## Abstract

Relational parametricity was first introduced by Reynolds for System F. Although System F provides a strong model for the type systems at the core of modern functional programming languages, it lacks features of daily programming practice such as complex data types. In order to reason parametrically about such objects, Reynolds' seminal ideas need to be generalized to extensions of System F. Here, we explore such a generalization for the extension of System F by Generalized Algebraic Data Types (GADTs) as found in Haskell. Although GADTs generalize Algebraic Data Types (ADTs) — i.e., simple recursive types such as lists, trees, etc. — we show that naively extending the parametric treatment of these recursive types is not enough to tackle GADTs. We propose a tentative workaround for this issue, borrowing ideas from the categorical semantics of GADTs known as “functorial completion”. We discuss some applications, as well as some limitations, of this solution.

*Keywords:* Parametricity, Generalized Algebraic Data Types, Logical relations

---

## 1 Introduction

Relational parametricity [Rey83] is a key technique for reasoning about programs in strongly typed languages. It can be used to enforce invariants guaranteeing strong properties of programs, programming languages, and programming language implementations supporting parametric polymorphism. A polymorphic program is a program that can be applied to arguments and return results of different types; a parametric polymorphic program is a program that not only is polymorphic over *all* types, but is also defined by the same type-uniform algorithm regardless of the concrete type at which it is applied. Since parametric polymorphic programs cannot perform type-specific operations, the computational behaviors they can exhibit are actually quite constrained. Parametricity was originally put forth by Reynolds [Rey83] for System F [Gir72, Rey74], the formal calculus at the core of all polymorphic functional languages. It was later popularized as Wadler's “theorems for free” [Wad89], so-called because it allows the deduction of properties of programs in such languages solely from their types, i.e., with no knowledge whatsoever of the text of the programs involved. However, to get interesting free theorems, Wadler actually treats System F extended with built-in lists; indeed, most of the free theorems in [Wad89] are essentially naturality properties for polymorphic list-processing functions. It is easy to extend the techniques developed there for handling lists to non-list algebraic data types (ADTs). Parametricity for such types can then be used to derive not just naturality properties, but also results — such as proofs of type inhabitance and correctness of the program optimization known as *short cut fusion* [GLP93] — that go beyond simple naturality.

In his original formulation, Reynolds gives each type expression of System F a *relational interpretation* defined inductively. Each type expression  $\Phi$  with type variables  $\alpha_1, \alpha_2, \dots, \alpha_n$  thus gives, for each tuple  $\bar{R}$  of relations  $R_i$  between types  $A_i$  and  $B_i$ , a relation  $\widehat{\Phi} \bar{R}$  between the type  $\Phi[\bar{A}/\bar{\alpha}]$  and  $\Phi[\bar{B}/\bar{\alpha}]$ . To capture the intended type-uniformity of System F's polymorphic expressions, these relational interpretations are defined in such a way that every function  $f : \forall \bar{\alpha}. \Phi \rightarrow \Psi$ , where  $\Phi$  and  $\Psi$  are two type expressions in the same type variables  $\bar{\alpha}$ , is *parametric* in the following sense: for each tuple of relations  $\bar{R}$ , the pairs related by  $\widehat{\Phi} \bar{R}$  are sent by  $f$  to pairs related by  $\widehat{\Psi} \bar{R}$ .

Better approximations of realistic programming languages result from adding built-in data types to System F. Each such added data type induces a type constructor, and this type constructor must also be given a relational interpretation. Wadler [Wad89] considers the case of lists that we review in detail in Section 2. In fact, to add a new inductive data type constructor  $T$  to an ambient parametric language in such a way that parametricity is preserved, the method is always the same: Define its relational interpretation as a (dependent) inductive family  $\widehat{T}$  with one data constructor  $\widehat{c}$ , for each data constructor  $c$  of  $T$ , expressing precisely that  $c$  is a parametric polymorphic function. The data constructors of such a data type's relational interpretation thus make formal the intuitive type-uniformity required of its data constructors by the grammars of languages such as Haskell. The relational interpretation  $\widehat{T}$  captures the intuition that, if we regard data types as containers, then two data structures of (two instances of)  $T$  are related by  $\widehat{T} R$  exactly when the data they store are related by  $R$ . This intuition also requires that  $\widehat{T} R$  preserves inclusion, i.e., that  $\widehat{T} R \subseteq \widehat{T} S$  whenever  $R \subseteq S$ . Indeed, if two data structures are related by  $\widehat{T} R$ , then the data they store are related by  $R$ , and thus by  $S$ , so the two data structures must be related by  $\widehat{T} S$ . Fortunately, for lists and other ADTs, the relation interpretations defined in this way enjoy this crucial inclusion-preservation property.

