 = .07). Although female infants looked longer at chimpanzee faces (M = .91 sec, SD = .78)

275   than human faces (M = .56 sec, SD = .51; $t(39)$ = 2.86, p = .007, d = .52), we detected no

276   difference in look durations between chimpanzee faces and non-face objects ($t(42)$ = .39, p =

277   .700), meaning that female infants looked the most at chimpanzee faces and non-face objects and

278   looked the least at human faces (Supplementary Figure 2). Male infants showed no difference in

279   look duration across species (ps > .05; Supplementary Table 2); however, male infants looked

280   longer at chimpanzee faces than non-face objects ($t(55)$ = 2.39, p = .020, d = .32), suggesting that

281   faces in general may hold male infants' gaze longer than objects.

282   *Detection*

283   We measured how likely infants were to look at each type of image. We found a main

284   effect of stimulus type, in which infants, overall, were more likely to detect human faces than

285   non-face objects (Supplementary Figure 1; $F(1, 99)$ = 6.83, p = .010, η_p^2 = .07). We detected no

286   main effect of infant sex ($F(1, 99)$ = .08, p = .782) nor did we detect any stimulus type × infant

287   sex interaction ($F(1, 99)$ = .04, p = .840). For additional results, see Supplementary Table 2.

288   Additionally, we found no main effect of species (human face, chimpanzee face; *ps* >

289   .05) nor did we detect a species × infant sex interaction (*ps* > .05; Supplementary Table 1).

290

291   **Discussion**

292   Attending to social partners in infancy is a foundational early capacity that enables

293   healthy social development (Capozzi & Ristic, 2018; Sclafani et al., 2016). However, social

294   attention in the first months after birth, beyond the newborn period, has been largely unexplored.

295   We addressed this gap by using eye tracking to measure whether 2-month-old infants rapidly

296   detect and look longer at human faces compared to non-face objects and animal faces, when

297   presented in four-item visual arrays. We found that infants, overall, were more likely to detect

298   human faces compared to objects, suggesting a remarkably early functional face detection

299   system. We also found a male advantage in face attention capture and holding at this age. The

300   first months after birth may reflect a unique stage of early infant social development.

301   Contrary to previous reports of female advantages in social attention from birth to one

302   year of age (Gluckman & Johnson, 2013; Leeb & Rejskind, 2004; Lutchmaya & Baron-Cohen,

303   2002; Lutchmaya, Baron-Cohen, & Raggatt, 2002), we found that male infants, but not female

304   infants, looked faster and longer at human faces compared to non-face objects. Male infants also

305   looked longer than female infants at human faces. Interestingly, female infants, unlike male

306   infants, spent the *least* amount of time looking at human faces, attending more to chimpanzee

307   faces and objects. For 2-month-old female infants, human faces did not appear to have the same

308   attention holding qualities that they had for male infants. Further, these findings suggest that, not

309   only do male infants attend more to human faces relative to other images, but female infants

310   attend *less* to human faces relative to other images. Whether females are avoiding human faces

Male infants' superior detection of faces   15

311   or are simply *less* socially interested remains to be determined. Indeed, on the surface, social

312   shyness can be difficult to disentangle from social disinterest (Coplan et al., 2004) or heightened

313   nonsocial interest (Gale et al, 2019); yet, these distinct motivational differences need to be

314   distinguished to improve social engagement (Koegel et al., 2014).

315   The present study is the first, to our knowledge, to document a male advantage in social

316   attention at 2 months of age. In addition, we observed these sex differences in both attention

317   capture—reflected by faster look latencies—and attention holding—reflected by longer look

318   durations—suggesting male infants, at 2 months, have specialized processing of human faces

319   across multiple interrelated attentional systems (Cohen, 1972). Our findings highlight the

320   importance of studying social attention in the second month after birth—a period of rapid

321   perceptual, cognitive, and social development (Bradshaw et al., 2019; Johnson, 1990; Lavelli &

322   Fogel, 2005; Tzourio-Mazoyer et al., 2002)—and emphasize the significance of considering

323   individual differences in infant attentional patterns to multi-image stimuli, even at this very

324   young age (Maylott et al., 2020; Simpson et al., 2020; Wass & Smith, 2014).

325   Because our findings diverged from the more commonly reported female advantages in

326   social attention, we examined a number of other factors that could potentially explain our

327   findings (e.g., gestational age, birth weight; data quality, overall attentiveness); however, we

328   found no sex differences in any other factors (see supplementary materials, including

329   Supplementary Table 3). In sum, it seems unlikely that these factors can account for our findings.

330   While caution is warranted given the quasi-experimental nature of the study, we nonetheless

331   think our findings may reflect a true sex difference at 2 months of age.

