Abstract

Merging galaxies play a key role in galaxy evolution, and progress in our understanding of galaxy evolution is slowed by the difficulty of making accurate galaxy merger identifications. We use GADGET-3 hydrodynamical simulations of merging galaxies with the dust radiative transfer code SUNRISE to produce a suite of merging galaxies that span a range of initial conditions. This includes simulated mergers that are gas poor and gas rich, and that have a range of mass ratios (minor and major). We adapt the simulated images to the specifications of the SDSS imaging survey and develop a merging galaxy classification scheme that is based on this imaging. We leverage the strengths of seven individual imaging predictors (Gini, M_{20}, concentration, asymmetry, clumpiness, Sérsic index, and shape asymmetry) by combining them into one classifier that utilizes Linear Discriminant Analysis. It outperforms individual imaging predictors in accuracy, precision, and merger observability timescale (>2 Gyr for all merger simulations). We find that the classification depends strongly on mass ratio and depends weakly on the gas fraction of the simulated mergers; asymmetry is more important for the major mergers, while concentration is more important for the minor mergers. This is a result of the relatively disturbed morphology of major mergers and the steadier growth of stellar bulges during minor mergers. Since mass ratio has the largest effect on the classification, we create separate classification approaches for minor and major mergers that can be applied to SDSS imaging or adapted for other imaging surveys.

Key words: galaxies: active – galaxies: interactions – galaxies: kinematics and dynamics – galaxies: nuclei

1. Introduction

In the current Λ cold dark matter (ΛCDM) framework for structure formation in the universe, galaxies form as gas cools at the center of dark matter halos (e.g., White & Rees 1978; White & Frenk 1991; Cole et al. 2008). These galaxies then grow through gas accretion and mergers from small, irregular galaxies with high rates of star formation to large, quiescent galaxies with lower rates of star formation in the local universe (e.g., Glazebrook et al. 1995; Lilly et al. 1995; Giavalisco et al. 1996).

Simultaneously, supermassive black holes (SMBHs), which are found at the centers of all massive galaxies, have accumulated mass over time. Both SMBHs and galaxies grow through the accretion of gas; SMBHs that are actively accreting gas are known as active galactic nuclei (AGNs) and can be among the most luminous objects in the universe. Observational correlations suggest a co-evolution between SMBHs and their host galaxies (Magorrian et al. 1998; Ferrarese & Merritt 2000; Gebhardt et al. 2000), but it remains unclear which processes are most important for triggering AGNs and star formation.

Observational work has identified three main processes that drive evolution, but disagrees on the relative import of each process. Tidal torques from major mergers (where the mass ratio of the galaxies is less than 1:4) can drive gas accretion; some work indicates that these tidal torques from major mergers are primarily responsible for fueling both star formation (Mihos & Hernquist 1994, 1996) and rapid SMBH growth (Di Matteo et al. 2005; Hopkins et al. 2005; Ellison et al. 2011; Koss et al. 2012; Treister et al. 2012; Satyapal et al. 2014). Other work suggests that minor mergers or continuous "cold flow" gas accretion are the most important mechanism for shaping the morphologies of galaxies, driving star formation, and contributing to the mass growth of SMBHs (e.g., Daddi et al. 2007; Noeske et al. 2007; Cisternas et al. 2011; Kocevski et al. 2012; Kaviraj 2013;

Villforth et al. 2014). Yet other studies find that secular instabilities driven by disks and spiral arms in the local universe, as well as highly irregular morphologies and high gas fractions in the high-redshift universe, can dominate galaxy evolution. These secular instabilities can grow pseudobulges locally and contribute to significant gas inflows and disk and bulge growth in high-redshift galaxies (e.g., Bournaud 2016 and references therein). Many details of these processes that could drive evolution remain unclear, such as when and how these processes operate on AGNs and galaxies.

One main reason these details are unknown is that it is difficult to build a clean observational sample of galaxy mergers (major and minor). Imaging studies that rely upon one or a couple of imaging predictors can fail to accurately identify mergers, which leads to inconclusive results (e.g., Conselice 2014 and references therein). Recent work has relied increasingly upon nonparametric tools to identify merging galaxies from imaging surveys, such as the Gini$-M_{20}$ method or the *CAS* (Concentration$-$Asymmetry$-$Clumpiness) method (Conselice et al. 2003; Lotz et al. 2004). These methods are each individually limited by different merger initial conditions, such as mass ratio and gas fraction, and by merger stage. For instance, although identifying merging galaxies using asymmetry tends to be more sensitive to early-stage mergers, Gini$-M_{20}$ tends to identify late-stage mergers. Additionally, previous simulations of galaxy mergers have demonstrated that the merger observability timescale varies strongly for different nonparametric tools (e.g., Lotz et al. 2008, 2010a, 2010b).

We combine the sensitivities of different imaging predictors to create an imaging classification method that is better able to identify merging galaxies over a larger range of merger initial conditions and merger stages. In R. Nevin et al. (2019, in preparation), we will incorporate kinematic predictors as well.

Table 1
Key Parameters of Our Suite of GADGET-3 Galaxy Merger Simulations

Model	M_{tot} (10^{11} $M_\odot$)	Stellar Mass (10^{10} $M_\odot$)	Gas Fraction	Mass Ratio
q0.5_fg0.3	20.8	5.9	0.3	1:2
q0.333_fg0.3	18.7	5.2	0.3	1:3
q0.333_fg0.1	18.7	6.3	0.1	1:3
q0.2_fg0.3_BT0.2	16.8	5.0	0.3	1:5
q0.1_fg0.3_BT0.2	15.1	4.6	0.3	1:10

It is challenging to identify galaxy mergers directly from observations because each merger is observed at only a single viewing angle and moment in time, whereas the full duration of a merging event is several Gyr. Since the observational signatures of a merger depend so heavily on the merger initial conditions and stage of the merger, we create our classification scheme from hydrodynamics simulations that cover a range of merger initial conditions. In this way, we determine the fundamental capabilities of different imaging predictors. We utilize the GADGET-3 smooth-particle hydrodynamical code coupled with the SUNRISE dust radiative transfer code to construct mock observations of the simulated galaxies. From these mock observations, we create the imaging classification and determine its accuracy and precision for identifying galaxy mergers of different gas fractions, mass ratios, and merger stages. We tailor our classification for SDSS imaging, although the code will be publicly available and can be easily modified for different imaging surveys.

The remainder of this paper is organized as follows. We describe the hydrodynamics and radiative transfer simulations, techniques for matching the simulated galaxies to SDSS's specifications, and merger classification scheme in Section 2. In Section 3, we describe the performance of the classification scheme and the sensitivities of the individual imaging predictors. We compare the technique to previous imaging methods for merger identification and discuss the implications for merging galaxy identification in imaging surveys in Section 4. We present our conclusions in Section 5. A cosmology with $\Omega_m = 0.3$, $\Omega_\Lambda = 0.7$, and $h = 0.7$ is assumed throughout.

2. Methods

We create the imaging classification scheme from simulated galaxy mergers, which we introduce in Sections 2.1 and 2.2. In order to develop the classification for SDSS imaging data, we "SDSS-ize" the simulations to create mockup images matching SDSS specifications in Section 2.3. Next, we determine the separation of the stellar bulges to assign galaxy merger stage in Section 2.4. Finally, we develop the imaging classification scheme using LDA (Linear Discriminant Analysis) in Section 2.5.

2.1. N-body/Hydrodynamics Merger Simulations

To develop our imaging classification scheme, we begin with a suite of simulated merging and isolated galaxies. Specifically, we use two of the high-resolution simulations from Blecha et al. (2018), to which we have added three new simulations to cover a larger parameter space of initial conditions. We also have a set of isolated galaxies that is matched by stellar mass and gas fraction to each merger simulation.

These simulations were carried out with GADGET-3 (Springel & Hernquist 2003; Springel 2005), a smoothed-particle hydrodynamical (SPH) and N-body code that conserves energy and entropy, and includes subresolution models for physical processes such as radiative heating and cooling, star formation and supernova feedback, and a multiphase interstellar medium (ISM). All simulations have a baryonic mass resolution of 2.8×10^4 $M_\odot$ and a gravitational softening length of 23 pc. SMBHs are modeled as gravitational "sink" particles that accrete via an Eddington-limited Bondi−Hoyle (Bondi & Hoyle 1944) prescription. AGN feedback is also incorporated by coupling 5% of the accretion luminosity ($L_{bol} = \epsilon_{rad}\dot{M}c^2$) to the gas as thermal energy. We assume a radiative efficiency $\epsilon_{rad} = 0.1$ for accretion rates $\dot{M} > 0.01\dot{M}_{Edd}$ (where $\dot{M}_{Edd}$ is the Eddington limit); below this we assume radiatively inefficient accretion following Narayan & McClintock (2008). GADGET has been used for many studies concerning merging galaxies (e.g., Di Matteo et al. 2005; Blecha et al. 2011, 2013; Snyder et al. 2013).

The merger progenitor galaxies include a dark matter halo, a disk of gas and stars, a stellar bulge in some cases, and a central SMBH. The initial conditions for each simulated galaxy merger are given in Table 1, and the initial conditions for the matched isolated galaxy simulations are given in Table 2. In this work, we focus primarily on the effects of varying the merger mass ratio and initial gas fraction, since these two parameters have been shown to have the largest effect on the morphology and star formation rates of merging galaxies in previous work (Cox et al. 2008; Lotz et al. 2008, 2010a, 2010b; Blecha et al. 2013). We include three major merger simulations (q0.5_fg0.3, q0.333_fg0.3, and q0.333_fg0.1) with mass ratios 1:2, 1:3, and 1:3, respectively. The initial progenitor gas fractions in these simulations (defined as $M_{gas,disk}/(M_{gas,disk} + M_{*,disk})$), which are identical for both merging galaxies in a given simulation, are 0.3, 0.3, and 0.1. These major merger simulations have a bulge-to-total mass (B/T) ratio of 0. We design the two 1:3 major merger simulations to have different gas fractions but identical mass ratios to investigate the effects of varying gas fractions on the morphology of mergers. We also create two minor merger simulations (q0.2_fg0.3_BT0.2 and q0.1_fg0.3_BT0.2), both of which have a B/T ratio of 0.2. These two minor mergers have initial gas fractions of 0.3 and mass ratios of 1:5 and 1:10, respectively. We design these two minor mergers to have a gas fraction of 0.3 so that we can directly compare mass ratios of 1:2, 1:3, 1:5, and 1:10 across simulations with identical gas fractions. We further justify our choice of initial conditions in Appendix A.

2.2. Radiative Transfer Simulations

In order to directly compare the simulated galaxies with observations, we use the 3D, polychromatic, Monte Carlo dust radiative transfer code SUNRISE (Jonsson 2006; Jonsson et al.

Table 2
Key Parameters of the Matched Sample of Isolated Galaxies

Model	M_{tot} $(10^{11}\,M_\odot)$	Stellar Mass $(10^{10}\,M_\odot)$	Gas Fraction	Matched Model(s)
m1_fg0.3	13.9	3.9	0.3	q0.5_fg0.3, q0.333_fg0.3
m0.5_fg0.3	6.9	2.0	0.3	q0.5_fg0.3
m1_fg0.1	14.0	4.7	0.1	q0.333_fg0.1
m0.333_fg0.1	4.7	1.6	0.1	q0.333_fg0.1
m1_fg0.3_BT0.2	13.7	4.2	0.3	q0.2_fg0.3_BT0.2, q0.1_fg0.3_BT0.2

Note. These are matched to the mass of the primary or secondary galaxy in the merger for each simulation and the gas fraction. The gas fraction is the same for each merger progenitor in a given simulation.

2010) to produce resolved UV to IR spectra and broadband images.

It has been used extensively in combination with GADGET galaxy merger simulations (e.g., Lotz et al. 2008, 2010a, 2010b; Narayanan et al. 2010; Wuyts et al. 2010).

Age- and metallicity-dependent spectral energy distributions for each star particle are calculated using the STARBURST99 stellar population synthesis models (Leitherer et al. 1999). Emission from H II regions (including dusty photodissociation regions) around young stars is calculated by applying MAPPINGSIII models (Groves et al. 2008) to newly formed star particles, based on their age, metallicity, and surrounding gas pressure. The AGN spectrum is determined using the SMBH accretion rate and the luminosity-dependent templates of Hopkins et al. (2007).

To calculate the dust distribution, we use the Draine & Li (2007) Milky Way dust model with $R_V = 3.1$ and assume that 40% of gas-phase metals are in dust (Dwek 1998). A 3D adaptively refined grid is placed on the simulation domain to map the gas-phase metal distribution. Following Snyder et al. (2013) and Blecha et al. (2018), we assume that gas in the cold phase of the GADGET-3 multiphase ISM model has a negligible volume filling factor and therefore does not contribute to the attenuation of radiation. Although this may not be an appropriate choice for extremely gas-rich, high-redshift galaxies that produce extreme IR and submillimeter luminosities (e.g., Hayward et al. 2011; Snyder et al. 2013), it is a reasonable assumption for the low-redshift analog galaxy simulations in our suite.

SUNRISE performs Monte Carlo radiative transfer through this grid, computing emission from stars, H II regions, and AGNs, as well as energy absorption (including dust self-absorption) to obtain the emergent, attenuated resolved SEDs for seven different isotropically distributed viewing angles.

For each merger simulation, we perform SUNRISE calculations on snapshots at ∼50–100 Myr intervals during the merger. The spatial resolution of all images and resolved spectra is 167 pc, which exceeds the resolution of the SDSS survey (see Section 2.3). We divide each merger simulation into early-stage, late-stage, and post-coalescence snapshots based on the projected separations of the stellar bulges in the images. We describe this process in more depth in Section 2.4. In brief, early-stage mergers are defined as the snapshots with average stellar bulge separations $\Delta x \geqslant 10$ kpc. Late-stage mergers are defined to have stellar bulges with separations of $1\,\text{kpc} < \Delta x < 10\,\text{kpc}$. Post-coalescence snapshots are those in which two stellar bulges are no longer resolvable in SDSS ($\Delta x \leqslant 1$ kpc) since the spatial resolution of SDSS is 1–2 kpc. For each merger simulation, we run SUNRISE at ∼100 Myr

intervals in the early stage of the merging galaxies, at ∼50 Myr intervals in the late stage, and at ∼100 Myr intervals for the post-coalescence stage. This creates a roughly equal number of ∼5–10 SUNRISE snapshots per merger stage. In Figure 2, we show r-band images for early-stage, late-stage, and post-coalescence snapshots from the 1:2 major merger gas-rich simulation q0.5_fg0.3.

We also simulate isolated galaxies with matched stellar mass and gas fraction for each merger simulation (Table 2). Additionally, because the progenitor galaxies are still isolated and undisturbed in the very early stages of the merger simulations, we include snapshots prior to first pericentric passage in our sample of isolated galaxy snapshots as well. We confirm, using the supplemental outputs of SUNRISE, that the star formation rate and AGN luminosity have yet to be affected by the merger in these snapshots. Additionally, the imaging predictors are not yet significantly different than the matched sample of isolated galaxies.

We also include merger snapshots at times >0.5 Gyr after final coalescence as isolated galaxies. Our motivation for this is twofold. First, after >0.5 Gyr following final coalescence, the simulated galaxies begin to lose tidal features but remain centrally concentrated when compared to the isolated matched sample of galaxies. If we include these post-coalescence galaxies in the analysis as mergers, the technique becomes overly sensitive to the central concentration of galaxies and is most efficient at identifying early-type galaxies. Second, since we wish to develop a tool that best identifies galaxy mergers in the early, late, and beginning of the post-coalescence stage, we terminate the merger period at 0.5 Gyr after final coalescence for all simulations. We find that this choice of cutoff time allows the sensitivity of our merger detection technique to decay smoothly during the post-coalescence stage. We include an isolated galaxy snapshot in Figure 2 as well as several isolated snapshots prior to first pericentric passage and 0.5 Gyr following final coalescence.

Broadband images for each snapshot are produced for seven isotropically distributed viewpoints. We focus on the SDSS r-band filter, since the r-band is a good tracer of stellar populations in low-redshift galaxies. Since we next plan to incorporate kinematic predictors into the analysis (R. Nevin et al. 2019, in preparation), we will apply the classification technique to the MaNGA (Mapping Nearby Galaxies at Apache Point) survey, which is an integral field spectrograph (IFS) survey of a subsample of ∼10,000 SDSS galaxies. We therefore place the simulated galaxies at the average redshift of the MaNGA survey ($\langle z \rangle \sim 0.03$) and extract the r-band images, which we process further to match the specifications of the SDSS survey in Section 2.3.

To understand the range of redshift and surface brightness for which our merger classification can return consistent classifications, we experiment with adjusting the surface brightness and redshift of the simulated images. The consistency of the classification is closely tied to the behavior of the imaging predictors, which are sensitive to both resolution and the average signal-to-noise ratio (S/N) per pixel ($\langle$S/N$\rangle$). For instance, Lotz et al. (2004) find that Gini, M_{20}, C, A, and S are reliable to 10% for $\langle$S/N$\rangle \geqslant 2$ and systematically decrease with $\langle$S/N$\rangle$ below this level. We implement an $\langle$S/N$\rangle$ cutoff of 2.5 (which is calculated for all pixels within the segmentation mask) because the measurements of the imaging predictors (especially A and S) from statmorph are unreliable below this threshold (V. Rodriguez-Gomez 2019, private communication). For instance, A systematically decreases to negative values below this threshold. We also use this $\langle$S/N$\rangle$ cutoff value to assess the magnitude limit of the method (described below).

We find that the surface brightness of the simulated galaxies changes over the course of each simulation. This happens as the galaxies brighten and dim with star formation and AGN activity as the merger proceeds. This corresponds to a range in r-band apparent magnitude from 14–16 (at $z = 0.03$). We convert from surface brightness to r-band magnitude using the conversion in Section 2.3 to convert to units of nanomaggies, which we then convert to apparent magnitude using the Petrosian radius as the aperture. We experiment with dimming the images to determine how the r-band Petrosian magnitude of a mock image relates to the S/N per pixel. The classification becomes significantly different (since the mock images begin to drop below an $\langle$S/N$\rangle$ value of 2.5) when the r-band Petrosian magnitudes are $\geqslant 17$. In other words, the classification only works for r-band magnitudes $\geqslant 17$, and it should not be used for fainter galaxies. For context, typical SDSS galaxies from this paper (in Section 13) have $\langle$S/N$\rangle$ values between 5 and 10, which corresponds roughly to r-band magnitudes of ~ 16. Since SDSS imaging has a flux limit of 17.77 in the r-band, the LDA classification technique applies to the majority of galaxies in the SDSS photometric catalog (Strauss et al. 2002).

Likewise, we move the simulated galaxies to higher redshifts while maintaining the same surface brightness and find that the predictor coefficients in the classification change significantly at $z \sim 0.5$. The average redshift of the SDSS photometric survey is $z \sim 0.4$, so the LDA technique should still function well for the majority of SDSS galaxies (Sheldon et al. 2012).

2.3. SDSS-izing Images from the Simulations

In order to construct a classification scheme that can be applied directly to SDSS galaxies, we first "SDSS-ize" or degrade the simulated images to match the specifications of the SDSS survey. In this section, we describe the relevant SDSS imaging properties and data products. Then, we provide a detailed description of the process of SDSS-izing the simulated images. Finally, we detail how we determine the stage of the merger snapshots.

