### Just Accepted

“Just Accepted” manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides “Just Accepted” as a service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. “Just Accepted” manuscripts appear in full in PDF format accompanied by an HTML abstract. “Just Accepted” manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are citable by the Digital Object Identifier (DOI®). “Just Accepted” is an optional service offered to authors. Therefore, the “Just Accepted” Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the “Just Accepted” Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these “Just Accepted” manuscripts.

**ABSTRACT**

This paper describes the relationship between molecular structure, and the rectification of tunneling current, in tunneling junctions based on self-assembled monolayers (SAMs).

Molecular dipoles from simple organic functional groups (amide, urea, and thiourea) were introduced into junctions with the structure  $\text{Ag}^{\text{TS}}/\text{S}(\text{CH}_2)_n\text{R}(\text{CH}_2)_m\text{CH}_3//\text{Ga}_2\text{O}_3/\text{EGaIn}$ . Here, R is an *n*-alkyl fragment ( $-\text{CH}_2-$ )<sub>2 or 3</sub>, an amide group (either  $-\text{CONH}-$  or  $-\text{NHCO}-$ ), a urea group ( $-\text{NHCONH}-$ ), or a thiourea group ( $-\text{NHCSNH}-$ ). The amide, urea, or thiourea groups introduce a localized electric dipole moment into the SAM and change the polarizability of that section of the SAM, but do not produce large, electronically delocalized groups or change other aspects of the tunneling barrier. This local change in electronic properties correlates with a statistically significant, but not large, rectification of current ( $r^+$ ) at  $\pm 1.0$  V (up to  $r^+ \sim 20$ ). The results of this work demonstrate that the simplest form of rectification of current at  $\pm 1.0$  V, in EGaIn junctions, is an interfacial effect, and is caused by a change in the work function of the SAM-modified silver electrode due to the proximity of the dipole associated with the amide (or related) group, not to a change in the width or mean height of the tunneling barrier.

**Keywords:** rectification, EGaIn electrode, dipole moment, work function, molecular electronics, self-assembled monolayers, charge tunneling.

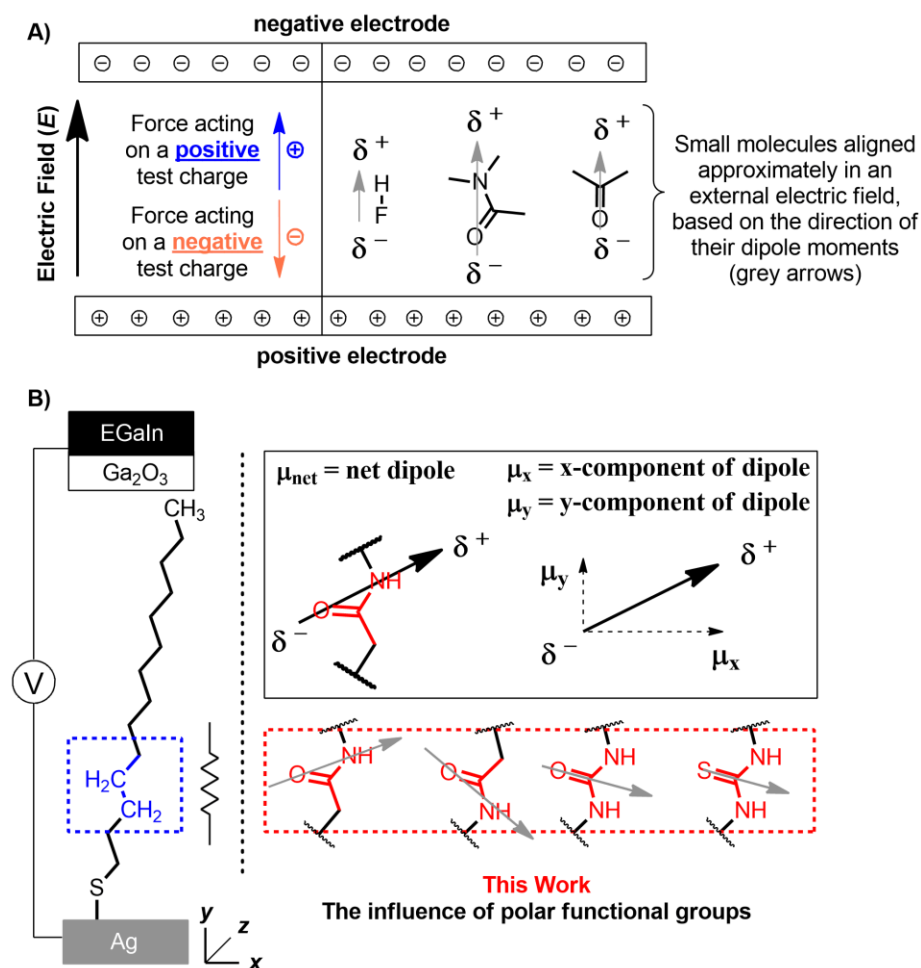

## INTRODUCTION

Interest in molecular electronics has developed, in part, based on the proposition that organic synthesis would enable so-called “wave-function engineering,” and that current-voltage characteristics of junctions containing organic compounds could be tailored through modifications of molecular structure.<sup>1-7</sup> One of the original stimuli in this field was a paper by Aviram and Ratner,<sup>8</sup> which proposed that a single organic molecule with a  $\pi$ -donor and a  $\pi$ -acceptor separated by an insulating sigma bridge—a so-called donor-sigma-acceptor (D- $\sigma$ -A) system—could, under an applied field, rectify current. This proposal—based on a general consideration of rectification in terms of a favorable molecular orbital framework—has been interpreted to be in agreement with results obtained in a number of studies using molecular rectifiers,<sup>9-17</sup> although not with systems incorporating ferrocene<sup>13;18-26</sup> and bipyridyl<sup>27</sup> groups, where rectification seems to reflect a combination of hopping and tunneling. The *mechanisms* of rectification in most systems involving tunneling are still being established.

Molecular orbital theory formed the basis of the Aviram-Ratner proposal for rectification. In this model, the alignment of donor and acceptor energy levels in the molecule, in addition to those of the electrodes, contributes to the passage of current. This model suggested that the internal energetic topography of the molecule is capable of influencing the tunneling barrier, and that effect is dependent on the sign of the applied bias. The design of an Aviram-Ratner-type rectifier proved to be difficult to implement experimentally, but many (and many types of) molecular rectifiers and diodes have been demonstrated in Langmuir-Blodgett films,<sup>28-29</sup> in SAMs,<sup>20-21;23;27;30-34</sup> and in single-molecule devices.<sup>35-37</sup> Rectification is also possible in a purely tunneling system (e.g. not a combination of hopping and tunneling<sup>21</sup>) if the energy barrier is sufficiently asymmetric.<sup>17;37-39</sup>

1  
2  
3 Our objective for this work was to understand if the presence of a simple dipolar group  
4 within a SAM—in the absence of accessible delocalized molecular orbitals—would alter the  
5 shape of the tunneling barrier (and perhaps the work function of the electrodes) sufficiently to  
6 induce the rectification of current, and/or to alter tunneling current density (Figure 1). We also  
7 wished to test the influence of the position of this polar group in the SAM—relative to each  
8 electrode—using junctions of the form  $\text{Ag}^{\text{TS}}/\text{SAM}/\text{Ga}_2\text{O}_3/\text{EGaIn}$  (here  $\text{Ag}^{\text{TS}}$  is a template-  
9 stripped silver substrate, and EGaIn is eutectic gallium-indium alloy, with its surface film of  
10 electrically conducting  $\text{Ga}_2\text{O}_3$ ).<sup>40-42</sup>

21 ~~The dipole moment induced in an *n*-alkanethiolate-based SAM under an external electric~~  
22 ~~field is assumed to be negligible.~~<sup>43</sup> Among the possible dipolar groups that can generate  
23 permanent dipole moments in SAMs we chose amide, urea, and thiourea groups. These  
24 functional groups are relatively redox-inert, and will not strongly perturb the structure of the  
25 HOMO or LUMO, but have a substantial dipole moment ( $\sim 4\text{-}5$  Debye)<sup>44-49</sup>. We incorporated  
26 these groups systematically in place of  $-(\text{CH}_2)_2-$  or  $-(\text{CH}_2)_3-$  groups in the SAM, while keeping  
27 both interfaces (Metal/SAM and SAM// $\text{Ga}_2\text{O}_3$ ) unaltered. We examined tunneling currents  
28 through two homologous series of molecules (Figure 2) with structures (i)  
29  $\text{HS}(\text{CH}_2)_m\text{XY}(\text{CH}_2)_n\text{H}$ , where  $-\text{XY}-$  is  $-\text{CH}_2\text{CH}_2-$ ,  $-\text{CONH}-$  and  $-\text{HNCO}-$ , and  $m + n = 12$   
30 such that  $1 \leq m \leq 11$ , and (ii)  $\text{HS}(\text{CH}_2)_2\text{XYZ}(\text{CH}_2)_6\text{CH}_3$ , where  $-\text{XYZ}-$  is  $-\text{CH}_2\text{CH}_2\text{CH}_2-$ ,  $-\text{CH}_2\text{CONH}-$ ,  
31  $-\text{NHCONH}-$ ,  $-\text{NHCSNH}-$ , or  $-\text{NHCOCH}_2-$ .