332   One interpretation of our findings is that males may exhibit the same patterns in social

333   attention that females display, but may do so later than females (Barbu, Cabanes, & Le Maner-

334   Idrissi, 2011). In other words, the male advantage we found may reflect a deferred social

335   preference. A similar finding has been reported in older children: Females engage in associative

336   play (3-4 years), cooperative play (4-5 years), and social interactions with peers (5-6 years)

337   systematically earlier than males of the same age; as females move on to develop other complex

338   social skills, males display more associative play (4-5 years) and cooperative play (5-6 years)

339   than females of the same age (Barbu et al., 2011). In our study, females may no longer display a

340   strong social preference at 2 months as they did when they were newborns (Connellan et al.,

341   2000) because they have already moved on to develop other advanced social abilities (e.g.,

342   attending more to dynamic or socially responsive faces). This pattern of development is also seen

343   in emotion regulation, with female infants, from 3 to 4 month of age, and male infants at 6

344   months of age, displaying the same emotion regulation strategy, demonstrating more distress and

345   negative emotions during a still face interaction with their caregiver (Mayes & Carter, 1990;

346   Weinberg et al., 1999); while female infants at 6 months of age begin employing social

347   avoidance (e.g., looking away from their caregiver) to regulate their emotions (Weinberg et al.,

348   1999).

349   However, there are alternative or additional interpretations as well. For instance, during

350   the initial months after birth, infants' social attention is theorized to be driven primarily by

351   subcortical mechanisms that are automatic, rather than consciously controlled (Johnson,

352   Dziurawiec, Ellis, & Morton, 1991; Johnson, Senju, & Tomalski, 2015; Morton & Johnson,

353   1991; Salley & Colombo, 2016). After the first months of life, infants' social attention shifts,

354   becoming more cortically-based, and reflecting more endogenous social orienting. Johnson et al.

355   (1991) theorized that, during this maturation from subcortical to cortical functioning, the pre-

356   established, subcortical, automatic social attention may be disrupted, inhibiting automatic

Male infants' superior detection of faces   17

357   preferential social attention during this time, with social attention remaining lessened until

358   attention to faces via more cortically controlled processes are strengthened. Our results may

359   reflect this temporary disruption of social attention in female infants due to an earlier shift to

360   more cortically-based attention, while male infants' attention may be less mature, still reflecting

361   automatic, exogenous orienting to faces at 2 months.

362   Another potential interpretation of our findings is that males are more socially attentive

363   than females at this age, not due to a trailing social or attentional trajectory, but because they

364   have differential early experiences. Male infants' heightened social attention at 2 months may be,

365   at least in part, due to differential interactions with caregivers (Fausto-Sterling, Coll, & Lamarre,

366   2012). For instance, caregivers attend to male neonates more than females at 3-weeks of age.

367   Males receive more parental physical contact, stimulation, and gaze, while females receive

368   comparably less attention (Moss, 1967). However, for male infants, this high rate of caregiver

369   attention seems to decline with age. By 3 to 6 months of age, female infants are more often

370   looked at, imitated, and spoken to by their caregiver than male infants (Lewis, 1972; Moss,

371   1967). By 2 months of age, male infants are receiving less parental attention than what they were

372   accustomed to, and as a result, may be more attuned to disruptions in social contact. For

373   example, in a mother-infant interaction paradigm (i.e., face-to-face still-face) at 6 months of age,

374   males spent proportionately more time engaging with their mothers, and were more distressed

375   when mothers stopped responding, often producing more intense negative responses and

376   attempts to reengage their mothers in the social interaction (Weinberg et al., 1999). Furthermore,

377   male infants' eye gaze towards social, relative to nonsocial, toys (e.g., dolls vs. cars) declines

378   with age between 6 and 20 months, modulated by parental attitudes about gender norms (Liu,

379   Escudero, Quattropani, & Robbins, 2020). Together, the current study and previous findings

Male infants' superior detection of faces   18

380   expose the developmental complexity of sex differences. An overarching female advantage may

381   be an oversimplified view of early infant social development.

382   Considering disorders with disruptions in social development, such as autism spectrum

383   disorder (ASD), which is four times more common in males than females (Constantino, 2017;

384   Baron-Cohen et al., 2011; Jones & Klin, 2013), it is important to carefully document the

385   different trajectories of males and females in infancy. While our findings of stronger social

386   attention in males compared to females could signify a dysfunction or unhealthy pattern of

387   attention in males, it may be adaptive for infants to develop different phenotypes that best suit

388   their environments (Dufty et al., 2002). Drawing parallels between social disorders and the

389   present findings, therefore, should be done with this limitation in mind.

390   The present study is limited by our testing of only one age group. Ideally, a longitudinal

391   design would track infants' social attention from birth through the first year of life or beyond, to

392   determine whether male infants are delayed in their social trajectories relative to females, or to

393   see if these sex differences are stable with age. Unfortunately, eye tracking technology has not

394   been successfully used, to our knowledge, in human infants younger than 2 months of age.