Here, we report our ongoing efforts to add the generalization of ADTs known as *Generalized Algebraic Data Types (GADTs)* to System F in such a way that parametricity is preserved. Since GADTs are inductive data type constructors, we might expect that following the method outlined above will suffice. In Section 2, we show that naively doing so results in relational interpretations of GADTs that do not satisfy the inclusion-preservation property identified at the end of the preceding paragraph. In Section 3, we explore a promising approach to overcoming this issue. In Section 4 we offer some applications of parametricity for GADTs. In Section 5 we discuss some issues arise in formalizing our proposed approach precisely, and offer some thoughts about how to resolve them.

## 2 Naive approach: The problem

In this section, we first review Wadler's relational interpretation of the standard built-in type constructor `List` for the ADT of lists, and then try to extend the method directly to GADTs. As mentioned above, the resulting relational interpretations for GADTs lack the desired inclusion-preservation property.

The type constructor `List` for the ADT of lists is given in Agda by:

$$\begin{aligned} \text{data List} : \text{Set} &\rightarrow \text{Set} \text{ where} \\ \text{nil} : \forall \{\alpha\} &\rightarrow \text{List } \alpha \\ \text{cons} : \forall \{\alpha\} &\rightarrow \alpha \rightarrow \text{List } \alpha \rightarrow \text{List } \alpha \end{aligned} \tag{1}$$

Wadler effectively gave a relational interpretation for `List` informally when he declared two lists  $[a_1, a_2, \dots, a_n] : \text{List } A$  and  $[b_1, b_2, \dots, b_n] : \text{List } B$  to be related by  $\widehat{\text{List}} R$  for a relation  $R$  between the types  $A$  and  $B$  exactly when each pair of their corresponding elements is related by  $R$ , i.e., when he required

$$\widehat{\text{List}} R [a_1, a_2, \dots, a_n] [b_1, b_2, \dots, b_n] \quad \text{if and only if} \quad \forall i = 1, \dots, n, R a_i b_i$$

If we represent the type relation  $\text{Rel } A B$  of relations between  $A$  and  $B$  by the function type  $A \rightarrow B \rightarrow \text{Set}$ , we can formalize Wadler's relational interpretation for lists as the (dependent) inductive family represented

in Agda by:

```
data  $\widehat{\text{List}}$  :  $\forall\{\alpha\beta\} \rightarrow \text{Rel } \alpha\beta \rightarrow \text{Rel } (\text{List } \alpha) (\text{List } \beta)$  where
   $\widehat{\text{nil}} : \forall\{\alpha\beta\}(R : \text{Rel } \alpha\beta) \rightarrow \widehat{\text{List}} R \text{ nil nil}$ 
   $\widehat{\text{cons}} : \forall\{\alpha\beta\}(R : \text{Rel } \alpha\beta)(a : \alpha)(b : \beta)(as : \text{List } \alpha)(bs : \text{List } \beta) \rightarrow$ 
     $R a b \rightarrow \widehat{\text{List}} R as bs \rightarrow \widehat{\text{List}} R (\text{cons } a as) (\text{cons } b bs)$ 
```

Notice that only terms both constructed from the same data constructor can be related, and that the definition of  $\widehat{\text{List}}$  mimics the recursive structure of  $\text{List}$ 's data type declaration. Moreover, this definition has exactly the feature announced in the introduction, namely that  $\widehat{\text{nil}}$  and  $\widehat{\text{cons}}$  express that  $\text{nil}$  and  $\text{cons}$  are parametric, respectively.

