ABSTRACT

The joint detection of gravitational waves (GWs) and γ -rays from a binary neutron star (NS) merger provided a unique view of off-axis gamma-ray bursts (GRBs) and an independent measurement of the NS merger rate. Comparing the observations of GRB170817 with those of the regular population of short GRBs (sGRBs), we show that an order unity fraction of NS mergers result in sGRB jets that breakout of the surrounding ejecta. We argue that the luminosity function of sGRBs, peaking at $\approx 2 \times 10^{52}$ erg s $^{-1}$, is likely an intrinsic property of the sGRB central engine and that sGRB jets are typically narrow with opening angles $\theta_0 \approx 0.1$. We perform Monte Carlo simulations to examine models for the structure and efficiency of the prompt emission in off-axis sGRBs. We find that only a small fraction (~ 0.01 –0.1) of NS mergers detectable by LIGO/VIRGO in GWs is expected to be also detected in prompt γ -rays and that GW170817-like events are very rare. For an NS merger rate of ~ 1500 Gpc $^{-3}$ yr $^{-1}$, as inferred from GW170817, we expect within the next decade up to ~ 12 joint detections with off-axis GRBs for structured-jet models and just ~ 1 for quasi-spherical cocoon models where γ -rays are the result of shock breakout. Given several joint detections and the rates of their discoveries, the different structure models can be distinguished. In addition the existence of a cocoon with a reservoir of thermal energy may be observed directly in the ultraviolet, given a sufficiently rapid localization of the GW source.

Key words: gravitational waves – gamma-ray burst: general.

1 INTRODUCTION

The connection between neutron star–neutron star (NS–NS) or neutron star–black hole (NS–BH) mergers with short-duration gamma-ray bursts (sGRBs) and the nucleosynthesis of r -process elements dates back to a few seminal works from the 1970s and 1980s (Lattimer & Schramm 1974, 1976; Blinnikov et al. 1984; Paczynski 1986; Goodman 1986; Eichler et al. 1989). In recent years, the rate of r -process formation has been constrained using various observational lines of argument (Hotokezaka, Piran & Paul 2015; Ji et al. 2016; Beniamini, Hotokezaka & Piran 2016; Macias & Ramirez-Ruiz 2016; Hotokezaka, Beniamini & Piran 2018; Beniamini, Dvorkin & Silk 2018). It was shown to be broadly consistent with the rate of sGRBs (Guetta & Piran 2006; Guetta & Stella 2009; Coward et al. 2012; Wanderman & Piran 2015; Ghirlanda

et al. 2016) and with the rate of NS mergers as inferred from observations of Galactic double NSs (Kochanek & Piran 1993; Kim, Perera & McLaughlin 2015). However, a clear determination of NS–NS mergers being the progenitors of sGRBs and the main source of r -process elements remained somewhat uncertain until the recent discovery of the kilonova AT2017gfo (Tanvir et al. 2017) and GRB170817 (Goldstein et al. 2017), accompanying the NS–NS merger event GW170817 (Abbott et al. 2017b). This recent discovery also leads to a new and independent estimate of the rate of NS–NS mergers. Furthermore, the observations of a very weak GRB accompanying the event, and detailed modelling of the peculiar and long-lived afterglow that followed the event, provides us with information regarding the opening angle, viewing angle, and core luminosity of GRB170817.

The GW170817/GRB170817 event provides an unprecedented opportunity to explore sGRB jets in a broader context: how frequently do sGRB jets manage to break through the ejecta material surrounding the NS–NS mergers? What are the typical opening

* E-mail: paz.beniamini@gmail.com

angles of sGRB jets? What determines the shape of the sGRB luminosity function? These topics have been partially explored in the past, either from an observational point of view, using the data from electromagnetically detected sGRBs (i.e. not accompanied by a gravitational wave, GW event) (Wanderman & Piran 2015; Ghirlanda et al. 2016; Moharana & Piran 2017), or from hydrodynamical studies of the GRB jet propagation through the NS–NS merger ejecta (Aloy, Janka & Müller 2005; Hotokezaka et al. 2013; Nagakura et al. 2014; Murguia-Berthier et al. 2014; Lazzati et al. 2017b; Bromberg et al. 2018; Duffell et al. 2018). Here, we show that by combining this knowledge with the unique constraint from GW170817 we can probe these questions in greater detail, thus significantly improving our understanding of these issues.

The discovery of GRB170817 raised perhaps as many new questions as answers. In particular, the extremely dim prompt GRB accompanying the event has led to different interpretations, according to which the observed γ -ray emission is either arising from the ‘wings’ of the jet (material beyond the core that is less energetic) due to the same physical process that produces the prompt emission along the jet’s axis (Kathirgamaraju, Barniol Duran & Giannios 2018; Lamb & Kobayashi 2017; Granot, Guetta & Gill 2017), or is due to shock breakout from the thermal energy stored in the cocoon that was produced by the jet–ejecta interaction (Lazzati et al. 2017b; Gottlieb et al. 2017; Kasliwal et al. 2017). Although GRB170817 alone is not enough to distinguish between the proposed models, we show that our understanding can be significantly improved once a sample of joint GRB and GW detections has been established and their luminosity and viewing angle distributions have been studied.

The paper is organized as follows. In Section 2, we revisit the rate and luminosity function of sGRBs and show that the latest results from GW170817 strongly constrain: the fraction of NS–NS mergers accompanied by sGRBs, the opening angles of sGRBs, and the interpretation of their luminosity function. In Section 3, we consider different models for the off-axis prompt GRB emission. By performing Monte Carlo (MC) simulations, we compare the observed properties arising from different emission models, in cases with a joint GW and prompt GRB detection. In Section 4, we focus on the cocoon model and discuss an additional observable signal that can directly constrain the thermal energy stored in the cocoon. Finally, we discuss some implications of this work and conclude in Section 5.

2 SUCCESSFUL SGRB JETS AND THE SGRB LUMINOSITY FUNCTION

2.1 General considerations – rate comparison

The observed luminosities of sGRBs are a convolution of the intrinsic luminosity function $\Phi(L)$ and the volumetric rate $R(z)$. Wanderman & Piran (2015) find that, in the local universe, the rate of sGRBs is:

$$R_{\text{sGRB}} = 4.1^{+2.3}_{-1.9} f_b^{-1} L_{\text{m},49.7}^{-\alpha_L} \text{Gpc}^{-3} \text{yr}^{-1} \quad (1)$$

where $\alpha_L = 0.95$, $L_{\text{m},49.7} \equiv L_{\text{min}}/(5 \times 10^{49} \text{ ergs}^{-1})$, f_b is the beaming factor, and L_{min} is the minimum luminosity of the GRB luminosity function, which is typically assumed. Note that the lowest observed luminosity of an sGRB in the sample considered by Wanderman & Piran (2015) is $\approx 2 \times 10^{50} \text{ ergs}^{-1}$. This is an absolute maximum on the true value of L_{min} .