395   Therefore, studies that precisely track newborns' attention to multiple concurrently presented

396   stimuli remain difficult without further technological advancements. Nonetheless, researchers

397   could follow infants beyond 2 months, to determine the developmental epochs in which male or

398   female infants increase or decrease in social attentiveness. Additionally, we were limited in our

399   analytic approach, and could not compare gaze behavior to images within each array without

400   violating the assumption of independence. It should be noted that looking behavior to each item

401   may vary based on the competing stimuli, as reported in adults (Simpson et al., 2014a; 2014b).

402   Further, our stimuli, while including multiple images, were not dynamic or multimodal, which

Male infants' superior detection of faces   19

403   are qualities that also increase social attention (Kittler et al., 2020; Maylott et al., 2020). Our

404   stimuli were, therefore, less engaging. Social attentiveness in more varied, real-world contexts

405   will, therefore, be another important future direction.

406   Despite these limitations, this study makes novel contributions to the field of

407   developmental science. First and foremost, this is the first study to find greater attentiveness to

408   faces in males, challenging the widely-held view that females are more attentive to faces. It is

409   also one of only a few studies to use eye tracking in 2-month-old infants to measure attention to

410   multi-image visual stimuli (i.e., presenting more than two items at a time). The increased spatial

411   and temporal precision afforded by remote eye tracking offers a powerful way to unobtrusively

412   monitor early infant attention. This approach enabled us to find that, already by this early age,

413   infants, overall, show greater detection of human faces relative to objects. Our findings suggest

414   that, while infants overall may show an impressive early functional face detection system, male

415   infants appear to specialize in processing human faces. These findings might at first seem

416   surprising, and in contrast to findings at other ages; however, there are few other studies of face

417   detection at this age. More developmental studies during this important transitional age are

418   needed. Prospective research should utilize high-powered, longitudinal designs to better

419   understand the complex influences of sex and early experiences on individual differences in

420   social interest over the course of development.

421   As we look to the future, the goal of examining sex differences in social attention is not

422   simply to determine the causes of such differences, but to understand the malleability of these

423   capacities and the extent to which we can improve social competencies (Hines, 2020; Moore,

424   2012). Individual differences in infants' social interest have wide-ranging developmental

425   consequences, impacting not only social communication (Morales et al., 2000), but also

426   opportunities for learning (Charman et al., 2000; De Klerk, Gliga, Charman, Johnson, & BASIS

427   team, 2014). Early developmental plasticity may enable interventions to improve infants' social

428   attention, with downstream consequences for later social skills (Kasari, Freeman, Paparella,

429   2006; Minar & Lewkowicz, 2018). Ultimately, as modern societies evolve to become more

430   gender equitable, children's early experiences may help reduce any inborn differences in social

431   development, allowing all children to reach their full potential.

661

662   **Table 1**. Previous studies of face attention capture and holding (i.e., eye gaze capture and

663   holding) in infants. These studies used a modified visual search (e.g., passive-viewing with 4- to

664   25-item arrays) with typically developing human infants. Sample sizes (*n*) are reported next to

665   each age tested. All the studies reported here compared visual attention (eye gaze) to human and

666   animal faces and bodies (Target Types) to various non-face objects. Trials are the minimum,

Male infants' superior detection of faces
33

667   maximum, or average number of arrays presented, and Images are the number of images (items)

668   per array. Trial duration is the length of each array presentation. Attention capture refers to the

669   latency to fixate on the target or the proportion or percentage of first looks to the target, out of

670   the total number of first looks to all items. Attention holding refers to the duration or the number

671   of fixations produced while looking at the target. Null represents null results, while "Pos" stands

672   for positive (statistically significant) results. The final column denotes if the study reported a sex