35 **Figure 1.** (A) Representation of small molecules aligned in an external electric field, based on  
 36 the direction of their dipole moments. (B) Schematic representation of an alkanethiol SAM,  
 37 within an electrical circuit made from the EGaIn junction, where the  $-\text{CH}_2\text{CH}_2-$  groups (blue)  
 38 act as resistive elements in the circuit. The red box shows the dipolar functional groups used in  
 39 this work. Approximations of their associated dipole moments are represented by grey arrows.  
 40  
 41 The black box (above) shows the convention that we use for drawing a dipole moment. The net  
 42 dipole moment ( $\mu_{\text{net}}$ ) can be decoupled into its x- and y-components ( $\mu_x$  and  $\mu_y$ ) relative to the  
 43 mean plane of the surface of the electrode, and points towards the region of positive electrical  
 44 charge.

3 **Dipole Moment Convention.** This paper uses the convention used by physicists for  
4 drawing dipole moments. That is, we draw the dipole as an arrow that points towards the region  
5 of positive electrical charge; this arrow represents the direction with which a polar molecule will  
6 align in an external electric field (Figure 1A). Chemists, in contrast (and despite the IUPAC  
7 definition), usually draw dipole moments in the opposite direction, where the arrowhead points  
8 towards the region of negative electrical charge.<sup>50</sup>

## 10 11 12 13 14 15 16 17 **BACKGROUND**

18  
19 **Definition of the Rectification Ratio.** We define the rectification ratio ( $r$ ) as the absolute  
20 value of the larger current density at a particular voltage divided by the absolute value of the  
21 current density at the opposite bias but the same magnitude of voltage. We also include an  
22 indication of polarity:  $r^+ = |J(+V)|/|J(-V)|$  or  $r^- = |J(-V)|/|J(+V)|$ ; in this definition,  $r$  is always  $\geq$   
23 1. In EGaIn junctions, the bottom electrode (Ag<sup>TS</sup> in this study) is always grounded, and the sign  
24 of the voltage is defined by the polarity of the EGaIn electrode; “+V” means the polarity of  
25 EGaIn is positive and it (or, more precisely, its electrically conducting Ga<sub>2</sub>O<sub>3</sub> surface film) is  
26 oxidizing relative to the Au or Ag electrode, and “-V” means the polarity of the Ga<sub>2</sub>O<sub>3</sub>/EGaIn  
27 electrode is negative and it is reducing, relative to that electrode.

40 Factors unrelated to the molecular structure might—in principle—induce rectification,  
41 due perhaps to i) the presence of oxides or contaminants on the surface of the electrodes; ii) a  
42 difference in the work function of the electrodes; iii) asymmetric contact at electrode-molecule  
43 interfaces, or iv) experimental uncertainty. Junctions composed of SAMs of  
44  $n$ -alkylthiolates on gold and silver surfaces, and using EGaIn as the top electrode, seem to  
45 produce  $r^+$  values of up to  $3 \pm 2$ . We attribute these values to differences between the bottom and  
46 top electrodes, including differences in the interfaces between the SAM and the Au or Ag

3 junction and the SAM and the Ga<sub>2</sub>O<sub>3</sub>/EGaIn electrode, and the polarizability of the sulfur atom  
4 which is covalently bound to the Ag or Au (bottom) electrode.<sup>51</sup> We do not consider a value of  
5 this size to demonstrate the occurrence of rectification due to electronic features of the SAM. We  
6 use this value of  $|r|$ —a value generated for SAMs of *n*-alkanethiolates—as a threshold for  
7 determining significant *r* values in other molecular systems. In practice, and with a degree of  
8 subjectivity, we consider any value of  $r < 5$  to be too small to be reliably assigned to (or  
9 mechanistically interpreted in terms of) molecular rectification,<sup>40</sup> although smaller values of *r* are  
10 routinely observed (and reported) even with the structurally simplest SAMs.

22 **Factors that may Lead to Rectification of Current in a Tunneling Junction.** The  
23 proposal of Aviram-Ratner for D-σ-A rectifiers<sup>8</sup> is based on a specific molecular orbital  
24 framework in which the frontier molecular orbitals of the D/A system align energetically with  
25 the Fermi levels of the electrodes at one particular bias; application of the opposite bias does not  
26 lead to such alignment of energy levels, with the result of asymmetry in the *I/V* trace.  
27  
28 Experimental evidence for this type of rectifier (with  $r^+$  of  $\sim 5$ ) was claimed by Metzger and  
29 coworkers<sup>52</sup> using a D-π-A system ( $\gamma$ -hexadecylquinolinium tricyanoquinodimethanide). The  
30 authors suggested two origins for rectification: i) the position of the frontier molecular orbitals  
31 relative to the Fermi levels of the electrodes and, ii) an asymmetric drop in the electrostatic  
32 potential across the molecule due to the presence of a large dipole moment.<sup>52-53</sup>  
33  
34  
35  
36  
37  
38  
39  
40  
41  
42  
43  
44