It has been long theorized (Blinnikov et al. 1984; Paczynski 1986; Goodman 1986; Eichler et al. 1989) and recently proved by the dual detection of GW170817/GRB170817 (Abbott et al. 2017b) that NS

mergers (either NS–NS or NS–BH) lead to sGRBs. However, it is possible that not all NS mergers result in a successful GRB. We denote the ratio of failed to successful sGRBs rates by $r_{\text{fail}} \equiv R_{\text{fail}}/R_{\text{sGRB}}$. The NS merger rate as inferred by the LIGO event, GW170817, is $R_{\text{merg}} = 1540^{+3200}_{-1220} \text{ Gpc}^{-3} \text{yr}^{-1}$ (Abbott et al. 2017b). Combining this with equation (1) and assuming a double-sided top-hat jet with opening angle $\theta_0 \approx 0.1\theta_{0,1}$, we find:

$$r_{\text{fail}} = \frac{R_{\text{merg}}}{R_{\text{sGRB}}} - 1 \approx 2 L_{\text{m},49.7}^{\alpha_L} \theta_{0,1}^2 R_{\text{m},1540} - 1 \quad (2)$$

where $R_{\text{m},1540} \equiv R_{\text{merg}}/(1540 \text{ Gpc}^{-3} \text{yr}^{-1})$ and the numerical value holds for $\alpha_L = 0.95$. Note that for clarity we have dropped here and in the following the errors in R_{merg} , but our main conclusions remain unaltered, when considering the minimum and maximum allowed value of R_{merg} . Since neither L_{min} can be larger than $5 \times 10^{49} \text{ ergs}^{-1}$ nor θ_0 can change significantly compared to the canonical value used above, the ratio of failed to successful jets cannot be very large. On the contrary, this ratio is estimated to be $r_{\text{fail}} \sim 4 \times 10^2$ in long (collapsar) GRBs; here we apply equation (4) but with $\alpha_L = 0.2$, $\beta_L = 1.4$, $L_{\text{min}} = 2 \times 10^{50} \text{ ergs}^{-1}$, and $L_* = 3 \times 10^{52} \text{ ergs}^{-1}$, as appropriate for long GRBs (Wanderman & Piran 2010, see also Petropoulou, Barniol Duran & Giannios 2017; Sobacchi et al. 2017). This huge difference in the expected rates of failed short and long GRBs may be related to the nature of the ejecta that the jet has to propagate through. For example, the expansion of the dynamical ejecta in the case of an NS merger may facilitate the jet breakout (Duffell et al. 2018) in contrast to the jet propagation through the quasi-static outer layers of the collapsing star expected in the case of long GRBs (Bromberg et al. 2011).

2.2 Interpretation of the sGRB luminosity function

The (isotropic equivalent) luminosity function of both short and long GRBs (after de-convolving with the rate function) is described by a broken power law (PL):

$$\phi(L) \equiv \frac{dN_{\text{GRB}}}{d \log L} = \begin{cases} \left(\frac{L}{L_*}\right)^{-\alpha_L} & L_{\text{min}} \leq L \leq L_* \\ \left(\frac{L}{L_*}\right)^{-\beta_L} & L > L_* \end{cases} \quad (3)$$

For sGRBs, $\alpha_L \approx 0.95$, $\beta_L \approx 2.0$, and $L_* \approx 2 \times 10^{52} \text{ ergs}^{-1}$ (Wanderman & Piran 2015). Henceforth, we adopt the luminosity function reported by Wanderman & Piran (2015), while noting that none of our main conclusions would change, if we were to adopt other values for the PL slopes and/or break luminosity reported in the literature (Guetta & Piran 2006; Salvaterra et al. 2008; Ghirlanda et al. 2016). We next explore three different interpretations to the broken PL nature of $\Phi(L)$: (i) arising due to the increasing fraction of failed GRB jets for $L \leq L_*$, (ii) being the result of the angular structure of sGRBs, or finally (iii), being an intrinsic property of the sGRB central engine.

2.2.1 Failed jets

Petropoulou et al. (2017) have argued that the broken PL nature of $\Phi(L)$ in long GRBs could result from an underlying single PL distribution of luminosities, that is then modified at lower luminosities due to an ever increasing fraction of failed GRB jets. This provides a natural explanation for the apparent more complicated luminosity function whereby the interpretation for L_* is the maximum luminosity for which not all long GRB jets manage to break out of the stellar envelope.

Interestingly, the same interpretation cannot hold for sGRBs. This is clear from the fact that within the Petropoulou et al. (2017) framework, the slope of $\Phi(L)$ above L_* is that of the true underlying distribution. In this context, the ratio of failed sGRB to successful sGRB engines at $L < L_*$ can be then extrapolated to lower luminosities as:

$$r_{\text{fail}} = \frac{R_{\text{merg}}}{R_{\text{sGRB}}} - 1 \approx \left(\frac{L_{\text{min}}}{L_*} \right)^{-\beta_L + \alpha_L} \approx 540 L_{\text{m,49.7}}^{-1}, \quad (4)$$

which is clearly in contradiction with equation (2) by more than two orders of magnitude.

2.2.2 Angular structure

Another potential way to explain the broken PL nature of the luminosity function is to consider that GRBs have a wide structure beyond the jet core, i.e. the jet luminosity is constant up to some θ_0 and then decreases for larger angles (Lipunov, Postnov & Prokhorov 2001; Frail et al. 2001; Rossi, Lazzati & Rees 2002; Zhang & Mészáros 2002; Granot & Kumar 2003; Eichler & Levinson 2004; van Eerten & MacFadyen 2012; Pescalli et al. 2015). In this context, the distribution $\Phi(L)$ below L_* may become dominated by GRBs that are marginally above the critical core luminosity L_* , but are seen progressively more off-axis as $L \ll L_*$. This particular scenario would imply an increased intrinsic minimal core luminosity, $L_{\text{min}} \approx L_*$, and hence would increase the ratio of failed to successful jets given by equation (2), which could help to reduce (and potentially resolve) the inconsistency with the estimate given by equation (4). As an illustration, let us consider that the jet (isotropic equivalent) luminosity is constant up to a latitude θ_0 and then declines as $\theta^{-\delta}$ for $\theta > \theta_0$. Assuming an isotropic distribution of solid angles and the same structure for all sGRB jets, this will lead to $\Phi(L) \propto L(dN/d\theta)(d\theta/dL) \propto L^{-2\delta}$. This matches the observed $\Phi(L) \propto L^{-\alpha_L}$, only if the typical value of the jet structure slope is $\delta \approx 2$. Such a shallow profile however (close to the so-called universal jet structure; see Rossi et al. 2002; Zhang & Mészáros 2002) could be in contention with observations of the X-ray afterglow luminosity to γ -ray energy ratio, unless the Lorentz factors of GRBs remain $\gtrsim 50$ at large angles (Beniamini & Nakar 2018).

It is constructive to compare the value of δ obtained above, with the constraints from GRB170817. Unless the efficiency of γ -ray production decreases significantly at angles beyond the core (in which case the angular structure hypothesis for the luminosity function is clearly invalid), the observed γ -ray luminosity of that event, $L_{\text{GRB170817}}$, must be at least as large as the extrapolation of the core luminosity L_0 to the observed angle (so as not to overproduce γ -rays compared to observations). This leads to a lower limit on δ , i.e. $\delta \geq \log(L_{\text{GRB170817}}/L_0)/\log(\theta_0/\theta_{\text{obs}})$, where $L_{\text{GRB170817}} = 1.6 \times 10^{47} \text{ ergs}^{-1}$ (Goldstein et al. 2017) and $\theta_{\text{obs}} \approx 0.35$ (Moolay et al. 2018a). Taking $L_0 \approx L_*$, which is roughly the minimal core luminosity under the interpretation that the shape of the luminosity function is driven by the angular structure, and adopting the minimum allowed value for $\theta_0 \approx 0.05$ (see Section 2.2.2), we find $\delta \gtrsim 6$; larger values of θ_0 would require even steeper profiles. The obtained value of δ is in contention with $\delta \approx 2$ derived previously.

Thus, the interpretation that the luminosity below L_* is dominated by off-axis events is challenged by observations, under the assumptions of a common jet structure among all sGRBs and large efficiency beyond the jet core.