The method we used to construct  $\text{List}$  can easily be extended to other ADTs, or even to more general inductive definitions. This is the approach explored by the authors of [BJP10] for generic inductive families, which encompass, in particular, GADTs. Although interesting in its own right, this approach fails to recognize GADTs as data types, in the sense that their relational interpretations do not necessarily preserve inclusion as is intuitively expected. To illustrate the issue, consider the GADT of sequences given in Agda by:

```
data Seq : Set  $\rightarrow$  Set where
  inj :  $\forall\{\alpha\} \rightarrow \alpha \rightarrow \text{Seq } \alpha$ 
  pairing :  $\forall\{\alpha_1\alpha_2\} \rightarrow \text{Seq } \alpha_1 \rightarrow \text{Seq } \alpha_2 \rightarrow \text{Seq } (\alpha_1 \times \alpha_2)$  (2)
```

The same method used above yields the following relational interpretation  $\widehat{\text{Seq}}$  for  $\text{Seq}$ :

```
data  $\widehat{\text{Seq}}$  :  $\forall\{\alpha\beta\} \rightarrow \text{Rel } \alpha\beta \rightarrow \text{Rel } (\text{Seq } \alpha) (\text{Seq } \beta)$  where
   $\widehat{\text{inj}} : \forall\{\alpha\beta\}(R : \text{Rel } \alpha\beta)(a : \alpha)(b : \beta) \rightarrow R a b \rightarrow \widehat{\text{Seq}} R (\text{inj } a) (\text{inj } b)$ 
   $\widehat{\text{pairing}} : \forall\{\alpha_1\alpha_2\beta_1\beta_2\}(R_1 : \text{Rel } \alpha_1\beta_1)(R_2 : \text{Rel } \alpha_2\beta_2) \rightarrow$ 
     $\forall(s_1 : \text{Seq } \alpha_1)(s_2 : \text{Seq } \alpha_2)(t_1 : \text{Seq } \beta_1)(t_2 : \text{Seq } \beta_2) \rightarrow$ 
     $\widehat{\text{Seq}} R_1 s_1 t_1 \rightarrow \widehat{\text{Seq}} R_2 s_2 t_2 \rightarrow \widehat{\text{Seq}} (R_1 \widehat{\times} R_2) (\text{pairing } s_1 s_2) (\text{pairing } t_1 t_2)$ 
```

Here,  $\widehat{\times}$  is the relational interpretation of the product type constructor  $\times$  defined on relations  $R_1 : \text{Rel } A_1 B_1$  and  $R_2 : \text{Rel } A_2 B_2$  by  $(R_1 \widehat{\times} R_2)(a_1, a_2)(b_1, b_2) = (R_1 a_1 b_1) \times (R_2 a_2 b_2)$  for all  $a_1 : A_1$ ,  $a_2 : A_2$ ,  $b_1 : B_1$ ,  $b_2 : B_2$ .

Now, if  $R$  is the equality relation on  $\text{Bool} \times \text{Bool}$ , where  $\text{Bool}$  is the type of booleans, then  $\widehat{\text{Seq}} R$  is the equality relation on  $\text{Seq}(\text{Bool} \times \text{Bool})$ . On the other hand, if  $S$  is the binary relation on  $\text{Bool} \times \text{Bool}$  with only  $S(\text{false}, \text{false})(\text{true}, \text{true})$  uninhabited, then  $\widehat{\text{Seq}} S (\text{pairing } s_1 s_2) (\text{pairing } t_1 t_2)$  is uninhabited for any  $s_1$ ,  $s_2$ ,  $t_1$ , and  $t_2$  because  $S$  is not a product of relations. However,  $S$  contains  $R$ , so  $\widehat{\text{Seq}} S t$  should be inhabited at least whenever  $\widehat{\text{Seq}} R s t$  is. That it is not violates the inclusion-preservation property expected of  $\widehat{\text{Seq}}$ .