The process of SDSS-izing the simulated images to create mock images that match the specifications of the SDSS imaging involves the following steps (Figure 1):

1. Clip the images.
2. Convolve and rebin to the spatial resolution and pixel scale of SDSS imaging.
3. Introduce residual background noise.
4. Create an error image.

To complete these steps, we utilize the imaging properties (i.e., noise, instrumental gain, sky levels, etc.) of SDSS imaging, which are described in Albareti et al. (2017) and Blanton et al. (2011). The SDSS imaging procedure involves producing large field images that are composed of six long rectangular images of the sky called "camcols." The camcols are then further split into individual filters (u, g, r, i, and z) and six smaller "frame" images. Frame images are the basic data product of SDSS; these images are background-subtracted and include an extension with background sky levels, instrumental gain, dark variance, and a calibration factor to convert between flux and photoelectrons. The frame images can be further cut to postage stamp images (in our case, with a field of view of $80\overset{''}{.}0 \times 80\overset{''}{.}0$). The most recent SDSS data release (DR13) uses a specific NASA-Sloan Atlas (NSA) reprocessing of the original SDSS DR7 imaging data, which includes a new background subtraction that improves the photometry of large galaxies (Blanton et al. 2011). We use DR13 imaging properties to compare to SDSS-ized images below. The median seeing, which is the effective width (FWHM) of the PSF, for SDSS imaging is $1\overset{''}{.}43$, and the pixel scale is $0\overset{''}{.}396$ pix^{-1} (Ivezić et al. 2004; Blanton et al. 2011).

We start with the imaging output of SUNRISE for the five broadband SDSS filters (u, g, r, i, z). Here, we focus on the SDSS r-band images since they best capture light from stellar bulges for nearby galaxies. To best mimic the placement of the imaging camera from SDSS, we use aperture photometry to identify the brightest pixels over which to center the camera. We identify the brightest source using Source Extractor, which is a useful tool to extract sources through aperture photometry on astronomical images (Bertin & Arnouts 1996). Source Extractor separates an object from the background noise, applies a convolution filter to separate low surface brightness sources from spurious detections, and deblends sources. We use a detection threshold of 1.5σ above the local sky background and a minimum group number of two pixels to trigger a detection. We use a normal convolution kernel with size 3×3 pixels, an FWHM of two pixels, and a deblending threshold of 32 (the recommended value for Source Extractor). The output from Source Extractor includes the x and y positions of sources and aperture photometry, which includes Petrosian radii and corresponding fluxes. We determine the brightest source from these fluxes and then clip the image in an $80\overset{''}{.}0$ square around this source. We select an $80\overset{''}{.}0$ square cutout because it allows us to accurately determine the image background for the extraction of the imaging predictors. Some of our simulation snapshots have smaller fields of view (down to $50\overset{''}{.}0$) since the simulated galaxies are on the edge of the simulation field of view. We include these smaller snapshots in the interest of maximizing the temporal resolution of our method. We find that very few mock images have a smaller field of view than $80\overset{''}{.}0$ and that this does not affect the imaging predictors for these snapshots.

After clipping the mock images, we convolve them with a PSF with FWHM $1\overset{''}{.}43$, which is the median PSF for the r-band (Ivezić et al. 2004). Then, we rebin the images to the pixel scale of SDSS ($0\overset{''}{.}396$ pixel^{-1}).

We then convert to flux units typical of SDSS, introduce residual background noise, and produce an error image, as outlined below. The units of the simulated image are surface brightness (W/m/m^2/sr). We convert to flux density in

**Figure 1.** Steps of the process to create mock images from the simulated images (1–3). We first clip the simulated image to the $80\overset{\prime\prime}{.}0$ field of view (1). We then convolve the image with the $1\overset{\prime\prime}{.}43$ FWHM PSF and rebin to the $0\overset{\prime\prime}{.}396$ pixel scale of SDSS imaging (2). Finally, we add residual background noise that is characteristic of SDSS imaging (3) to create a mock image (upper right panel). We compare to an SDSS image (lower right panel) that has been centered on a galaxy and cut to the same $80\overset{\prime\prime}{.}0$ field of view as the mock image.

nanomaggies:

$$\mathrm{nanomaggy} = \mathrm{Janskys} \times 3.631 \times 10^6,$$

where we first convert to Janskys using the pixel scale and angular diameter distance of a simulated galaxy at the average redshift of the MaNGA survey, $z \sim 0.03$. Again, we use the average redshift of the MaNGA survey since we plan to further develop the kinematic technique for MaNGA IFS in R. Nevin et al. (2019, in preparation).

Then, we extract a nanomaggy to data number (dn) conversion rate from each frame image (c). This conversion rate is used to produce a mock image in units of counts (from here on dn is synonymous with counts). We find an average c value of 0.005 with a standard deviation of 0.0002. The conversion rate varies little across the frames and camcols.

In order to introduce background noise to the mock images, we characterize the residual background of the SDSS frame images using bilinear interpolation. We also determine other imaging properties such as background sky levels (prior to background subtraction), instrumental gain, and dark variance from the frame images. Since the gain and background sky levels vary in complicated ways across the frames and camcols (M. Blanton 2019, private communication), we characterize these values based upon several locations from the larger frame images.

For instance, we use 50 postage stamps (from the frame images) that are selected to belong to all six camcols and locations on the frame images. We extract a region from the background and characterize its mean and standard deviation. The postage stamp images have already been background-subtracted, so this region is characteristic of the residual background of SDSS images following the sky subtraction step. We find that the typical residual background has a mean of 0.33 dn (counts) with a standard deviation of 5.63 dn. After conducting an improved background subtraction for the SDSS-III DR8 imaging data (which is the same imaging reduction used for DR13), Blanton et al. (2011) find a residual standard deviation of 0.02 nanomaggies in the r-band photometry. This is $\sim$4 dn, so our standard deviation of 5.63 dn is a good approximation of the residual noise.

We reintroduce this background into our images by adding a standard normal with a mean of 0.33 and a standard deviation of 5.63 dn to each pixel. This mock image is used in the calculation of the imaging predictors in Section 2.5.1. We use both the conversion factor, c, and the residual background value, $\mathrm{bg_{resid}}$, to produce an image that is representative of an SDSS image (in counts):

$$\mathrm{dn} = \mathrm{nanomaggies}/c + \mathrm{bg_{resid}}.$$

We use the images in units of dn for display purposes and for the extraction of the imaging predictors.

Finally, we create an error image. To calculate the photometric uncertainty, we use the average gain and dark variance from the r-band frame images (4.7 photoelectrons per dn and 1.2 dn^2, respectively) in combination with the simulated galaxy image to produce an error image in dn,

$$\sigma_{\mathrm{dn}} = \sqrt{(\mathrm{dn}+\mathrm{bg_{sky}})/\mathrm{gain} + \mathrm{dark\ var}},$$

where we also include the background counts prior to background subtraction ($\mathrm{bg_{sky}}$). The photometric uncertainty is dominated by the galaxy flux except for low surface brightness features such as tidal tails, where the background sky dominates. To determine the background sky level, we extract a region from each sky image and measure the average value. We find that this value varies between frame images and that the mean background value is 121.2 dn with a standard deviation of 37.4.

Figures 1 and 2 show examples of simulated images after the image has been spatially convolved and rebinned, and the residual background has been introduced to match the specifications of the SDSS survey.
Figure 2. Time series of *r*-band "SDSS-ized" images from the q0.5_fg0.3 merger simulation (mass ratio 1:2, gas fraction 0.3). To SDSS-ize simulated images, we convert to counts, convolve to the seeing limit of the survey, rebin to the SDSS imaging pixel scale, and add background noise typical of SDSS imaging. All images are centered on the brightest `Source Extractor` selected source and cut to the 80″.0 (~50 kpc) SDSS imaging camera field of view. The merger images at $t = 0.05$, 0.2, and 3.62 Gyr are included as isolated galaxies in the analysis. The merger images at $t = 0.39$, 0.78, 1.17, and 1.56 Gyr are early-stage mergers; the images at $t = 1.81$ and 2.05 Gyr are late-stage mergers; and the images at $t = 2.2$, 2.35, and 2.54 Gyr are post-coalescence mergers. The bottom middle image is an isolated galaxy snapshot that is matched to the q0.5_fg0.3 simulation for mass and gas fraction.

2.4. Measuring Stellar Bulge Separations

We use `Source Extractor` and `GALFIT` (Bertin & Arnouts 1996; Peng et al. 2002) to identify, pinpoint, and measure the separation of stellar bulges from the SDSS-ized *r*-band images. Using `Source Extractor`, we first determine if there are one or two stellar bulges within the field of view and pinpoint their locations. We eliminate spurious detections from `Source Extractor` using the above prescription for a detection threshold (1.5σ above sky) combined with a normal convolution kernel (a 3×3 pixel mask with an FWHM of 2 pixels). We avoid the detection of star-forming regions by requiring that the flux within the measured Petrosian radius of the secondary source be greater than 10% of the primary source.

Under these prescriptions, `Source Extractor` performs well, detecting the primary and secondary stellar bulges for four of the merger simulations without spurious detections or detections of star-forming regions. To ensure that `Source Extractor` is not detecting star-forming regions, we require that the location of the regions identified by `Source Extractor` correspond to the locations of the SMBHs tracked by `GADGET`.

`Source Extractor` fails to accurately identify the secondary source for the q0.1_fg0.3_BT0.2 simulation. Since we require that the flux of the secondary source detected by `Source Extractor` be greater than 10% of the flux of the primary source, the 1:10 minor merger often falls below this level. We do not lower the 10% detection cutoff since we wish to avoid star-forming region detection, so we use the locations of the SMBHs for the q0.1_fg0.3_BT0.2 simulation to identify the secondary sources in order to determine merger stage.

Then, we use `GALFIT`, which is a two-dimensional fitting algorithm that extracts structural components from images of galaxies. It can fit one or more two-dimensional models such as exponential disks, Sérsic profiles, Gaussian profiles, or Moffat functions to the light profile of a galaxy. We use `GALFIT` to fit a Sérsic profile to each source identified by `Source Extractor` and extract the projected separations of the stellar bulges (if there are two). With the `GALFIT` output in hand, we average the projected separation of the stellar bulges for all viewpoints of a given snapshot of a merger and use this average to determine the merger stage. Again, if the average separation is $\Delta x \geqslant 10$ kpc, the merger is early stage, if the separation is $1\,\mathrm{kpc} < \Delta x < 10\,\mathrm{kpc}$ the merger is late stage, and separations $\Delta x \leqslant 1$ kpc are post-coalescence.

2.5. Creating the Classification Scheme

Using the simulated galaxies, we know a priori whether a galaxy is a merging or nonmerging galaxy. In this section, we discuss the preparation of the imaging parameters that we use as an input to a supervised Linear Decomposition Analysis (LDA). We refer to these imaging parameters as "predictors" from here on because they help predict whether a galaxy is undergoing a merger. We also describe the LDA technique, which allows us to determine which imaging predictors are critical for best separating the classes of merging and nonmerging galaxies for each simulation.

2.5.1. Imaging Predictors

In this section, we first describe the imaging predictors and then the methods used to extract them from the SDSS-ized galaxy images. We discuss their weaknesses and strengths; no one imaging predictor is the best determination of a merging galaxy. Instead, they are sensitive to different orientations, merger stages, and mass ratios. The statistical power of the LDA methodology allows us to select the most successful predictors for various types of merging systems. We discuss these results in Section 3.

There are two main approaches to identifying a galaxy merger from imaging: parametric and nonparametric modeling of the surface brightness of the galaxy image. The parametric approach requires modeling the surface brightness of the galaxy using integrated light profiles such as bulges, disks, or Sérsic profiles. Since parametric modeling tends to assume a symmetric profile for the surface brightness of a galaxy, it fails for irregular galaxies as well as those with structures such as compact nuclei, spiral arms, or bars (Lotz et al. 2004). More recent work on merger identification has focused on the nonparametric modeling of the surface brightness of galaxies. Nonparametric tools can be applied to irregular galaxies as well as the more standard early or late Hubble-type galaxies. We employ two widely used nonparametric approaches as imaging predictors: the *CAS* morphological classification technique and the Gini$-M_{20}$ method. We also use a binary variation of *A*, the shape asymmetry (A_S) from Pawlik et al. (2016). Finally, we incorporate one parametric approach, the Sérsic index (*n*). Overall, we utilize seven different imaging predictors, defined below: Gini, M_{20}, *C*, *A*, *S*, *n*, and A_S.

Concentration is defined by Lotz et al. (2004) as the ratio of light within circular radii containing 80% and 20% of the total flux of the galaxy:

$$C = 5 \log\left(\frac{r_{80}}{r_{20}}\right),$$

where r_{80} is the circular radius that contains 80% of the total flux, and r_{20} is the circular radius that contains 20% of the total flux. We use the approach from Conselice et al. (2003) that defines the total flux as that within 1.5 Petrosian radii (r_P) of the galaxy's center. We measure the Petrosian radius using `Source Extractor`.

A galaxy with a higher value for *C* has more light contained within the central regions of the galaxy and is therefore more likely to be an early-type galaxy.

The imaging rotational symmetry predictor, *A*, is from Conselice et al. (2000):

$$A = \sum_{ij} \frac{|I(i,j) - I_{180}(i,j)|}{|I(i,j)|} - \sum_{ij} \frac{|B(i,j) - B_{180}(i,j)|}{|I(i,j)|},$$

where asymmetry is summed over all pixels (i, j), $I(i, j)$ is the image, $I_{180}(i, j)$ is the image rotated by 180° about the center, $B(i, j)$ is the background image (the background image is described in Section 2.3 and includes only the residual background typical of SDSS imaging following background subtraction), and B_{180} is the background image rotated by 180° about the same center. We define the center of the galaxy as the location that minimizes the value of asymmetry as in Lotz et al. (2008). Again, the galaxy image and background image are both masked to $1.5r_\mathrm{P}$.

A galaxy with a higher value of *A* has a disturbed structure and/or bright tidal tails and is therefore more likely to be a galaxy undergoing a merger. *A* is particularly good at

identifying early-stage merging galaxies (following first pericentric passage) when the structure of a merging galaxy is most disturbed and tidal tails are most prominent.

The shape asymmetry, A_S, is measured using the same procedure as the asymmetry, but with a binary detection mask. The technique is described in detail in Pawlik et al. (2016) and Rodriguez-Gomez et al. (2019). Since it is measured using a binary mask, A_S is more sensitive to low surface brightness tidal features than A.

Clumpiness or smoothness (S) is defined by Conselice et al. (2003) and Lotz et al. (2004) to be the fraction of light within clumpy distributions in a galaxy:

$$S = \frac{\sum_{ij}|I(i, j) - I_S(i, j)|}{|I(i, j)|} - B_S,$$

where $I(i, j)$ is the image and $I_S(i, j)$ is the smoothed image, which is smoothed using a boxcar of width $0.25r_P$. B_S is the average smoothness of the background calculated in a 10×10 pixel box using the same $0.25r_P$ boxcar. S is summed over all pixels (i, j) within $1.5r_P$ of the galaxy's center. However, the pixels within $0.25r_P$ of the galaxy center are excluded for the calculation of S because the central regions of galaxies are highly concentrated, and this increases the value of S (see Conselice et al. 2003).

Since S measures the fraction of light from a galaxy that can be found in clumpy distributions, it identifies merging galaxies that have recently undergone star formation (e.g., Conselice et al. 2003). For instance, galaxies with a low value of S tend to be elliptical galaxies and galaxies with a high value of S are either undergoing mergers (with star formation) or undergoing bursty star formation without experiencing a merger event.

The CAS morphological classification system was put forth as a method for cleanly separating galaxies based on their morphologies using their location in CAS space. However, it is limited in several ways. First, concentration assumes circular symmetry and therefore fails for some irregular galaxies (Lotz et al. 2004). For instance, Conselice et al. (2003) found that the average value of C for ULIRGs (ultraluminous infrared galaxies; $L_{IR} > 10^{12} L_\odot$) is not significantly different from that of Hubble sequence galaxies. This is problematic for merger identification since a significant fraction of ULIRGs (at least in the local universe) are gas-rich major mergers (e.g., Veilleux et al. 2002; Draper & Ballantyne 2012). Second, not all mergers are asymmetric, and not all asymmetric galaxies are mergers (Thompson et al. 2015). Third, clumpiness is very dependent on the choice of boxcar width (smoothing length) used to smooth the image (Andrae et al. 2011), which has not been studied in detail. In this work, we find that clumpiness is most sensitive to viewing angle and therefore a poor merger predictor, so while we include it in the analysis, we focus more on concentration and asymmetry. This decision is supported by previous findings that focus on C and A alone from the CAS morphology (e.g., Lotz et al. 2008).

The Gini coefficient is used to describe the relative concentration of light in a galaxy and is insensitive to whether the light lies at the center of the galaxy. Gini is sensitive to major and minor mergers and is most sensitive for face-on systems (Thompson et al. 2015). Gini is defined by Abraham

et al. (2003) and Lotz et al. (2004) as

$$\text{Gini} = \frac{1}{|\bar{f}|n(n - 1)}\sum_{i}^{n}(2i - n - 1)|f_i|,$$

where $\bar{f}$ is the average flux value, n is the number of total pixels in the image, and f_i is the flux value for each pixel where the n pixels are ordered by brightness in the summation.

Gini is high for galaxies with very bright single or multiple nuclei and low for galaxies with more distributed light, such as late-type disk galaxies. Therefore, a higher value of Gini will select for merging galaxies during late-stage mergers (with multiple bright nuclei) as well as post-coalescence merging galaxies.

The M_{20} coefficient is often combined with Gini to identify merging galaxies. It measures the relative concentration of the light in a galaxy and also does not assume a central concentration. The second-order moment of the light in a galaxy (M_{tot}) is the sum of the flux in each pixel, f_i, multiplied by the distance squared to the center of the galaxy,

$$M_{tot} = \sum_{i}^{n} M_i = \sum_{i}^{n} f_i [(x_i - x_c)^2 + (y_i - y_c)^2],$$

where M_i is the flux in a single pixel multiplied by the distance squared to the center of the galaxy. The center (x_c, y_c) is chosen to minimize the value of M_{tot}. M_{tot} is a tracer for the spatial distribution of any bright areas in the galaxy. M_{tot} is then used to compute M_{20}, which is defined by Lotz et al. (2004) to be the normalized second-order moment of the brightest 20% of the galaxy's flux:

$$M_{20} = \log_{10}\left(\frac{\sum_i M_i}{M_{tot}}\right), \text{ while } \sum_i f_i < 0.2 f_{tot},$$

where f_{tot} is the total flux of all of the pixels that are identified by the segmentation map (defined below), and f_i are the fluxes rank-ordered from brightest to faintest. The division by M_{tot} removes all dependence on the total galaxy flux.

M_{20} is similar to C, but the center of the galaxy is a free parameter, allowing it to be more sensitive to spatial variations of light. Also, M_{20} is always a negative value due to the logarithm. Clear mergers with multiple bright nuclei have higher values of M_{20} ($M_{20} > -1$) and early-type galaxies have lower values ($M_{20} \leqslant -2$; Lotz et al. 2008). Therefore, higher values of M_{20} select for merging galaxies.

Since Gini and M_{20} are sensitive to the ratio of low surface brightness pixels to high surface brightness pixels, we use a segmentation map to measure both of these predictors, as in Lotz et al. (2008). The segmentation map assigns pixels to the galaxy that are above the threshold value given by the surface brightness at the Petrosian radius. We use a segmentation map instead of making S/N cuts, because galaxies with the same morphologies but different intrinsic luminosities will have different Gini values if the cut is made based on S/N.

