Identifying the sources of CO$_2$ in carbonic springs in the Albuquerque-Belen Basin

Valerie Blomgren, Amy Williams, Laura Crossey, Karl Karlstrom, and Fraser Goff, 2016, pp. 419-427

This is one of many related papers that were included in the 2016 NMGS Fall Field Conference Guidebook.

Annual NMGS Fall Field Conference Guidebooks

Every fall since 1950, the New Mexico Geological Society (NMGS) has held an annual Fall Field Conference that explores some region of New Mexico (or surrounding states). Always well attended, these conferences provide a guidebook to participants. Besides detailed road logs, the guidebooks contain many well written, edited, and peer-reviewed geoscience papers. These books have set the national standard for geologic guidebooks and are an essential geologic reference for anyone working in or around New Mexico.

Free Downloads

NMGS has decided to make peer-reviewed papers from our Fall Field Conference guidebooks available for free download. Non-members will have access to guidebook papers two years after publication. Members have access to all papers. This is in keeping with our mission of promoting interest, research, and cooperation regarding geology in New Mexico. However, guidebook sales represent a significant proportion of our operating budget. Therefore, only *research papers* are available for download. *Road logs*, *mini-papers*, *maps*, *stratigraphic charts*, and other selected content are available only in the printed guidebooks.

Abstract—Understanding groundwater resources in the Albuquerque basin region requires an understanding of the geochemistry of carbonic springs and potential mixing among different water sources. Carbonic springs are defined as high P$_{CO2}$ springs (P$_{CO2}$ >10-1.8). This paper evaluates the sources of the high dissolved CO$_2$ in these springs by summarizing the geochemistry of carbonic springs found along faults of the Rio Grande rift. Major ion chemistry helps define chemical characteristics of endogenic (deeply sourced) fluids entering the groundwater system and their variable mixing with epigenic waters (meteoric recharge). We also use major ion water chemistry analyses to estimate the percentage of CO$_2$ derived from dissolution of carbonates (both rock and minerals) (C$_{carb}$) in groundwater. We then use carbon isotopes to estimate the percentage of the remaining external CO$_2$ (C$_{ext}$) that was derived from organic material such as soil gas (C$_{org}$) plus endogenic CO$_2$ that is from deeply derived sources (C$_{endo}$). The results show a high percentage of endogenic components in the west flank of the Rio Grande rift spring waters with a range of 17.5 - 74.8% C$_{endo}$ (mean value of 55.3%±19.8%). We analyzed dissolved gases to illustrate a spectrum of mixing between air and air-saturated groundwater with helium-rich deeply sourced fluids. The high endogenic CO$_2$ in springs and travertines that occur within the Rio Grande rift at San Acacia and along much of the western rift faults from Socorro to I-40 is interpreted to reflect degassing of magmatic volatiles from the Socorro magma body. The wide distribution of springs suggests that similar waters may be cryptically entering Santa Fe Group aquifers from below and affecting water quality by adding salinity and trace metals as well as deeply sourced volatiles. These endogenic inputs are tepid (up to 26°C) and have geochemical similarities to geothermal waters. The variation in hydrochemistry of the Albuquerque basin can be attributed in part to mixing of endogenic fluids with other groundwater and has implications for future management of groundwater resources.

INTRODUCTION

Carbonic springs are defined as high P$_{CO2}$ springs, with the lower limit of P$_{CO2}$ in this study of 10$^{-1.8}$ which is nearly 2 orders of magnitude higher in CO$_2$ than waters equilibrated with air which have P$_{CO2}$ = 10$^{-3.5}$. Distinctive carbonic springs discharge in the Albuquerque basin along fault and fault zones of the Rio Grande rift (Fig. 1). These springs often produce large volume travertine (Priewisch et al., 2014). A major question involves the source of the CO$_2$. This is important because the high total CO$_2$ (HCO$_3$ and CO$_2$ gas) is also associated with high salinity, high metal content, and the presence of mantle–derived helium (Crossey et al., 2011) as part of deeply sourced (endogenic) fluid end members that mix within the aquifer system. Williams et al. (2013) presented a hypothesis that diverse water quality and hydrofacies of springs in the Sevilleta Game Refuge and Albuquerque basin can be explained by mixing of meteoric recharge (epigenic) waters with deeply sourced (endogenic) waters. This hypothesis is summarized and further tested in this paper.