2.2.3 Intrinsic structure

A third possibility is that the broken PL luminosity function determined by observational studies (Guetta & Piran 2006; Guetta & Stella 2009; Wanderman & Piran 2015; Ghirlanda et al. 2016) actually reflects the intrinsic power produced by the central engine. We turn next to explore the implications of this interpretation of the luminosity function on the typical opening angles of sGRBs and on the expected distributions of luminosities and observation angles as probed by future joint detections of prompt GRBs and GWs.

2.3 Constraining the opening angles of short GRBs

We now use the connection between the rate of NS mergers and sGRBs to constrain the jet opening angle, θ_0 , as described below. Following our reasoning in Section 2.2.2, we assume here that there is a typical (or universal) sGRB opening angle, and that sGRB angular profiles are sufficiently steep, such that they are typically observed at $\theta_{\text{obs}} \lesssim \theta_0$. Different arguments and constraints point to jets having a narrow range of opening angles centred around $\theta_0 \approx 0.1$.

First, since $R_{\text{merg}} \geq R_{\text{sGRB}}$, equation (2) provides a *lower* limit on the allowed opening angles of sGRBs (or equivalently on the beaming factor) which is roughly:

$$\theta_0 \geq \theta_{\text{min}} \equiv 0.07 L_{\text{m,49.7}}^{-1/2} R_{\text{m,1540}}^{-1/2} \quad (5)$$

At the same time, observations of sGRBs over the last 14 yr with *Neil Gehrels Swift* satellite, provide us with an *upper* limit on the allowed value for sGRB opening angles. Considering the sample of observed *Swift*-BAT bursts with $T_{90} < 2$ s,¹ we search the online data base² and find that the maximum peak photon flux of sGRBs within $\Delta T_{\text{obs}} = 14$ yr of observations (in the 15–150 keV range) is $P_{\text{max}} = 12.1 \text{ photons cm}^{-2} \text{s}^{-1}$. For a given redshift z and corresponding luminosity distance $d_L(z)$, this can be translated to a γ -ray peak luminosity as :

$$L(z, P_{\text{max}}) = \frac{4\pi d_L^2(z)}{1+z} \frac{\int_{1\text{keV}}^{10\text{MeV}} EN(E)dE}{\int_{15(1+z)\text{keV}}^{150(1+z)\text{keV}} N(E)dE} P_{\text{max}}, \quad (6)$$

where $N(E)$ is the differential photon spectrum described by the so-called Band function (computed in the source frame, Band et al. 1993). Here, we have considered the spectral range at the source to be 1 keV–10 MeV. The latter is the same spectral range over which the luminosities in Wanderman & Piran (2015) were computed and is therefore the appropriate choice in order to make a comparison with their values, as we do below. In what follows we assume typical observed sGRB parameters: $\alpha = -0.5$, $\beta = -2.25$, $E_{\text{p,source}} = 500 \text{ keV}$ (Nava et al. 2011). Using equation (6) and requiring that $L(z, P_{\text{max}}) > L_{\text{min}} = 5 \times 10^{49} \text{ ergs}^{-1}$ (the same value of L_{min} considered above), we find a conservative minimum distance from which current *Swift*-BAT bursts could have originated $d_L(z) \equiv d_{P_{\text{max}}} \geq 250 \text{ Mpc}$. In other words, even a burst that had an intrinsic (isotropic equivalent) luminosity at the core as low as $L_{\text{min}} \approx 5 \times 10^{49} \text{ ergs}^{-1}$ would have resulted in a peak flux larger than any of the observed *Swift*-BAT bursts, if its distance from us was less than 250 Mpc. Thus, the opening angle of sGRBs has to be small enough to be consistent with the non-detection of bursts with

¹This choice does not result in a pure non-collapsar GRB sample. The contamination by collapsar GRBs, however, can only increase P_{max} and in turn θ_{max} with respect to its true value.

²https://swift.gsfc.nasa.gov/archive/grb_table/

$L > L_{\min}$ at $d_L(z) < 250$ Mpc. For a fixed rate of NS mergers, the upper limit on θ_0 is independent of the inferred local sGRB rate given by equation (1):

$$\theta_{\max} = \sqrt{\frac{2(r_{\text{fail}} + 1)}{R_{\text{merg}} \Delta T_{\text{obs}} V_{\max} \eta_{\text{Sw}}}} = 0.1 (r_{\text{fail}} + 1)^{\frac{1}{2}} \times R_{\text{m,1540}}^{-1/2} \left(\frac{14 \text{ yr}}{\Delta T_{\text{obs}}}\right)^{\frac{1}{2}} \left(\frac{250 \text{ Mpc}}{d_{P_{\max}}}\right)^{\frac{3}{2}} \left(\frac{0.12}{\eta_{\text{Sw}}}\right)^{\frac{1}{2}}, \quad (7)$$

where $V_{\max} \equiv (4\pi/3) d_{P_{\max}}^3$, and where we have conservatively used an efficiency of $\eta_{\text{Sw}} = 0.12$ for the detectability of *Swift* sGRBs above the BAT threshold (Burns et al. 2016). We note also that a comparable, though somewhat larger estimate for θ_{\max} can be obtained by using *Fermi* GBM data. In this case, the efficiency is larger $\eta_{\text{GBM}} = 0.6$ (Racusin et al. 2017), while the observation period is slightly shorter $\Delta T_{\text{obs}} = 9$ yr. According to Lu et al. (2017), $P_{\max} = 138$ photons $\text{cm}^{-2} \text{s}^{-1}$ (between 8 keV and 40 MeV) for this period. Using the typical spectral parameters for GBM bursts, namely $\alpha = -1.5$, $E_p = 600$ keV (Nava et al. 2011), we find $d_{P_{\max}} = 130$ Mpc and $\theta_{\max}^{(\text{GBM})} = 0.16$.

As we show next, comparing the ratio of merger rates to sGRB rates as given by equation (2) to the fraction of successful jets as probed by recent numerical analysis of the jet-merger outflow interaction (Duffell et al. 2018) provides in turn, an *estimate* of θ_0 (instead of a lower and upper limit as presented above).

Duffell et al. (2018) find that jets are successful if the beaming corrected energy in the jet E_j is larger than a critical value $E_{\text{cr}} \equiv 0.05\theta_0^2 E_{\text{ej}}$, where E_{ej} is the energy deposited in the NS merger ejecta. Throughout this work, we assume that the opening angle of the injected jet in the simulations by Duffell et al. (2018) is equal to the jet opening angle after breakout from the NS merger ejecta. This is an appropriate approximation for jets propagating in a non-expanding medium (Bromberg et al. 2011), but it remains to be shown whether this also holds for jets pummelling through an expanding medium. Taking $E_{\text{ej}} = 10^{51}$ erg as a typical value for the kinetic energy of the NS merger ejecta (Hotokezaka et al. 2018)³ and a constant time of engine activity given by the typical sGRB duration (in the central engine frame) $t_e = 0.3 t_{e,3}$ s (Kouveliotou et al. 1993), the condition $E_j > E_{\text{cr}}$ translates to:

$$L > L_{\text{cr}} \simeq 5 \times 10^{49} \frac{E_{\text{ej},51}}{t_{e,3}} \left(\frac{\eta_{\gamma}}{0.15}\right) \text{erg s}^{-1}, \quad (8)$$

where $E_{\text{ej},51} \equiv E_{\text{ej}}/(10^{51} \text{ erg})$, η_{γ} is the efficiency of converting the injected jet power into observed γ -rays in the prompt phase and is normalized to a characteristic value $\eta_{\gamma} = 0.15$ inferred from observations (Beniamini et al. 2015; Beniamini, Nava & Piran 2016). Notice that L_{cr} is very close to the canonical value for L_{\min} . Were $L_{\text{cr}} \gg L_{\min}$, then a second break in the sGRB luminosity function should be present, which is not observed.⁴ The ratio of failed to successful sGRB rates can also be estimated from the sGRB luminosity function (see equation 3) and it may be written as $r_{\text{fail}} \approx (L_{\text{cr}}/L_{\min})^{\alpha_L} - 1 \approx 1$. This condition is satisfied when

$$\theta_0 = 0.07 \left(\frac{E_{\text{ej},51}}{t_{e,3}} \frac{\eta_{\gamma}}{0.15}\right)^{\frac{\alpha_L}{2}} L_{\text{m,49.7}}^{-\alpha_L} R_{\text{m,1540}}^{-1/2}, \quad (9)$$

³This is inferred from the modelling of the kilonova emission following GW170817 (Kasen et al. 2017; Tanaka et al. 2017).