In addition to the CAS and Gini$-M_{20}$ nonparametric predictors, we measure the shape asymmetry (A_S) for each galaxy. Shape asymmetry is similar to the imaging asymmetry we also describe above; it is calculated using the same method, but with a binary detection mask instead of the image itself. This weights all parts of the galaxy equally regardless of relative brightness, making it a useful probe of morphological asymmetry (as opposed to the asymmetry of the light

distribution). It has proven useful for detecting faint asymmetric tidal features that are suggestive of a merger (Pawlik et al. 2016).

Our final imaging predictor is the Sérsic index, which is used to define the exponential surface brightness profile of a galaxy:

$$I(R) = I_e \exp\left(-b_n\left[\left(\frac{R}{R_e}\right)^{1/n} - 1\right]\right),$$

where $I(R)$ is the intensity within a given circular radius; I_e is the intensity at the effective radius (R_e), which is the radius that contains half of the total light; and b_n is a constant that depends on the Sérsic index, n (Sérsic 1963).

A Sérsic index of $n = 1$ denotes an exponential disk, indicative of a spiral galaxy, while $n = 4$ denotes a de Vaucouleurs profile, indicative of an elliptical galaxy. In general, a higher n indicates light that is more centrally concentrated. A division between morphologies has been standardized as $n \lesssim 2.5$ for spirals and $n \gtrsim 2.5$ for ellipticals (van der Wel et al. 2008). Fisher & Drory (2008) predicted that values of $n > 2$ (steeper surface brightness profiles) are produced by major mergers.

To extract the values of Gini, M_{20}, C, A, S, and A_S for each galaxy, we utilize the galaxy morphology tool `statmorph` (Rodriguez-Gomez et al. 2019). Within this tool, we invoke the segmentation map defined from the surface brightness at $1.5r_p$, which is measured using `Source Extractor`. We measure the value of n for each galaxy with `GALFIT`.

2.5.2. Identifying Mergers with Imaging Predictors

We seek a classifier that can separate merging and nonmerging galaxies of various merger mass ratios, gas fractions, viewing angles, and merger stages. We also need to incorporate multiple different imaging predictors. LDA is uniquely suited for these purposes. LDA is able to maximize the separation between multiple classes (in our case, we only need to separate two classes, "merging" versus "nonmerging" galaxies). In this work, we use LDA as a classifier. Here, we train LDA on our SDSS-ized simulation data to determine the most important imaging predictors for each simulation. Then, we combine all simulated galaxies to prepare an LDA classifier. In a subsequent paper, we will apply the LDA classifier to the SDSS galaxies.

Past work on simulated galaxies has shown that the effectiveness of the imaging predictors depends strongly on merger stage, the initial mass ratio, and the gas fraction of the merging galaxies (Lotz et al. 2008, 2010a, 2010b). We therefore run LDA for each simulation individually so that we can compare the LDA outputs from different merger initial conditions. In this way, we are able to compare the sensitivity of different imaging predictors for minor and major mergers with low and high gas fractions at three different merger stages (early, late, post-coalescence). For each iterative LDA run, we use simulated nonmerging galaxies that are matched for gas fraction and stellar mass to the merging galaxies, since Lotz et al. (2010b) found that gas fraction can alter the performance of CAS and Gini$-M_{20}$. We therefore approach the LDA classification with a set of galaxies for which we know a priori if a galaxy belongs to the nonmerging (0) or merging (1) class. We include enough nonmerging galaxies to roughly balance the number of merging galaxies. Our motivation is to achieve an accurate LDA classification by ensuring that the isolated galaxies cover a realistic range of imaging predictor space and roughly balance the number of galaxies in the merging class. We later account for the lack of merging galaxies in nature with a prior (described below). We use disk-dominated simulated galaxies to create the LDA, so it is important to note that this classification technique is most applicable to galaxies with similar properties.

The purpose of LDA is to use Bayesian likelihood to calculate a posterior probability that a galaxy belongs to a given class (for a review of LDA, see James et al. 2013):

$$p(\pi_0|x) = \frac{e^{\hat{\delta}_0(x)}}{e^{\hat{\delta}_0(x)} + e^{\hat{\delta}_1(x)}}, \tag{1}$$

where π_0 is the prior probability of the nonmerging class (described below), $\hat{\delta}_0$ is the score of the nonmerging class, and $\hat{\delta}_1$ is the score of the merging class. The score is the relative probability that the galaxy belongs to a class, so a galaxy will be classified into the class that has the maximum score. This classifier is nonbinary; instead of classifying galaxies as simply nonmerging or merging, we will assign a probability that a galaxy belongs to each class.

When there is only one input predictor, the discriminant score for the nonmerging class is defined as

$$\hat{\delta}_0(x) = x \cdot \frac{\hat{\mu}_0}{\hat{\sigma}^2} - \frac{\hat{\mu}_0^2}{2\hat{\sigma}^2} + \log(\hat{\pi}_0),$$

where $\hat{\delta}_0(x)$ is the discriminant score for class 0 (the nonmerging class) for a set of galaxies, x is the list of the one measured predictor value for all simulated galaxies, $\hat{\mu}_0$ is the mean vector for the predictor for the nonmerging class, $\hat{\sigma}^2$ is the variance of the predictor for the nonmerging class, log ($\hat{\pi}_0$) is the prior probability of belonging to the nonmerging class, and $\hat{\delta}_1(x)$ is defined the same way but for mergers.

For the priors of the two classes for the major mergers, we use $\hat{\pi}_0 = f_{\mathrm{nonmerg}} = 0.9$ and $\hat{\pi}_1 = f_{\mathrm{merg}} = 0.1$ based on the fraction of nonmerging and merging galaxies from observations and simulations (e.g., Rodriguez-Gomez et al. 2015; Lotz et al. 2011; Conselice et al. 2009; López-Sanjuan et al. 2009; Shi et al. 2009). We use $\hat{\pi}_0 = f_{\mathrm{nonmerg}} = 0.7$ and $\hat{\pi}_1 = f_{\mathrm{merg}} = 0.3$ for the minor mergers, since minor mergers are three to five times more frequent in the local universe (e.g., Bertone & Conselice 2009; Lotz et al. 2011). We find that the LDA analysis is relatively insensitive to the chosen priors within a range of values ($0.1 < f_{\mathrm{nonmerg}} < 0.9$). For a full discussion of priors, see Appendix B.

For multiple predictor variables (seven in our case), the LDA score can be generalized:

$$\hat{\delta}_0(x) = x^T \Sigma^{-1} \hat{\mu}_0 - \frac{1}{2} \hat{\mu}_0^T \Sigma^{-1} \hat{\mu}_0 + \log(\hat{\pi}_0),$$

where x, Σ, and $\hat{\mu}_0$ are now vectors for the values of the predictors, covariance matrix, and mean value of each predictor, respectively. LDA assumes that the data are normally distributed, that the input predictors are independent, and that each class has identical covariance matrices. The assumption of homogeneity of the covariance matrices leads to the simplification $\Sigma_0 = \Sigma_1 = \Sigma$. We examine these statistical assumptions in more detail in Appendix C.

Table 3
LD1 Predictor Coefficients with 1σ Confidence Intervals

| Simulation | $\hat{w}$ | | | | | | | $\hat{w}_0$ |

q0.333_fg0.3	**4.18 ± 0.22**	⋯	⋯	**6.15 ± 0.68**	⋯	⋯	**22.17 ± 1.2**	**−0.44 ± 0.14**
q0.333_fg0.1	⋯	⋯	**5.38 ± 0.19**	**5.66 ± 0.28**	⋯	⋯	**11.41 ± 0.39**	**−0.56 ± 0.1**
q0.2_fg0.3_BT0.2	**19.34 ± 2.89**	−4.08 ± 3.29	**24.69 ± 1.87**	**5.88 ± 0.43**	⋯	⋯	**3.97 ± 0.31**	**−0.87 ± 0.07**
q0.1_fg0.3_BT0.2	**11.39 ± 1.17**	⋯	**33.27 ± 2.0**	**29.74 ± 2.33**	⋯	⋯	−5.05 ± 1.95	**−1.75 ± 0.11**

Note. Bolded values are significantly greater than zero (to 3σ). We include only the predictors that are selected by the forward stepwise selection; for example, in q0.5_fg0.3, M_{20}, C, A, and A_S are excluded by this selection. $\hat{w}$ and $\hat{w}_0$ are the weight vector (composed of the predictor coefficients) and the intercept, respectively. Together, they describe the ld1 hyperplane that best separates the populations of merging and nonmerging galaxies for each simulation. The coefficients have positive or negative values; a positive coefficient indicates that increasing the corresponding predictor increases the likelihood that the galaxy is a merger.

We classify a galaxy as "nonmerging" if $\hat{\delta}_0 > \hat{\delta}_1$ and "merging" if $\hat{\delta}_1 > \hat{\delta}_0$. Since we are working in a multidimensional space, this is equivalent to searching for the dividing hyperplane that satisfies

$$x^T \Sigma_0^{-1} \hat{\mu}_0 - \frac{1}{2}\hat{\mu}_0^T \Sigma_0^{-1} \hat{\mu}_0 + \log(\hat{\pi}_0)$$
$$= x^T \Sigma_1^{-1} \hat{\mu}_1 - \frac{1}{2}\hat{\mu}_1^T \Sigma_1^{-1} \hat{\mu}_1 + \log(\hat{\pi}_1).$$

The terms with the covariance matrices can be expanded fully to yield a quadratic classifier, as is done in Quadratic Discriminant Analysis (QDA). We assume the equality of covariance matrices, which means the covariances between predictors are roughly equivalent for the nonmerging and merging classes ($\Sigma_0 = \Sigma_1$). This assumption yields a linear classifier (LDA),

$$\Sigma^{-1}(\mu_0 - \mu_1) + \frac{1}{2}\mu_0^T \Sigma^{-1}\mu_0$$
$$+ \frac{1}{2}\mu_1^T \Sigma^{-1}\mu_1 + \log(\frac{\hat{\pi}_0}{\hat{\pi}_1}) = 0.$$

We solve for the hyperplane that satisfies the above equation, LD1,

$$\text{LD1} = \hat{w}^T x + \hat{w}_0 = 0,$$

where the slope, $\hat{w}$, is the weight vector

$$\hat{w} = \Sigma^{-1}(\mu_0 - \mu_1)$$

and the intercept is given by $\hat{w}_0$

$$\hat{w}_0 = \frac{1}{2}\mu_0^T \Sigma^{-1}\mu_0 + \frac{1}{2}\mu_1^T \Sigma^{-1}\mu_1 + \log\left(\frac{\hat{\pi}_0}{\hat{\pi}_1}\right).$$

LD1 is also known as the first discriminant axis. Since we have only two classes (merging and nonmerging) to separate in this analysis, the second, third, and so on discriminant axes are unnecessary. Instead, we are able to focus only on one hyperplane to separate the populations.

We run the LDA on the imaging input predictors, which are the Gini, M_{20}, C, A, S, n, and A_S. We specifically utilize the Python package sklearn for this analysis. By focusing on the imaging predictors, our goal is to produce a result that is useful for observational samples of galaxies with imaging only. Since the imaging predictors are cross-correlated, meaning that

combinations of two of the predictors have a linear relationship with one another (Appendix C), we also include "interaction" terms that are multiples of all combinations of the imaging predictors (e.g., Gini $* M_{20}$, Gini $* C$, Gini $* A$, etc.). We refer to these as "interaction" terms, but they can be better thought of as multiplicative terms that allow us to explore the synergistic effects of combining predictors. These interaction terms allow us to remove cross-correlation effects from the original "primary" (Gini, M_{20}, C, A, S, n, and A_S) imaging predictors. We can then directly explore how these primary imaging predictors affect the classifier in Section 3.1.

Including the interaction terms, we have 34 input terms for each run of LDA. Therefore, we first use forward stepwise selection with k-fold cross-validation to select the best input variables for each simulation. In brief, forward stepwise selection proceeds by introducing one predictor at a time; we choose the number of predictors that minimizes the number of misclassifications determined with cross-validation. We specifically implement k-fold cross-validation, which is a method to divide the full sample of merging and nonmerging galaxies (for each run) into k equally sized subsamples, where $k = 10$. We then train the LDA on nine of the subsamples, and test on the 10th sample. We repeat this procedure 10 times, and the mean number of misclassifications in all 10 test samples allows us to decide which set of input predictors to select. We proceed, adding one predictor at a time, until the minima of the misclassifications are determined. We describe this process in more detail in Appendix D.

The input predictors that are selected by the forward stepwise selection are given in Tables 3 and 4, along with their coefficient values and standard errors from the LDA run. The standard errors are obtained using k-fold cross-validation (Appendix D). If a predictor is selected by the forward stepwise selection but the 3σ standard error indicates that it is consistent with zero, we eliminate it from the selected predictors. We refer to the remaining imaging predictors and imaging predictor interaction terms as "required" predictors henceforth because they are necessary to separate the merging galaxies from the nonmerging galaxies along LD1 for each simulation. LD1 is a linear combination of the selected input imaging predictors and interaction terms, with weights $\hat{w}$ and intercept term $\hat{w}_0$. Each element of $\hat{w}$ corresponds to an imaging predictor or interaction term, and their relative absolute values represent their degree of importance to the classification. We report and interpret these

Table 4

coefficients, their relative signs, and their order of importance in Section 3.

After running LDA on each simulation individually, we assess their differences in Sections 4.3 and 4.4. Since the major and minor merger LDA runs are significantly different, we caution against combining all runs into one overall classifier. We do attempt, however, to combine all simulations into one classifier and find that it does not adequately separate merging from nonmerging galaxies for all merger simulations. Instead, we create two classifiers, one from the combined major merger simulations and one from the combined minor merger simulations, that will be used to classify the SDSS galaxies. They could also function as a diagnostic tool to determine the mass ratio of the merging galaxies.

In subsequent work, we will calculate the value of LD1, or the score of a given galaxy, using the linear combination of the terms from $\hat{w}$ and the input predictors and $\hat{w}_0$ given in Section 3. For example, LD1 for the combined overall run for major mergers is

$$
\begin{aligned}
\mathrm{LD1}_{\mathrm{major}} = {} & 0.69 \, \mathrm{Gini} + 3.84 \, C + 5.78 \, A + 13.14 \, A_S \\
& - 3.68 \, \mathrm{Gini} * A_S - 6.5 \, C * A_S - 6.12 \, A * A_S \\
& - 0.81,
\end{aligned}
\tag{2}
$$

where all predictor inputs must be standardized before using this equation. To standardize, we subtract the mean and divide by the standard deviation of the set of all predictor values.

Likewise, LD1 for the minor merger combined simulation is

$$
\begin{aligned}
\mathrm{LD1}_{\mathrm{minor}} = {} & 8.64 \, \mathrm{Gini} + 14.22 \, C + 5.21 \, A + 2.53 \, A_S \\
& - 20.33 \, \mathrm{Gini} * C - 4.32 \, A * A_S \\
& - 0.87.
\end{aligned}
\tag{3}
$$

The decision boundary for LD1 for the major merger combined run is 1.16 and 0.42 for the combined minor merger run; all galaxies with values of LD1 greater than these values will be classified as merging. This decision boundary is the halfway mark between the mean of the merging and nonmerging galaxy distributions. From here on, we use "LD1" to describe the linear combination of predictor coefficients for each run of LDA.

LD1 is a hyperplane, so it is unable to capture complicated nonlinearities in the imaging predictors. For instance, there is some migration for different merger stages that occurs for predictors such as M_{20}, where merging galaxies occupy different regions of predictor space for different phases of the merger. Since the LDA captures the bulk behavior of each imaging predictor, it searches for the overall trend for all stages within each merger simulation and is unable to describe these nonlinearities.

LDA adequately separates nonmerging from merging galaxies. For instance, Figure 3 presents the histograms for the imaging predictors for all simulations, and it is clear that the imaging predictors are each individually unable to separate the populations of merging and nonmerging galaxies. After performing LDA, we find that we are able to more cleanly separate the two classes using the first discriminant axis LD1 (Figures 4 and 5).

Although it is possible to classify a galaxy as merging or nonmerging given a decision boundary and a value of LD1, we use the posterior probability that a galaxy belongs to a given class from Equation (1). Since we standardize the input predictors to train the LDA, classifying galaxies after the determination of LD1 is complicated. Instead of simply plugging in measured values of predictors into LD1, it is

necessary to apply the same standardization used in this work prior to classification.

We discuss the statistical assumptions made by LDA in Appendix C. We discuss the coefficients of LD1 in Section 3.1 and the implications for each run and the combined run. Finally, we demonstrate in Appendix E that LDA classification is able to accurately separate the classes of merging and nonmerging galaxies.

3. Results

After running LDA for each galaxy merger, we compare the results. We describe our methodology to compare the LDA classifications from different simulations in Section 3.1. Finally, we compute the observability timescales for Gini–M_{20}, A, A_S, and the LDA technique in Section 3.2. We describe the LDA classification in more statistical detail in Appendices B–E, where we include an investigation of the merging galaxy priors used, a multivariate analysis of the assumptions of LDA, a description of the k-fold error estimation, and an examination of the accuracy and precision of the tool, respectively.

3.1. Analyzing the LD1 Coefficients

Since we run LDA on each merger simulation individually and LD1 is a vector, we produce different values for each coefficient of LD1. An advantage of LDA is that we are able to directly interpret the relative weights of each individual predictor (Tables 3 and 4) for each simulation. We focus on the primary predictors, which are in Table 3, since they are a more straightforward way to interpret the influence of the imaging predictors than the interaction terms in Table 4. We compare the values of these primary coefficients of LD1 for each simulation. The coefficients have positive or negative values; since a larger value of LD1 indicates that a galaxy is a merger, a positive coefficient indicates that increasing the corresponding predictor increases the likelihood that the galaxy is a merger. Our goal is to determine if the classification is significantly different for different simulations and if it differs for different merger initial conditions.

We use stratified k-fold cross-validation (Appendix D) to determine the standard error on the coefficients of LD1 that are selected by forward stepwise selection. In brief, we randomly split the sample into 10 parts, where nine parts are the training sample and the 10th part is the test sample. Stratified k-fold cross-validation ensures that the percentage of merging and nonmerging galaxies in the test set matches that of the full sample. We perform this operation 10 times and then calculate the mean value and standard deviation (standard error) for the LD1 coefficients and intercept ($\hat{w}$ and $\hat{w}_0$) from the 10 iterations of the training and test sets.