Several recent papers have highlighted the importance of understanding mixing of different fluids within the aquifer as an explanation for variable groundwater composition across the Colorado Plateau region (Newell et al., 2005; Crossey et al., 2006, 2009, 2011; Williams et al., 2013). Similarly, groundwater inputs are noted to have an important influence on surface water quality. For example, endogenic inputs can explain the abrupt increase in salinity of the Rio Grande when it passes San Acacia (Mills, 2003; Hogan et al., 2007; Williams et al., 2013). However, the sources of the salts and the CO$_2$ remain poorly

understood and there may be more than one type of endogenic fluid. For example, Cl/Br ratios suggest that abrupt increase in salinity of the Rio Grande at San Acacia and San Marcial cannot be explained by agricultural inputs, but could reflect upwelling of basin brines (Mills, 2003; Hogan et al., 2007), inputs from the mantle (Newell et al., 2005; Williams et al., 2013), and/or mixing of geothermal fluids during ascent from depth.

The goal of this paper is to explore the sources of CO$_2$ in the carbonic springs of the Albuquerque basin. We analyze multiple geochemical tracers in groundwater to help recognize and unravel the components from meteoric recharge, water-rock interaction along flow paths, and variable mixing of different groundwater sources such as geothermal fluids. This paper presents major ion chemistry, stable isotope data, and dissolved gas tracers. We also explore the possibility that the chemical characteristics of endogenic fluids (elevated salinity, CO$_2$ gas, and mantle-derived helium) can be explained by input of magmatic volatiles from the Socorro magma body. If so, this would suggest tectonic interconnections between deep fluids, travertines, fault conduits, and magmatic volatiles in the Albuquerque basin of the Rio Grande rift (Fig. 2).

We also integrate our data with a previous study of springs of the Lucero Uplift (Goff et al., 1983) that was designed to test the geothermal potential of springs along the west margin of the Rio Grande rift and adjacent Lucero Uplift. These workers noted that this region had an unusual set of mesothermal springs (12 to 26°C) that were associated with a region of Quaternary faulting, volcanism, regional high heat flow, and the potential for geothermal reservoirs (Callendar and Zillinski, 1976; Train-
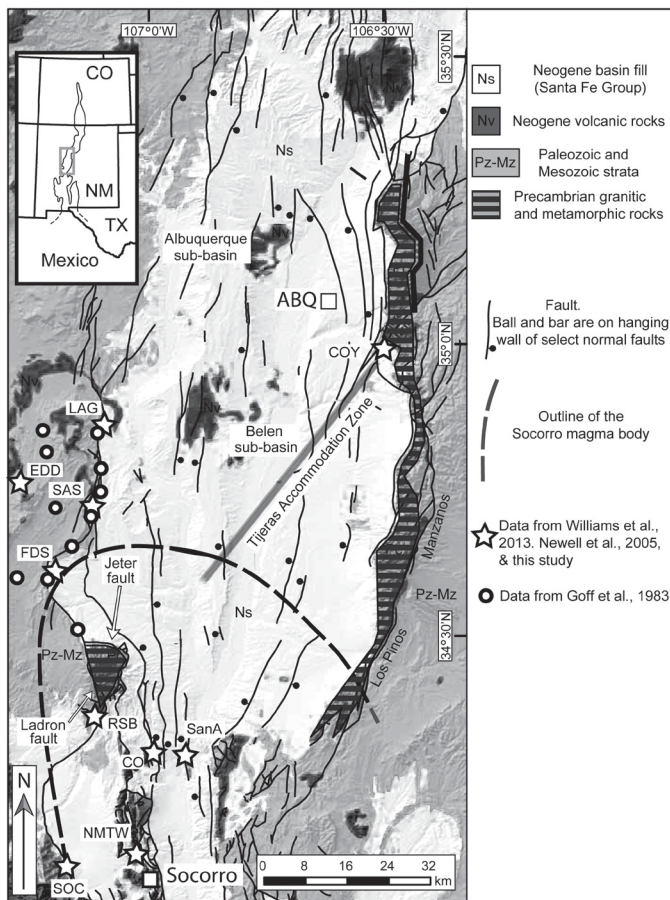

FIGURE 1. Digital elevation model of the Rio Grande rift showing rift-bounding faults. The Socorro magma body underlies the area outlined by the dashed line at ~19-km depth. Fault-related carbonic springs analyzed are Coyote (COY), Laguna Pueblo (LAG), Eddleman (EDD), Salado Arroyo (SAS), Four Daughters (FDS), Rio Salado Box (RSB), Canyon del Ojito (CO), San Acacia (SanA). The Socorro spring (SOC) and New Mexico Tech Well (NMTW) are located on the southern end of the study site. Spring samples from Goff et al. (1983) are shown in hollow circles on the western side of the rift.