673   differences (F = female; M = male). Only one study reported a sex difference (top row).
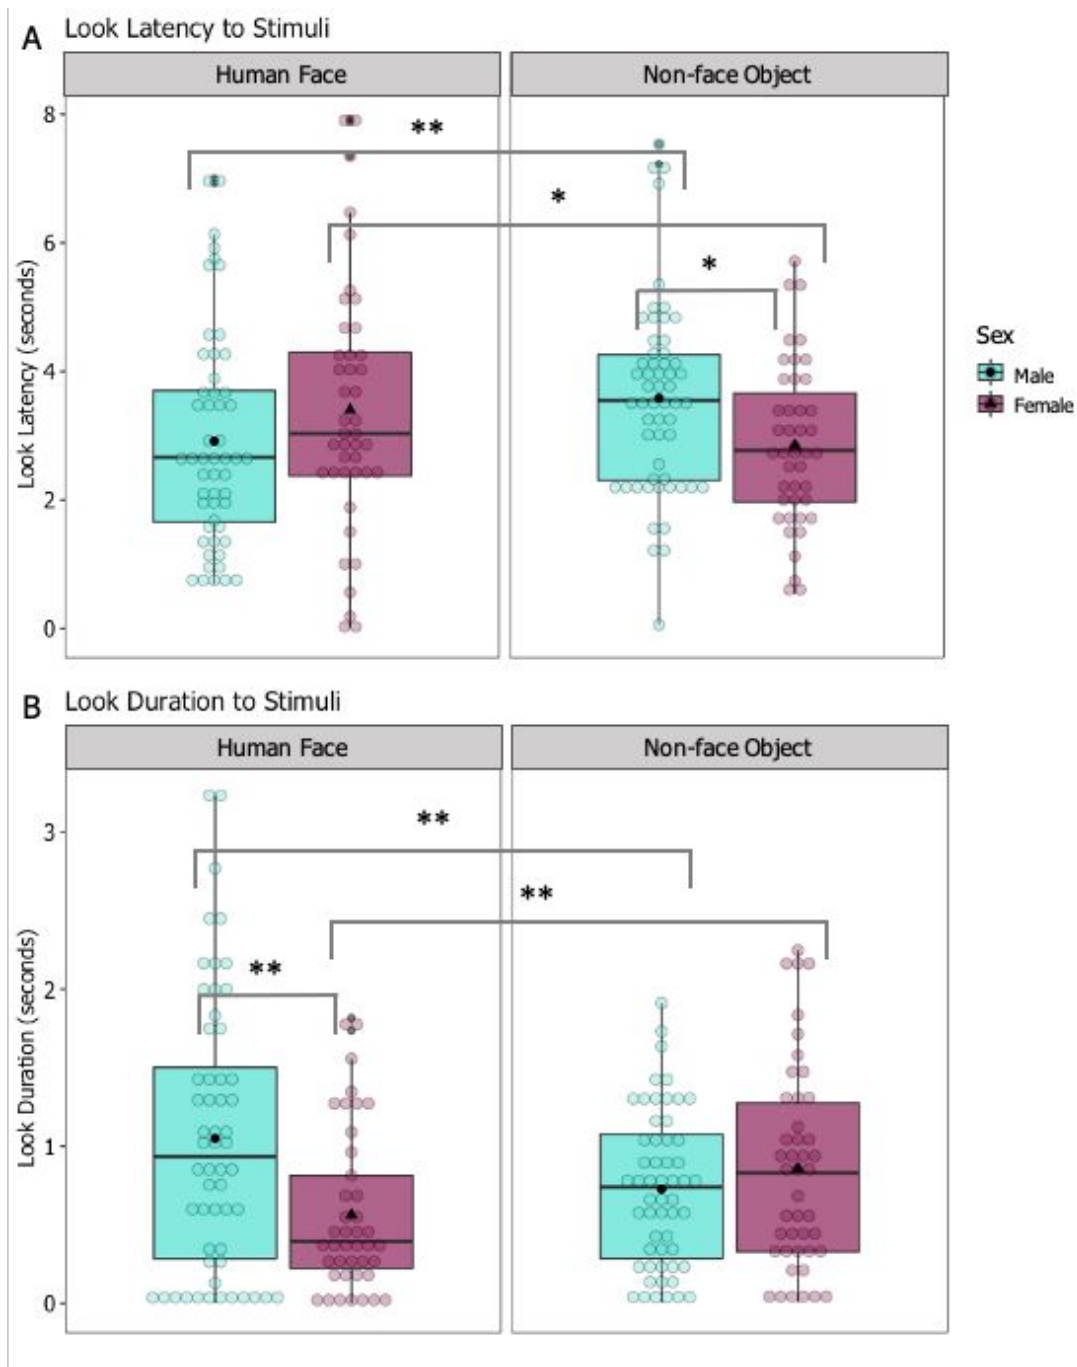

674

Figure 2. (A) Experimental set-up. Infants sat in their caregiver's lap at eye-level with the

screen. Video cameras monitored the infant and caregiver. (B) Areas of interest (AOIs) around

each image (faces and non-face objects). We extracted our dependent measures—look latency,

look duration, and detection—from these regions.

Male infants' superior detection of faces   36

684

685   **Figure 3.** Male infants (light blue; circles) looked faster (A) and longer (B) to human faces (left

686   column) than non-face objects (right column), and longer to human faces than female infants

687   (dark purple; triangles). In contrast, female infants looked slower (A) and a shorter amount of

688   time (B) to human faces compared to non-face objects, *ps* < .05, ***ps* < .01. Boxes represent

Male infants' superior detection of faces
37

689   the interquartile range, and whiskers represent error, which is measured as 1.5 times the

690   interquartile range. Horizontal lines within the boxes represent the medians, and points within

691   the boxes represent the means. Black points outside of the boxes represent outliers (for more

692   information see supplemental material). Colored circles represent raw data points, binned to

693   demonstrate the size of the sample, as well as the spread of the data.