For both Tables 3 and 4, include the predictors that are selected by the forward stepwise selection. Additionally, we put in bold the input predictors that are significant (to 3σ above zero) according to their errors provided by k-fold cross-validation. We use both of these predictor selection techniques to determine which predictors are selected and significant (we exclude all other predictors from our analysis and discussion). We show a visualization in Figure 6 of the order of importance of the individual primary imaging predictors for each simulation. Overall, we can only discard the clumpiness (S) primary predictor from our analysis; it is always either excluded by the forward stepwise selection of predictors or $<3\sigma$ above zero.
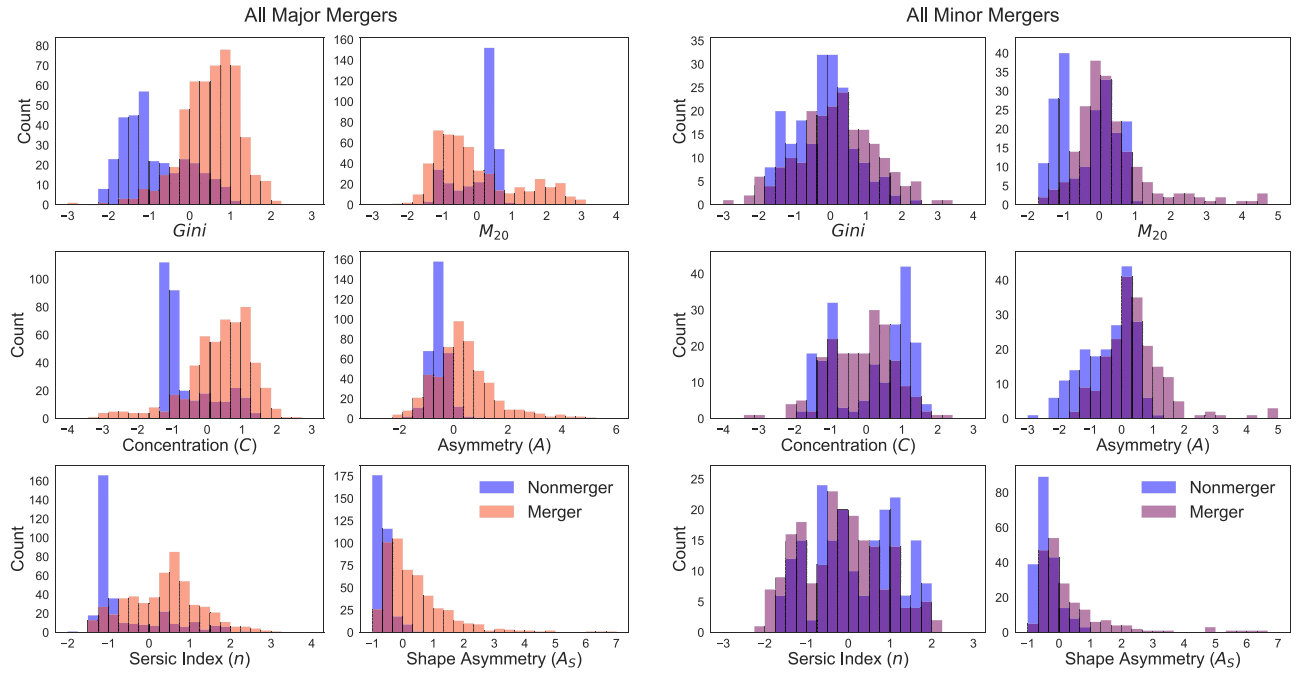

Figure 3. Individual histograms for each imaging predictor for the combined major merger simulations (left) and combined minor merger simulations (right). We show for all of the simulations combined that we are unable to cleanly separate the nonmerging (blue) and merging (pink and purple for major and minor mergers, respectively) galaxies using any individual imaging predictor. The y-axis is the "Count" or number of merger simulation snapshots in each bin. The x-axis of each subplot is the standardized predictor value for the seven imaging predictors, where the mean of the combined merging and nonmerging populations for each predictor is 0 and the standard deviation is 1. Standardizing the input predictor values acts to stabilize the LDA but has no effect on the relative value of each predictor; for example, a greater value of Gini corresponds to an increased likelihood that a given galaxy is a merger. This statement is valid both for the measured Gini value and the standardized Gini value given here.

There are significant differences between the rankings of imaging predictors for each simulation. For instance, we find that the major merger simulations (q0.5_fg0.3, q0.333_fg0.3, and q0.333_fg0.1) have different rankings of predictor importance; A_S and A are more important for the major mergers. For minor mergers, A_S is unimportant, while C and Gini become very important.

We interpret the sign of each coefficient individually for each simulation in Section 4, compared to previous work. We further interpret the relative importance of the coefficients for different merger initial conditions and discuss how the value of the predictors evolve as the merger progresses in Section 4.

3.2. Observability Timescales

To compare our new LDA technique to previous works that identify merging galaxies, we calculate the observability timescales of Gini$-M_{20}$, A, A_S, and the LDA technique for the simulated galaxies. We focus on these particular predictors because past work has defined cuts for Gini$-M_{20}$, A, and A_S, and classified galaxies lying above these thresholds as merging. Likewise, the observability timescale of Gini$-M_{20}$, A, and A_S are measured from these cuts in predictor space, where a simulated galaxy is "identifiable" as a merger for the duration of the time it spends above these thresholds. For Gini$-M_{20}$, Lotz et al. (2008) used

$$\text{Gini} > -0.14 \, M_{20} + 0.33,$$

where everything above the line is defined as a merger. The asymmetry cut is defined by Conselice et al. (2003):

$$A > 0.35,$$

where galaxies with A values above 0.35 are mergers. The shape asymmetry cut is from Pawlik et al. (2016):

$$A_S > 0.2,$$

where galaxies with A_S values above this cut are mergers.

We show these cuts in predictor space in Figures 7–9, respectively, for the combined major and minor merger simulations. We plot C with A in Figure 8 to include the evolution of C, although there are is no formal cut in predictor space for this predictor. For the same reason, we plot n against A_S in Figure 9. In these three predictor space plots, we are able to show all of the predictors (we only exclude S because it is unimportant to the analysis).

For each snapshot in each merger simulation, we determine the viewpoint-averaged value for Gini$-M_{20}$, A, and A_S. If a given snapshot exceeds the cut threshold for a merging galaxy, we designate that snapshot as "identifiable." By combining all identified snapshots, we determine the observability timescale, which we list in Table 5. If zero snapshots were successfully identified, the observability timescale is less than the time resolution (i.e., <0.1 Gyr). The timescale of observability from the LDA technique is shown in Figure 10; we label a snapshot of a merger as identifiable if the viewpoint-averaged mean of LD1 is above the decision boundary (shown with a horizontal black line).

For all simulations, we find that the timescale of observability for the LDA technique is longer than the individual Gini$-M_{20}$, A, and A_S timescales of observability. The overall trend is $\sim$0.2–0.8 Gyr observability timescales in Gini$-M_{20}$, very short timescales of observability for A (<0.1 Gyr), and longer observability timescales in A_S that are >1 Gyr. The observability window for LDA comprises $\sim$80%–90% of the
Figure 4. Histograms of the distribution of score values for galaxies in the nonmerging and merging class for all of the major merger simulations and the combined major merger run (top). The vertical black line marks the decision boundary—the halfway mark between the mean of the nonmerging and merging distributions. A galaxy with a score above (to the right) of this value has a higher probability of being a merging galaxy, and a galaxy with a score to the left of this value has a higher probability of being a nonmerging galaxy. The decision boundaries are in similar locations for all major merger runs of LDA because the separation of the merging and nonmerging populations is so similar. The histograms have different colors to distinguish different LDA runs, and the blue bars are the matched nonmerger sample for each run.

total length of the merger event, which translates to 2.0–2.5 Gyr timescales for the major mergers and 3.5–8.8 Gyr timescales for the minor mergers.

Overall, the LDA observability timescale dominates because it relies upon multiple different imaging predictors that are sensitive to the merging galaxies at different stages of the merger. However, for the major mergers, the A_S timescale is comparable to the LDA observability timescale. We discuss these trends, how observability timescales scale with the merger initial conditions, and how these timescales compare to previous work in Section 4.2.

4. Discussion

We explore the behavior of the individual predictors in the LDA technique. Since we remove correlations between predictors with the interaction terms, we are able to discuss the positive or negative signs of the primary predictors (we refer to Gini, M_{20}, C, A, S, n, and A_S as the "primary predictors") in Section 4.1. We also compare these results to

past work with these imaging predictors and discuss how their values change for merging and nonmerging galaxies. Then, we discuss the strengths of the LDA technique. First, we focus on the increased observability timescale of the LDA technique in Section 4.2 and how it is sensitive to different stages of the merger. We also discuss how different imaging predictors change in sensitivity throughout the timeline of a merger. Second, we focus on how the classification changes for different mass ratios and gas fractions in Section 4.3 and Section 4.4, respectively. Finally, we assess the overall accuracy and precision of the LDA technique in Section 4.5 and test it on a subsample of SDSS galaxies in Section 4.6.

4.1. The Signs of the LD1 Coefficients are Consistent with Previous Works

One of the strengths of LDA is that we can independently interpret the behavior of each predictor. We compare the primary coefficients of LD1 to previous works by Conselice
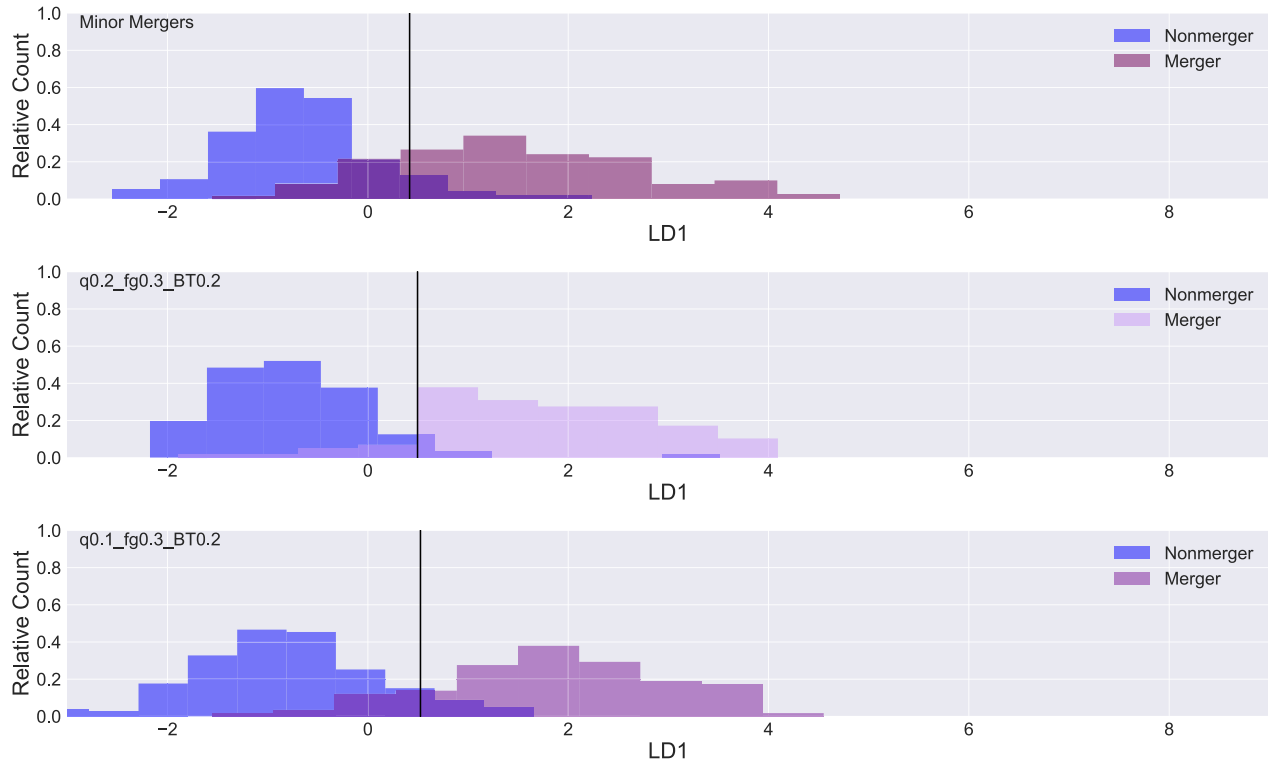

Figure 5. Same as Figure 4 but for all of the minor merger runs of LDA and the combined minor merger run (top). The decision boundaries for these simulations are lower than for the major merger runs because the separation between classes is not as extreme for the minor mergers.

et al. (2003) and Lotz et al. (2008, 2010a, 2010b) in terms of the signs (positive or negative) of the predictor coefficients.

In Figures 4 and 5, a higher value of LD1 indicates that a galaxy is more likely to be identified as a merger. Since LD1 is linear, we can interpret the individual signs of the coefficients in a similar way. If a coefficient is positive, this indicates that a higher value of the coefficient will increase the probability that a galaxy is classified as a merger and vice versa. We provide Figures 7–9 to visually compare the location in predictor space of the population of merging galaxies relative to the population of nonmerging galaxies. Figures 11 and 12 examine the time evolution of the values of individual predictors for the q0.5_fg0.3 and q0.2_fg0.3_BT0.2 runs, respectively. We select these two runs since they are representative of the predictor evolution for a typical major and minor merger simulation.

Since this discussion relies upon the time evolution of predictors, we quickly recap the definitions of merger stage. A merger begins at first pericentric passage and ends 0.5 Gyr following the final coalescence of the nuclei. An early-stage merger is one where the separation of the stellar bulges is $\Delta x \geqslant 10$ kpc, a late-stage merger is 1 kpc $< \Delta x < 10$ kpc, and a post-coalescence merger is $\Delta x \leqslant 1$ kpc.

Overall, we conclude that the positive/negative signs of the individual predictor coefficients are as expected from past studies of merger identification. We discuss the predictor coefficients in more detail and how they change for different mass ratios and gas fractions in Sections 4.3 and 4.4.

4.1.1. Gini

The Gini coefficients are significant and positive for the combined major and minor merger simulations, as well as

q0.333_fg0.3, q0.2_fg0.3_BT0.2, and q0.1_fg0.3_BT0.2, which is unsurprising because a higher Gini index has been shown to identify merging galaxies with one or more bright nuclei (e.g., Conselice 2014 and references therein).

4.1.2. M_{20}

The M_{20} coefficient is insignificant for all runs. Interestingly, the value of M_{20} for the mergers evolves with time; this behavior can be examined in Figure 11, which shows the evolution of all the imaging predictors with time for the q0.5_fg0.3 simulation. This time evolution is especially apparent for the major merger simulations. Early stage mergers evolve to the left toward the merger region of the Gini−M_{20} diagram as their concentration decreases early in the merger (recall that M_{20} is similar to C but does not depend on the location of the center of the galaxy). This leftward migration toward the merger domain would correspond to a negative value for the M_{20} coefficient.

Then, in the post-coalescence stages, the merging galaxies evolve away from the merger region on the Gini−M_{20} diagram, to the right. Lotz et al. (2008) also find this trend in which galaxies evolve away from the merger region of the Gini−M_{20} diagram for the later stages of a merger. This rightward migration makes sense because post-coalescence galaxies begin to lose visually disturbed features such as tidal tails and appear more concentrated in their light distributions. This evolution of M_{20} in both directions for major mergers leads to a washing out of any dominant trend of M_{20} for the major merger simulations.

4.1.3. Concentration

The central concentration of light, C, is important for all LDA runs except q0.333_fg0.3, where it is insignificant. The
Figure 6. Visualization of the LD1 coefficient values of each predictor, weighted relative to the maximum primary predictor for each run. This includes each LDA run for each individual simulation and all of the major merger simulations combined (first row) and all of the minor merger simulations combined (second row). We find that the relative importance of predictors changes between all simulations.

value of the C coefficient is positive for all runs except q0.5_fg0.3, where it is negative. A positive C coefficient indicates that mergers tend to have a higher value of C. We first discuss the overall behavior of C and then focus on the nuances of C, such as the decrease of C during the early stages of major mergers.

Since C is positive for the majority of merger simulations, we can conclude that, in general, merging galaxies have more centrally concentrated light than isolated galaxies. Lotz et al. (2008) found that concentration is not a strong predictor of a merger, but that it is higher for the later stages of a merger. This is expected given that mergers tend to build elliptical galaxies, which has been shown in detail for major mergers (e.g., Bendo & Barnes 2000; Bournaud et al. 2005). It has additionally been shown that minor mergers can contribute to stellar bulge growth and drive a less dramatic transformation of galaxy morphology (e.g., Walker et al. 1996; Cox et al. 2008). We discuss C in more detail for different mass ratios in Section 4.3.

We observe a gradual increase of C with the progression of the merger from the beginning of the early stage to the end of the post-coalescence stage. We examine Figure 11 for the time evolution of the C predictor for the q0.5_fg0.3 run. The value of C for q0.5_fg0.3 demonstrates an increase with a slight decrease during the early and late stages of the merger. It remains heightened for the nonmerging snapshots following final coalescence. This overall increase is typical behavior for

the rest of the merger simulations and happens for the minor merger simulations, without the dip during the end of the early and beginning of the late stages (Figure 12). The increase of C throughout the lifetime of each individual merger simulation leads to positive coefficients of the C predictor in the LDA technique. However, the dip in C values for q0.5_fg0.3 is pronounced during the early stages and results in a negative coefficient of C in the LDA.

4.1.4. Asymmetry and Shape Asymmetry

The LD1 coefficients for the asymmetry (A) and shape asymmetry (A_S) predictors both have positive values for all simulations (A_S is insignificant only for q0.1_fg0.3_BT0.2). This indicates that the more asymmetric a galaxy, the more likely we are to identify it as a merger. Asymmetry shows this same relationship in Lotz et al. (2008) and Conselice et al. (2003), where the value increases for mergers.