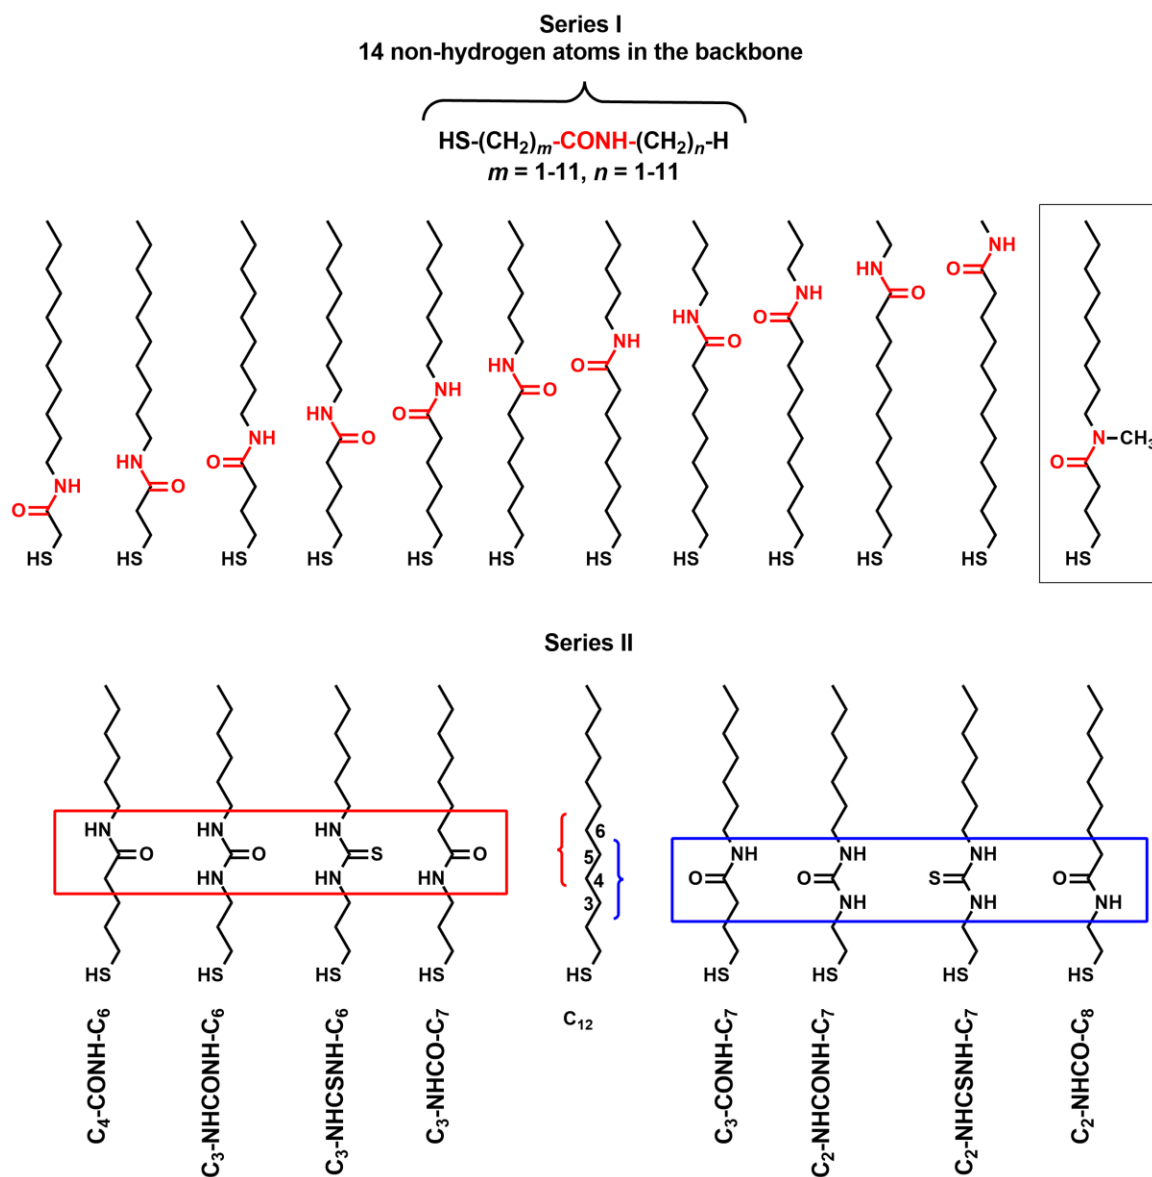

45 Ratner and coworkers suggested,<sup>54</sup> as an alternative source of rectification, that  
46 asymmetry in *I/V* curves could be achieved from perturbations in the electrostatic potential  
47 profile of a molecular junction; these changes in electrostatic potential could take place across  
48 the molecular bridge or at the metal/molecule interfaces.<sup>17,51 38,55</sup> For this type of rectification  
49 two mechanisms have been suggested. i) *A dipole-induced mechanism.* In this mechanism the  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 profile of the potential generated by the applied bias is perturbed by an electrical dipole  
4  
5 (permanent or induced) localized in a molecule or group<sup>29;35;55-57</sup>. Accordingly, the energy levels  
6  
7 of the molecular orbitals (especially the HOMO for hole tunneling) change with the bias. Bias in  
8  
9 one direction might bring a molecular orbital closer to resonance with the Fermi level,  $E_F$ , of an  
10  
11 electrode, and reduce the tunneling barrier, while a bias of the same magnitude in the opposite  
12  
13 direction would have an inverse effect and increase the tunneling barrier. ii) *Molecular*  
14  
15 *asymmetry*. Rectification might appear in a molecular orbital structure that is coupled differently  
16  
17 to the two electrodes. Such asymmetric couplings might lead to an asymmetric electric potential  
18  
19 profile along the molecule, and lead to rectification (although a detailed mechanism of  
20  
21 rectification has not been clearly identified).<sup>38;51;55</sup>

## 22 23 24 25 26 **EXPERIMENTAL DESIGN**

27  
28 **Structural Design of Dipole-Embedded Alkylthiolates.** To determine the influence of  
29  
30 an embedded dipole moment (that is, a dipole in an otherwise non-polar SAM) on the  
31  
32 rectification of current, we compared two series of compounds (Series I and II; Figure 2). In  
33  
34 Series I, we placed an amide group,  $-\text{CONH}-$ , at each position along the backbone of a  $\text{C}_{14}$ -  
35  
36 alkylthiolate chain to determine if the position of the dipole, and (perhaps) the inter-chain H-  
37  
38 bonding between amide groups, has an effect on the rate of tunneling currents at either positive  
39  
40 or negative bias. We designed the structural perturbations to include a minimum of at least one  
41  
42 methylene group ( $-\text{CH}_2-$ ) as spacer between the amide group and the electrodes; this spacer  
43  
44 serves to isolate (at least by direct conjugation<sup>58</sup>) the amide/urea group and its dipole from the  
45  
46 sulfur atom and the electrode.<sup>27;59-62</sup> The mixture of interactions between HOMOs is, however,  
47  
48 apparently more delocalized than anticipated by direct interaction of  $\pi$ -orbitals, and we have not  
49  
50 quantified this interaction.  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

**Figure 2.** Schematic representation of the structural variations upon the inclusion of the amide group in the backbone of  $\text{C}_{14}$ -alkanethiol (Series I) and the inclusion of the amide, the urea, and the thiourea groups in the backbone of  $\text{C}_{12}$ -alkanethiol (Series II). “ $m$ ” indicates the number of methyl groups between the sulfur anchoring atom and the amide group and “ $n$ ” indicates the number of methyl groups between the amide group and the terminal hydrogen atom in contact with the top electrode.

1  
2  
3 In the second series of molecules (Series II, Figure 2), we embedded different functional  
4 groups and changed the orientation of the amide group by replacing  $-\text{CONH}-$  with  $-\text{NHCO}-$ .  
5  
6 We also changed the chemical structure, polarizability and dipole moment of the polar group by  
7  
8 introducing urea ( $-\text{NHCONH}-$ ), and thiourea groups ( $-\text{NHCSNH}-$ ), and compared their charge-  
9  
10 transport characteristics. To understand the influence of a urea or thiourea moiety on charge  
11  
12 transport, we kept the overall length of the molecule equivalent to dodecanethiol ( $\text{C}_{12}$ ) (Figure  
13  
14 2); that is, we kept the width of the tunneling barrier very close to the same, so the change in  
15  
16 current density, if any, should allow us to recognize a change in tunneling current that correlates  
17  
18 with the chemical (or electronic) structure of the molecule or the dipole groups embedded in it.  
19  
20  
21  
22

23  
24 **Electronic Influence of Dipolar Groups.** Amide ( $\mu \sim 4 \text{ D}$ ),<sup>44-46</sup> urea ( $\mu \sim 4\text{-}5 \text{ D}$ ),<sup>47-49</sup>  
25  
26 and thiourea ( $\mu \sim 4\text{-}5 \text{ D}$ )<sup>47;63</sup> groups have large dipole moments and high polarizabilities,  
27  
28 relative to those associated with the  $-(\text{CH}_2)_{n=2,3}-$  groups ( $\mu \sim 0 \text{ D}$ ) they replace.<sup>64</sup> This change in  
29  
30 electronic structure can, in principle, induce changes in rates of charge transport.<sup>54</sup> Amide and  
31  
32 urea/thiourea groups also introduce a different orientation of the dipole vector relative to the  
33  
34 (assumed) direction of charge tunneling (Figure 1B). Thus, the inclusion of an  
35  
36 amide/urea/thiourea group in the structure of a tunneling junction might result in a significant  
37  
38 change in the electrostatic potential along the charge-transport pathway, and change either the  
39  
40 rate of charge tunneling through the junction, or the rectification ratio ( $r$ ) (that is, relative the  
41  
42 rates of tunneling in opposite directions at the same absolute value of voltage  $|V|$ ).  
43  
44  
45  
46  
47

48 **Structure of SAMs Containing Amide and Urea Groups.** We<sup>65</sup> and others<sup>66-68</sup>  
49  
50 observed that the replacement of  $-\text{CH}_2\text{CH}_2-$  by an amide group (either a  $-\text{CONH}-$  or a  
51  
52  $-\text{NHCO}-$ ) enhances the stability of the SAM, possibly through inter-chain H-bonding. Structural  
53  
54 studies on amide-<sup>66-68</sup> and urea-<sup>69-71</sup> containing SAMs have shown that the  $\text{C}=\text{O}$  and  $\text{N}-\text{H}$  of the  
55  
56  
57  
58  
59  
60