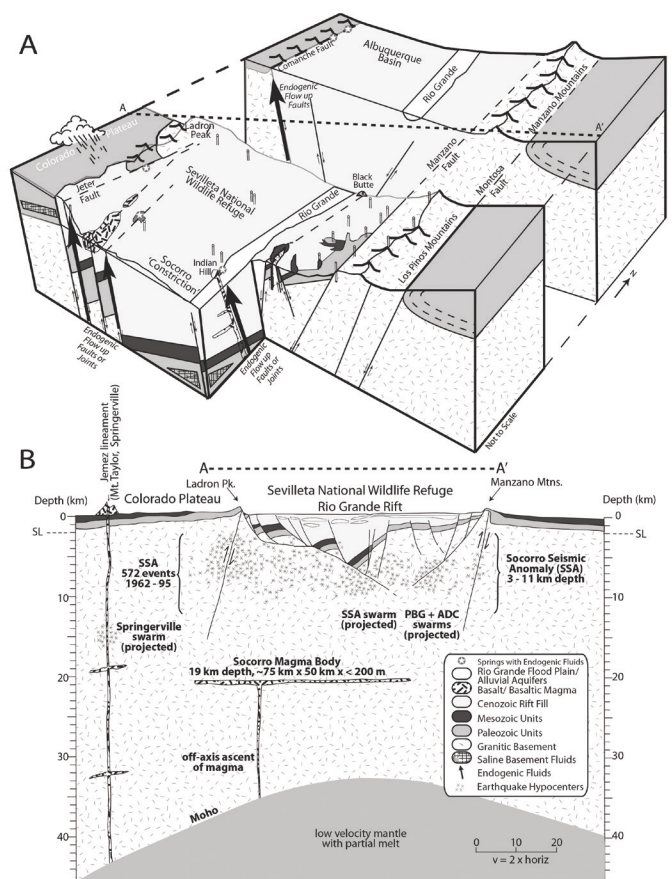

FIGURE 2. Block diagram (from Williams et al., 2013) of the Rio Grande rift illustrating endogenic fluids flowing upwards along rift-related normal faults (large black arrows). Rift flank meteoric recharge flows from both sides of the rift into the valley and then southward (small black arrows). The Colorado Plateau is located to the west of the study area and influences the meteoric recharge into the basin.

er and Lyford, 1979). One study had reported calculated subsurface reservoir temperatures of >100°C using Na-K-Ca chemical geothermometers (Fournier and Truesdell 1973).

GEOLOGIC BACKGROUND

The Albuquerque basin is within the central portion of the Rio Grande rift that has been undergoing extension in the last 25-30 Ma (Chapin and Cather, 1994; Russell and Snelson, 1994; Keller and Baldridge, 1999) and is still active (Ricketts et al., 2014). The basin is composed of half grabens bound by normal faults; the west-dipping Sandia-Manzano range-bounding faults on the east side of the northern part of the Albuquerque basin and the east-dipping Jeter and Santa Fe fault systems on the west side of the southern part of the basin. The change in half graben asymmetry on the opposite sides of the Albuquerque basin requires an accommodation zone in the central part of the basin (Fig. 1) that Grauch et al. (2013) and Ricketts et al. (2014) considered to be a distributed zone of *en echelon* anticlines rather than a single fault zone (c.f. Lewis and Baldridge, 1994).

Springs described in this paper are listed in Tables 1-4 and shown in Figure 1. One set occurs along the western rift-bounding faults. From north to south, these are: Laguna Pueblo (LAG), Salado Arroyo Spring (SAS), Four Daughters Spring (FDS), Rio Salado Box springs (RSB), Canyon del Ojito spring (CO), New Mexico Tech Well (NMTW) and Socorro spring (SOC). Eddleman Spring (EDD) is on the Colorado Plateau just west of the rift boundary. San Acacia spring (SanA) is along the Cliff fault in the center of the rift. Coyote springs (COY) are along the eastern rift boundary at the intersection of the rift bounding Sandia fault zone and Tijeras fault zone. Water and gas analyses of most of the above springs were compiled from Williams et al. (2013) and Newell et al. (2005). These authors also reported helium isotope data (R_C/R_A) for these springs ranging from 0.256 to 1.907 R_A indicating that 3-15% of the helium in these springs was derived from the mantle. New water chemistry data is presented for Laguna Pueblo spring and new gas data for Four Daughters, New Mexico Tech Well and Socorro spring.