4.1.5. Clumpiness

Clumpiness (S) is insignificant for LD1 for all simulations. This result is anticipated given that Lotz et al. (2008) found clumpiness to be a less powerful predictor, but disagree with Conselice et al. (2003), who found that clumpiness is higher for merging galaxies. However, the sample of merging galaxies from Conselice et al. (2003) is built from local luminous and
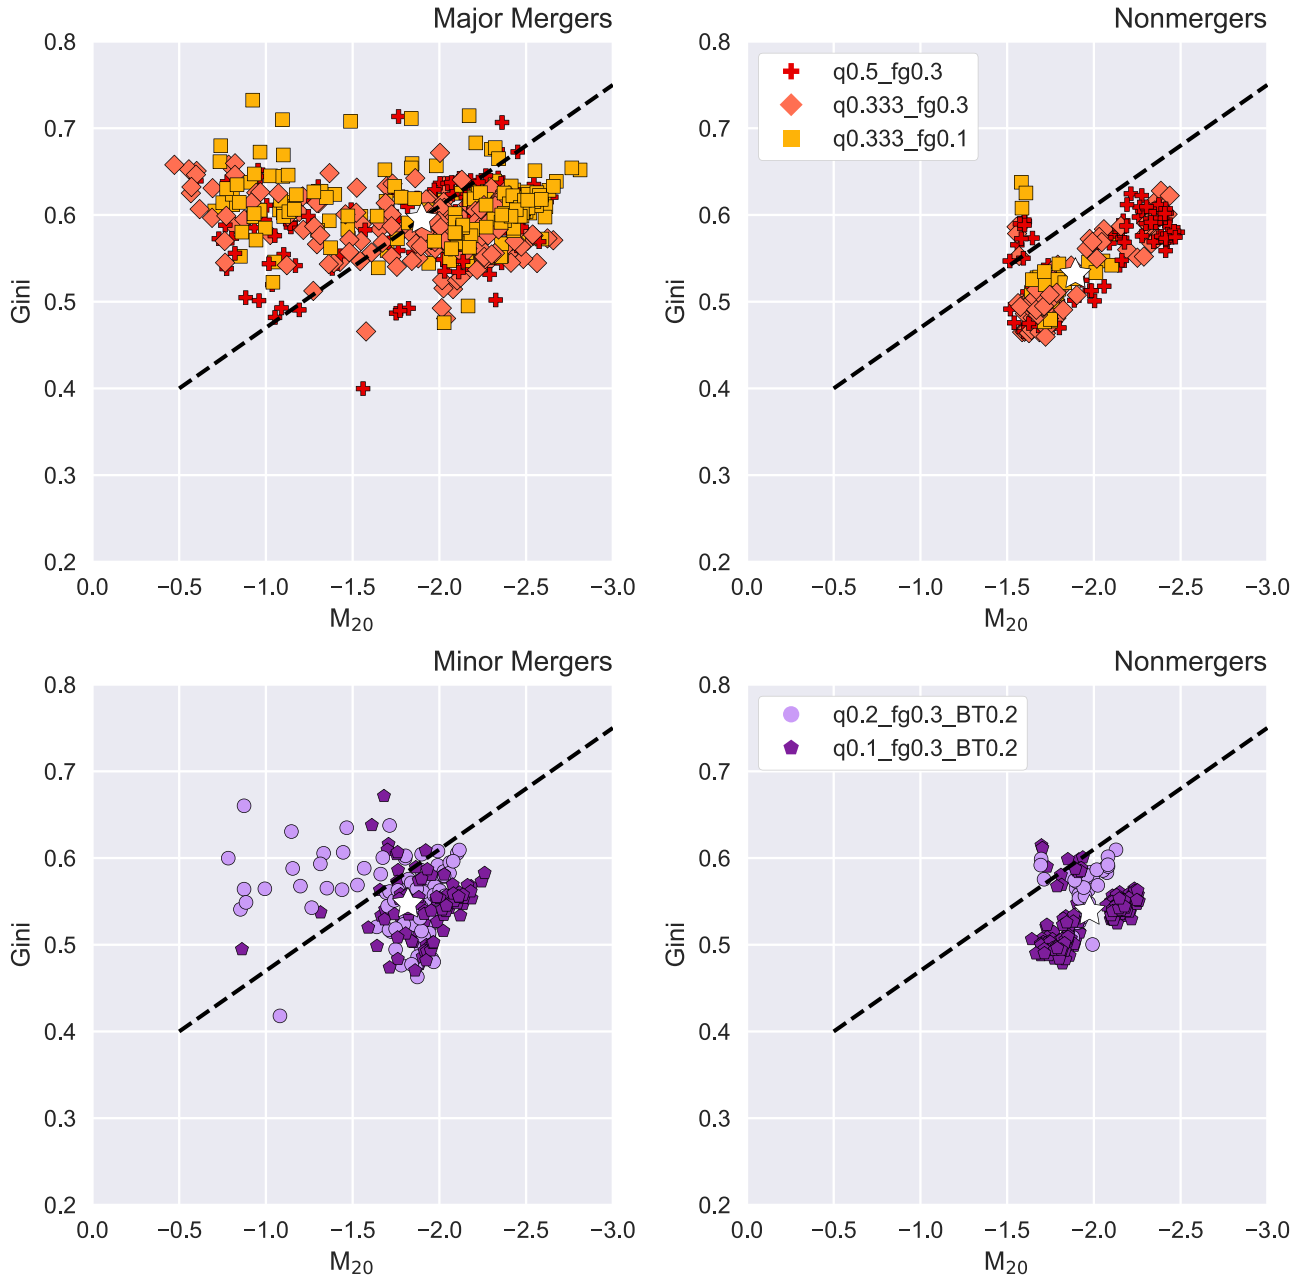

Figure 7. Viewpoint-averaged values at each snapshot of a merger for the three major merger simulations (top) and two minor merger simulations (bottom) in the Gini$-M_{20}$ two-dimensional predictor space. Red is q0.5_fg0.3, pink is q0.333_fg0.3, yellow is q0.333_fg0.1, light purple is q0.2_fg0.3_BT0.2, and dark purple is q0.1_fg0.3_BT0.2. The stars mark the mean of the data presented on each plot. We show the merging galaxies in the left plots and the matched nonmerging isolated galaxies on the right. We include the cuts in predictor space from Section 3.2 used to identify merging galaxies in other work. The cut in Gini$-M_{20}$ is Gini $> 0.14 M_{20} + 0.33$; all galaxies above this cut are identified as mergers in other work (e.g., Lotz et al. 2008).

ultraluminous infrared galaxies (LIRGs and ULIRGs), both of which are inherently very high in clumpiness. Thus, it is expected that we do not see the same importance of S for the merging galaxies in this work.

4.1.6. Sérsic Index

The Sérsic index, n, is also unimportant for all simulations. If n is higher for merging galaxies, this indicates that merging galaxies have steeper light profiles. The evolution of n is closely tied to that of C, which is unsurprising given that these predictors are correlated (Appendix C). n evolves toward higher values for later stages in the merger, where only a single

nucleus is present. The key difference between C and n is that n has a smaller separation in value between merging and nonmerging galaxies for most simulations, so it is an unimportant coefficient for the classification.

4.2. LDA Lengthens the Timescale of Observability of Merging Galaxies

The various LDA predictors evolve with time over the course of a galaxy merger. By incorporating seven different imaging predictors, we are able to capture a longer timeline for merging galaxies with the LDA technique than with individual predictors. In this section, we discuss the time evolution of the
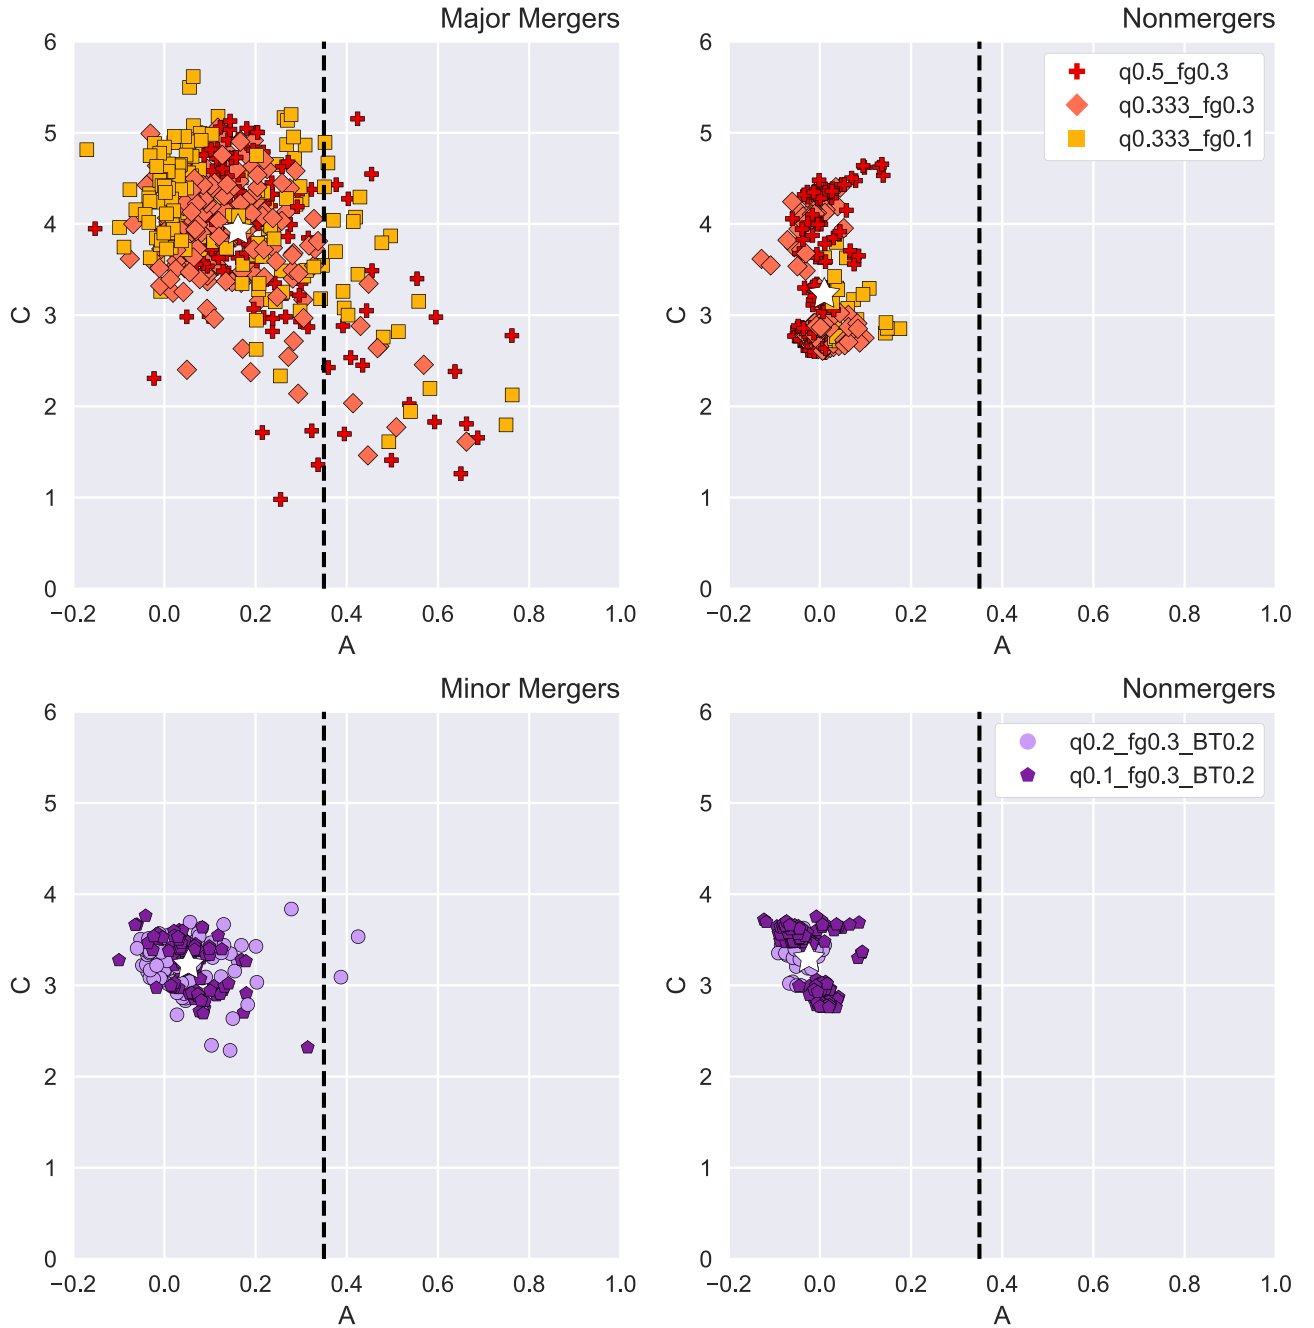

Figure 8. Same as Figure 7 but for the *CA* predictor space. The cut in *CA* space is $A > 0.35$; all galaxies to the right of this line are identified as mergers in other work (e.g., Conselice et al. 2003).

imaging predictors and how this limits their observability timescales. We also compare the estimates of observability time of different imaging predictors to past work.

We show the time evolution of the individual predictors (and LD1) in Figures 11 and 12 for the q0.5_fg0.3 and q0.2_fg0.3_BT0.2 simulations, respectively. We include the cutoff values of A and A_S; if a galaxy exceeds these values it is "identifiable" as a merger as in Section 3.2. We show one major and one minor merger simulation to demonstrate the main differences between the time evolution of the predictors for different mass ratios.

Using the Gini$-M_{20}$ cut in predictor space from Section 3.2, most of the simulated merging galaxies would be identified as merging by the cut in Gini$-M_{20}$ during the early and late

stages of merging, but for a shorter total time than with the LDA technique. The Gini$-M_{20}$ 0.59 Gyr time frame (indicated by the spike in M_{20} values) for the q0.5_fg0.3 major merger is shown in Figure 11. The q0.333_fg0.3 and q0.333_fg0.1 simulations are also identified by this cut during the early and late stages of merging for a similar time frame. However, as the mass ratio begins to increase for minor mergers, the observability timescale of the merger from the Gini$-M_{20}$ technique decreases. For instance, the q0.2_fg0.3_BT0.2 merger is identified by this cut during the early and late stages of merging, but only for a 0.19 Gyr time frame (also indicated by a spike in M_{20} values in Figure 12). These results are consistent with previous work; Lotz et al. (2008) found that Gini$-M_{20}$ is most sensitive to mergers during the first pass
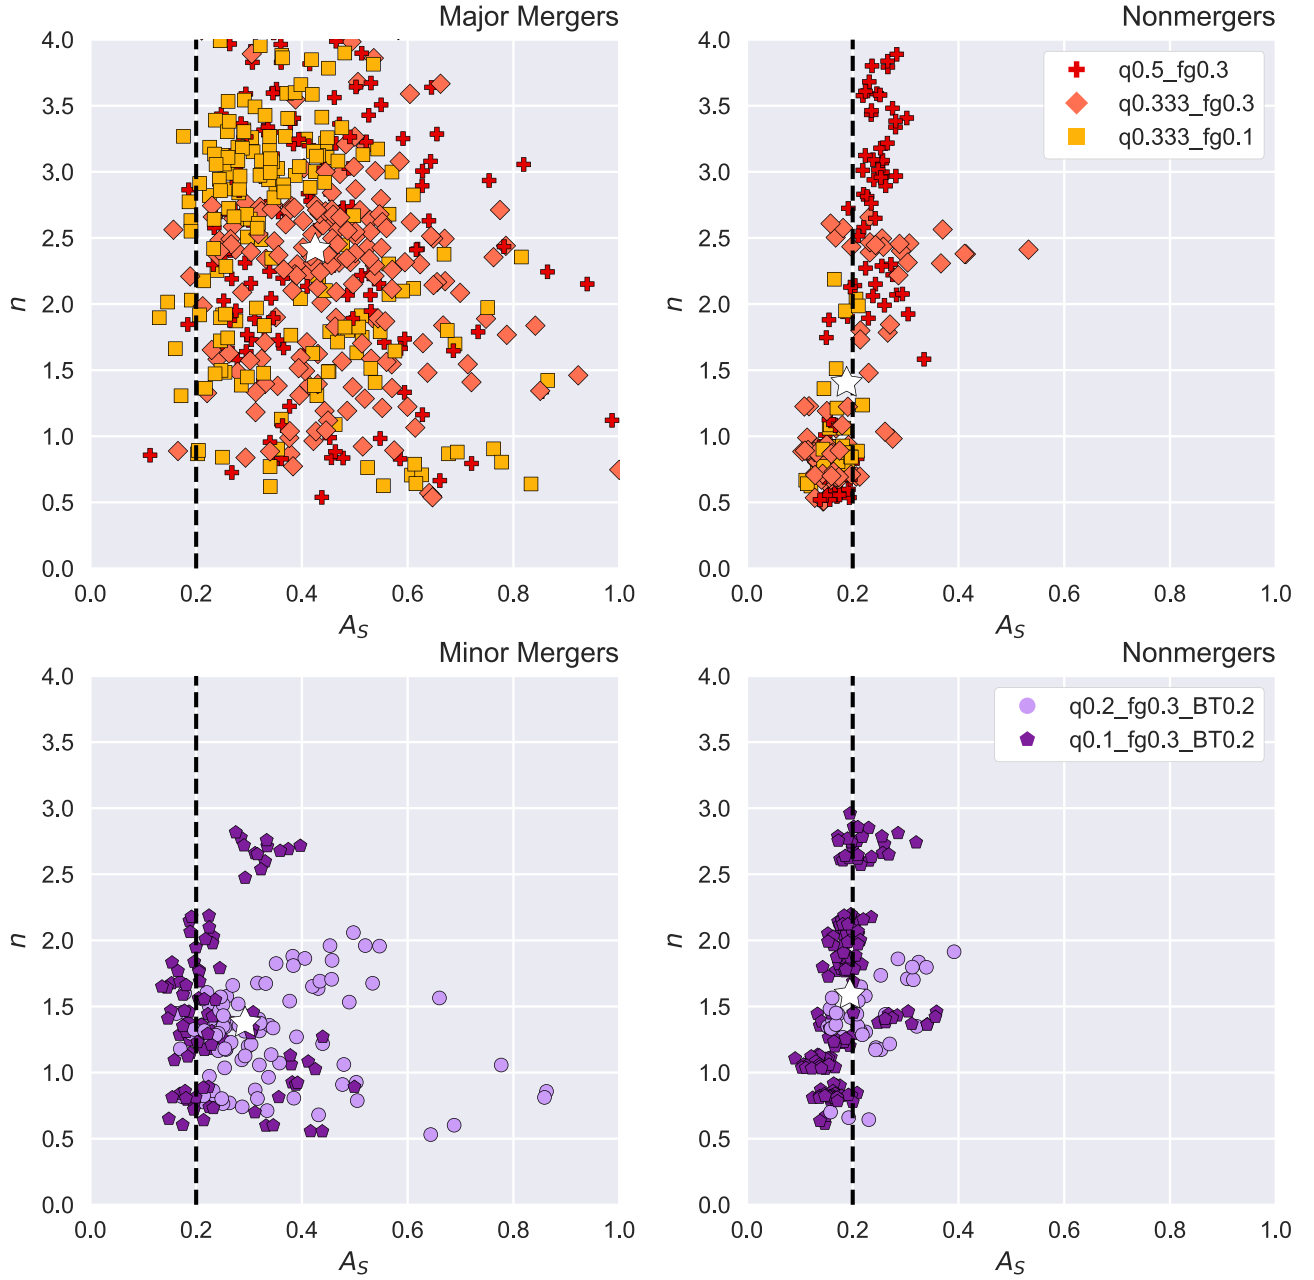

Figure 9. Same as Figure 7 but for the $n-A_S$ diagrams. The dashed line for the $n-A_S$ diagram is for $A_S > 0.2$; all galaxies to the right of this cut are identified as mergers in Pawlik et al. (2016).

Table 5
Observability Timescales in Gyr for the Four Different Merger Identification Techniques Compared in Section 3.2 as Well as the Total Time of the Merger

Simulation	Total Merger Time	LDA	Gini$-M_{20}$	A	A_S
q0.5_fg0.3	2.20	1.96	0.59	<0.1	2.20
q0.333_fg0.3	2.64	2.45	0.34	<0.1	2.64
q0.333_fg0.1	2.83	2.05	0.78	<0.1	2.34
q0.2_fg0.3_BT0.2	3.52	3.52	0.19	<0.1	3.52
q0.1_fg0.3_BT0.2	9.17	8.78	0.73	<0.1	7.79

(early stage) and the final coalescence of the nuclei (late stage), and Lotz et al. (2010a) showed that Gini$-M_{20}$ is sensitive to merger mass ratios less than 1:9. Also, our 0.2–0.8 Gyr Gini$-M_{20}$ timescale of observability for the simulations with a mass ratio >1:9 is consistent with the 0.2–0.6 Gyr timescale of observability from Lotz et al. (2008).