1  
2  
3 H-bonded amides or ureas are oriented approximately parallel to the metal surface (Figure 2).  
4  
5 The formation of intermolecular hydrogen bonding between the chains in the SAM causes a  
6  
7 change in the tilt angle<sup>72</sup> (the tilt angle decreases from  $\sim 24^\circ$  to  $18^\circ$  on gold) in order to  
8  
9 accommodate a conformation favorable for formation of the C=O---H—N H-bond between  
10  
11 molecules. This change in the tilt angle—concurrent with a change in the inter-chain distance  
12  
13 caused by the H-bonding networks—leads to a change in the order and conformation of the alkyl  
14  
15 chains in the SAM.<sup>65</sup> The change in the tilt and twist angles is also dependent on the position of  
16  
17 the amide group relative to the metal-thiol interface, and on the overall length of the alkyl chain  
18  
19 in the overlayer.<sup>65-68</sup> The structure of SAMs containing a urea group is slightly more  
20  
21 complicated; each urea group has been suggested to form *four* hydrogen bonds—two acceptors  
22  
23 and two donors—with neighboring urea groups.<sup>69-71</sup>  
24  
25  
26  
27  
28

## 29 **EXPERIMENTAL METHODS**

30  
31 **Synthesis of Urea- and Thiourea-Containing Alkylthiolates.** Amide-, urea- and  
32  
33 thiourea-based compounds were synthesized using a previously reported protocol (see SI for  
34  
35 details).<sup>73</sup> For convenience, we abbreviated the names of the compounds using the assignments  
36  
37 in Figure 1.  
38  
39

40  
41 **Formation of the SAMs on Silver Bottom Electrodes.** SAMs of amide-, urea- and  
42  
43 thiourea-based compounds were formed on the template-stripped surface of silver ( $\text{Ag}^{\text{TS}}$ )<sup>74</sup> using  
44  
45 a thiol anchoring group. We immersed the surface in a nitrogen-purged ethanolic solution of the  
46  
47 thiol (3 mM). After 12 hours of incubation under a nitrogen atmosphere, we rinsed the SAMs  
48  
49 with ethanol (30 mL) and dried them by evaporation under a gentle stream of nitrogen. We used  
50  
51 SAMs for electrical measurements immediately after drying.  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3       **Measurements of Work Function (WF).** We performed measurements of work function  
4 using a K-Alpha XPS system. This system is equipped with an X-ray source with energy 1486.6  
5 eV. A biasing stage held the samples in electrical contact with the analyzer; -30 V applied to the  
6 stage accelerated the secondary electrons and helped to detect their cut-off. We recorded the  
7 secondary electron cut-off from 32 to 38 eV (kinetic energy), and the Fermi edge from -35 to -25  
8 eV (binding energy). We extrapolated the secondary electron cut-off to the x-axis to determine  
9 the vacuum level ( $E_v$ ). Using the vacuum energy and Fermi level ( $E_f$ ), we calculated the WF (WF  
10 =  $E_v - E_f$ ) of the SAM-modified Ag surfaces, which is the energy required to eject a  
11 photoelectron from the surface of the metal-sulfur interface, through the monolayer, to the  
12 detector located within a vacuum chamber at  $1 \times 10^{-8}$  mbar. Work functions calculated in this way  
13 are generally used to represent the Fermi level of the modified metal surface: that is, the energy  
14 level of the electrons in the highest energy occupied states at the SAM-modified metal surface.  
15  
16

17       **Measurement of Current Density.** We measured the current density along SAMs of the  
18 molecules (Series I and II; Figure 2) on  $\text{Ag}^{\text{TS}}$  surfaces in steps over a range from + 1.0 V to -1.0  
19 V (the Ag electrode was always grounded, and potentials are referenced to ground potential). For  
20 each SAM, the values of  $\log|J(V)|$  are approximately normally distributed and could be fit to  
21 Gaussian curves. (We thus assume—incorrectly, at some level—no systematic error in the  
22 experiments—that is, only random noise—and a single peak. In fact, although a majority of the  
23 data are compatible with this assumption, some compounds seem to yield data with intrinsic  
24 heterogeneity; see the SI for the raw data). Figures S1-S6 (in Supporting Information) show the  
25 histograms for the values of  $\log|J(V)|$  ( $J$ ,  $\text{A}/\text{cm}^2$ ) for SAMs of *n*-alkylthiolates and amide-  
26 containing compounds on  $\text{Ag}^{\text{TS}}$ . The Supporting Information summarizes details of electrical  
27 measurements.

2  
3       **Statistics.** For every molecule used in this work, we collected data on three separate  
4 chips (separately prepared SAMs). We analyzed at least ten (and maximum twenty three)  
5 junctions for each chip and collected 21 J(V) traces per junction. Each J(V) trace involves a  
6 forward-bias sweep and a reverse-bias sweep; see supporting information for details. This  
7 procedure provides a minimum of 420 measured values of current density (J) for each applied  
8 voltage. The histograms take into account every measured value of J at a given voltage. We fit  
9 the histograms with Gaussian curves to obtain the log-mean and log-standard deviations. The  
10 plots of  $\log|J|-V$  are derived from the average of all traces. We calculate the values  
11 of rectification ( $r^+$ ) for each molecule by averaging the values at  $|J(+V)|/|J(-V)|$  for every  
12 measured J(V) trace (i.e., the reported value of  $r^+$  is an average of all values of  $r^+$  that we  
13 measured). The corresponding histograms of  $r^+$  were fitted to Gaussian functions to obtain the  
14 log-mean and the log-standard deviation.

## 30       **RESULTS AND DISCUSSION**

31       **At  $\pm 0.5$  V the Presence of an Amide, Urea, or Thiourea Bond does not Influence**  
32  
33       **Rates of Charge Tunneling.** We reported previously that the inclusion of an amide group (–  
34 CONH– or –NHCO–) in place an ethylene group (–CH<sub>2</sub>CH<sub>2</sub>–), in alkylthiolates, 11 or 12 atoms  
35 from the sulfur anchoring group, has no statistically significant effect on the rate of charge  
36 tunneling at  $\pm 0.5$  V.<sup>73;75-77</sup> Here, we made systematic substitutions along the backbone of a C<sub>14</sub>-  
37 alkylthiolate (Figure 2, Series 1) by replacing an ethylene group (–CH<sub>2</sub>CH<sub>2</sub>–) with an amide  
38 group (–CONH–) at each position. The values of  $J(\pm 0.5$  V) for the *n*-alkylthiolates and amide-  
39 containing compounds examined here are not distinguishable (at the precision of our  
40 measurements; Figures S1, S7, Table S1); that is, the values of  $\langle \log|J(V)| \rangle$  for amide-containing  
41 compounds are not distinguishable from that of a C<sub>14</sub>-alkylthiolate. Similarly, the values of  $J(\pm$

1  
2  
3 0.5 V) for the amide-, urea-, and thiourea-containing C<sub>12</sub>-alkylthiolates of Series II are not  
4 distinguishable from a C<sub>12</sub>-alkylthiolate standard (Table 1, Figure S2, S3, S7; see SI for  
5  
6 additional details, including apparent trends in  $\log|J|$  at  $\pm 0.5$  V).  
7  
8  
9

10 Measurements of  $J(V)$  at an applied bias of  $\pm 0.5$  V resulted in almost symmetric voltage  
11 profiles at forward and reverse biases for all compounds; that is, none of the compounds  
12 measured showed a rectification ratio larger than 2.5 (Tables S1 and S3). In our judgment,  
13  
14 rectification ratios that are  $< 5.0$  should not, in the absence of other information, be interpreted to  
15 originate from the SAM and its molecular orbitals or electrical characteristics.<sup>53</sup> These data  
16  
17 indicate that incorporation of chemical linkages such as amide or urea groups—even with large  
18  
19 dipoles ( $\mu \sim 5$  Debye)—into SAMs across the pathway of a tunneling current does not cause  
20  
21 rectification of current at  $\pm 0.5$  V.  
22  
23  
24  
25  
26  
27