### 3 Completing GADTs: Toward a solution

To remedy the problem exposed in Section 2, we first observe that we can obtain an alternative relational interpretation for  $\text{Seq}$  by first embedding it into (a data type that is essentially) an ADT  $\text{S}$  and then constructing the relational interpretation of  $\text{S}$  as above. The data type  $\text{S}$  is given by:

```
data S : Set  $\rightarrow$  Set where
  i :  $\forall\{\alpha\} \rightarrow \alpha \rightarrow \text{S } \alpha$ 
  p :  $\forall\{\alpha_1\alpha_2\alpha\} \rightarrow (\alpha_1 \times \alpha_2 \rightarrow \alpha) \rightarrow \text{S } \alpha_1 \rightarrow \text{S } \alpha_2 \rightarrow \text{S } (\alpha_1 \times \alpha_2)$  (3)
```

The embedding  $\iota$  of  $\text{Seq}$  into  $\mathbf{S}$  is obtained by mapping a sequence of the form  $\text{inj } a$  to  $\mathbf{i } a$  and one of the form pairing  $s_1 s_2$  with  $s_1 : \text{Seq } A_1$  and  $s_2 : \text{Seq } A_2$  to  $\mathbf{p } \text{id}_{A_1 \times A_2} \iota s_1 \iota s_2$ . We can now compute the relational interpretation of  $\mathbf{S}$  as above. This gives:

```

data  $\widehat{\mathbf{S}} : \forall \{\alpha\beta\} \rightarrow \text{Rel } \alpha\beta \rightarrow \text{Rel } (\mathbf{S } \alpha) (\mathbf{S } \beta) \text{ where}$ 
   $\widehat{\mathbf{i}} : \forall \{\alpha\beta\} (\mathbf{R} : \text{Rel } \alpha\beta) (\mathbf{a} : \alpha) (\mathbf{b} : \beta) \rightarrow \mathbf{R } \mathbf{a } \mathbf{b} \rightarrow \widehat{\mathbf{S}} \mathbf{R } (\mathbf{i } \mathbf{a}) (\mathbf{i } \mathbf{b})$ 
   $\widehat{\mathbf{p}} : \forall \{\alpha_1\alpha_2\beta_1\beta_2\alpha\beta\} (\mathbf{R}_1 : \text{Rel } \alpha_1\beta_1) (\mathbf{R}_2 : \text{Rel } \alpha_2\beta_2) (\mathbf{R} : \text{Rel } \alpha\beta) \rightarrow$ 
     $\forall (\mathbf{s}_1 : \mathbf{S } \alpha_1) (\mathbf{s}_2 : \mathbf{S } \alpha_2) (\mathbf{t}_1 : \mathbf{S } \beta_1) (\mathbf{t}_2 : \mathbf{S } \beta_2) (\mathbf{f} : \alpha_1 \times \alpha_2 \rightarrow \alpha) (\mathbf{g} : \beta_1 \times \beta_2 \rightarrow \beta) \rightarrow$ 
     $((\mathbf{R}_1 \widehat{\times} \mathbf{R}_2) \widehat{\Rightarrow} \mathbf{R}) \mathbf{f } \mathbf{g} \rightarrow \widehat{\mathbf{S}} \mathbf{R}_1 \mathbf{s}_1 \mathbf{t}_1 \rightarrow \widehat{\mathbf{S}} \mathbf{R}_2 \mathbf{s}_2 \mathbf{t}_2 \rightarrow \widehat{\mathbf{S}} (\mathbf{R}_1 \widehat{\times} \mathbf{R}_2) (\mathbf{p } \mathbf{f } \mathbf{s}_1 \mathbf{s}_2) (\mathbf{p } \mathbf{g } \mathbf{t}_1 \mathbf{t}_2)$ 

```

Here,  $\_ \widehat{\Rightarrow} \_$  is the relational interpretation of the function type constructor  $\_ \rightarrow \_$  defined for any  $\mathbf{R} : \text{Rel } A B$  and  $\mathbf{S} : \text{Rel } C D$  by  $(\mathbf{R} \widehat{\Rightarrow} \mathbf{S}) \mathbf{f } \mathbf{g} = \forall (a : A) (b : B) \rightarrow \mathbf{R } \mathbf{a } \mathbf{b} \rightarrow \mathbf{S } (\mathbf{f } a) (\mathbf{g } b)$ . With  $\widehat{\mathbf{S}}$  in hand, we can now define the relational interpretation of  $\text{Seq}$  by  $\widehat{\text{Seq }} R s t = \widehat{\mathbf{S}} \mathbf{R } (\iota s) (\iota t)$ . It is easy to see that this relational interpretation  $\widehat{\text{Seq}}$  not only ensures that the constructors of  $\text{Seq}$  are parametric, but also satisfies the inclusion-preservation property.