The A cutoff identifies some of the early and late stages of the major mergers, but has an even shorter timescale of observability than Gini$-M_{20}$. This behavior is apparent in Figure 11 when the A value exceeds the 0.35 cutoff value during the beginning of the early stage and in a spike during the late stage of the merger. This is consistent with Lotz et al. (2008), where the first passage and final coalescence (during the late stage) show the largest asymmetries. Although the A value exceeds 0.35 for more snapshots in the major merger simulations, we find a <0.1 Gyr timescale for both major and minor mergers. This <0.1 Gyr timescale for minor mergers can be seen in Figure 12, where the A value only approaches the cutoff value for one snapshot. Lotz et al. (2010a) found an A timescale of 0.2–0.4 Gyr for major mergers and then less than
Figure 10. Average value of LD1 (mean for all viewpoints) of each snapshot of a merger for all galaxy merger simulations with confidence intervals 1σ above and below the mean. The horizontal black line is the decision boundary; galaxies above this line are classified as mergers and galaxies below this line are nonmergers. LD1 and the decision boundary are different for each merger. The vertical dashed lines mark the beginning of the late stage, the beginning of the post-coalescence stage, and the end of the merger (0.5 Gyr following final coalescence). The blue line and confidence intervals are for the matched samples of nonmerging galaxies for each simulation. LD1 provides sensitive identification of merger morphology at many stages throughout the merger.
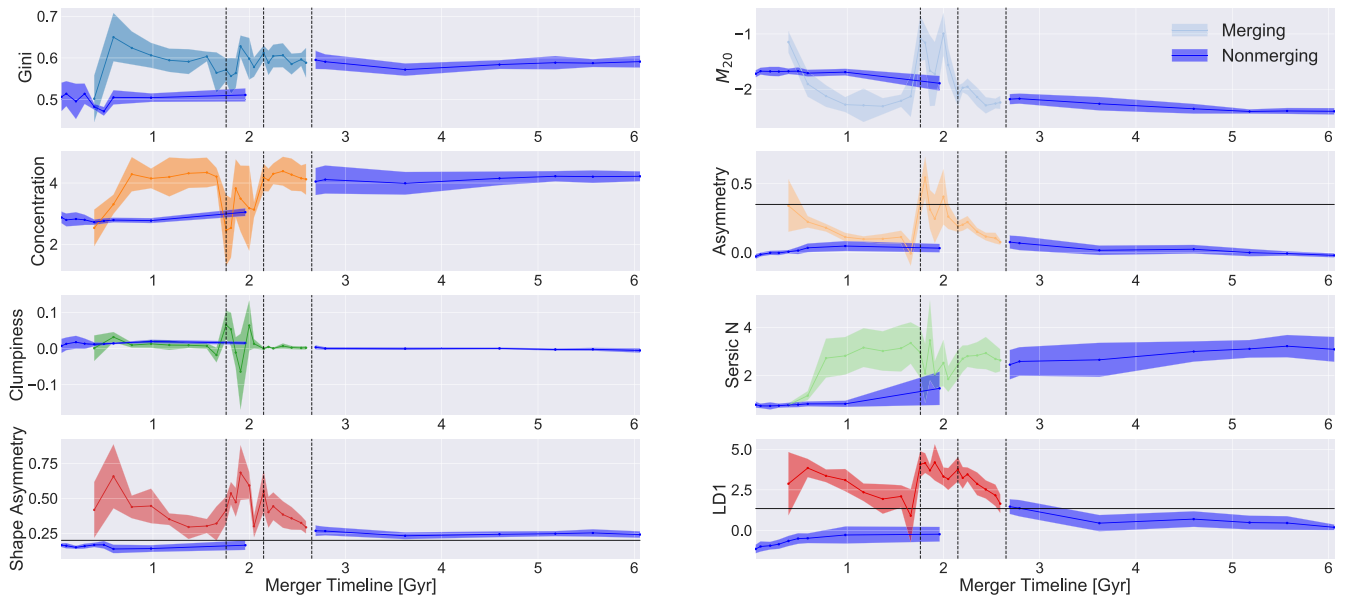

Figure 11. Time evolution of the imaging predictors for the q0.5_fg0.3 simulation. The LD1 sensitivity is shown in the bottom-right panel for comparison; the dashed vertical lines mark the beginning of the late stage, beginning of the post-coalescence stage, and end of the merger. We plot the nonmerging galaxies in dark blue for comparison purposes. We also plot horizontal lines for the A_S and A cutoffs in the literature (0.2 and 0.35, respectively) and for the decision boundary for LD1. The dark blue lines are for the matched sample of isolated galaxies. The most powerful predictors for the q0.5_fg0.3 simulation are A_S, A, and C.

0.06 Gyr for minor mergers. Although we have a shorter timescale of continuously heightened A values for the major merger simulations, we find that the major mergers result in more snapshots where the value of A exceeds 0.35, which is consistent with the longer observability timescale of A for major mergers from Lotz et al. (2010a).

A_S has a longer timescale of observability than A and Gini$-M_{20}$ for both major and minor mergers. The merging galaxies evolve to have large values of A_S at various times throughout the early, late, and post-coalescence stages of the merger. A_S identifies the major mergers at nearly all points throughout the simulation, expanding the sensitivity of the LDA technique in time. It only fails to identify the major mergers at some post-coalescence stages. A_S is notably much better at identifying the minor mergers as mergers than both A and Gini$-M_{20}$, and it is most sensitive to the early and late stages of these mergers. Overall, A_S shows less dependence on time in the merger and is a more consistent identifier of merging galaxies during the early, late, and early post-coalescence stages. This makes sense because A_S is sensitive to faint tidal features; it should therefore be more successful than A at identifying disturbed structures at all times.

Finally, we focus on the time evolution of C, which is not assigned a cutoff value in the literature but which has significant importance within the LDA technique. We find that all mergers show elevated values of C, especially for the post-coalescence stages, meaning that C is critical within the LDA technique for capturing the post-coalescence snapshots in time. Gini exhibits a similar behavior to C for the minor mergers, becoming most enhanced during the late and post-coalescence stages.

Snyder et al. (2018) applied a random forest classifier to the Illustris galaxies and found that features that rely on concentration are more important for selecting recent mergers while features that rely on asymmetries are more important for selecting galaxies that are about to merge. Although the Illustris simulation is a cosmological merger tree simulation, it is

informative that the results are consistent with the time sensitivities of various imaging predictors in this work.

Unlike the individual imaging predictors, we find that the sensitivity of the LDA depends only minimally on merger stage. It is slightly less sensitive for the very early stages and very late post-coalescence stages of the merger; this is expected since the galaxies often appear visually to be isolated galaxies prior to first pericentric passage and after coalescence. As discussed in Section 2.1, we use the very early and very late stages of the merger (prior to first passage and >0.5 Gyr following final coalescence) as isolated galaxies in this analysis, so these galaxies are very similar in imaging to galaxies at an adjacent point in time. This explains why the 1σ confidence intervals overlap with the decision boundary for many of these very early-stage and very late-stage snapshots in Figure 10.

The individual imaging classification techniques are sensitive to the different stages of a merger. For instance, A and Gini$-M_{20}$ identify early and late-stage mergers; A_S identifies early-stage, late-stage, and some post-coalescence mergers; and C is most sensitive to post-coalescence mergers. LDA is able to combine these imaging techniques into one more complete classifier that maintains sensitivity throughout the lifetime of a merger.

4.3. The Coefficients of LD1 Change with Mass Ratio

When we examine the relative importance of various predictors for merger simulations with varying mass ratios, we determine that A_S and A are relatively more important for the major mergers and that C and Gini are relatively more important for the minor mergers. A is important for all merger simulations.

First, we address the major mergers, where A_S and A are both important coefficients and indicators of disturbed visual morphology. The A coefficient has a normalized value of 0.28–1.0 for the three major mergers and the combined major
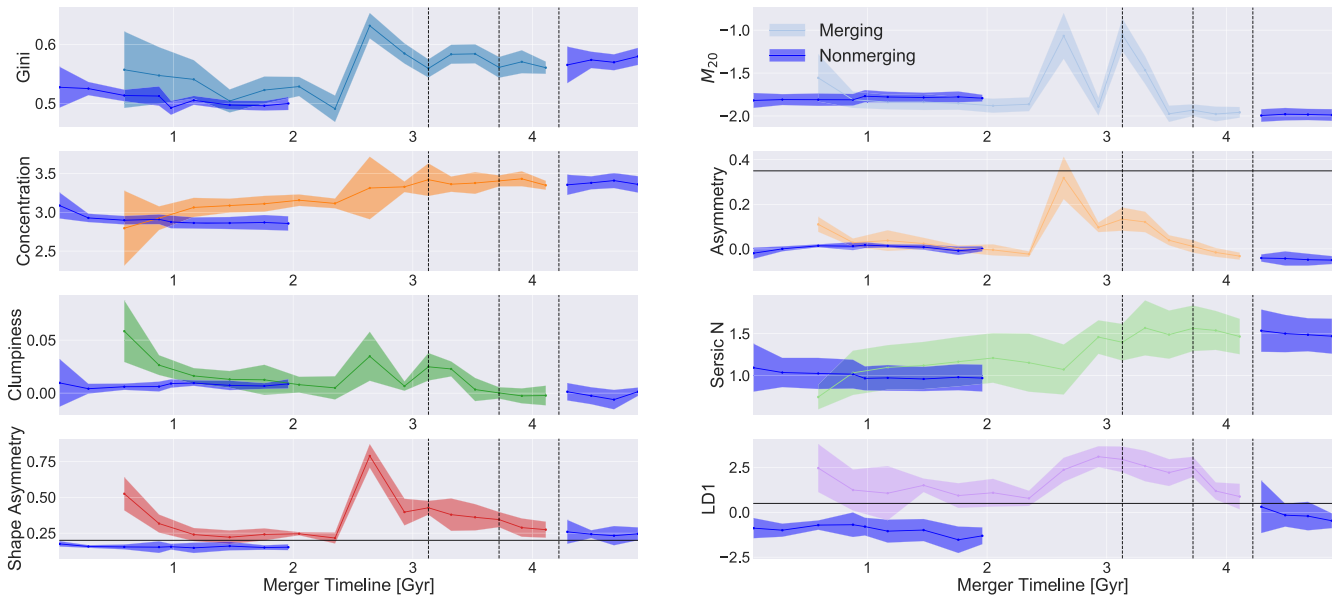

Figure 12. Same as Figure 11 but for the q0.2_fg0.3_BT0.2 simulation. The most powerful predictors for the q0.2_fg0.3_BT0.2 simulation are C, Gini, A, and A_S.

merger runs, indicating that it is one of the most important primary predictors. It is less important for the minor mergers and the combined minor merger simulation, but its relative importance is still high, $\sim$0.24–0.89 (Figure 6). This result agrees with Lotz et al. (2010a), who found that A is a good probe of major mergers with mass ratios between 1:1 and 1:4. This is because the major mergers have more disturbed morphologies, especially during the early stages of the merger. However, the A predictor remains important for the minor mergers, where the visual morphology is less disturbed.

A_S is more sensitive (than A) to faint tidal tails in galaxies. The A_S coefficient ranges in normalized values from 0.25–1.0 for the major mergers and 0.16–0.18 for the minor mergers. Since both A and A_S track visual morphology, it is significant that while A is important for all runs, A_S is less important for the minor mergers. This suggests that the more disturbed visual morphology of major mergers is best identified with both measures of asymmetry. On the other hand, minor mergers rely more on measures of concentration like C and Gini, so while A is still an important predictor for them, it is less dominant.

Next, we address C and Gini, where their importance to the minor mergers can be attributed to two main factors: scatter and necessity. The major mergers show more scatter in C value, while the minor mergers show a general trend of C enhancement as the mergers progress. In Figure 8, the major mergers range from values of 1–5.5, while the minor mergers only span 2–4 in C. Upon examination of the predictor values with time (Figures 11 and 12), we verify that C increases steadily with time for the minor mergers and reaches a peak value of $\sim$3–3.5. For major mergers, C shows a general increase with time but also decreases during the most visually disturbed epochs of the merger (early and late stage). However, the major mergers do ultimately build more concentrated remnants than the minor mergers, with C values peaking at 4–4.5.

Gini is heightened for both major and minor mergers in Figures 11 and 12. The LDA for the major mergers was able to rely upon stronger predictors such as A and A_S to fully separate the populations of merging and nonmerging galaxies.

However, the minor mergers are less distinguishable from nonmerging galaxies using these predictors. Therefore, Gini becomes more important for the minor mergers. This result is consistent with Lotz et al. (2010a), who found that Gini$-M_{20}$ remains effective for identifying minor mergers down to mass ratios of 1:9.

Figure 6 also shows an important difference between the 1:2 major merger and the 1:3 major mergers. Between the two mass ratios, measurements of concentration (C and Gini) become slightly more important in the 1:3 major mergers, initiating the trend toward minor mergers.

Our findings regarding C make sense given the current understanding of galaxy morphological evolution. To first order, equal mass ratio major mergers build large elliptical galaxies (e.g., Bendo & Barnes 2000; Bournaud et al. 2005) while intermediate mass ratio mergers (down to 1:10) are predicted to build galaxies with spiral-like morphologies and elliptical-like kinematics (e.g., Jog & Chitre 2002; Bournaud et al. 2004). Very high mass ratio mergers (minor mergers, $\geqslant$1:10) build disturbed spiral-like galaxies (e.g., Naab et al. 2014 and references therein). However, some work has found that multiple minor mergers can still build elliptical surface brightness profiles in the remnant galaxy (Bournaud et al. 2007; Jesseit et al. 2009; Bois et al. 2011) and that even one merger of a very minor mass ratio can build stellar bulges in the remnant (Cox et al. 2008).

Statistically, minor mergers are much more common than major mergers, accounting for three times as many mergers (e.g., Bertone & Conselice 2009; Lotz et al. 2011). The ubiquitous nature of minor mergers increases their relative importance for galaxy evolution. For example, Ownsworth et al. (2014) found that the majority of stellar mass is added to galaxies by star formation (24% of stellar mass) and minor mergers (34% of stellar mass), whereas major mergers only account for 17% of the total galaxy stellar mass at $z = 0.3$. Other observations of local elliptical galaxies and the dearth of major mergers indicate that minor mergers may be more important than previously thought for building local elliptical galaxies with more concentrated light profiles (Trujillo et al. 2009; Taylor et al. 2010).

The above picture of galaxy morphological evolution is consistent with the differences between C for the major and minor merger simulations. C is more important for the minor mergers, because it exhibits less scatter, than for the major mergers, where the dip in C weakens the overall strength of the coefficient in the LDA technique. The major merger remnants show a greater overall enhancement of C by the end of the merger, building galaxies with $C \sim 4$–5 that are more consistent with the classical picture of large elliptical galaxies. Visually, the galaxy remnants for major and minor mergers still have disk profiles with a more concentrated center, indicative of an enhancement of the stellar bulge. This means that by the end of the merger, minor and major mergers have both enhanced the concentration of the light profile of the galaxy and therefore contributed to the morphological evolution of galaxies.

4.4. The Coefficients of LD1 Do Not Change (Significantly) with Gas Fraction

Next, we examine differences between the gas-rich and gas-poor simulations. We specifically compare q0.333_fg0.3 to q0.333_fg0.1, which are both 1:3 mass ratio major mergers matched for all properties except gas fraction. The important predictors for the gas-poor merger are A_S, A, and C, while A_S, A, and Gini are important for the gas-rich merger. Overall, these coefficients are very similar between the gas-rich and gas-poor simulations. Both rely upon measurements of asymmetry (A and A_S). Both simulations also rely upon measurements of concentration (Gini and C). Although C is more important for the gas-poor merger, Gini is more important for the gas-rich merger.

Lotz et al. (2010b) established that Gini$-M_{20}$ is weakly dependent on gas fraction whereas A is relatively enhanced for gas-rich mergers. Since A and A_S are relatively important for both gas-rich and gas-poor simulations, we conclude that the dominant initial condition must be mass ratio for A to remain important for the gas-poor major merger.

Although there is little difference in A_S in terms of the coefficients for the gas-rich and gas-poor simulations, there is a small difference in the observability timescales for A_S and Gini$-M_{20}$. The observability times for A_S is shorter for the gas-poor major merger in Table 5. The timescale of observability for A_S for q0.333_fg0.1 is 2.34 Gyr while it is 2.64 Gyr for q0.333_fg0.3. Since the overall merger timescales are so similar for these two simulations, the A_S observability timescale is significantly longer for the gas-rich major merger. The Gini$-M_{20}$ timescale is also significantly different for the gas-rich and gas-poor simulations; it is longer for the gas-poor major merger (0.78 Gyr) and shorter for the gas-rich major merger (0.34 Gyr). This result is consistent with Lotz et al. (2010b), where the result is that the Gini$-M_{20}$ observability timescale decreases slightly with increasing gas fraction while the A observability timescale increases with gas fraction. The Gini$-M_{20}$ timescale may be decreasing slightly with gas fraction here for similar reasons as stated in Lotz et al. (2010b): the increased dust obscuration at the central nuclei lowers the Gini values for gas-rich simulations. The gas-poor simulation has the longest Gini$-M_{20}$ observability timescale of all the simulations.

Kormendy et al. (2009) suggested that both dry and wet mergers (gas poor and gas rich, respectively) build up the bulge mass of a galaxy, contributing to its elliptical morphology (or

Table 6
LDA Performance

Simulation	Accuracy	Precision	Recall	F_1 Score
All Major	0.85	0.97	0.80	0.88
All Minor	0.81	0.94	0.66	0.78
q0.5_fg0.3	0.91	0.98	0.82	0.90
q0.333_fg0.3	0.90	0.97	0.87	0.92
q0.333_fg0.1	0.86	0.96	0.83	0.89
q0.2_fg0.3_BT0.2	0.88	0.96	0.78	0.86
q0.1_fg0.3_BT0.2	0.89	0.89	0.79	0.84

Note. We list the accuracy, precision, recall, and F_1 score as defined in Appendix E for all runs of the LDA classification.

an increased value of C). Overall, dry mergers are more important for building elliptical galaxies but wet mergers can also increase the central concentration of a galaxy since they drive starbursts that contribute to bulge growth. The C value for the gas-rich major merger increases with time to a peak value of ~ 4.3, while the gas-poor major merger increases to a peak value of ~ 4.7. The gas-poor major merger seems to have a slightly higher concentration, possibly reflecting the tendency for dry mergers to build galaxies with elliptical morphologies. However, these values are not significantly different when we take into consideration the viewpoint-averaged standard deviation for these snapshots. Therefore, the difference in gas fraction is not producing a significant difference in the concentration of the remnant.

Overall, while the timescale of observability for A_S is longer for the gas-rich major merger and the timescale of observability of Gini$-M_{20}$ is longer for the gas-poor major merger (which is consistent with Lotz et al. 2010b), the differences in LDA coefficients are most pronounced for mergers of different mass ratios (Section 4.3). This is why we choose to separate the combined runs by mass ratio as opposed to gas fraction.

4.5. The LDA Technique Is Accurate and Precise at Identifying Merging Galaxies

The accuracy and precision of the LDA technique are very high (the accuracy is 85% and 81%, and the precision is 97% and 94% for the major merger and minor merger combined simulations, respectively; Table 6 in Appendix E). We use accuracy to determine the relative number of true detections (TP, true positives, and TN, true negatives) to all detections (includes FP, false positives, and FN, false negatives); the accuracy is defined as (TP + TN)/(TP + TN + FP + FN). If the accuracy is high, this means that our method does a good job of minimizing the number of false positives and false negatives. We use precision to determine the relative number of true positives to all positive detections, including false positives; the precision is defined as (TP/(TP+FP)). If the precision is high, then there is a low percentage of false positives, which is desirable because false positives are nonmerging galaxies that are incorrectly included as mergers. We want to avoid contamination in the sample of merging galaxies when we apply the technique to real imaging.

In this section, we compare the accuracy and precision of the LDA technique to those of past work, which utilizes pair studies or cuts in Gini$-M_{20}$ space, A, or A_S. We also compare to other works that have utilized machine learning tools to identify merging galaxies.

First, we compare the LDA accuracy and precision to those of close pair studies with SDSS. Darg et al. (2010) compared Galaxy Zoo classifications of major mergers to all SDSS galaxy pairs with a projected separation of <30 kpc and a line-of-sight velocity offset <500 km s^{-1}. After visually examining all 2308 close pair objects, they find that 28% of objects are chance superpositions and/or have no signs of interaction. Although this is an imperfect comparison to our work since close pair studies only capture a brief snapshot of a merger, the overall result is that 28% of the close pairs are false positives. Darg et al. (2010) also estimated that only 20% of advanced mergers identified in Galaxy Zoo are pairs in SDSS, which is a small fraction of true positives. In comparison to the LDA technique, pair studies have low accuracy, since many mergers are missed by the technique, and low precision, since there is also a significant fraction of false positives.