28 **At  $\pm 1.0$  V, the Presence of an Amide, Urea, or Thiourea Bond Can Influence the**  
29 **Current Density, and Result in Rectification.** Increasing the applied voltage to  $\pm 1.0$  V  
30  
31 produced rectification of current; the magnitude of rectification depended on the location and  
32  
33 direction of the dipolar group (Table 1, Figures S2, S3, S7, S8). For the molecules in Series I, we  
34  
35 observed a small (relative to that observed with Fc and BIPY terminal groups at the SAM/Ga<sub>2</sub>O<sub>3</sub>  
36  
37 interface) but statistically significant rectification ratio ( $r^+ = |J(+1.0 \text{ V})|/|J(-1.0 \text{ V})| > 5$ ) when  
38  
39 the dipole—the amide group—was located close to the bottom (Ag<sup>TS</sup>) electrode, and in  
40  
41 particular, when the aliphatic spacer between the sulfur anchoring atom and the dipole group was  
42  
43 no more than three carbon atoms in length.  
44  
45  
46  
47  
48

49 By comparing the molecules in Series I that rectify current, and those that do not, we  
50  
51 conclude that rectification is caused predominantly by a larger increase in tunneling current at  
52  
53 positive bias (EGaIn is oxidizing) than at negative bias (EGaIn is reducing).  
54  
55  
56  
57

**Table 1.** Current density ( $\log|J|$ ) values and rectification ratios observed for SAMs composed of Series I compounds in a Ag/SAM//Ga<sub>2</sub>O<sub>3</sub>/EGaIn junction.

$$^a r^+ = \langle |J(+1.0 \text{ V})|/|J(-1.0 \text{ V})| \rangle.$$

1  
2  
3 For the amides that rectify, at positive bias, the increase in tunneling current from +0.5 V to +1.0  
4 V is larger (average  $\log|J(+1.0 \text{ V})| - \log|J(+0.5 \text{ V})| = 1.5 \text{ A/cm}^2$ ) than the increase observed for  
5  $\text{C}_{14}$  (average  $\log|J(+1.0 \text{ V})| - \log|J(+0.5 \text{ V})| = 0.8 \text{ A/cm}^2$ ). The amides that do not rectify,  
6  
7 however, show an increase in current at positive bias that is approximately the same as that  
8 observed for  $\text{C}_{14}$  ( $\log|J(+1.0 \text{ V})| - \log|J(+0.5 \text{ V})| = 0.9 \text{ A/cm}^2$ ). At negative bias the increase in  
9  
10 tunneling current observed from -0.5 V to -1.0 V for both rectifying amides (average  $\log|J(+1.0$   
11  $V)| - \log|J(+0.5 \text{ V})| = 0.8 \text{ A/cm}^2$ ) and non-rectifying amides (average  $\log|J(+1.0 \text{ V})| - \log|J(+0.5$   
12  $V)| = 0.6 \text{ A/cm}^2$ ) is nearly the same as that observed for  $\text{C}_{14}$  ( $\log|J(+1.0 \text{ V})| - \log|J(+0.5 \text{ V})| =$   
13  $0.6 \text{ A/cm}^2$ ). Clearly, these results (displayed graphically in Figure S11 in the supporting  
14  
15 information) demonstrate that rectification is the result of an increased rate of tunneling at  
16  
17 positive bias.

28

29 The molecules in Series II were designed to preserve the length of the aliphatic spacer  
30 (between the sulfur anchoring atom and the dipole) that results in (or is correlated with)  
31 rectification ( $m = 2, 3$ ), while changing the dipolar group. We observed that urea and thiourea  
32 groups all rectified current (Figure 3, S9, S10, Table 2, S2). Amide groups oriented in the  
33 opposite direction of those in Series I (*i.e.*,  $\text{C}_3\text{-NHCO-C}_7$  and  $\text{C}_2\text{-NHCO-C}_8$ ), however, did not  
34 rectify current. The only obvious difference in polarity between the  $\text{C}_m\text{-NHCO-C}_n$  amides and  
35 the  $\text{C}_m\text{-CONH-C}_n$  amides, is that the  $y$ -component of their dipoles must be aligned in opposing  
36 directions. Although the conformation of the chains and the exact orientations of the amide  
37 groups and of the associated dipoles is not known, no plausible configuration of the SAM (for a  
38 *trans*-extended conformation of the organic molecule, but independent of the tilt angle) reverses  
39 the direction of the component of the amide dipole relative to the mean plane of the surface.

$$^a r^+ = \langle |J(+1.0 \text{ V})| / |J(-1.0 \text{ V})| \rangle.$$

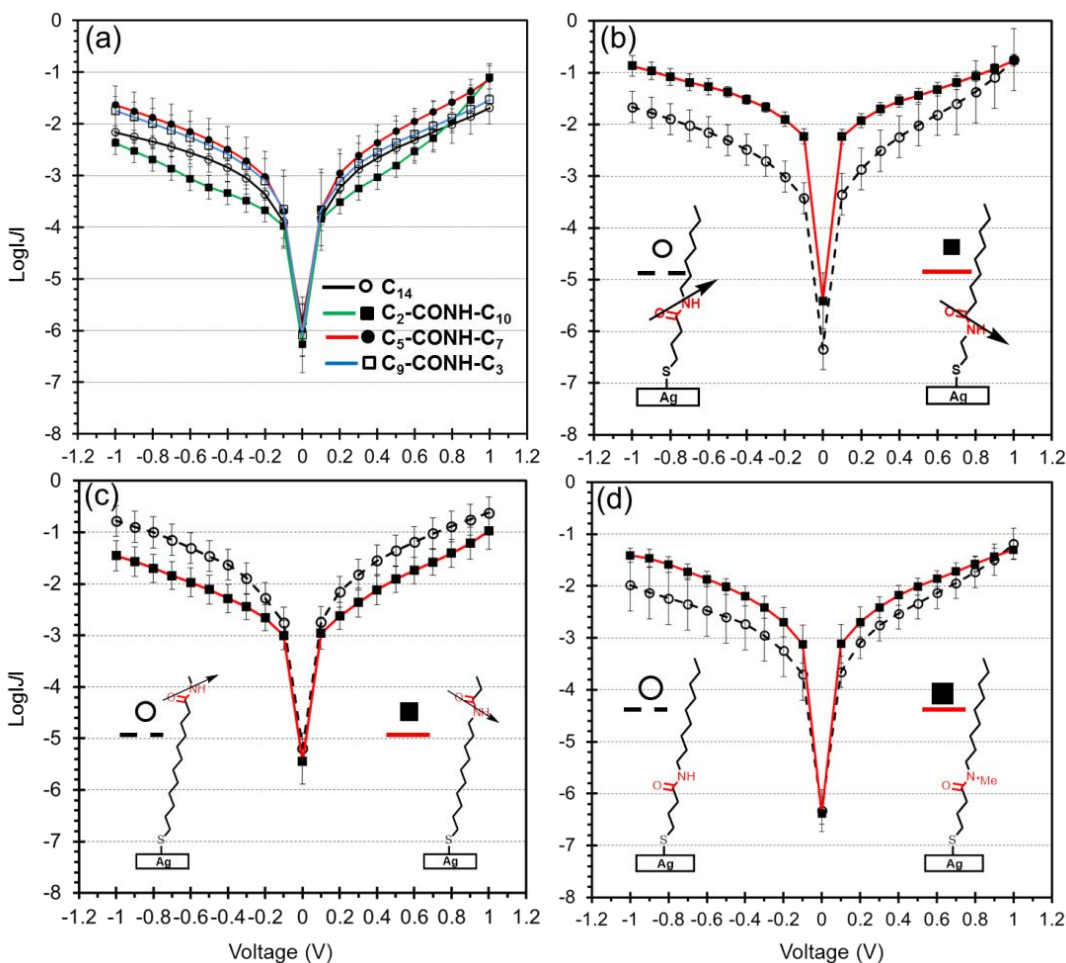

**Figure 3.** Plot of the rectification ratio ( $r^+ = \langle |J(+1 \text{ V})|/|J(-1 \text{ V})| \rangle$ ) at  $\pm 1.0 \text{ V}$ , for Series II compounds. The dashed line at  $r^+ = 5$  indicates the minimum value of rectification that we believe is statistically significant and is not a consequence of artifacts. The error bars represent the standard deviation of the mean values, and are asymmetric about the mean because of the conversion from log scale to linear scale. The error bars are relatively large because their size scales with: (a) the value of the log standard error and (b) the value of rectification with which the error is associated.