S1

1   **Supplementary Information Text**

2

3   **Supplementary Methods**

4   **Participants.** Infants were 65% Caucasian, 17% Black or African-American, 1%

5   American Indian/Alaska Native, Asian, Native Hawaiian or Pacific Islander, 1% Black or

6   African-American and Asian, 1% Black or African-American and Caucasian, 5% American

7   Indian/Alaska Native and Caucasian, 1% Asian and Caucasian, 1% Black or African-American,

8   Caucasian, American Indian/Alaska Native, and Native Hawaiian or Pacific Islander, 1% Asian,

9   Caucasian, and unknown, 2% American Indian/Alaska Native, Asian, Native Hawaiian or

10   Pacific Islander, and unknown, and 5% unknown. More than half of the infants were Hispanic or

11   Latino (59.4%). Parents (both mothers and fathers) had an average education level of a 2-year

12   college degree. For mothers, 6% had a high school level education, 19% attended some college,

13   9% had a 2-year college education, 31% had a 4-year college education, and 35% had an

14   advanced level of education. For fathers, 2% had less than a high school level education, 23%

15   had a high school level education, 13% attended some college, 10% had a 2-year college

16   education, 29% had a 4-year college education, and 23% had an advanced level of education.

17   Parents had an average household income between $40,000 and $50,000 (USD). Four percent of

18   parents had an income between $5,000-$9,999 a year, 4% had an income between $10,000-

19    $19,000, 7% had an income between $20,000-$29,000, 10% had an income between $30,000-

20    $39,000, 3% had an income between $40,000-$49,000, and 72% had an income over $50,000. In

21   sum, our sample was racially, ethnically, educationally, and economically diverse for [city

22   Blinded for review].

Sex differences in face attention   S2

23   **Calibration.** There is no agreed upon method for calibrating infants (Oakes, 2012),

24   particularly very young infants who are notoriously difficult to calibrate (Aslin & McMurray,

25   2004; Oakes, 2010). Therefore, in the spirit of full transparency, we report all our

26   methodological choices and make our data fully available for others to use different

27   inclusion/exclusion criteria as they choose to improve replicability (Bakker & Wicherts, 2014;

28   Davis-Kean & Ellis, 2019; Gennetian et al., 2020).

29   We calibrated each infant using at least five calibration points to Tobii Studio's preset

30   locations. Infants looked at each dynamic, colored image as it flashed to at least five different

31   locations on the black calibration screen. If we were unable to successfully calibrate an infant,

32   the calibration was repeated, and if still unsuccessful, we used a calibration from another 2-

33   month-old ($n = 11$ males; $n = 12$ females). Although not ideal, this is an approach that enables us

34   to reduce the amount of missing data, due to the difficulty of obtaining eye tracking data from 2-

35   month-old infants. Therefore, we retained all participants and followed best-practices for data

36   disclosure (Carter & Luke, 2020), which may help reduce the Type 1 error rate (Bakker &

37   Wicherts, 2014), and allow for more transparency, increasing study replicability (Gennetian,

38   Tamis-LeMonda, & Frank, 2020). To ensure this approach did not negatively impact the quality

39   of our data, these sessions with failed calibration were individually checked (i.e., looks were

40   manually inspected and looking behaviors were coded, frame-by-frame, from video). Visual

41   inspection of playback revealed high enough data quality for inclusion (i.e., infants' points of

42   fixation were clearly within the target image areas of interest during playback). In a separate

43   project we further compared infants with and without personalized calibrations, at this age and

44   later ages, and found no differences accuracy ([Blinded for review]).

45   **Data Quality Analysis.** As an additional check of data quality, for comparison's sake,

46   we ran the main analyses comparing human faces to objects with only individually-calibrated

47   infants (i.e., who had their own calibrations) and found the same results: For look latency, we

48   found no main effects of stimulus type (human face, non-face object; ($F(1, 72) = 1.77$, $p = .187$)

49   or infant sex ($F(1, 72) = .02$, $p = .888$). However, there was a statistically significant stimulus

50   type × sex interaction ($F(1, 72) = 10.83$, $p = .002$, $\eta_p^2 = .13$). Look durations revealed no main

51   effects of stimulus type ($F(1, 75) = .87$, $p = .355$) or infant sex ($F(1, 75) = .77$, $p = .384$);

52   however, there was a stimulus type × infant sex interaction ($F(1, 75) = 5.24$, $p = .025$, $\eta_p^2 = .07$).