⁴The possibility of $L_{\text{cr}} = L_*$ is ruled out by the rate comparison in equation 2, as was demonstrated explicitly in Section 2.2.1.

where equation (2) was used. Interestingly, the allowed values of θ_0 obtained from equations (5), (7), and (9) are consistent with two independent estimates of the opening angle in GRB170817:

(i) recent measurements of superluminal motion in GRB170817 (Mooley et al. 2018a) using very long baseline interferometry data demonstrated that $\theta_0 \lesssim 0.09$ in GRB170817.

(ii) the peak time of the GRB170817 afterglow in X-rays and radio suggested that $0.04 \lesssim \theta_0 \lesssim 0.1$ (Mooley et al. 2018b; Pooley et al. 2018).

Our analysis suggests that the majority of sGRB jets (or even all) is successful in breaking out of the surrounding ejecta. In addition, assuming that the opening angle of sGRBs is independent of their luminosity, we showed that $\theta_0 \approx 0.1$; these are tighter constraints than existing ones for the sGRB population (Janka et al. 2006; Fong et al. 2015). Note that these results do not depend too strongly on the value of R_{merg} , which will be better constrained in the future with more observations of GWs from NS mergers (see also Hotokezaka et al. 2018, for comparison with *r*-process rates suggesting a comparable but possibly slightly lower rate).

3 PROBING GRB MODELS WITH JOINT GW AND PROMPT GRB DETECTIONS

The detection of a GW signal could boost the likelihood of association of an otherwise marginal γ -ray signal with an underlying GRB and of the identification of the host galaxy (Patricelli et al. 2016; Abbott et al. 2017a; Kathirgamaraju et al. 2018; Beniamini et al. 2018). NS mergers detected by GWs also select nearby events. The observed distribution of sGRB luminosities that are also detected in GWs is therefore expected to be different than that of sGRBs with no GW detection. This implies that joint GW and prompt GRB detections could provide a unique probe to the distribution of the γ -ray luminosity as a function of angle θ with respect to the jet symmetry axis $L_{\gamma,\text{iso}}(\theta)$, and therefore, to the underlying jet and/or cocoon physics.

Indeed, the observation of the first sGRB with a GW signal is a demonstration of this point. This GRB had a prompt γ -ray luminosity which is approximately four orders of magnitude lower than the previously weakest sGRB with confirmed redshift and it was observed from a relatively large viewing angle, i.e. $\theta_{\text{obs}} > \theta_0$ (Finstad et al. 2018). In this case, the low observed luminosity may be the result of a quasi-isotropic radiatively inefficient⁵ component (e.g. due to a cocoon) that accompanies GRB jets or of the intrinsic angular jet structure, which could suppress the emission at angles $\theta \gtrsim \theta_0$ (Kathirgamaraju et al. 2018; Fraija et al. 2017; Lamb & Kobayashi 2017; Lazzati et al. 2017b,a; Gottlieb et al. 2017; Kasliwal et al. 2017; Margutti et al. 2018; Troja et al. 2018; Barkov et al. 2018; Lazzati et al. 2018).

3.1 Monte Carlo simulations

We focus here on two extreme cases for the angular/radial profile of the jet: (i) a ‘structured-jet’ (SJ) model, in which the luminosity is a PL or Gaussian (GS) function of the angle from the core and the radiative efficiency remains constant as a function of latitude and (ii) a ‘cocoon-like’ (CL) model, where a top-hat jet is accompanied by a quasi-spherical, radiatively inefficient outflow, possibly with

⁵This is compared to the available energy along the line of sight to the observer.

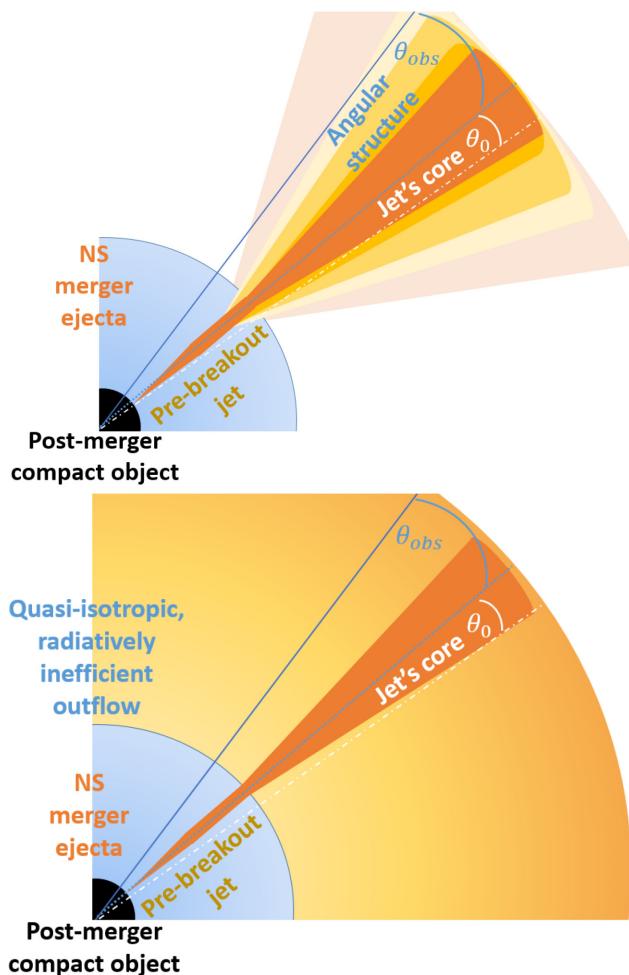

Figure 1. A schematic illustration of a short GRB jet that was successful in breaking out of the NS merger ejecta. Top: an SJ with a strong angular profile beyond the jet core defined by angle θ_0 . An off-axis observer (located at an angle θ_{obs}) receives emission from the less energetic material (compared to the jet core) moving along their line of sight (SJ model). Bottom: the jet core is surrounded by a radiatively inefficient quasi-isotropic component with a likely radial structure in its properties (CL model).

significant radial structure. A schematic illustration is presented in Fig. 1. We stress that in reality the situation may lie somewhere in between these two extremes.