1  
2  
3 This difference between S(CH<sub>2</sub>)<sub>2-3</sub>CONHR and S(CH<sub>2</sub>)<sub>2-3</sub>NHCOR provided clear evidence that  
4 the orientation of the dipole moment is important for current rectification. We do not know the  
5 exact orientation of the dipoles of the urea and thiourea groups, relative to the Ag<sup>TS</sup> surface, and  
6 the differences in  $r^+$  for these molecules when  $m = 2$  and  $m = 3$  may be a consequence of the  
7 distance between the dipole and the Ag surface, or changes in the orientation of the molecules  
8 (and thus net dipole moment). Thus, we interpret these results to indicate that different dipolar  
9 groups, when positioned close to the bottom electrode, can cause rectification of current.

19 A comparison within Series II, between the molecules that rectify current, and those that  
20 do not, indicates that—as observed in Series I—rectification is a result of an increased rate of  
21 tunneling at positive bias. At positive bias, the molecules that rectify current showed larger  
22 increases in tunneling current from +0.5 V to +1.0 V (average  $\log|J(+1.0\text{ V})| - \log|J(+0.5\text{ V})| =$   
23  $1.4\text{ A/cm}^2$ ) than observed for C<sub>12</sub> ( $\log|J(+1.0\text{ V})| - \log|J(+0.5\text{ V})| = 0.7\text{ A/cm}^2$ ), or for the  
24 molecules that do not rectify (average  $\log|J(+1.0\text{ V})| - \log|J(+0.5\text{ V})| = 0.8\text{ A/cm}^2$ ). At negative  
25 bias, the increase in tunneling current from -0.5 V to -1.0 V was approximately the same for  
26 molecules that rectified (average  $\log|J(+1.0\text{ V})| - \log|J(+0.5\text{ V})| = 0.8\text{ A/cm}^2$ ), molecules that did  
27 not rectify (average  $\log|J(+1.0\text{ V})| - \log|J(+0.5\text{ V})| = 0.7\text{ A/cm}^2$ ), and C<sub>12</sub> ( $\log|J(+1.0\text{ V})| -$   
28  $\log|J(+0.5\text{ V})| = 0.6\text{ A/cm}^2$ ). Thus, the rectification observed with different dipolar groups is  
29 also the result of an increased rate of tunneling at positive bias. (These results are displayed  
30 graphically in Figure S12 in the supporting information)

46 **The Orientation of the Amide Bond Influences the Rectification.** A comparison  
47 between the current densities at  $\pm 1.0\text{ V}$  across SAMs of C<sub>4</sub>-CONH-C<sub>6</sub> ( $r^+ = 7.9$ ), C<sub>3</sub>-CONH-C<sub>7</sub>  
48 ( $r^+ = 9.5$ ), C<sub>3</sub>-NHCO-C<sub>7</sub> ( $r^+ = 1.8$ ), and C<sub>2</sub>-NHCO-C<sub>8</sub> ( $r^+ = 1.2$ ) demonstrates that the ratio of  
49 rectification is sensitive to the orientation of the amide bond (Figure 3).  
50  
51  
52  
53  
54  
55  
56

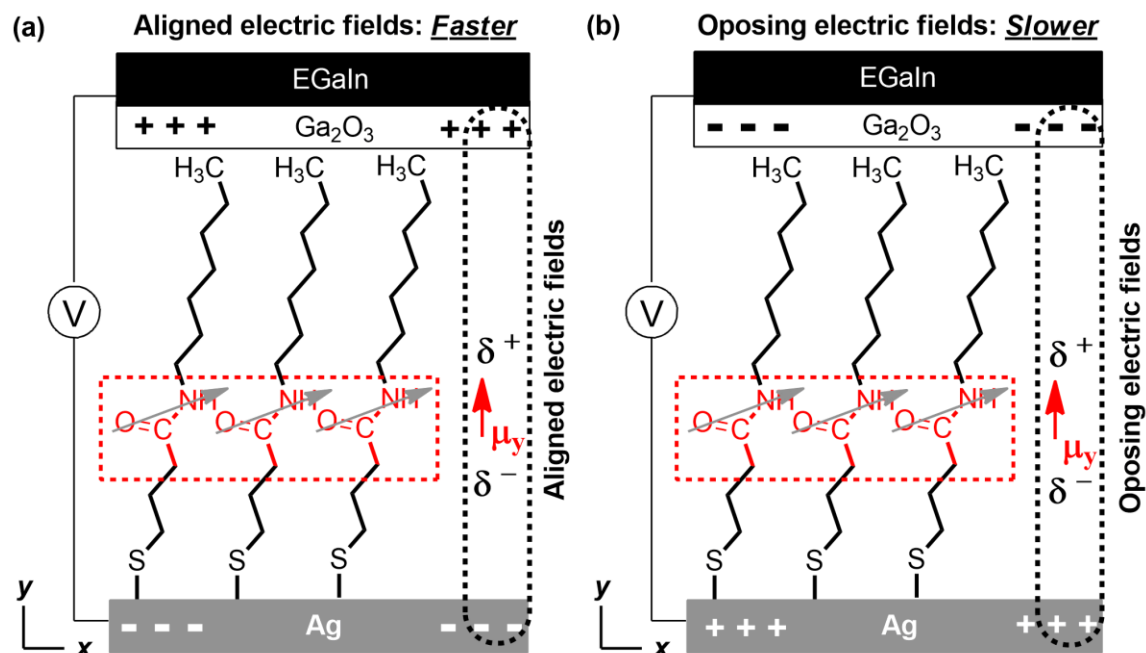

**Figure 4.**  $\text{Log}|J|$ - $V$  responses for four compounds investigated in this study: a) Position of dipole causes a rectification;  $\text{C}_{14}$  with an alkyl chain,  $\text{C}_2\text{-CONH-C}_{10}$  with the amide group close to the bottom interface,  $\text{C}_5\text{-CONH-C}_7$  with an amide group in the middle of the backbone, and  $\text{C}_9\text{-CONH-C}_3$  with an amide group close to the top interface. b) The direction of dipole, when the dipole is close to the bottom electrode, is important in observing rectification in current. c) The direction of dipole, when the dipole is close to the top electrode, does not influence the current density. d) The presence of intermolecular hydrogen bonds is important for the observation of rectification.

1  
2  
3 When the NH group is the group closer to the bottom ( $\text{Ag}^{\text{TS}}$ ) electrode (e.g.,  
4  $\text{S}(\text{CH}_2)_3\text{NHCOR}$  rather than  $\text{S}(\text{CH}_2)_3\text{CONHR}$ ), the y-component of the dipole ( $\mu_y$ ) changes  
5  
6 direction, and is oriented towards the  $\text{Ag}^{\text{TS}}$  electrode (Figure 4b). This change in dipole moment  
7  
8 orientation was accompanied by a decrease in the rectification ratio from  $r^+ = 9.5$  ( $\text{C}_3\text{-CONH-C}_7$ )  
9  
10 to  $r^+ = 1.2$  ( $\text{C}_2\text{-NHCO-C}_8$ ) and from  $r^+ = 7.9$  ( $\text{C}_4\text{-CONH-C}_6$ ) to  $r^+ = 1.8$  ( $\text{C}_3\text{-NHCO-C}_7$ ) (Figure  
11  
12  
13 3, 4b).  
14  
15

16  
17 When we analyzed the effect of inverting the dipole close to the EGaIn electrode,  
18  
19 however, by comparing the current density along  $\text{C}_{11}\text{-CONH-C}_1$  and  $\text{C}_{10}\text{-NHCO-C}_2$ , at  $\pm 1.0$  V  
20  
21 (Figure 4c), we observed no rectification of either, and thus no influence of the orientation of the  
22  
23 amide bond on the rectification ratio.  
24  
25

26 **The Rectification of Current Is Sensitive to the Supramolecular Structure of the**  
27 **SAM.** Our results (Figure 4a-d) showed that, for Series I molecules, the observed rectification  
28  
29 correlates with having a dipole moment close to the bottom electrode, with its y-component ( $\mu_y$ )  
30  
31 oriented perpendicular to (and away from) the mean plane of the Ag (bottom) electrode. Amide  
32  
33 bonds, when embedded in the SAMs of alkanethiolates, form hydrogen bonds. This network of  
34  
35 hydrogen bonds could help to order the molecules, and thus influence the magnitude and  
36  
37 direction of the fixed dipole. In the absence of intermolecular hydrogen bonds the structure of the  
38  
39 SAM might, in principle, be disordered; disorder would undoubtedly influence the net dipole  
40  
41 moment.<sup>72;78</sup> To examine the effect of hydrogen bonding on the rectification of current, we  
42  
43 compared the current density across SAMs of  $\text{C}_3\text{-CONH-C}_9$  and  $\text{C}_3\text{-CONMe-C}_9$  (Figure 4d).  
44  
45 These two compounds have (in principle) indistinguishable extended lengths, and differ only in  
46  
47 the elimination of the potential for interchain hydrogen bonding and in the substitution of  $\text{CH}_3\text{N}$   
48  
49 for HN in the amide group.