53   Finally for detection, we found a main effect of stimulus type, in which infants were more likely

54   to detect human faces than non-face objects ($F(1, 75) = 6.20$, $p = .015$, $\eta_p^2 = .08$). We detected

55   neither a main effect of infant sex ($F(1, 75) = .03$, $p = .863$), nor any stimulus type × sex

56   interaction ($F(1, 75) = .16$, $p = .691$). Given that these results are the same as the results with all

57   of the infants included (even those without their own calibrations), we opted to include all

58   infants.

59   **Primary Data Analysis.** Because we used chimpanzee face images and non-face object

60   images from the chimpanzee arrays (control) to compare infant attention to human face images,

61   we were unable to run an overall ANOVA in one analysis that included all of our variables

62   (image type and species) because that would violate the independence assumption (Kenny &

63   Judd, 1986). That is, both control variables were located in the same array, therefore, attention to

64   one was not independent of attention to the other. Therefore, explored each of our variables of

65   interest (image type and species) in separate ANOVAs for each dependent measure.

66   **Preliminary Data Exploration, Preparation, and Analysis.** Data were visualized using

67   R version 3.4.4 and Rstudio version 1.1.423 and analyzed using IBM SPSS Statistics Version 24.

Sex differences in face attention   S4

68   Before running our main analyses, we examined descriptive statistics, and checked data for

69   normalcy assumptions. Specifically, we assessed kurtosis and skewness of our continuous

70   independent and dependent variables, visualizing the data with histograms.

71   Further, within each sex and between infants, we removed trials (a presentation of one

72   array) in which an infant's looking (duration or latency) at each type of stimulus was more than

73   2.5 standard deviations from the group mean of each dependent variable. This resulted in the

74   combined exclusion of less than 1% of the data (.007%). When we removed these outlier trials

75   from one dependent variable, we retained inliers for the other two dependent variables for those

76   trials. More specifically, for look duration, only four trials (1 male; 3 females) were removed

77   from the human stimuli, only two trials (1 male; 1 female) were removed from the chimpanzee

78   stimuli, and only two trials (2 males) were removed from the object stimuli. For look latency,

79   one trial (1 male) was removed from the human stimuli, and two trials (1 male; 1 female) were

80   removed from the object stimuli. There were no outliers in the detection measure. We also

81   analyzed demographic data and found no sex differences (Table 1).

82
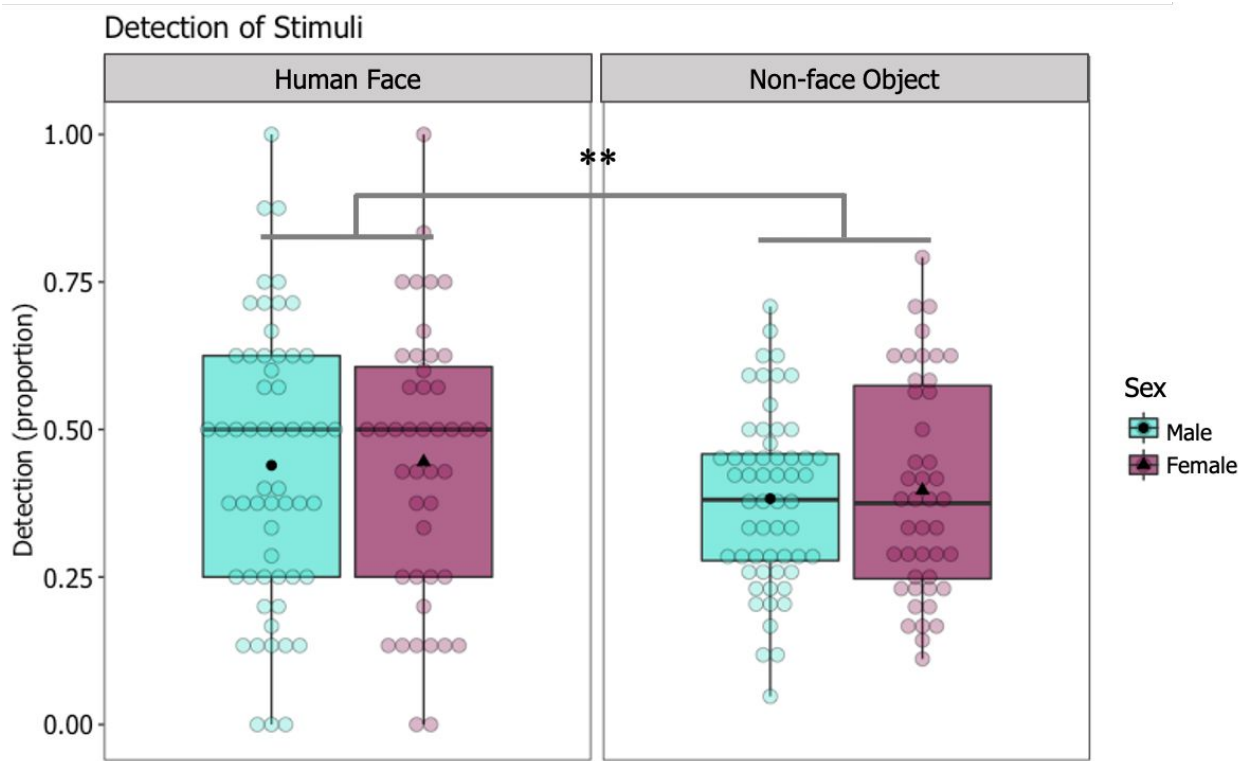

83   **Supplemental Results**

84   **Data Quality**. Using a multi-faceted approach, we explored whether there were