Because springs are located along rift bounding faults, all of the springs have the potential to derive meteoric recharge from adjacent uplifted rift flanks, from the shallow Santa Fe

Group basin-fill aquifer system, Mesozoic aquifers, Paleozoic carbonate and sandstone aquifers, and from basement penetrating faults that can convey deep fluids.

METHODS

The multiple tracer method evaluates mixing end members and allows for inferences regarding fluid sources and mixing. Consistency among tracers such as general chemistry, gas abundance, and isotopes of carbon is explored. Major ions identify locations with increased salinity and evidence for water-rock interaction. Gas abundance data, in particular dissolved N$_2$-Ar-He, display the range of gas results from helium-rich endogenic gases to air and air-saturated water and can also show mixing patterns (Giggenbach et al., 1992; Newell et al., 2005).

In the field, the spring temperature, pH, conductivity and total dissolved solids were measured using an Oakton meter. Two

Nalgene 125-mL bottles were collected at each spring. The first bottle was collected without head space for preserving alkalinity; water from this bottle was used to measure anions and carbon isotopes. The spring water for the second bottle was filtered with a 0.45-micron filter and acidified with HNO$_3$ to preserve dissolved metals and cations. Gas samples were collected with two methods (1) by placing a plastic funnel over bubbling springs and drawing the gases into an evacuated glass flask or glass bottle filled with concentrated NaOH, or (2) water samples were drawn into an evacuated and NaOH-filled container and then gases were extracted out of solution (Newell et al., 2005).

Water analyses were run in the Analytical Laboratory of the Earth and Planetary Department of the University of New Mexico. Alkalinity was determined by titration with sulfuric acid. The anions were analyzed using an ion chromatographer (EPA Method 300.1, Revision 1.0, Hautman and Munch, 1997), and cations were analyzed with an inductively coupled plasma optical emission spectrometry (EPA Method 200.7, Revision 4, Creed, et al., 1994). Gas samples were analyzed for He, H$_2$, Ar, N$_2$, O$_2$, CH$_4$, and CO with a gas chromatograph after Giggenbach and Goguel (1989) in the University of New Mexico Volcanic Geothermal Fluid Analysis Laboratory.

Our method to help quantify the components of the CO$_2$ load is summarized in Chiodini et al., (2004) and Crossey et al. (2009). Three potential sources of carbon within groundwater are identified: (1) C$_{carb}$ = carbon derived from dissolving carbonates (both rock and minerals) in the aquifer system, for example from limestone aquifers like the Madera Group and San Andres Formation, (2) C$_{org}$ = carbon derived from organic sources such as soil gas derived from plant respiration, and (3) C$_{endo}$ = carbon derived from endogenic (deeply derived) sources such as magmatic volatile inputs or CO$_2$ released by ascending geothermal fluids below the aquifer system. The method for estimating the proportions of these components relies first on major element chemistry of the water, and then carbon isotope data.

First, the total dissolved inorganic carbon (DIC) is modeled with PHREEQC using major ion chemistry and pH (Parkhurst, 1995). The modeled DIC is a combination of the titratable bicarbonate (HCO$_3^-$) and carbonic acid (H$_2$CO$_3$). Considering the percentage of carbonic acid is especially important for springs

* CO_2 is water-free (Newell et al., 2005)

with a pH below 6.5. The C_{carb} is calculated via
$$C_{carb} = Ca + Mg - SO_4.$$
The molar balance of Ca + Mg accounts for CO_2 released from dissolution of calcite and dolomite (Ca, Mg, CO_3), and the – SO_4 term accounts for any extra Ca and Mg that may have come from dissolution of gypsum (Ca, Mg, SO_4). The remaining carbon is called external carbon such that
$$C_{ext} = DIC_{total} - C_{carb},$$
and is composed of two end members C_{org} and C_{endo} ($C_{ext} = C_{org} + C_{endo}$).