**Figure 5.** A schematic representation of a Ag<sup>TS</sup>/SC<sub>2</sub>CONHC<sub>7</sub>/EGaIn junction: (a) at +1.0 V applied voltage (EGaIn is oxidizing); the polarity of the electrodes is aligned with the y-component of the electric field generated by the dipole moment ( $\mu_y$ ) of the amide bond. The tunneling current is faster. (b) at -1.0 V applied voltage (Ag is oxidizing) the polarity of the electrodes is mis-aligned with the y-component of the electric field generated by the dipole moment ( $\mu_y$ ) of the amide bond. The tunneling current is slower.

1  
2  
3 Substituting a hydrogen atom for a methyl group—a change that converts C<sub>3</sub>-CONH-C<sub>9</sub> to C<sub>3</sub>-  
4 CONMe-C<sub>9</sub>—eliminates the possibility of hydrogen-bonding; it also has the potential to change  
5 local conformations in the SAM. Measurements of current density for these two compounds  
6  
7 yielded very different values of  $r^+$ : C<sub>3</sub>-CONH-C<sub>9</sub> ( $r^+ = 15.1$ ) and C<sub>3</sub>-CONMe-C<sub>9</sub> ( $r^+ = 1.3$ )  
8  
9 (Figure 4d). (We do not know the conformation of the individual molecules containing -CONH-  
10  
11 or -CONMe- groups.)

14  
15  
16  
17

18 **Proposed Origin of Dipole-Induced Rectification** Figure 5 shows a schematic of a SC<sub>2</sub>-  
19 CONH-C<sub>10</sub> SAM on a Ag<sup>TS</sup> surface, the polarity of the electrodes, and the directions of the  
20 dipole moments of the amides within the SAM. The y-component of the dipole ( $\mu_y$ ) generates a  
21 local electric field along the y-axis (perpendicular to the electrode surface). When the direction  
22 of  $\mu_y$  is aligned with the polarity of the electrodes the rate of the tunneling current is larger  
23 (Figure 5a) than when the applied electric potential is reversed (Figure 5b; cathodic top (EGaIn)  
24 electrode to anodic bottom (Ag<sup>TS</sup>) electrode), and the direction of the electrostatic field generated  
25 by the dipole opposes the polarity of the electrodes. We make these empirical observations from  
26 these results. i) Rectification occurs only when the dipole of the amide (or urea/thiourea) is close  
27 to the silver electrode. ii) Rectification reflects primarily an increase in J(V) at positive bias (that  
28 is, with Ga<sub>2</sub>O<sub>3</sub> oxidizing). iii) There is no rectification when the direction of the y-component of  
29 the dipole moment (perpendicular to the plane of the electrode surface) is reversed, and points  
30 toward the Ag surface

2  
3 dipole ( $\mu_y$ ) of the amide group points toward the EGaIn electrode. Rectification does not occur  
4  
5 when the dipolar group is separated from the bottom electrode by more than three carbon atoms.  
6

7  
8 Other groups have also reported a similar influence of the dipole moment on charge  
9  
10 transport using single molecule junctions (using peptides)<sup>79</sup> and/or large area junctions (with 1,2-  
11  
12 diazine,<sup>38</sup> and phenyl bromide<sup>80</sup>). The reported rectifications ( $r > 8$ ) in those studies, were similar  
13  
14 in size (although slightly smaller) than those we observe in this study. The rectification ratios in  
15  
16 these reports are also dependent on the magnitude of applied voltage.  
17  
18

19 **Analysis of Work Function Indicates that the Position of the Dipole Moment**  
20  
21 **Contributes to the Rectification of Current.** Previous work has shown that collective  
22  
23 electrostatic properties of SAMs, such as net dipole moment, can modify the work function of  
24  
25 the surface, relative to that of the bare metal.<sup>80-83</sup> To rationalize the mechanism of molecular  
26  
27 rectification, we measured the work function (WF) of the SAM-modified bottom-electrodes  
28  
29 using XPS (Table S3). We note here that our measurements of the vacuum level ( $E_v$ ) and the  
30  
31 Fermi level ( $E_f$ ), which we used to calculate the WF ( $WF = E_v - E_f$ ), are performed on the SAM-  
32  
33 modified Ag-electrodes. Thus, the values that we obtain are those of the SAM-modified Ag-  
34  
35 surface and they represent the energy of the emitted photo-electron outside of the surface of the  
36  
37 SAM and not just outside the Ag/S interface. Figure 6 summarizes the values of the WF as a  
38  
39 function of  $m$  (the number of methylene groups between S and the -CONH- group) for Series I.  
40  
41 Our measurements indicate that the WF of the SAM-modified surface changes (relative to C<sub>14</sub>-  
42  
43 alkylthiolate SAM) as a function of the position of the -CONH- group. In particular, when -  
44  
45 CONH- is positioned away from bottom electrode ( $m > 5$ ), the WF is less than that of a C<sub>14</sub>-  
46  
47 alkylthiolate SAM (3.78 eV), and when it is close to the bottom electrode ( $m = 1-4$ ), the WF is  
48  
49 larger (by 0.21 eV to 0.42 eV) than that of a C<sub>14</sub>-alkanethiolate SAM. The molecules in Series I  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 have similar chemical structures and surface coverage, and the amides are not expected to alter  
4 the Ag-S bonding energy (because they are separated by at least one -CH<sub>2</sub>- group).<sup>84</sup>  
5  
6 Nevertheless, molecules with a net dipole moment in the same direction as -CONH- are known  
7  
8 to decrease the WF relative to alkanethiolate-modified Ag. Our observation that -CONH-, when  
9  
10 positioned close to the Ag/S interface, increases the WF relative to a C<sub>14</sub>-alkanethiolate SAM  
11  
12 suggests that polarizable dipole moments, such as an imbedded amide group, can interact  
13  
14 electrostatically with the metal/organic interface. In this instance, the positional dependence  
15  
16 could be caused by the amide group withdrawing charge from the highly polarizable Ag<sup>δ+</sup>-S<sup>δ-</sup>  
17  
18 surface dipole (~0.6 Debye<sup>85</sup>) when they are in close proximity.  
19  
20  
21  
22  
23

24 Although the amide (-CONH-) groups embed a large dipole moment into individual  
25 molecules (Table S5), and we assume, into the SAM, the orientation of molecules within a SAM  
26 might cause some cancellation of dipole moments,<sup>86-87</sup> and lead to SAMs with a lower net-dipole  
27 moment ( $\mu_{\text{net}}$ ) than expected by considering only isolated molecules. The influence of orientation  
28 on the net dipole is supported by the difference in WF measurements and rectification ratios  
29 between C<sub>3</sub>-CONH-C<sub>9</sub> (WF = 4.2 eV,  $r^+$  = 15.1), which we expect to be more conformationally  
30 ordered and have better alignment of dipoles, and C<sub>3</sub>-CONMe-C<sub>9</sub> (WF = 3.6 eV,  $r^+$  = 1.3), which  
31 we expect to be less ordered and have poorer alignment of dipoles. (we expect both molecules to  
32 have group dipole moments that are similar in magnitude and direction. This premise—that  
33 conformation influences dipole alignment (and thus WF and  $r^+$ ), may also explain why the  
34 rectification ratio of C<sub>2</sub>-CONH-C<sub>10</sub> ( $r^+$  ≈ 18) is higher than that of C<sub>1</sub>-CONH-C<sub>11</sub> ( $r^+$  ≈ 8),  
35 although its dipole is closer to the Ag<sup>TS</sup> electrode (Figure 4a). That is, the orientation of SAMs is  
36 influenced by the location of hydrogen bonds between adjacent amide groups.<sup>88-89</sup>

**Figure 6. Main Plot:** Plot of  $r^+$  ( $r^+ = \langle |J(+1\text{ V})|/|J(-1\text{ V})| \rangle$ ) at 1.0 V of Series I compounds (amides) and the work function of the silver substrate when covered with SAMs of these amides.