The method described for  $\text{Seq}$  can easily be extended to any GADT. Indeed, given any GADT  $G$ , its completion  $G_c$  is obtained by first identifying each constructor  $c : \forall \bar{\alpha}. \Phi \rightarrow G \bar{\Psi}$  whose return instance  $\bar{\Psi}$  of  $G$  is not simply  $\bar{\alpha}$  and replacing it by  $c_c : \forall \bar{\alpha}\bar{\beta}. (\bar{\Psi} \rightarrow \bar{\beta}) \rightarrow \Phi \rightarrow G \bar{\beta}$ . The name *completion* is justified by the embedding  $\iota_G$  of  $G$  into  $G_c$  defined on each element of the form  $c x$  by  $c_c \text{id}_{\bar{\Psi}} x$ . The completion  $G_c$  is akin to an ADT in the sense that the return type of each of its constructors is a variable instance of  $G_c$ ; however, it is not an ADT *per se* because each of its constructors  $c_c : \forall \bar{\alpha}\bar{\beta}. (\bar{\Psi} \rightarrow \bar{\beta}) \rightarrow \Phi \rightarrow G \bar{\beta}$  quantifies over a possibly non-empty vector  $\bar{\alpha}$  of type variables as well as over the vector  $\bar{\beta}$  of types variables appearing in  $c_c$ 's return instance. Nevertheless, the relational interpretation  $\widehat{G}_c$  of  $G_c$  can be constructed as in Section 2, and the relational interpretation  $\widehat{G}$  of  $G$  is then defined by restriction as  $\widehat{G} \mathbf{R } g h = \widehat{G}_c \mathbf{R } (\iota_G g) (\iota_G h)$ . The resulting relational interpretation  $\widehat{G}$  inherits the inclusion-preservation property of  $\widehat{G}_c$  and also ensures that each of the constructors  $c$  of  $G$  is parametric.

When  $G$  is simply an ADT its completion  $G_c$  is just a copy of  $G$  itself (since then there is no constructor  $c : \forall \bar{\alpha}. \Phi \rightarrow G \bar{\Psi}$  whose return instance  $\bar{\Psi}$  is not  $\bar{\alpha}$ ). In this case, the relational interpretation  $\widehat{G}$  defined in this section is trivially the same as the relational interpretation associated to it by the method described in Section 2. The construction of  $\widehat{G}$  in this section for an arbitrary GADT  $G$  thus produces true generalizations of the relational interpretations of ADTs, as introduced for lists by Wadler and subsequently developed for more general data types by others (see, e.g., [BJP10, JG07]).

## 4 Applications

### 4.1 Free theorems

The relational interpretations defined for GADTs in the previous section can be used to establish free theorems à la Wadler. We illustrate this with the data type  $\text{Seq}$ . Given a type  $A$  and an element  $a : A$ , we say that a sequence  $s : \text{Seq } A$  contains only  $a$  as data either when  $s = \text{inj } a$  or when  $s = \text{pairing } s_1 s_2$  — which forces  $a$  to be of the form  $(a_1, a_2)$  — and  $s_1$  contains only  $a_1$  as data and  $s_2$  contains only  $a_2$  as data.

**Proposition 4.1** *Let  $f : \forall \alpha. \alpha \rightarrow \text{Seq } \alpha$  be a parametric polymorphic function. For any type  $A$  and any element  $a : A$ , the sequence  $f A a$  contains only  $a$  as data.*