Carbon isotopes and C_{ext} concentrations were used to create a mixing curve between C_{org} and C_{endo} end members, allowing us to estimate their relative contributions. Before creating this mixing curve, the concentrations and isotopes must be corrected for carbonate contributions; the $\delta^{13}C$ of external carbon is adjusted with the equation
$$(\delta^{13}C_{ext} * C_{ext}) = (\delta^{13}C_{DIC} * DIC) - (\delta^{13}C_{carb} * C_{carb}).$$
The final step is defining a set of mixing curves that envelop the data and help define isotopic values of the end members. For example, for soil gas respiration sources, an organic end member ranges from -22 to -34‰ for C3 plants and -9 to -16‰ for C4 plants (Robinson and Scrimgeour, 1995). Possible values for the carbon isotope endogenic end member at high C_{ext} were bracketed empirically by our data. Published ranges of $\delta^{13}C$ of mantle carbon are reported in Goff et al., (2000) as -3.5‰, by Gerlach and Taylor (1990) as -4.1 to -3.5‰ and by Sano and Marty (1995) at -6±2‰.

RESULTS

Major ion chemistry is presented in a Piper diagram (Piper, 1944) in Figure 3. The diagram displays cations in the lower left triangle and the anions in the lower right, and the ions are then projected into the parallelogram. Epigenic waters fall near the left apex of parallelogram. The Albuquerque basin waters also plot in each corner of the parallelogram and these were interpreted by Williams et al. (2013) to represent different endogenic endmembers. The springs with highest endogenic input tend to plot near the Na-SO_4 (right apex) corner. As shown in Figure 3, these springs correspond to the "type-s" (saline mineral waters) of Goff et al. (1983). Springs near the top of the parallelogram are similar to their "type-d" waters (dilute mineral waters).

Results from the C_{ext} calculations (Fig. 4) show that most carbonic springs fall on binary mixing curves between C_{org} and C_{endo}, with endogenic end members of $\delta^{13}C_{ext}$ = -3.5 to 6‰ and [C_{ext}]= 0.03 to 0.32 mol/L. The C_{ext} diagram can be used to estimate carbon proportions for each sample as shown in Table 3 and Figure 5. C_{endo} dominates the carbon proportion for most samples and the overall average for the carbonic springs of the ABQ basin is:
$$C_{carb} = 22.9\% \pm 21.4\%,$$
$$C_{org} = 22.6\% \pm 11.6\%, \text{ and}$$
$$C_{endo} = 55.3\% \pm 19.8\%.$$
Results of our new gas analyses are similar to what was reported by Newell et al. (2005) where gas chemistry, in particular for Salado Arroyo springs, shows a wide spectrum of mixing between a helium-rich endogenic end-member in lower left corner and air or air-saturated water on the right axis (Fig. 6).

IMPLICATIONS AND DISCUSSION

The multiple tracer method shows similar trends among hydrochemistry, carbon isotopes and gas chemistry. Springs that lie along a mixing line from meteoric (Ca-Mg-HCO_3-Cl) to endogenic (Na-SO_4) end members in the Piper diagram (Fig. 3)
FIGURE 3. Piper diagram projects cation and anion triangles in lower part of the diagram into central parallelogram and shows three mixing trends for epigenic and endogenic mixing, with the epigenic end member, Ca-HCO$_3$, shown in the left corner of the parallelogram and three different endogenic end-members shown in the remaining three corners. The western and central rift carbonic springs and Coyote springs along the Tijeras fault are mostly Na-SO$_4$ waters. The next endogenic end member is Ca-SO$_4$, present in the Eddlemen spring of the Colorado Plateau and southeast Sevilleta springs. The last endogenic member is Na-HCO$_3$, found in the southwestern Sevilleta springs. This paper is mainly interested in the Na-SO$_4$ and Na-Cl endogenic end member, which is interpreted to reflect input of magmatic volatiles from the Socorro magma body. Springs displayed as small black dots are from Goff et al. (1983); these springs plot in all three endogenic water types on the Piper diagram and provide supporting evidence of complex mixing among multiple geothermal end members.

also have δ^{13}C$_{ext}$ values around -5‰, typical of deeply sourced CO$_2$, as shown in the C$_{ext}$ plot (Fig. 4). Among these springs the highest concentrations of endogenic carbon are at San Acacia Spring with 0.33 mol/L, Four Daughters with 0.09 mol/L and Salado Arroyo springs with 0.027 mol/L. These springs also have high conductivities: San Acacia has 23,000 µS, Four Daughters has 38,000 to 59,000 µS and Salado Arroyo has 5950 µS. In the non-reactive gas plot (Fig. 6), results from Salado Arroyo springs creates a mixing line between helium-rich to air-like gases. The other gas sample plotted is Four Daughters spring, which plots close to air-saturated water.