We perform an MC simulation to explore the resulting γ -ray luminosity, $L_{\gamma, \text{iso}}$ and observation angle, θ_{obs} , distributions arising from different parameters of the two underlying models mentioned above. We begin each realization of the MC by drawing a random orientation between the jet core (which is taken to be perpendicular to the merger plane) and the line of sight (i.e. uniform in $\cos \theta$ and ϕ) and a distance, d , of the event according to the rate function $R(z)$ of Wanderman & Piran (2015). We impose a cut-off at the maximum distance for which NS mergers can be detected in GWs with future capabilities, $d_{\text{max}} = 220$ Mpc (Abbott et al. 2017b)⁶; later on we test the dependence of the results on d_{max} , by adopting $d_{\text{max}} = 50$ Mpc for all explored models. Following our reasoning

⁶For the distance scales relevant for GW detection, cosmological effects can, to a good approximation, be neglected, and the bursts can be assumed to be randomly distributed within a sphere of radius d_{max} .

in Section 2.2, we then simulate the luminosity of the jet core according to the luminosity function in (3). From the discussion in Section 2.3, we expect $\theta_0 \approx 0.1$. We consider this as the canonical value for all simulated bursts, but for completeness, consider also the cases of $\theta_0 = 0.05$ and $\theta_0 = 0.2$. For a given structure model, the emissivity is then extrapolated to larger angles. For each event, we calculate both the on line-of-sight contribution to the emission (i.e. from emitters that see the observer within their relativistic beaming cone) and the off line-of-sight contribution (Eichler & Levinson 2004; Granot & Ramirez-Ruiz 2010; Kasliwal et al. 2017; Granot et al. 2017; Ioka & Nakamura 2018; Kathirgamaraju et al. 2018). The latter is calculated in the following way (see e.g. Kasliwal et al. 2017). Assuming $\Gamma \gg \theta_0^{-1}$, the observed energy scales as:

$$\frac{E_{\gamma, \text{obs}}(\theta_{\text{obs}})}{E_{\gamma, \text{em}}(\theta_0)} = \begin{cases} 1 & \theta_{\text{obs}} < \theta_0 \\ \max \left[\frac{E_{\gamma, \text{em}}(\theta_{\text{obs}})}{E_{\gamma, \text{em}}(\theta_0)}, q^{-4} \right] & \theta_0 < \theta_{\text{obs}} < 2\theta_0 \\ \max \left[\frac{E_{\gamma, \text{em}}(\theta_{\text{obs}})}{E_{\gamma, \text{em}}(\theta_0)}, q^{-6} (\theta_0 \Gamma)^2 \right] & 2\theta_0 < \theta_{\text{obs}}, \end{cases}$$

where the subscript ‘em’ denotes emitted quantities, the subscript ‘obs’ denotes observed ones, $q = (\theta_{\text{obs}} - \theta_0)\Gamma$ and we set $\Gamma = 100$ in our simulations. The duration scales as $\Delta t_{\text{obs}} = q^2 \Delta t_{\text{em}}$ if the burst duration is set by a ‘single’ emission episode that takes place at some location r that extends over a range of radii $\Delta r \lesssim r$ or as $\Delta t_{\text{obs}} = \Delta t_{\text{em}}$ if the burst duration is set by the radial width of the outflow. In what follows, we assume that the duration is set by the radial width of the outflow and that $\Delta t_{\text{obs}} = \Delta t_{\text{em}} = 0.3$ s. The luminosity then scales as the ratio of $E_{\gamma, \text{obs}}$ to Δt_{em} . This provides an upper limit on the off line-of sight luminosity and is therefore a conservative choice for our simulations. Even in this case, we find that the off line-of sight emission is sub-dominant to the on line-of sight emission, unless the angular profile is extremely steep and the observation angle is close to jet core.

Computing the emission from SJ simulated events is meaningful only if the jet has successfully broken out of the ejecta. This is in accord with results of hydrodynamical simulations of jet and NS merger interaction (Duffell et al. 2018). Furthermore, as shown in Section 2, a large fraction of sGRB jets (and possibly all) are expected to successfully break out of the expanding ejecta. We therefore assume $r_{\text{fail}} = 1$ in all SJ models. We explore three variants of the SJ models described below:

(i) A power-law (SJPL) model, where $L = L_0$ for $\theta < \theta_0$ and $L = L_0(\theta/\theta_0)^{-\delta}$ for $\theta > \theta_0$. The value of δ in this model is constrained by the observations of GRB170817. For a given value of θ_0 , δ must satisfy⁷ $\delta \geq \log(L_{\text{GRB170817}}/L_{\text{min}})/\log(\theta_0/\theta_{\text{obs}})$, since the lowest core luminosity is given by L_{min} and the extrapolation of this luminosity to $\theta_{\text{obs}} \approx 0.35 \pm 0.09$ (Mooley et al. 2018a; van Eerten et al. 2018) should not overproduce γ -rays as compared with those observed for GRB170817. This consideration implies $\delta \geq 3$ for $\theta_0 = 0.05$, $\delta \geq 4.5$ for $\theta_0 = 0.1$ and $\delta \geq 10$ for $\theta_0 = 0.2$ (where we have taken here into account the uncertainty θ_{obs} quoted above).

(ii) A Gaussian (SJG) model, where $L = L_0 \exp[-(\theta/\theta_0)^2]$. As in the SJPL case, this family of models can be limited by the requirement to not overproduce γ -rays compared to GRB170817.

⁷This condition is at first glance similar to the condition discussed in Section 2.2.2 when considering whether it is possible to explain the broken PL nature of the luminosity function with angular structure (in which case the minimum core luminosity is given by L_*). However, since we argue that this possibility is unlikely and that the luminosity function $\Phi(L)$ is intrinsic, we conservatively replace here L_* by L_{min} .

Applied to this model, this consideration puts an upper limit on θ_0 of: $\theta_0 \leq \theta_{\text{obs}} (\log(L_{\text{min}}/L_{\text{GRB170817}}))^{-1/2} \approx 0.14$ (where once more we have taken here into account the uncertainty θ_{obs} quoted previously).

(iii) A simplified CL model, where $L = L_0 + L_{\gamma,\text{co}}$ for $\theta_{\text{obs}} < \theta_0$ and $L = L_{\gamma,\text{co}}$ for $\theta_{\text{obs}} > \theta_0$. Here, $L_{\gamma,\text{co}}$ is the peak (isotropic equivalent) cocoon breakout luminosity. An estimate of this luminosity (and related observational consequences of the thermal energy reservoir stored in the cocoon) is provided in Section 4 (and in particular equation 14).

For each simulated event, we compute the γ -ray flux by taking all relevant contributions for the SJ and CL models, as described above. Then, a simulated GRB is assumed to be detectable, if its prompt γ -ray flux exceeds the *Fermi* GBM threshold $F_{\text{lim}} = 5.8 \times 10^{-7}$ ergs $^{-1}$ cm $^{-2}$ (Goldstein et al. 2017); note that for sGRBs one can neglect the duration in the definition of the limiting flux. The detectability of GWs is a complex function of the viewing angle with respect to the merger plane (Schutz 2011; Allen et al. 2012; Hilborn 2018). Using the angular dependence of the detection probability given in Schutz (2011) [see equation (27) therein] and scaling with the horizon distance for binary mergers of 220 Mpc, we define as detectable in GWs any simulated events that satisfy the condition:

$$\frac{220 \text{ Mpc}}{d} \left(\frac{1 + 6 \cos^2 \theta_{\text{obs}} + \cos^4 \theta_{\text{obs}}}{8} \right)^{1/2} > 1. \quad (10)$$

The MC process is repeated 10^5 times, and the burst properties are recorded for events with joint γ -ray and GW detection or with just one of the two.