**Proof.** Since the function  $f$  is parametric, for any types  $A$  and  $B$ , any relation  $R : \text{Rel } A B$ , any  $a : A$  and any  $b : B$ , the sequences  $f A a$  and  $f B b$  are related by  $\widehat{\text{Seq }} R$  whenever  $R a b$  holds. Now, fix a type  $A$  and an element  $a : A$  and consider the relation  $\delta_a : \text{Rel } A A$  that relates  $x$  and  $y$  only when both are  $a$  itself. Because  $\delta_a a a$ , we get a witness of  $\widehat{\text{Seq }} \delta_a (f A a) (f A a)$ . It remains to show, by induction on  $s : \text{Seq } A$ , that if  $\widehat{\text{Seq }} \delta_a s s$  then  $s$  contains only  $a$  as data. If  $s = \text{inj } x$  for some  $x : A$ , then the element we have in  $\widehat{\text{Seq }} \delta_a s s = \widehat{\mathbf{S}} \delta_a (\mathbf{i } x) (\mathbf{i } x)$  must be of the form  $\widehat{\mathbf{i }} \delta_a x x w$  with  $w : \delta_a x x$ . By definition of  $\delta_a$ ,  $w$  entails that  $x$  is  $a$  itself,

and thus  $s = \text{inj } a$  does indeed contain only  $a$  as data. If  $s = \text{pairing } s_1 s_2$ , then  $A$  is of the form  $A_1 \times A_2$ ,  $a$  is of the form  $(a_1, a_2)$ , and the element we have in  $\widehat{\text{Seq}} \delta_a s s = \widehat{\mathbb{S}} \delta_a (\mathbf{p} \text{id}_{A_1 \times A_2} (\iota s_1) (\iota s_2)) (\mathbf{p} \text{id}_{A_1 \times A_2} (\iota s_1) (\iota s_2))$  must be of the form  $\widehat{\mathbf{p}} R_1 R_2 \delta_a s_1 s_2 s_1 s_2 \text{id}_{A_1 \times A_2} \text{id}_{A_1 \times A_2} w w_1 w_2$  with  $R_1 : \text{Rel } A_1 A_1$ ,  $R_2 : \text{Rel } A_2 A_2$ ,  $w : R_1 \widehat{\times} R_2 \widehat{\rightarrow} \delta_a \text{id}_{A_1 \times A_2} \text{id}_{A_1 \times A_2}$ ,  $w_1 : \widehat{\text{Seq}} R_1 s_1 s_1$ , and  $w_2 : \widehat{\text{Seq}} R_2 s_2 s_2$ . From  $w$ , we can prove that  $R_1 \subseteq \delta_{a_1}$  and  $R_2 \subseteq \delta_{a_2}$ . Then from  $w_1$  and  $w_2$ , inclusion-preservation of  $\widehat{\text{Seq}}$  gives witnesses  $v_1$  and  $v_2$  of  $\widehat{\text{Seq}} \delta_{a_1} s_1 s_1$  and  $\widehat{\text{Seq}} \delta_{a_2} s_2 s_2$ , respectively. By the induction hypothesis,  $v_1$  gives that  $s_1$  has only  $a_1$  as data and  $v_2$  gives that  $s_2$  contains only  $a_2$  as data. That is,  $s = \text{pairing } s_1 s_2$  contains only  $a = (a_1, a_2)$  as data.  $\square$

#### 4.2 Graph lemma

If  $R$  is the graph of a function  $f : A \rightarrow B$ , then  $\widehat{G} R$  is of particular interest. When  $G$  is an ADT, then the graph lemma says that  $\widehat{G} R$  is exactly the graph of the function  $\text{map}_G f : G A \rightarrow G B$ , where  $\text{map}_G$  is the usual map function associated with the ADT  $G$ . However, when  $G$  is a more general GADT, then there can be no map function associated with  $G$  ([JP19, JC22]). In other words, the relation  $\widehat{G} R$  is not necessarily the graph of a function from  $G A$  to  $G B$ . Significantly,  $\widehat{G} R$  can still be understood as the graph of a *partial* function from  $G A$  to  $G B$ ; see Proposition 4.2 below. The key observation is that the completion  $G_c$  of  $G$  has a map function  $\text{map}_{G_c} : (A \rightarrow B) \rightarrow G_c A \rightarrow G_c B$  whose application to  $f$  is defined for each constructor  $c_c$  by  $\text{map}_{G_c} f (c_c h x) = c_c (f \circ h) x$ .