The chemical tracers in the carbonic springs of the Albuquerque basin plot along linear trends in each figure (Piper, carbon isotopes, and dissolved gases) implying mixing among end members. The linear trends extend toward accepted endogenic values. Pure endogenic endmember fluids, for example gases from the mantle, are not available to sample, but the consistency among tracers supports the hypothesis of mixing between epigenic and endogenic end members.

The linear mixing patterns shown in the Albuquerque basin springs are similar to the mixing trends of the Socorro spring and New Mexico Tech well from Williams et al. (2013). Similarities include Na-SO$_4$ as the dominate ions and δ^{13}C values around -4 to -5‰. Socorro waters are different from the Albuquerque basin because they are lower in external carbon concentrations at 0.006 mol/L. According to non-reactive gases (Fig. 6), Socorro waters plot along the helium-rich to air-saturated water end members, clearly showing endogenic He additions.

Western rift margin waters suggest a mixing trend involving endogenic waters. This region overlies the Socorro magma body and the Socorro seismic anomaly (Fig. 1). The Socorro magma body may be the source of endogenic input in the Albuquerque Basin springs, and the Socorro seismic anomaly may help fluids flow upwards along faults. The conduit system for ascent of endogenic fluids likely involves basaltic magmas originating as partial melt from the mantle, CO$_2$ degassing from above the magma body, interaction with basin

FIGURE 4. C$_{ext}$ (concentration of external carbon) plotted versus δ^{13}C (of C$_{ext}$) allows calculation of C$_{org}$ versus C$_{endo}$ components of the C$_{ext}$. External carbon is the concentration of only the organic and endogenic sources of carbon, in other words the carbon from dissolution of carbonates is subtracted out. This figure shows binary mixing curves between C$_{org}$ (at -28‰ and low concentrations of external carbon) and C$_{endo}$ (ranging from -3 to -6‰, with high concentrations of external carbon). The springs with the highest concentration of C$_{ext}$ are Laguna (LAG), Four Daughters (FDS) and Rio Salado Box (RSB) along the western rift faults, San Acacia (SanA) along the Cliff fault, and Coyote (COY) at the intersection of the Sandia and Tijeras fault zones. The carbonic western rift-flank springs have δ^{13}C values around -5‰, a typical endogenic end member.
FIGURE 5. Triangular plot of the carbon sources for each spring derived from the C_{ext} (external carbon) analysis (see figure 4 caption). Western rift springs Laguna (LAG), Four Daughters (FDS), Rio Salado Box (RSB), Canyon del Ojito (CO), Salado Arroyo (SAS) range from 17.5 to 74.8% endogenic carbon.

FIGURE 6: Trilinear plot of non-reactive gases in different springs. The non-reactive gases, Ar-N_2-He, create a mixing line from endogenic (helium rich) to epigenic gases (air and air saturated water). Air and air-saturated waters have trace concentrations of helium compared to Ar and N_2, and are defined by their N_2/Ar ratios.

brines, upward ascent on faults, and near-surface degassing of CO_2 around spring vents that causes deposition of travertine (Crossey et al., 2016).

The high CO_2 in the endogenic fluids is interpreted to be derived in part from the Socorro Magma body. This is not incompatible with the finding of Goff et al. (1983) based on chemical geothermometers that waters along the Comanche fault (their S-type waters) equilibrated at temperatures of less than

30-60°C and groundwaters of the Lucero uplift (their D-type waters) equilibrated at temperatures of <30°C. Based on current data, we agree with their conclusion that these waters have little potential for geothermal electricity generation, but that inputs of geothermal water helps explain the hydrochemistry and that geothermal direct use potential may be present.

CONCLUSIONS

The results show that endogenic volatiles and solutes are present in springs on both sides of the Rio Grande rift and on intra-rift faults. These spring waters are dominated by Na-SO_4, high concentration of endogenic carbon and $\delta^{13}C_{ext}$ values around -5‰. We suggest the CO_2 along the west flank of the rift of the Albuquerque basin was derived in part from magmatic degassing of the Socorro magma body that likely affects a large region beneath west flank springs, including the Socorro spring and New Mexico Tech well. This paper shows the importance of studying tectonic controls on spring water chemistry because it highlights the need to better understand the influence of even small volumes of geothermal fluids on regional groundwater and mixing processes within the deep aquifer.