3.2 Results

The distributions of observation angles and prompt luminosities of GRBs with joint γ -ray and GW detections are presented respectively in the left- and right-hand panels of Fig. 2 (solid lines). The dotted-dashed histogram (left-hand side panels) shows the probability that a GW signal is detected for a given observation angle, as given by equation (10), i.e. independent of the detectability of the prompt GRB emission. The typical observation angle is slightly larger than θ_0 , with the median values, $\tilde{\theta}_{\text{obs}}$, typically being in the range 0.1–0.25 and approaching θ_0 as the structure becomes steeper. This conclusion remains true even for the cocoon models explored here, due to their intrinsically weak emission. Only very radiatively efficient cocoon models, for which the cocoon is seen much more often than the on-axis GRB, may be seen much further off-axis. For example, for $\theta_0 = 0.1$, one would require $\eta_{\text{br}} \geq 0.1$ in order to obtain $\tilde{\theta}_{\text{obs}} \gtrsim 0.4$. As a comparison, the typical observation angle of a GW detection alone is $\tilde{\theta}_{\text{obs}} \approx 0.65$ (see black vertical lines in the left-hand side panels of Fig. 2).

The luminosity distribution is typically double-peaked, with a high-luminosity peak corresponding to jets seen on-axis (peaking at $\approx 2L_{\text{min}}$) and a low-luminosity peak corresponding mostly to off-axis jets (peaking at $\approx 2L_{\text{min}}(\tilde{\theta}_{\text{obs}}/\theta_0)^{-\delta}$, $2L_{\text{min}} \exp[-(\tilde{\theta}_{\text{obs}}/\theta_0)^2]$) for the SJPL and SJG models, respectively. A smaller low-luminosity peak is seen also for the CL model, this corresponds to the off line-of-sight contribution discussed in Section 3.1. The location of this peak in the figure is dominated by the γ -ray detectability threshold: $\approx 2 \times 4\pi\tilde{r}^2 F_{\text{lim}}$ where \tilde{r} is the median distance of jointly detected events. A small contribution to the low-luminosity peak in the CL model, comes from the breakout luminosity of failed jets. The bimodality is naturally more prominent for steeper structure models (see e.g. top right-hand side panel in Fig. 2) and becomes apparent when the two peaks discussed above are sufficiently separated. GSJ models

produce symmetric bimodal luminosity distributions for $\theta_0 \lesssim 0.2$, while the two peaks merge into one for larger θ_0 values (see middle right-hand side panel).

It is constructive to consider the likelihood of the three following outcomes: (i) no sGRB detection given a GW detection, (ii) a joint GW and a ‘regular’ sGRB detection ($\theta_{\text{obs}} \lesssim \theta_0$), and (iii) a joint GW and misaligned sGRB detection ($\theta_{\text{obs}} > \theta_0$). The probabilities for the different models considered above and the median observation angles, given a joint detection, are presented in Table 1. Excluding the SJG model with $\theta_0 = 0.2$ that is in contention with our results in Section 2.3 and with limits from GRB170817, the probability for a detection of GW from an NS merger without an accompanying γ -ray signal is very large in all models considered here (i.e. ≈ 90 per cent–99 per cent). In the more rare case of a joint detection, the sGRB is typically 1–10 times more likely to be seen off-axis.

We explored also the effect of the limiting distance d_{max} on the aforementioned probabilities. In most simulations we performed, we took as a canonical value $d_{\text{max}} = 220$ Mpc, which as described above is the maximum distance to which NS mergers can be detected with near future GW detectors. A smaller limiting distance ($d_{\text{max}} = 50$ Mpc) has an interesting effect on the detectability of events (see Table 1). While the fraction of events that can be detected electromagnetically increases as d_{max}^{-2} , the probability of an sGRB detection given a GW observation does not change significantly by switching d_{max} from 220 to 50 Mpc. This can be understood as follows. The detectability of GWs becomes 100 per cent for events with $d < 50$ Mpc and the typical observation angle of a GW-detected event increases as d_{max} decreases. Consequently, the probability of observing an on-axis sGRB actually goes down for smaller d_{max} . Similar conclusions hold for any sGRB (not only on-axis), if the angular profile is very steep or its isotropic component is very dim.

GRB170817 could have been detected in γ -rays up to a distance of 50 Mpc (Goldstein et al. 2017), but instead it occurred at a distance of 40 Mpc. Moreover, the large inferred isotropic equivalent core luminosity in GRB170817 (Mooley et al. 2018b), which is roughly two orders of magnitude above those of typical sGRBs, suggests an accordingly luminous off-axis γ -ray emission. With a detection horizon of 220 Mpc, only a small fraction of future events are expected to exhibit similar properties to those of GRB170817. In models with a strong angular structure (e.g. SJPL models), bursts must be observed at small enough θ_{obs} , so that there is still a significant amount of power in the material travelling towards the observer. This leads to a further reduction in the expected rate of future GRB170817-like events.

The effective LIGO horizon distance for the detection of GW170817 was 107 Mpc (Abbott et al. 2017b). Given a GW detection alone, we find that the probability of an event having $\theta_{\text{obs}} \leq 0.44$ (as inferred for GRB170817; see Mooley et al. 2018b) and occurring at a distance of $d \leq 50$ Mpc is ≈ 4 per cent (see also Lamb & Kobayashi 2017). This is demonstrated in Fig. 3, where we plot the observation angles and distances of events with joint γ -ray and GW detections (red crosses) from a simulation of SJPL model with $\theta_0 = 0.1$ and $\delta = 4.5$. Top and bottom panels show results for an effective GW horizon distance of 107 and 220 Mpc, respectively. The median distance of future joint detection events is ≈ 150 Mpc and correspondingly the median GRB luminosity is 7×10^{48} ergs $^{-1} \gg L_{\text{GRB170817}}$. The fact that GRB170817 is an atypical event of the sample of expected joint prompt and GW detections is also illustrated in Fig. 4, where we present the expected $L_{\gamma} - \theta_{\text{obs}}$ distributions of joint detections for two models of prompt emission