Next, we directly compare the accuracy and precision of the LDA technique to those of the cuts in predictor space introduced in Section 3.2. We measure the accuracy and precision of the Gini$-M_{20}$, A, and A_S cuts for the simulations and find that precision remains high. This means that these methods do not incorrectly identify nonmergers as mergers. In fact, they have the opposite problem and fail to identify merging galaxies as such, leading to low accuracies. We find that Gini$-M_{20}$ has accuracies from 60% to 70%, A has accuracies from 40% to 60%, and A_S has accuracies from 70% to 90%. The low accuracy of the A predictor agrees with Conselice et al. (2003), who found that the fraction of mergers (defined to be a sample of ULIRGs) that are correctly identified by A is ∼50%.

We also find that there is a difference in accuracy for different mass ratios. For example, the minor mergers fall at the bottom of the accuracy ranges given above. This is worrisome because the cuts in predictor space are preferentially selecting major mergers, which are much less numerous than minor mergers. In contrast, the LDA accuracy changes by less than 10% between all simulations, ranging from ∼85%–90% accuracy for all simulations. Using Gini$-M_{20}$, A, or A_S in isolation is not sensitive enough to correctly and consistently identify mergers of all mass ratios at all merger stages.

Our LDA technique is more accurate and precise than individual imaging predictor classifiers and is comparable to other techniques that combine many different imaging predictors. For instance, Snyder et al. (2018) and Goulding et al. (2018) used random forest classifiers with a collection of similar parametric and nonparametric imaging predictors to classify merging and nonmerging galaxies and find similar accuracies and precisions.

Snyder et al. (2018) used the Illustris cosmological simulation to produce synthetic deep *Hubble Space Telescope* images of merging galaxies at 12 time steps over a range of redshifts ($0.5 < z < 5$). While Snyder et al. (2018) work with galaxies dissimilar to our low-redshift SDSS galaxies, we are able to roughly compare the two methods because both rely upon similar imaging predictors. For instance, Snyder et al. (2018) used a binary classification that relies upon Gini, M_{20}, A, and C as inputs (among other imaging predictors). They find a similar accuracy and precision of their classifier when they test it using the simulated Illustris galaxies. The result is a classifier that relies on different imaging predictors for different merger stages, similar to the LDA technique in our work. The random forest has a completeness of ∼70% and a purity of 10% at $z = 0.5$ and 60% at $z = 3$. Completeness is defined as

TP/(TP+FN), which is defined as recall in our work, and purity is TP/(TP+FP), which is defined as precision here.

Since the isolated galaxy sample in Snyder et al. (2018) is different than the sample of isolated disks used in this work, we are unable to directly compare the false positive and false negative rates. We instead discuss one relative strength of the LDA technique. Some of the false negatives in Snyder et al. (2018) result from the failure of the method to detect some minor mergers, and some of the false positives result from a narrow temporal definition of the duration of the merger, which is restricted to 500 Myr. One relative strength of the LDA technique is that it is built from high temporal resolution simulations and is therefore able to use a more complete definition of merging galaxies. It also extends the definition of merging galaxies beyond the 500 Myr time frame used in Snyder et al. (2018). This is a general strength of high temporal resolution isolated simulations over large cosmological simulations.

Goulding et al. (2018) used a random forest to create a nonbinary classifier that separates their sample of Hyper Suprime-Cam (HSC) galaxies into subsamples of major mergers, minor mergers and irregulars, and non-interacting galaxies. The input imaging predictors include Gini, C, A, S, and n for the galaxy images as well as the residual images after subtracting a GALFIT surface brightness model. They visually classified galaxies in the HSC sample to test the performance of the classifier and found that the major mergers suffer from mild contamination (∼10%) with an overall completeness for the merger samples of 75%. The LDA technique has a comparable result with 4% contamination and 79% completeness for major mergers. The minor mergers are more difficult to distinguish from isolated and major mergers in Goulding et al. (2018) and therefore have increased contamination and decreased completeness. The LDA technique, on the other hand, only suffers from 6% contamination and 66% completeness for minor mergers. It should be noted that Goulding et al. (2018) created and tested the random forest method on real galaxy images, so this is an imperfect comparison, simply meant to roughly compare the accuracy and precision of different imaging merger identification methods. Additionally, since the LDA technique is developed from disk-dominated galaxies, its accuracy and precision apply best to galaxy samples that match the properties of the simulated galaxies used to construct the technique.

4.6. Testing the Technique on SDSS Galaxies

To preliminarily test the performance of the LDA technique on real images of galaxies, we apply the major and minor merger classification techniques to a sample of SDSS galaxies that have been identified as mergers, spirals, and ellipticals in Galaxy Zoo (Lintott et al. 2008, 2011). We randomly select 50 galaxies from each galaxy morphology classification (merger, spiral, and elliptical) using a "superclean" cutoff value of p_{merg}, p_{el}, $p_{CS} > 0.95$, where p_{merg} is the probability that the galaxy is a merger, p_{el} is the probability that the galaxy is classified as elliptical, and p_{CS} is the probability that the galaxy is classified under the umbrella classification of "combined spirals." The probabilities are the percentage of Galaxy Zoo users that selected a given morphology type. We require that these galaxies exceed the $\langle S/N \rangle$ cutoff value of 2.5.

We apply the major and minor merger combined LDA techniques to each of the three subsamples of galaxy types and determine the fraction of galaxies that are classified by the LDA technique as merging and nonmerging. We show some example

Figure 13. *r*-band images of Galaxy Zoo mergers (top), elliptical galaxies (middle), and spiral galaxies (bottom) that are classified as mergers (left column) and nonmergers (right column) by the major merger classification technique. For each case, the probability that the galaxy is a merger as classified by the major merger technique ($p_{\mathrm{merg,major}}$) is given. The major merger technique identifies 86% of Galaxy Zoo mergers as mergers, 73% of Galaxy Zoo ellipticals as mergers, and 14% of Galaxy Zoo spirals as mergers.

classifications for the major merger classification tool in Figure 13. For the major merger classification tool, we find that 86% of the Galaxy Zoo mergers are identified as mergers, 73% of the Galaxy Zoo elliptical galaxies are identified as mergers, and 14% of the Galaxy Zoo spirals are classified as mergers. We show images of these classification categories in Figure 13 for the major merger classifier. For the minor merger classification, 93% of Galaxy Zoo mergers are classified as mergers, 61% of the Galaxy Zoo ellipticals are classified as mergers, and 43% of the Galaxy Zoo spirals are classified as mergers.
Figure 14. *r*-band images of a Galaxy Zoo spiral galaxy that is identified as a merger by the minor merger technique (left) and a nonmerger by the major merger technique (right). The probabilities that the galaxy is a merger are listed.

The difficulty in using the Galaxy Zoo sample as a test sample is that we do not know a priori which galaxies are merging. We are able to use the Galaxy Zoo merger sample as "true" mergers since they are obvious visual mergers (classified as such by Galaxy Zoo users), so the fraction of true positives and false negatives is reliable. The Galaxy Zoo users were conservative, only reluctantly classifying the most obvious mergers as such (Darg et al. 2010). However, we are unable to adequately establish the relative fractions of false positives and true negatives since the samples of Galaxy Zoo ellipticals and spirals may be contaminated by merging galaxies that lack the obvious visual signs of clear major mergers such as tidal tails. Therefore, our discussion mainly relies upon the fraction of true positives and false negatives from the classification of the Galaxy Zoo mergers and only briefly discusses true negatives and false positives from the Galaxy Zoo ellipticals and spirals population. We plan to delve into this discussion in more depth in a future work that presents the classification of real galaxies (R. Nevin et al. 2019, in preparation).

The major merger classifier recovers ∼86% of the Galaxy Zoo mergers. This fraction agrees with the fraction of true positives and false negatives from the simulation measured in Appendix E, where 82% of true mergers are identified as such. Figure 13 shows a failure mode of the major merger classifier. The classifier fails to identify the Galaxy Zoo merger in the top right of the figure as a merger because although it appears to be two separate galaxies by eye, the two galaxies are symmetrically aligned in such a way that A and A_S are low. We plan to investigate the failure modes of the technique in more detail in R. Nevin et al. (2019, in preparation).

The minor merger classification identifies 93% of the Galaxy Zoo mergers as such, which is more than predicted (62%) when testing on simulated galaxies. It is important to note that the Galaxy Zoo mergers are more likely to be major mergers in their early phases with clear visual disturbances. Therefore, the minor merger tool performs better than expected since it is applied to galaxies that are more easily identified than most minor mergers in the simulated galaxy sample.

The fraction of nonmergers (according to Galaxy Zoo) that are identified as mergers by the LDA technique is low for the spiral galaxies and high for the elliptical galaxies. For instance, the major merger classifier tool identifies 73% (14%) of the Galaxy Zoo elliptical (spiral) galaxies as mergers. The spiral galaxy false

positive rate is closer to the 3% false positive rate from the major merger classifier when it is tested on simulated galaxies. However, there is an excess of galaxies identified as mergers in the Galaxy Zoo elliptical galaxy population. It is not obvious that these galaxies have undergone mergers recently from visual inspection. Although it is possible that some of these galaxies have recently merged, many of them may be false positives. It is important to note that the galaxies that are classified as mergers among the Galaxy Zoo elliptical galaxies have p_{merg} values that are barely above the 0.5 threshold we define here for the LDA classification. In future work, we plan to set multiple probability thresholds to eliminate false positives among our merger samples. Finally, since the LDA technique was constructed from disk-dominated galaxies, it is most accurate and precise at classifying galaxies that most closely match the specifications of the simulated sample. Therefore, it may not be as accurate for elliptical galaxies. We plan to address this concern in future work (R. Nevin et al. 2019, in preparation) when we apply the classification to SDSS galaxies.

There is an interesting discrepancy between the false positive rate of the major and minor merger technique for the sample of Galaxy Zoo spirals. The major merger technique identifies 14% of the sample as merging whereas the minor merger technique identifies 43% of the sample as merging. Of the Galaxy Zoo spirals, there are 16 galaxies that are classified as merging by the minor merger technique that are classified as nonmerging by the major merger technique. We visually inspect these galaxies and find that ∼50% could be classified as spirals with a disturbed structure, while ∼40% have a secondary point source component that could either be a star-forming region or a stellar bulge. More follow-up work is required here, but preliminarily, it appears that the minor merger technique is identifying some possible minor mergers that have been missed by Galaxy Zoo users. It is possible that it could also be identifying star-forming regions because although we prescribe a 10% flux threshold for the fitting of n, it could be fitting bright star-forming regions that exceed this threshold. More work is required to distinguish between these two possibilities. It is expected that the major merger technique also misses some of these minor mergers. We show an example of a possible minor merger that was detected by the minor merger technique but not by the major merger technique in Figure 14. This galaxy has a disturbed spiral structure, and some possible secondary point sources that could be star-forming regions.

5. Conclusion

We create a suite of merging and nonmerging disk-dominated galaxies with different gas fractions, mass ratios, and bulge-to-total mass ratios using `GADGET-3` hydrodynamics simulations. We use the dust radiative transfer code `SUNRISE` to produce resolved dust-attenuated optical spectra from the simulations, from which we extract SDSS r-band images at ∼0.1 Gyr intervals. These snapshots cover the early, late, and post-coalescence stages of the simulated mergers. We then "SDSS-ize" the simulated images of galaxies, introducing residual noise and convolving to the seeing limit of the SDSS survey. We use these "SDSS-ized" images to measure seven different imaging predictors (Gini, M_{20}, concentration (C), asymmetry (A), clumpiness (S), Sérsic index (n), and shape asymmetry (A_S)), which we combine to create an LDA classification scheme. This classification technique is able to accurately identify merging galaxies over a range of mass ratios, gas fractions, viewing angles, and merger stages. We create two overall classifications, one for major mergers and one for minor mergers, that we will apply to classify SDSS galaxies, assigning each galaxy a posterior probability of being a merging galaxy. Based on these results, we make the following conclusions:

1. The LDA technique outperforms previous merger identification methods such as Gini−M_{20}, A, and A_S in terms of accuracy and precision. While the precisions of Gini−M_{20}, A, and A_S are high with few false positives, the accuracies vary between 40%–90% and change with merger mass ratio. The LDA technique improves upon this with accuracies of 85% (81%) and precisions of 97% (94%) for the combined major (minor) merger simulations. The LDA accuracy and precision vary little with merger initial conditions (<10%), indicating that the LDA technique is more stable and accurate than individual predictor merger identification techniques.
2. The LDA technique lengthens the timescale of observability of merging galaxies (>2 Gyr), and the galaxy mergers are identified at all stages (early, late, and post-coalescence) of a merger. The observability timescales for Gini−M_{20}, A, and A_S are 0.2–0.8, <0.1, and 2.2–7.8 Gyr, respectively. The LDA technique incorporates many imaging predictors and is therefore able to combine the strengths of all these imaging predictors to be sensitive to all stages of the galaxy mergers.
3. The predictor coefficients of LD1 change little with gas fraction and are most affected by the mass ratio of the merging galaxies. For instance, A and A_S are important for major mergers due to their visually disturbed morphology while C and Gini are more important for minor mergers, since they show consistent enhancement in light concentration as the merger progresses. This supports the idea that even minor mergers can build stellar bulges. A is an important coefficient for a range of mass ratios, identifying major and minor mergers alike.

We plan to apply this imaging LDA technique to the SDSS galaxies (R. Nevin et al. 2019, in preparation). Additionally, since the MaNGA survey is an imaging and IFS survey, we will incorporate several kinematic predictors based on the stellar velocity and stellar velocity dispersion maps from the hydrodynamics simulations into this analysis to improve the classification.

Appendix A
Initial Conditions

We vary the initial masses, mass ratios, gas fractions, and B/T (bulge-to-total mass) ratios of the merging galaxy models based upon previous works with similar merger simulations (e.g., Cox et al. 2008; Lotz et al. 2008; Blecha et al. 2011, 2018). Additionally, we select the values for these initial conditions based upon the range of observed values for present-day galaxies in SDSS as in Cox et al. (2008). Our goal is to produce simulated mergers that are typical of merging galaxies in SDSS and also comparable to previous works with the imaging predictors of simulated galaxies (e.g., Cox et al. 2008; Lotz et al. 2008).

Our simulations span a range in total stellar mass, $10.6 < \log M_\star (M_\odot) < 10.8$, which agrees well with the fiducial models used in Cox et al. (2008) that have a range in total mass $9.0 < \log M_\star (M_\odot) < 10.7$. SDSS galaxies span a range in stellar mass (for individual galaxies) of $9 < \log M_\star (M_\odot) < 11$. When we compare this to the total mass of the merger simulations (which combine two galaxies), we find that the simulated galaxies are in the middle of the expected mass range for SDSS galaxies.

We vary the total mass ratio between 1:2 and 1:10 to capture three major merger simulations and two minor merger simulations. We are able to compare to Lotz et al. (2010a) and Cox et al. (2008), who chose mass ratio ranges of 1:1–1:20 and 1:1–1:22.7, respectively.

We select gas fractions between 0.1–0.3. This range is typical of the SDSS galaxies, which have gas fractions between 0 and 0.5 (Catinella et al. 2010). The mean gas fraction of the SDSS population is ∼0.2–0.3, which is in good agreement with our choice to run most galaxy simulations with a gas fraction of 0.3. Additionally, Cox et al. (2008) and Lotz et al. (2010b) varied the gas fraction between 0.2–0.4 and 0.2–0.5, respectively, providing a good amount of overlap for comparison of results.

Most of our simulations do not have stellar bulges, but we do include bulges in the minor merger simulations. Cox et al. (2008) demonstrated that bulges act to stabilize the disk of the galaxy for large mass ratio mergers (they see this effect primarily for 1:5 to 1:20 mass ratio mergers), leading to less disturbed morphology than bulgeless mergers. Since this effect is most prominent for minor mergers, we include stellar bulges in the progenitor galaxies for these simulations. We lack the computational resources to additionally investigate this effect for major mergers.

The B/T ratio depends on the total stellar mass of a galaxy and SDSS galaxies range between $9 < \log M_\star (M_\odot) < 11$. Measured B/T ratios for this stellar mass range for galaxies in SDSS span 0–0.6 (Bluck et al. 2014). Therefore, our choice of a B/T ratio of 0.2 for the minor merger simulations is typical of SDSS galaxies. We use a matched sample of isolated galaxies so that the slightly enhanced C and n values for the minor mergers (relative to the major mergers) are accounted for in the LDA technique.

Appendix B
Merging Galaxy Priors

LDA requires a prior to characterize the data set if the relative numbers of objects in each class are not representative of the overall population. If the frequency of merging and nonmerging galaxies in our simulated data set exactly matched the frequency of merging and nonmerging galaxies in nature, our priors would be [0.5, 0.5] and would not need to be specified. However, because we have a lower frequency of nonmerging galaxies in our inputs to LDA relative to the frequency of nonmerging galaxies in reality, we use the fraction of merging galaxies in the universe ($f_{\rm merg}$) as our prior.

We use a different fraction for major and minor mergers. For major mergers, we use the fraction of merging galaxies, $f_{\rm merg} = 0.1$ from Lotz et al. (2011). This is an average, calculated from different $f_{\rm merg}$ measurements that rely upon Gini$-M_{20}$ and A to determine merger fractions for galaxies in the local universe (Lotz et al. 2008; Conselice et al. 2009; López-Sanjuan et al. 2009; Shi et al. 2009). We choose not to use pair fractions to determine $f_{\rm merg}$ as they tend to underestimate the fraction of merging galaxies because pair studies are only sensitive to the early stages of a merger.

It is important to note that Lotz et al. (2011) used individual predictors (such as Gini$-M_{20}$ or A alone) to identify mergers and found short timescales of observability (∼0.2–0.6 Gyr). As discussed in Section 3.2, we find timescales of observability >2 Gyr from the LDA technique, and therefore $f_{\rm merg} = 0.1$ is a conservative estimate. In reality, observed merger fractions may be underestimated in the local universe (particularly for minor mergers) because the observability timescales of past imaging methods are short. Using merging galaxies in the Millennium simulation, Bertone & Conselice (2009) found that the estimate of $f_{\rm merg}$ for minor and major mergers increases by a factor of 2–10 if the observability timescale is increased from 0.4 Gyr to 1 Gyr.

Although the fraction of minor mergers is less certain, studies have indicated that it is three to five times greater than the major merger rate, so we use $f_{\rm merg} = 0.3$ for the minor merger simulations (e.g., Bertone & Conselice 2009; Lotz et al. 2011).

For comparison purposes, we also estimate $f_{\rm merg}$ from the Illustris simulation. Using estimations of the timescale of the merger, we convert from merger rate (measured directly from Illustris to be ∼0.1 Gyr^{-1}; Rodriguez-Gomez et al. 2015) to the merger fraction of galaxies in the local universe. If we multiply this rate by the ∼2 Gyr timescale estimate from our work, we find $f_{\rm merg} = 0.2$, which is in good agreement with the 0.1 value for $f_{\rm merg}$ from observations of merging galaxies in the literature. If we use the 0.2–0.6 Gyr timescale from Lotz et al. (2008), we find a much lower merger fraction of $f_{\rm merg} = 0.02$–0.06.