**Proposition 4.2** *Let  $f : A \rightarrow B$  be a function and let  $G$  be a GADT. If  $R$  is the graph of  $f$ , then  $\widehat{G} R$  is the graph of a partial function, i.e., for any  $x : G A$ , there is at most one  $y : G B$  such that  $\widehat{G} R x y$  is inhabited.*

**Proof.** Let  $x : G A$  and  $y, y' : G B$  be such that  $\widehat{G} R x y$  and  $\widehat{G} R x y'$  are inhabited. Then  $\widehat{G}_c R (\iota x) (\iota y)$  and  $\widehat{G}_c R (\iota x) (\iota y')$  are inhabited as well. Since  $G_c$  has a map function,  $\widehat{G}_c R$  is also the graph of a function, so  $\iota y = \iota y'$ , and thus the injectivity of the embedding  $\iota$  implies  $y = y'$ .  $\square$

Using Proposition 4.2, we can *define* a “function mapping operation”  $\mathbf{m}_G$  for  $G$  by declaring  $\mathbf{m}_G f x$  to be  $y$  if  $\widehat{G} R x y$  is inhabited and undefined if no such  $y$  exists. This definition of  $\mathbf{m}_G$  generalizes the notion of mappability introduced in [JC22]: when  $f$  is mappable over  $x$  in the specification  $G$  in the sense of [JC22], then the partial function  $\mathbf{m}_G f$  above is defined on  $x$ . The converse does not hold, however, as shown in Example 4.3.

**Example 4.3** Consider the functions  $f : \text{Bool} \times \text{Bool} \rightarrow \text{Bool} \times \text{Bool}$  and  $g : \text{Bool} \rightarrow \text{Bool}$  defined by  $f(x, y) = (y, x)$  and  $g x = \neg x$ . It should be fairly intuitive to the reader that we can map (for  $\text{Seq}$ ) the function  $f \times g$  over the sequence  $s = \text{pairing} (\text{inj } (\text{true}, \text{false})) (\text{inj } \text{true})$ , with result  $s' = \text{pairing} (\text{inj } (\text{false}, \text{true})) (\text{inj } \text{false})$ . More formally, according to the algorithm of [JC22],  $f \times g$  is indeed mappable over  $s$  in the specification  $\text{Seq}$ , with result  $s'$ . In fact, writing  $R$  for the graph of  $f \times g$ , we can give an actual witness of  $\widehat{\text{Seq}} R s s'$ , namely

$$\widehat{\mathbf{p}} R_1 R_2 R (\mathbf{i} (\text{true}, \text{false})) (\mathbf{i} \text{ true}) (\mathbf{i} (\text{false}, \text{true})) (\mathbf{i} \text{ false}) \mathbf{id} \mathbf{id} w (\widehat{\mathbf{i}} R_1 (\text{true}, \text{false}) (\text{false}, \text{true}) w_1) (\widehat{\mathbf{i}} R_2 \text{true} \text{false} w_2)$$

Here,  $R_1$  is the graph of  $f$ ,  $R_2$  is the graph of  $g$ ,  $w$  is a proof of inclusion (actually equality) of  $R_1 \widehat{\times} R_2$  in  $R$ , and  $w_1$  and  $w_2$  are witnesses of  $f(\text{true}, \text{false}) = (\text{false}, \text{true})$  and  $g \text{true} = \text{false}$ , respectively. However, the partial function  $\mathbf{m}_{\text{Seq}} (f \times g)$  is also defined on elements on which the algorithm of [JC22] would not consider  $f \times g$  to be mappable, such as  $t = \text{pairing} (\text{pairing} (\text{inj } \text{true}) (\text{inj } \text{false})) (\text{inj } \text{true})$ . Indeed, the algorithm finds  $f \times g$  to not be mappable over  $t$  because  $f$  is not of the form  $f_1 \times f_2$  but the first argument of the outer pairing in  $t$  is again constructed from  $\text{pairing}$ . Nevertheless,  $\mathbf{m}_{\text{Seq}} (f \times g) t$  still exists and equals  $t' = \text{pairing} (\text{pairing} (\text{inj } \text{false}) (\text{inj } \text{true})) (\text{inj } \text{false})$  because there is a witness of  $\widehat{\text{Seq}} R t t'$ , namely

$$\widehat{\mathbf{p}} R_1 R_2 R (\mathbf{p} \text{id} (\mathbf{i} \text{ true}) (\mathbf{i} \text{ false})) (\mathbf{i} \text{ true}) (\mathbf{p} \text{id} (\mathbf{i} \text{ false}) (\mathbf{i} \text{ true})) (\mathbf{i} \text{ false}) \mathbf{id} \mathbf{id} w w_1 (\widehat{\mathbf{i}} R_2 \text{true} \text{false} w_2)$$