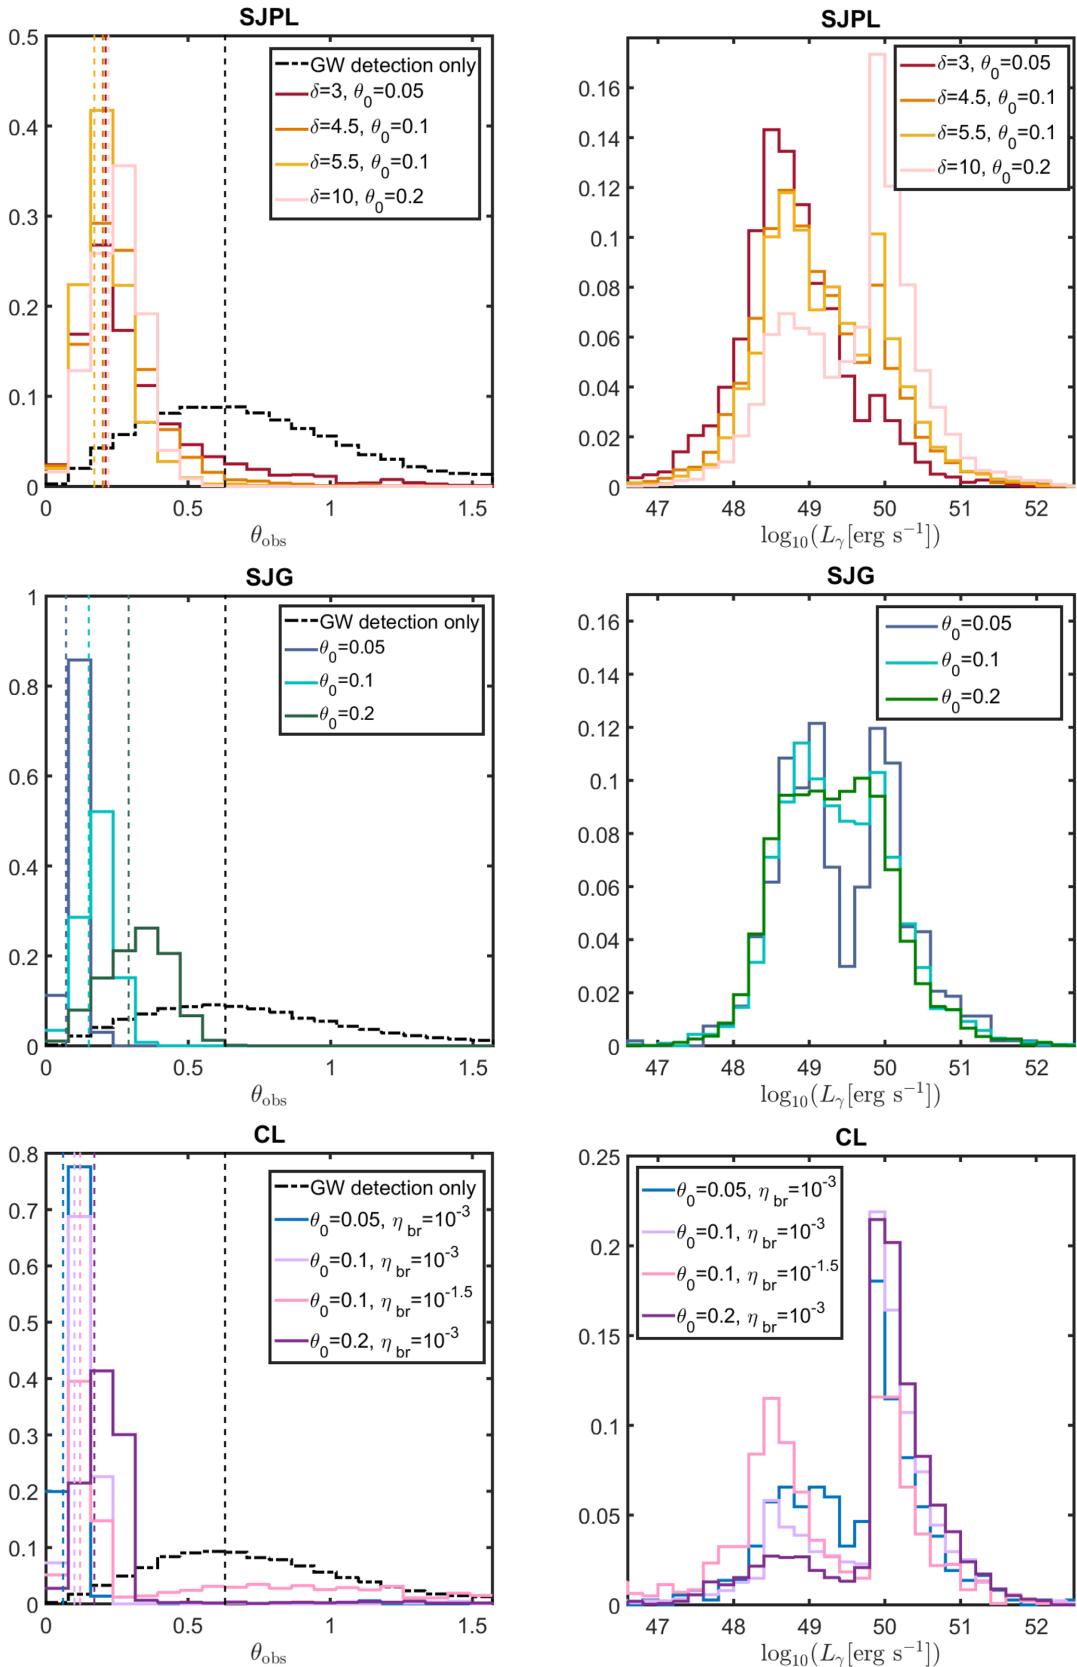

Figure 2. Probability distribution functions of observation angles ($dP/d\theta_{\text{obs}}$) and γ -ray (isotropic) luminosities ($dP/d\log L_{\gamma}$) for different structure models discussed in Section 3.1. Results for a joint prompt GRB and GW detection are shown with solid lines in all panels. The dotted-dashed histogram (left-hand side panels) shows the probability for a GW signal detection, as given by equation (10), without considering the prompt GRB emission. Dashed lines mark the median observation angle for different models, $\bar{\theta}_{\text{obs}}$.

Table 1. Detection probabilities of NS mergers obtained from our MC simulations for different emission models (see Section 3.1 for details). Values listed are calculated for $d_{\max} = 220$ and 50 Mpc (in parenthesis). Note that all the probabilities listed here are conditional probabilities assuming that there is a GW detection.

Model	θ_0	P_1^a	P_2^b	P_3^c	$\tilde{\theta}_{\text{obs}}^d$

^dMedian value computed from joint γ -ray and GW detections.

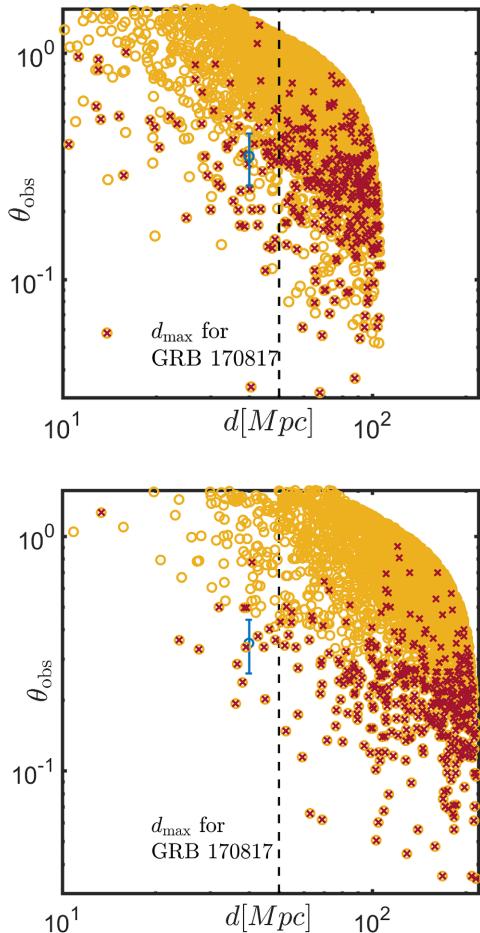

Figure 3. Distances and observation angles for mergers detected in GW alone (yellow circles) and for mergers with joint GW and γ -ray detections (red crosses). We present the distribution with a detection horizon of 107 Mpc (top), corresponding to the effective detection horizon for GRB170817 or 220 Mpc (bottom), suitable for future events. The inferred values for GRB170817 are shown with a blue symbol. The maximum distance at which it could have been observed in γ -rays is depicted by the vertical dashed line. Results are shown for an SJPL model with $\theta_0 = 0.1$ and $\delta = 4.5$.

given a detection horizon of 220 Mpc. For both models, the properties of GRB170817 (blue crosses) are not representative of the sample. Only ~ 0.16 per cent and 2 per cent of the simulated events (jointly detected in γ -rays and GWs) in the CL and SJPL models, respectively, is found to have $0.25 \leq \theta_{\text{obs}} \leq 0.45$ and $5 \times 10^{46} \leq L_{\gamma} \leq 4.8 \times 10^{47}$ erg s $^{-1}$. The shape of the observed two-dimensional distributions is driven by the emission model, since the emission is typically dominated by material that is radiating within its $1/\Gamma$ beaming cone from the observer. A differentiation between the underlying emission models would require a sufficiently large number of joint GW and GRB detections (see also Section 5).