85   differences in the data quality between male and female infants, an important factor to consider,

86   when group differences are observed (Wass, Forssman, & Leppänen, 2014). We found no

87   differences in data quality. First, we measured infants' overall attention to the screen—the total

88   fixation duration (seconds) to any location on the screen across the full stimuli presentation.

89   There were no differences in attention between males ($M = 40.03$, $SD = 20.29$) and females ($M =$

90   40.48, $SD = 23.21$; $t(99) = .103$, $p = .918$). Further, there were no differences in total looking to

91   individual arrays between males ($M = 5.46$, $SD = 2.29$) and females ($M = 5.49$, $SD = 2.65$; $t(99)$

92     $= .08$, $p = .940$). Next, we evaluated the average number of images an infant looked at per array.

93   There were no differences in the number of images that males ($M = 3.00$, $SD = 1.19$) and females

94   ($M = 2.99$, $SD = 1.24$) looked at within each of the arrays ($t(99) = .004$, $p = .997$). We also

95   checked whether there were sex differences in the number of successful calibration points, but

96   there were no differences between males (left eye: $M = 5.28$ points, $SD = 2.31$; right eye: $M =$

97   5.04, $SD = 2.34$) and females (left eye: $M = 5.28$ points, $SD = 2.08$; right eye: $M = 5.56$, $SD =$

98   2.09), left eye: $t(76) = .003$, $p = .998$; right eye: $t(76) = 1.01$, $p = .318$. Next, we examined the

99   gaze sample percentage, which is calculated by dividing the number of eye tracking samples

100   with usable gaze data that were correctly identified, by the number of attempts. 100% means that

101   one or both eyes were found throughout the recording. 50% means that one eye or both eyes

102   were found for half of the recording duration. Therefore, if the infants' eyes were not found (e.g.,

103   were off-screen) for a portion of the time the stimulus was displayed, it was reflected by a lower

104   gaze sampling percentage. This gaze sampling percentage, therefore, reflects a combination of

105   both time looking away and time looking but in which looks were not detected by the system

106   (misses). The gaze sample percentage did not differ between males ($M = 44.29\%$, $SD = 26.60$)

107   and females ($M = 39.27\%$, $SD = 24.85$), $t(99) = .968$, $p = .335$. Further, in a separate publication

108   we further assessed the accuracy of our eye tracker data at this age and later ages using a

109   previously established approach (Morgante et al., 2012), and found no sex differences (ps $> .05$;

110   [Blinded for review]). Together, these findings suggest that the spatial and temporal quality of

111   our eye tracking data appear to be comparable between male and female infants, and that the sex

112   differences observed in the present study are unlikely to be due to differences in data quality

113   between male and female infants.

114   **Face Stimulus Eye and Head Orientation.** While not the primary focus of the current

115   study, given that older infants appear sensitive to eye contact in studies of face detection

116   (Simpson et al., 2020), we confirmed that there were no main effects of face or eye orientation

117   (differing angles of the head and eyes, making eye-contact or not, for both human and

118   chimpanzee faces), nor were there any orientation × sex interaction effects. Specifically, for the

119   look latency human face and non-face object comparison, we found no effect of orientation (F(3,

120   42) = .46, p = .713) or orientation × sex (F(3, 42) = 1.04, p = .387). For the species look latency

121   (human face and chimpanzee face) comparison, we found no effect of orientation (F(3, 18) = .29,

122   p = .832), nor an orientation × sex interaction effect (F(3, 18) = .62, p = .612). For the look

123   duration human face and non-face object comparison, we found no main effect of orientation

124   (F(3, 177) = .1.51, p = .213), nor an orientation × sex interaction effect (F(3, 177) = .39, p =

125   .761). For the look duration species comparison, we found no main effect of orientation (F(3,

126   177) = .65, p = .586), nor an orientation × sex interaction effect (F(3, 177) = .48, p = .698). For

127   the detection measure comparing human face and non-face objects, we found no main effect of

128   orientation (F(3, 174) = 1.38, p = .252), nor an orientation × sex interaction effect (F(3, 174) =

129   .12, p = .946). For the detection measure comparing species, we found no main effect of

130   orientation (F(3, 174) = 2.51, p = .061) nor an orientation × sex interaction effect (F(3, 174) =

131   .58, p = .628). Given that we found no effect of eye or head orientation, we collapsed across

132   these variables in our primary analyses.