**Inset plot; upper right:** Plot of  $r^+$  and work function. The dashed line at  $r^+ = 5.0$  indicates the minimum value of rectification that we consider statistically significant (not resulting from artifacts unrelated to the molecules). The error bars represent the standard deviation of the mean values, and are asymmetric about the mean because of the conversion from log scale to linear. The error bar for C<sub>2</sub>-CONH-C<sub>9</sub> is relatively large because its size scales with: (i) the value of the log standard error and (ii) the value of rectification with which the error is associated. The uncertainties in the measured work function values are 0.1 eV, and are determined by the resolution of the XPS spectra.

1  
2  
3 An even-number of methylene (-CH<sub>2</sub>-) groups between the sulfur anchoring atom and the  
4 hydrogen bond acceptor (the carbonyl of the amide) produce more crystalline SAMs (which  
5 presumably have better aligned dipoles), than an odd-number of methylene (-CH<sub>2</sub>-) groups.  
6  
7  
8  
9  
10 Changes in WF correlate well with changes in the rectification ratio ( $r^+$ ) (Figure 6).  
11

12  
13 The relationship between WF and  $r^+$  can be rationalized by an interaction between the  
14 dipole moments perpendicular to the SAM surface ( $\mu_y$ ) and electrons at the Fermi level. This  
15 interaction changes depending on the distance and orientation of the -CONH- group relative to  
16  
17 the Ag<sup>TS</sup> surface. When the amide bond (in S-(CH<sub>2</sub>)<sub>m</sub>-CONH-(CH<sub>2</sub>)<sub>n</sub>-H) is located close ( $m \leq 4$ )  
18  
19 to the bottom (Ag<sup>TS</sup>) electrode, the change in internal dipole increases the WF of the bottom  
20  
21 electrode. This increase in WF lowers the current injection barrier at +1.0 V<sup>82;90-91</sup> (where the  
22  
23 Ag<sup>TS</sup> electrode is reducing) and leads to a higher tunneling rate across the SAM from the Ag<sup>TS</sup>  
24  
25 electrode to the EGaIn electrode, relative to the rate of tunneling at -1.0 V (where the EGaIn  
26  
27 electrode is reducing). We conclude, regardless of the mechanism, that to observe rectification in  
28  
29 current density, using EGaIn junctions, the internal dipole must be close to the metal-sulfur  
30  
31 interface (Figures 4 and 6).  
32  
33  
34  
35  
36  
37

38  
39 The relationship between work function and rectification (inset plot, Figure 6) indicates  
40  
41 that only when the WF of the Ag-electrode is above a threshold of ~4 eV, do we observe  
42  
43 rectification. We have not yet rationalized theoretically and quantitatively why (above a WF of >  
44  
45 ~4 eV) rectification increases linearly with the apparent WF (inset, Figure 6), since the thickness  
46  
47 of the SAM does not change. This increase probably reflects a change in the electronic profile of  
48  
49 the tunneling barrier. This observation must also be interpreted using a mechanism consistent  
50  
51 with the absence of rectification below  $\pm 0.5$  V. We speculate that the onset of rectification at WF  
52  
53 ~4 eV and voltage > 0.5 V might correspond to the onset of a new conduction mechanism. That  
54  
55  
56  
57

1  
2  
3 is, from direct tunneling to field emission<sup>92</sup>; or from direct tunneling to Fowler-Nordheim  
4 tunneling.<sup>93</sup> Using SC<sub>3</sub>-CONH-C<sub>9</sub> as an example, we plotted the tunneling current as  $\ln(J/V^2)$  vs.  
5  
6  $1/V$  and observed a transition from logarithmic dependency on voltage to linear dependency on  
7  
8 voltage; This transition took place at  $\sim 0.6$  V (Figure 7). This transition to a linear dependency  
9  
10 correlates with the observed threshold voltage required for rectification, and could, in principle,  
11  
12 arise from an asymmetric interfacial barrier height caused by the change in WF<sup>94-95</sup>. Using SC<sub>3</sub>-  
13  
14 CONH-C<sub>9</sub> as an example, we plotted the tunneling current as  $\ln(J/V^2)$  vs.  $1/V$  and observed a  
15  
16 transition from logarithmic dependency on voltage to linear dependency on voltage, which took  
17  
18 place at  $\sim 0.6$  V (Figure 7). This transition to a linear dependency correlates with the observed  
19  
20 threshold voltage required for rectification, and could, in principle, arise from an asymmetric  
21  
22 interfacial barrier height caused by the change in WF<sup>94-95</sup>.

**Figure 7.** Plot of the tunneling current  $\ln(J/V^2)$  as a function of  $1/V$  for  $SC_3-CONH-C_9$ . A transition from exponential dependency on voltage to linear dependency is apparent at  $\sim 0.6$  V.

## CONCLUSIONS

This study reaches four main conclusions and/or inferences:

- i) The magnitude of rectification is sensitive to the direction of the dipole of the molecule, but only when that dipole is close to the silver electrode ( $m \leq 4$ ).
- ii) The charge (e.g., the hole) tunnels along the SAM more rapidly when the direction of the amide dipole is aligned with the external electric field (e.g., Ga<sub>2</sub>O<sub>3</sub> electrode is oxidizing relative to the grounded Ag electrode) generated by the electrodes, than when it is aligned against the external field.
- iii) The supramolecular structure of the SAM influences the magnitude of rectification, we infer, by controlling the orientation of the local dipole of the SAM.
- iv) The mechanism of rectification is based on a change in the work function of the bottom (Ag<sup>TS</sup>) electrode, which is due to its electrostatic interaction with the local dipole (that, for example, from an amide group).
- v) Rectification occurs as a result of an increase in the rate of charge (hole) tunneling when the Ga<sub>2</sub>O<sub>3</sub> electrode is oxidizing (positive bias). The rate of charge transport in the opposite direction (negative bias) remains unchanged.
- vi) The process that leads to an increase in tunneling current at positive bias occurs at  $\sim 0.6$  V and is visible in the J(V) curves (in the inset in Figure 6, and the F-N plot in Figure 7).

This mechanism is different from the mechanism of rectification observed in SAMs with a redox active component (e.g. ferrocene and derivatives: the mechanism is less clear with bipyridyl but also seems to be a redox process), and from the original—historically significant—theoretical suggestion of Aviram and Ratner. It does not indicate that the Aviram/Ratner suggestion (which described rectification in terms of the shape of the tunneling barrier rather than the energy of the work function) is necessarily incorrect, or inapplicable to SAM-based junctions, but extensive work suggests that tunneling through most SAMs is (with exceptions

1  
2  
3 involving SAMs with low-lying HOMOs) not strongly influenced by the energetic topography of  
4 the barrier, and that using this approach to control tunneling may not be generally achievable. (It  
5 is, however, possible with certain SAMs containing a number of amide or other linkages, with  
6 interacting HOMOs)  
7  
8  
9  
10

11  
12 This work, like many others in the field, originally set out to change the shape of the  
13 tunneling barrier by synthetic modification of its molecular structure (in this case, with localized  
14 dipole moments), and to use that change to study the mechanism of rectification. Instead of  
15 finding evidence that a change in barrier shape was responsible for rectification, however, we  
16 conclude that the underlying effect of synthetic modification was to change the WF across the  
17  $\text{Ag}^{\text{TS}}$  electrode/SAM interface. This result is analogous to the operation of traditional  
18 semiconductor diodes, where rectification is caused by the Schottky barrier height<sup>94-95</sup>. Given  
19 the historical (and continued) significance in the semiconducting industry of controlling the  
20 Schottky barrier height, understanding this phenomenon in the context of molecule-electrode  
21 interfaces will be important for considering the potential (if any) of molecular electronics  
22 devices. (It *does* prove an important principal for design of passive electronic devices such as  
23 capacitors, where tunneling rates can contribute to rates of leakage of charge.)