Here,  $R_2$  is again the graph of  $g$ , and  $w_2$  is again a witness of  $g \text{true} = \text{false}$ , but  $R_1$  is the relation that only relates  $(\text{true}, \text{false})$  with  $(\text{false}, \text{true})$  (and nothing else),  $w$  is a witness that  $R_1 \widehat{\times} R_2$  is included (strictly!) in  $R$ , and  $w_1$  is of the form  $\widehat{\mathbf{p}} R'_1 R''_1 R_1 (\mathbf{i} \text{ true}) (\mathbf{i} \text{ false}) (\mathbf{i} \text{ true}) \mathbf{id} \mathbf{id} z (\widehat{\mathbf{i}} R'_1 \text{true} \text{false} w'_1) (\widehat{\mathbf{i}} R''_1 \text{false} \text{true} w''_1)$ ,

where  $R'_1$  relates **true** with **false** (and nothing else) with witness  $w'_1$ ,  $R''_1$  relates **false** with **true** (and nothing else) with witness  $w''_1$ , and  $z$  is a witness of inclusion (actually equality) of  $R'_1 \hat{\times} R''_1$  in  $R_1$ .

## 5 Issues

The research programme outlined above seems eminently reasonable. However, to carry it out precisely, we need to define a source language extending System F with built-in GADTs and a target (dependent) type theory strong enough to express the relational interpretations described in Sections 2 and 3. In trying to do so, the following issues concerning the target type theory arise:

- (i) We have chosen to model relations between  $A$  and  $B$  as functions  $A \rightarrow B \rightarrow \text{Set}$ , i.e., as proof-relevant relations. However, we have also freely used notions most naturally associated to proof-irrelevant relations, such as inclusion of relations. A rigorous treatment would likely replace inclusion with an operation mapping witnesses to witnesses. Technically speaking, that amounts to representing proof-relevant relations as spans and replacing inclusions of proof-irrelevant relations by morphisms between those spans.
- (ii) In Section 4.2, we investigated a graph lemma for GADTs. There again, proof-relevance plays an important role. Indeed, the graph of a function  $f : A \rightarrow B$  is the relation  $\text{Gr } f : \text{Rel } AB$  defined by  $\text{Gr } f a b = (f a \equiv b)$ , where  $\equiv$  is the equality type former of the prospective target type theory. Whether or not this relation  $\text{Gr } f$  is proof-relevant depends on whether or not the target type theory supports a version of Axiom K. Assuming Axiom K is, however, problematic: in a language like Agda, for example, Axiom K makes it possible to prove that the data constructors of inductive data types are injective. This is in direct opposition to the data constructors' expected parametric behavior.
- (iii) To interpret GADTs correctly, the target type theory needs an impredicative universe that supports inductive constructions. The Calculus of Inductive Constructions offers such a universe at the bottom of its hierarchy. However, this universe is proof-irrelevant, and thus is not suitable for our purposes. Indeed, carrying out our constructions in such a universe would effectively identify all data structures of any given instance of a GADT. In addition, it is well-known that impredicativity is inconsistent with strong dependent sums, which eliminates some obvious candidates for the target type theory.

Resolving Point (i) may require new technical ideas, but we do not expect it to pose fundamental difficulties. Points (ii) and (iii) pose a different challenge: either we design a target type theory with the desired features, or we prove that we cannot. The former would provide a framework for understanding parametricity of (languages with) GADTs. The latter would definitively show that GADTs cannot be understood parametrically, and thus the claim that GADTs *generalize* ADTs (implicit in the “GADT” terminology) is not justified.