133   **Look Proportions**. To further test our hypotheses, we ran an additional analysis

134   examining the proportion of time infants spent looking at the stimuli (human faces, objects) in

135   each array, out of the total time spent looking at that array. This enabled us to explore infants'

136   relative attentiveness (gaze fixations) to the different stimuli, in addition to their absolute levels

137   of attentiveness (e.g., Geeraerts et al., 2019; Pyykkö et al., 2019; Tummeltshammer & Amso,

138   2018; Yu & Smith, 2013). We found that infants overall looked longer at human faces than non-

139   face objects ($F(1, 99) = 4.14$, $p = .045$, $\eta_p^2 = .04$), but this was qualified by a stimuli × sex

140   interaction ($F(1, 99) = 4.79$, $p = .031$, $\eta_p^2 = .05$). Female infants showed no statistically

141   significant difference in their looking proportions at human faces ($M = .13$, $SD = .11$) and objects

142   ($M = .13$, $SD = .06$; $t(43) = .12$, $p = .908$), while male infants looked proportionally more at

143   human faces ($M = .17$, $SD = .14$) than objects ($M = .12$, $SD = .06$; $t(56) = 2.97$, $p = .004$, $d = .47$).

144   We also found that there was no effect of species (human, chimpanzee; $F(1, 99) = .01$, $p = .944$)

145   or a species × sex interaction ($F(1, 99) = 2.55$, $p = .114$). These human and object findings

146   directly parallel our look duration findings, and suggest that even when examining individual

147   proportions, male infants show a social bias compared to female infants.

148

149 **Supplementary Figure 1.** Both male (light blue) and female (dark purple) infants were more

150 likely to detect human faces (left column) than non-face objects (right column), **$ps < .01$.

151 Boxes represent the interquartile range, and whiskers represent error, which is measured as 1.5

152 times the interquartile range. Horizontal lines within the boxes represent the medians, and black

153 points (circles and triangles) within the boxes represent the means (of males and females,

154 respectively). Colored circles represent raw data points, binned to demonstrate the size of the

155 sample, as well as the spread of the data.

Supplementary Figure 2. Male (light blue) infants looked longer than females (dark purple) at human faces (left column). Male infants also looked longer at human faces than non-face objects (middle column), and they looked longer at chimpanzee faces (right column) than non-face objects. Female infants, in contrast, looked less at human faces relative to both non-face objects and chimpanzee faces. Boxes represent the interquartile range, and whiskers represent error, which is measured as 1.5 times the interquartile range. Horizontal lines within the boxes represent the medians, and points within the boxes represent the means. Black outlined points outside of the whiskers represent outliers. Colored circles represent raw data points, binned to demonstrate sample size and data spread. *ps < .05, **ps < .01.

Sex differences in face attention S12

170 **Supplementary Table 2.** Follow-up independent and paired samples *t*-tests for Look latency

171 (top), Look duration (middle), and Detection (bottom). Infants who were inattentive (i.e., did not

172 produce any fixations to the images of interest) did not receive a response latency variable (i.e.,

173 were considered missing data); whereas inattention for Look duration was counted as zero

174 seconds, so long as there was at least one fixation to the screen. Therefore, sample size in the

175 analysis varied for Look latency. See data inclusion criteria for further details.

Sex differences in face attention S13

Sex Differences in Additional Variables

	Sex	Mean	SD	*t*-value	*p*-value
Gestational Age	Male	38.99	1.50	.94	.350
	Female	39.28	1.61		
Birth Weight	Male	3263.54	438.47	.95	.344
	Female	3182.52	394.50		
Age at Visit	Male	61.16	7.31	.05	.962
	Female	61.10	4.98		
Father Education Level	Male	2.87	1.58	1.58	.117
	Female	3.37	1.51		
Mother Education Level	Male	3.50	1.33	1.77	.080
	Female	3.95	1.20		
Household Income	Male	5.10	1.48	.76	.452
	Female	5.33	1.39		
Number of People per Household	Male	3.32	1.51	.09	.931
	Female	3.30	1.43		

176
177 **Supplementary Table 3.** Descriptive statistics and paired samples *t* tests examining sex

178 differences in demographic variables. Gestational age was documented in weeks, birthweight

179 was measured in grams, and age at the visit was measured in days. Parental education level was

180 assessed on a scale from 0 (less than a high school education) to 5 (advanced degree), household

181 income was assessed on a scale from 0 (less than $5,000) to 6 (over $50,000), and number of

182 people per household included any people living in the home with the infant (e.g., mother, father,

183 siblings).