Since the estimates of $f_{\rm merg}$ are so uncertain, we compare the results of using different values for $f_{\rm nonmerg}$ on the outcome of the LDA in Figure 15. For each simulation, we have more snapshots of merging galaxies than nonmerging, which is not reflective of reality. We use the LDA accuracy to measure the sensitivity of the technique to the input priors. We find that the LDA is relatively insensitive to prior selection within a range of priors on the fraction of merging and nonmerging galaxies. This range exists from $0.1 < f_{\rm nonmerg} < 0.9$. As we increase $f_{\rm nonmerg}$ above 0.9, we start to see the accuracy decline from ∼80%–90% correct identifications to 60%–70%. Although this is a significant decline, the decline is somewhat asymptotic. Therefore, at our chosen prior for major mergers (0.9), the accuracy has declined to around 90% for the three major merger simulations pictured, which is still very high. Additionally, while the minor merger simulations are less accurate as $f_{\rm nonmerg}$ increases, the prior for minor mergers is 0.7, so they do not fall off as fast in accuracy at this point.
Figure 15. Accuracy of the LDA with varying choices for the priors, or the fraction of galaxies that are merging and nonmerging. The vertical dashed lines represent our choice of priors for minor ($f_{nonmerg} = 0.7$) and major mergers ($f_{nonmerg} = 0.9$).

Appendix C
Testing the Assumptions of LDA with a Multivariate Analysis

We carry out a simple multiple linear regression analysis to test the assumptions of LDA and examine the input predictors. Many of these techniques as well as an introduction to LDA are covered in James et al. (2013). The key assumptions of LDA include multivariate normality, homoscedasticity (that the covariance among groups is equal), and an absence of multicollinearity. However, it should also be noted that LDA is relatively robust to slight violations of these assumptions and can still be reliable even when certain assumptions are violated (Duda et al. 2001; Li et al. 2006). We conduct a preliminary multivariate analysis of the input predictors to screen for multicollinearity and violations of normality and homoscedasticity. We present our results for the major merger and minor merger combined simulations and show plots just for the major merger combined simulation.

We first address the multivariate normality assumption by examining the individual histograms of the input predictors for both of the combined simulations (the major merger combined simulation is Figure 16). Visually, the predictors do not seem to be drawn from a normal distribution. We conduct Shapiro–Wilke and Kolmogorov–Smirnov tests for normality, and in both cases, we are able to reject the null hypothesis that the data are drawn from a Gaussian multivariate normal distribution for the majority of predictors.

We also address the homoscedasticity assumption in Figure 16. By examining the distributions of the values for each class for a cross-section of input predictors, we are able to determine that the covariances for each class are not equal. We conduct a Levene test and confirm that we can reject the null hypothesis and that the covariance matrices are not equal. This is unsurprising given that multivariate normality is also violated.

We next examine the relationships between predictors to determine if the predictors demonstrate multicollinearity. A violation of multicollinearity could lead to a decrease in the predictive ability of LDA. We screen for multicollinearity visually in Figure 17 using a Hinton visual diagram where the size and color of the boxes indicate the strength and sign (positive is red and negative is blue) of the correlation. We find that many predictors have a large positive correlation. We further examine the strength of the correlation and find that n and C have the most significant correlation for the major mergers with a Pearson's r value of 0.72. For the minor mergers, M_{20} and A have the largest correlation with an r value of 0.66. All Pearson's r values are below 0.99, the threshold value for multicollinearity, so we can rule out multicollinearity in this data set. However, we must still deal with these correlations using interaction terms, which remove cross-correlation effects from the coefficients of LD1 so that we can individually assess trends with the seven main coefficients (James et al. 2013).

To screen for outliers, we use box and whisker plots. Outliers can affect the LDA classification, dominating the analysis. We find that a few inputs are greater than 1.5 times the interquartile range (as indicated by the extent of the whiskers). However, overall, there are very few outliers. We also calculate the Z-scores for each predictor and find that none are outside 3σ from the sample mean.

To verify that each predictor is necessary in the LDA, we conduct Ordinary Least Squares (OLS) fitting. We first linearly regress each predictor against the class label (a binary variable for merger/nonmerger classification). Although a logit regression would be a better tool with more than two classes, a linear regression is appropriate here because the response is binary (James et al. 2013). Additionally, for a binary response variable, LDA is quite similar to multiple linear regression. We find that almost all predictors have a p-value for the t-test
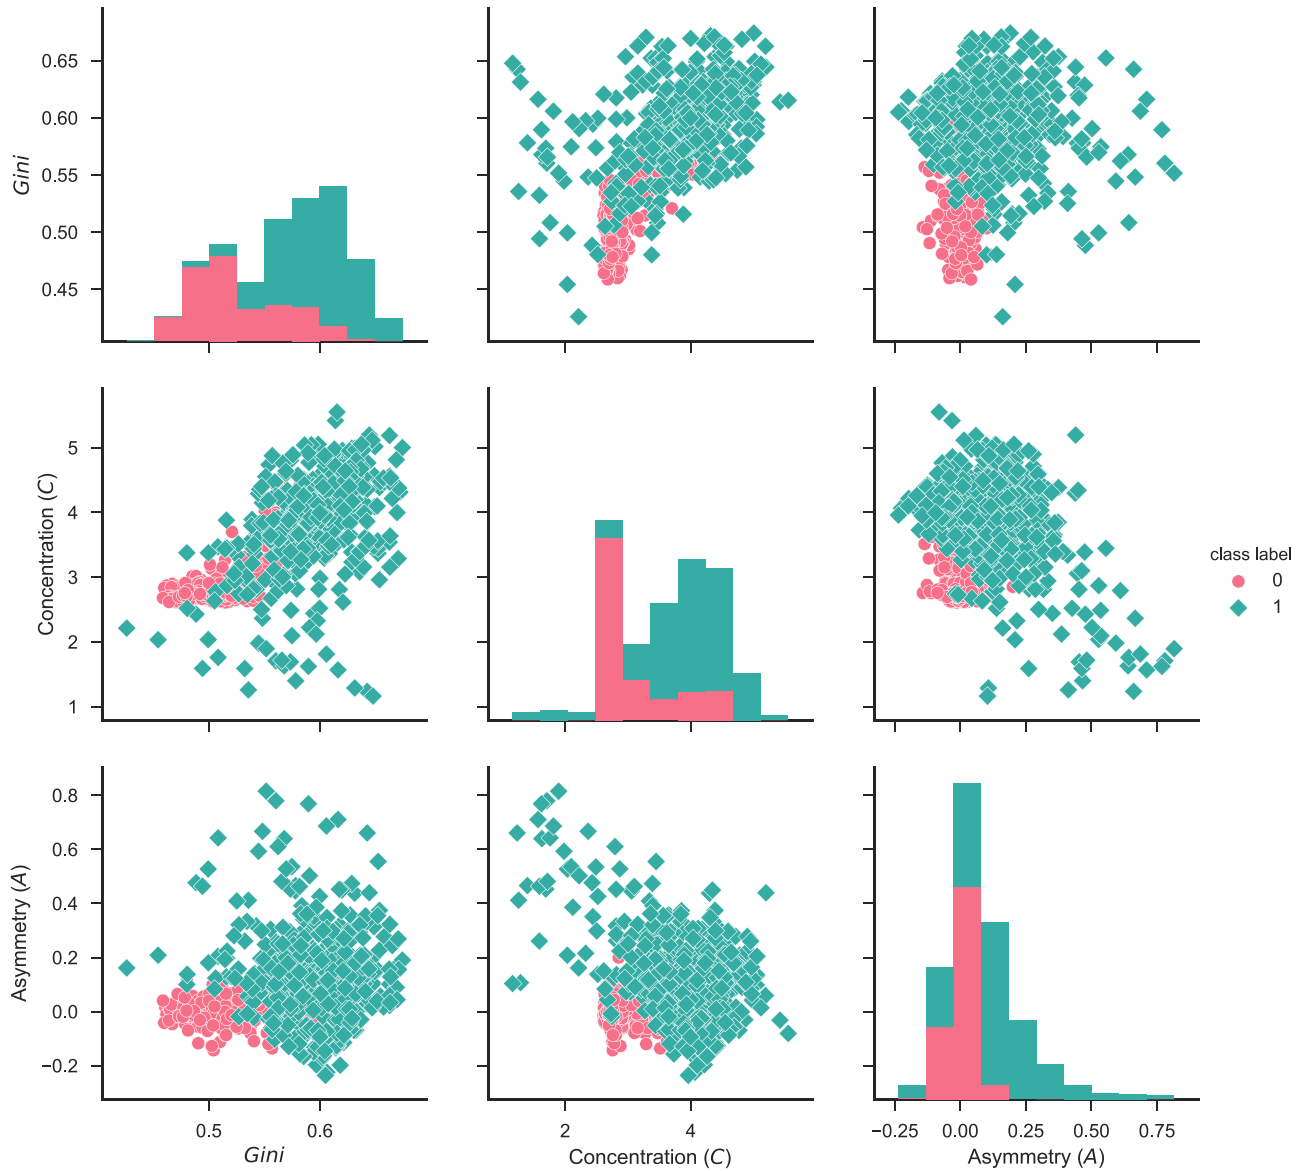

Figure 16. Scatter plots and marginalized histograms of the distribution for three input predictors (Gini, C, and A) for the major merger combined simulation. The nonmerging class is pink (0) and the merging class is green (1). The predictors violate normality and homoscedasticity assumptions.

below 0.05, indicating that there is a significant relationship between the predictor and the class, or in other words, that the predictor is required for classification. The only predictors that fail this test are the Gini, M_{20}, and S predictors, which fail for the minor merger simulations, and the n predictor, which fails for the major merger simulation. We also find in our LDA modeling that the Gini, M_{20}, and S predictors are fairly unimportant for the minor merger simulation and that n is unimportant for the major merger simulation. We also run the OLS fitting for all simulations and find that there are no predictors that are unimportant across the board. Therefore, we include all of the predictors in the LDA classification. We ultimately discover that all predictors are important according to the forward stepwise selection for certain simulations, so we cannot eliminate them prior to the LDA.

Overall, the data violate multivariate normality and homo-scedasticity while passing the tests for multicollinearity and extreme outliers. For classification purposes, LDA is very robust to varying distributions of the data and can still achieve

good performance even when the covariance matrices are not equal and normality assumptions are violated (Duda et al. 2001; Li et al. 2006).

One alternative approach to LDA is to utilize QDA, which does not rely on the equality of covariance matrices. We test the accuracy, precision, recall, and F_1 score of both an LDA and a QDA method (see Appendix E for the accuracy of LDA). We find that the LDA classifier performs very well, and while the QDA classifier increases accuracy, recall, and F_1 score by ∼5%, the LDA classifier is still above ∼85% for accuracy on all simulations. A downside to using QDA is that it is inherently nonlinear and does not allow us to directly interpret each predictor individually. We choose to use LDA because it allows for a more practical interpretation of the imaging predictors and because it does an adequate job of separating the merging and nonmerging classes across all simulations.

Additional ways to prepare the input data for better classification include increasing the number of observations (number of galaxy snapshots) and standardizing the data. We
Figure 17. Hinton visual correlation matrix for the major merger combined simulation. A red box represents a positive correlation, and a blue box is a negative correlation. The size of the box is the strength of Pearson's r correlation coefficient. For scale, the diagonal boxes have a Pearson's r values of one.

already have at least 20–30 snapshots per class and are therefore more robust to violations of normality and homogeneity of covariance. Also, when we combine all the individual runs of LDA for the final combined major and minor merger runs, we increase the sample size to at least 100 observations per class. This final analysis is robust to violations of normality and homoscedasticity.

We also find that the predictors require standardization prior to the input to LDA; they have very different means and standard deviations, which could affect the output of LDA. For instance, if one variable has a large mean, it could dominate the first discriminant axis (LD1). We standardize the input predictors to all have a mean of zero and a standard deviation of one prior to our LDA classification.

Appendix D
Forward Stepwise Variable Selection and k-fold Cross-validation

A limitation of LDA is that there are no standard errors on the LDA predictor coefficients. We use the stratified k-fold cross-validation method with 10 folds to return an estimate of the underlying distribution of possible values for the LDA coefficients given the data. k-fold cross-validation functions by dividing the sample into k equal-sized samples, where the first k − 1 samples will be used as the training set and the kth sample will be used as the test set. We repeat the LDA k times and estimate the mean and standard deviation of the LDA coefficients from the data. Stratified cross-validation specifically requires that the test sample includes a number of snapshots from each class that are representative of the overall sample.

This method is effective for minimizing bias and variance given the correct choice of k (James et al. 2013). For instance, Efron (1983) proved that k-fold cross-validation is "almost unbiased" if k is large and the sampling is random (this approaches leave-one-out cross-validation (LOOCV) when $k = n$, where n is the sample size). However, LOOCV has a high variance since it involves finding the variance of n fitted models which are trained on nearly identical data. The mean of highly correlated quantities has a higher variance, so we choose an intermediate value of k so that we avoid high bias and high variance. Kohavi (1995) found that stratified k-fold cross-validation with 10 folds is the most effective at model selection even if computation power allows for more folds. We also find that $k = 10$ is a good choice to ensure that the number of misclassifications (cross-validation error) is minimized and that the mean and standard error of the LD1 coefficients is stable.
Figure 18. Forward stepwise selection of the number of predictors for each run of LDA. We mark the minimum number of "required" predictors for each run with black x's. This point is within one standard error of the minima of the cross-validation error curve for each run. We run LDA for each simulation using the predictors selected from this method.

We use forward stepwise selection with k-fold cross-validation to determine which predictors are necessary to build LD1 for each simulation. The purpose of this process is to avoid introducing excess predictors that are unnecessary to the separation of the merging and nonmerging galaxies along LD1. We choose forward stepwise selection since it is less computationally expensive than the best subset selection (James et al. 2013).

Forward stepwise selection begins with a model without predictors. It then determines which predictor to add by comparing the cross-validation error for each predictor. The cross-validation error is also the number of misclassifications corresponding to each model. For instance, the first step of forward stepwise selection is comparing the cross-validation error from a model with only one predictor (i.e., Gini) to all other possible models with only one term (i.e., a model with M_{20}, a model with $M_{20} * $ Gini, etc.). The one-term model with the lowest number of misclassifications is selected. Next, the forward stepwise election iteratively attempts to add all remaining predictors to the model. It chooses to add a term only if the cross-validation error of the overall model is less than that of the previous step. Again, it adds the term that minimizes the cross-validation error as compared to all other possible terms.

The forward stepwise selection proceeds until no more terms are required to decrease the cross-validation error. We refer to the predictors in the final model as the "required" predictors. We show the process in Figure 18, where we determine the number of predictors necessary for the LD1 for each simulation by minimizing the cross-validation error with forward stepwise selection. We additionally use the one-standard-error rule from James et al. (2013) to select the best overall model. This allows us to select the simplest model for which the estimated cross-validation error is within one standard error of the lowest point on the curve in Figure 18. The standard error of the cross-validation error is the standard deviation of the number of misclassifications for all 10 k-folds.

Appendix E
LDA Performance: Accuracy and Precision of the Classifier

We investigate the performance of the classifier using the confusion matrix (Figure 19). The confusion matrix is constructed using the 10 randomized test and training sets of galaxies, which were created in the k-fold method described in Appendix D. It is the mean confusion matrix from the 10 k-fold runs.

The confusion matrix shows the number of nonmerging galaxies from the test set that were correctly classified as nonmerging (upper left) and the number of merging galaxies

that were correctly identified as merging (lower right), which are referred to as "True Negatives" (TN) and "True Positives" (TP), respectively. The top-right corner of the confusion matrix is the galaxies that were classified as merging although they are in fact nonmerging. These are the "False Positives" or FP. The bottom-left square is the galaxies that are merging but were not correctly identified as merging, or the "False Negatives," FN. In Figure 19, we show the normalized percentage of galaxies that fall into each category for the final combined major and minor merger runs of LDA.

From the confusion matrix, we quantify the accuracy, precision, recall, and F_1 score of the LDA classification in order to assess the overall performance of the LDA method for each simulation.

The accuracy is the number of correct classifications divided by the total number of classifications:

$$A = \frac{\text{TN} + \text{TP}}{\text{TN} + \text{TP} + \text{FN} + \text{FP}}.$$

We assess the precision of the LDA, or the fraction of correct positive predictions:

$$P = \frac{\text{TP}}{\text{TP} + \text{FP}}.$$

Recall is the fraction of true positives that are classified as such:

$$R = \frac{\text{TP}}{\text{TP} + \text{FN}}.$$

The F_1 score is the harmonic mean of recall and precision:

$$F_1 = \frac{2\text{TP}}{2\text{TP} + \text{FN} + \text{FP}}.$$

We collect the accuracy, precision, recall, and F_1 score values for all simulations in Table 6. We find that the LDA classification performs well, with all performance metrics around or above ~0.7–0.9. Accuracy ranges from 0.85 to 0.91, while precision is between 0.89 and 0.98 for all runs. This confirms our discussion from Appendix C; the LDA method is accurate, and therefore we are not concerned that our violations of normality and homoscedasticity are detrimental to the classification.

The LDA has a very high precision value. This indicates that it does an excellent job of identifying all merging galaxies as merging. This is critical to the next phase of analysis, which will include classifying SDSS galaxies; we do not wish to misidentify mergers and are more tolerant of false positives
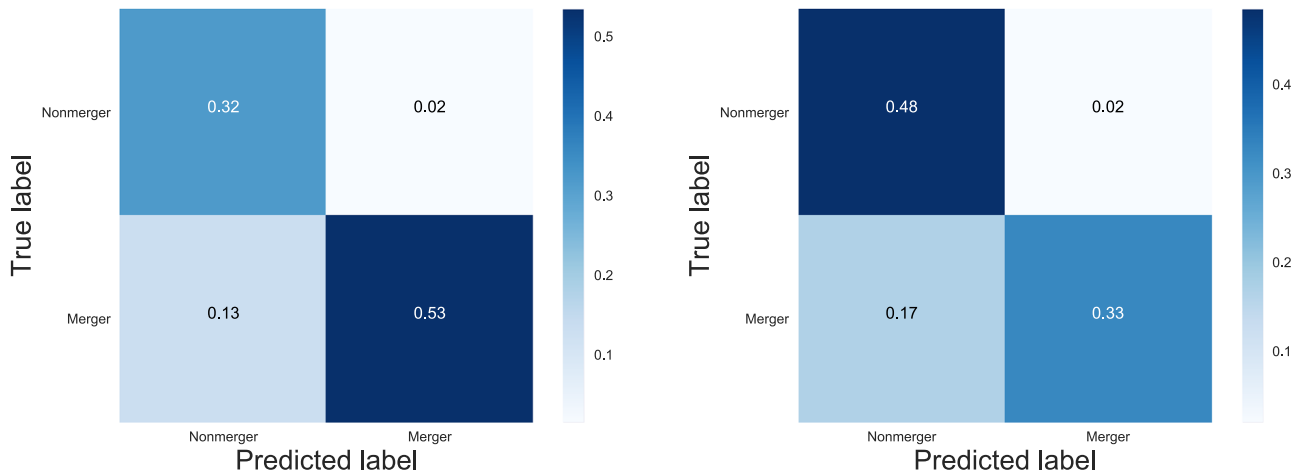

Figure 19. Confusion matrices for the major (left) and minor (right) combined simulations. The *y*-axis represents the true categories of the test set of galaxies from the simulation. The *x*-axis is the predicted category from the LD1 classifier for the test set of galaxies.

than false negatives, given that this initial classification is created from simulated galaxies.