4 THE COCOON EMISSION

We estimate here the thermal energy stored in the cocoon, the fraction of it radiated in γ -rays at breakout and the cooling emission signature arising when the thermal cocoon eventually becomes optically transparent. The latter corresponds to a \sim hours long ultraviolet (UV) signal, that may be detectable, provided sufficiently rapid localization of the NS merger.

The peak thermal energy stored in the cocoon (as a function of time) is found by Duffell et al. (2018). As mentioned above, here we assume that the that the injected opening angle is equal to the opening angle after breakout. Rewriting equations (10) and (21) in Duffell et al. (2018) in a slightly different form, we obtain:

$$E_{\text{Th}} = \begin{cases} 0.17E_{\text{j}} & E_{\text{cr}} \leq E_{\text{j}} \leq 30E_{\text{cr}} \\ 1.14E_{\text{cr}} & E_{\text{j}} > 30E_{\text{cr}}, \end{cases} \quad (11)$$

where $E_{\text{cr}} \approx 5 \times 10^{49} \theta_0^2$ erg and E_{j} is the beaming corrected kinetic energy of the jet, $E_{\text{j}} \approx 0.5 \theta_0^2 L_{\text{jet}} t_{\text{e}} / \eta_{\gamma}$. The peak thermal energy in equation (11) is reached at a time

$$t_{\text{peak}} = \begin{cases} 2t_{\text{e}} (< t_{\text{br}}) & E_{\text{cr}} \leq E_{\text{j}} \leq 30E_{\text{cr}} \\ t_{\text{br}} & E_{\text{j}} > 30E_{\text{cr}}, \end{cases} \quad (12)$$

where $t_{\text{br}} = 3t_{\text{e}} E_{\text{cr}} / E_{\text{j}}$ is the time it takes the jet to breakout from the ejecta. The thermal energy stored in the cocoon provides a strict upper limit on its radiated energy and luminosity. This is because the cocoon is expected to be initially optically thick, in which case only a small portion of the thermal energy, can escape to the observer (see Nakar & Sari 2010, and references therein). For GRB170817, the

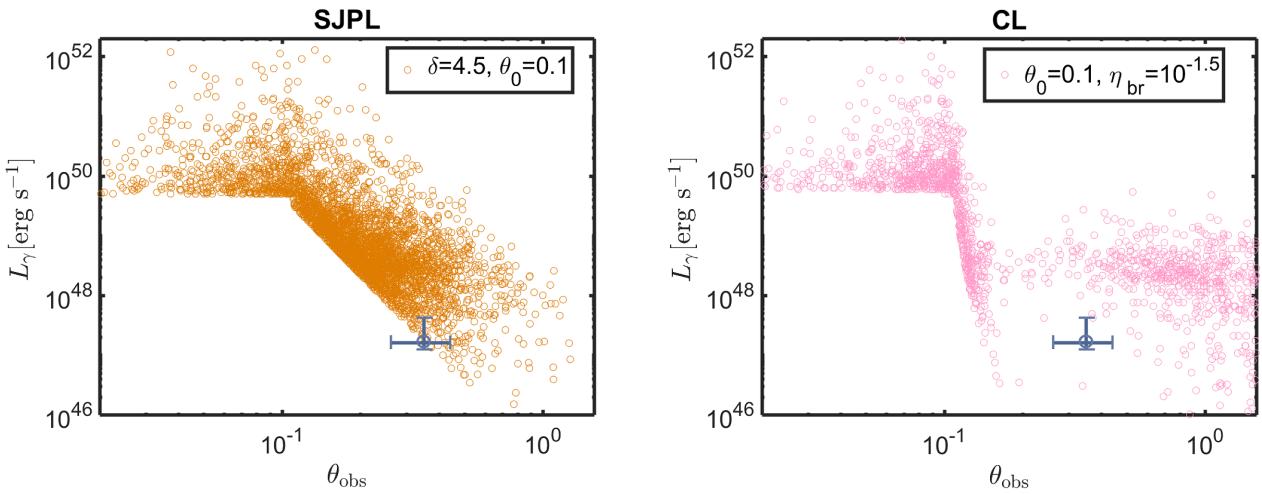

Figure 4. Two-dimensional distributions of observation angles and γ -ray luminosities for different structure models assuming a joint prompt GRB and GW detection. The location of GRB170817 on these plots is marked with blue crosses that denote the 1σ error in luminosity (Zhang et al. 2018) and observation angle (Mooley et al. 2018b).

latest modelling efforts suggest a total (beaming corrected) energy of 10^{50} erg (Mooley et al. 2018b) which corresponds to $E_{\text{Th}} \approx 3 \times 10^{49}$ erg. At the same time, cocoon breakout models for the prompt γ -rays radiate only $E_{\text{br}} = 4 \times 10^{46}$ erg at breakout (Gottlieb et al. 2017; Lazzati et al. 2017b), implying an efficiency of $\eta_{\text{br}} \equiv E_{\text{br}}/E_{\text{Th}} \sim 10^{-3}$ for this phase. In what follows, we adopt $\eta_{\text{br}} = 10^{-3}$ as a canonical value.

The entire thermal energy is eventually released on the time-scale for which the medium reaches transparency t_{thin} . As an indicative example, let us consider a characteristic velocity $v = 0.5c$ for the cocoon ejecta of mass M_{co} . Assuming that the kinetic energy of the cocoon is comparable to its thermal energy (Duffell et al. 2018) ($E_{\text{Th}} = 0.5M_{\text{co}}v^2$), t_{thin} is estimated as:

$$t_{\text{thin}} = \sqrt{\frac{\kappa M_{\text{co}}}{4\pi c v}} = \sqrt{\frac{2E_{\text{Th}}\kappa}{4\pi c v^3}} = \begin{cases} 1600E_{50}^{1/2}v_{.5}^{-3/2}\kappa_{0.1}^{1/2} \text{ s} & E_{\text{cr}} \leq E_{\text{j}} \leq 30E_{\text{cr}} \\ 300v_{.5}^{-3/2}\theta_{0.1}\kappa_{0.1}^{1/2} \text{ s} & E_{\text{j}} > 30E_{\text{cr}}, \end{cases} \quad (13)$$

where $E_{50} \equiv E_{\text{j}}/10^{50}$ erg, $v_{.5} \equiv c/0.5c$, $\theta_{0.1} \equiv \theta_0/0.1$, and $\kappa_{0.1} = \kappa/0.1 \text{ cm}^2 \text{ g}^{-1}$ is the Thomson opacity (cross-section per unit mass). For the adopted parameter values, we find that $t_{\text{thin}} \gg t_{\text{br}} \gtrsim t_{\text{peak}}$ (see equation 12). This is consistent with the small efficiencies for the cocoon breakout luminosity, $\eta_{\text{br}} \ll 1$ inferred for GW170817, as discussed above. The peak (isotropic equivalent) cocoon breakout luminosity can be approximated by using equations (11) and (12):

$$L_{\gamma, \text{co}} \approx \eta_{\text{br}} \frac{E_{\text{Th}}}{t_{\text{peak}}} \approx \frac{\theta_0^2}{2} \frac{\eta_{\text{br}}}{\kappa} k L_0, \quad (14)$$

where k is a numerical constant that is $k \approx 0.08$ for $E_{\text{cr}} \leq E_{\text{j}} \leq 30E_{\text{cr}}$ and $k \approx 0.38$ for $E_{\text{j}} > 30E_{\text{cr}}$. The spectrum of the cocoon is expected to be quasi-thermal (possibly following a Wien spectrum, see Gottlieb et al. 2017) with a characteristic temperature $k_B T = 50 \Gamma \text{ keV}$ (where $\Gamma_{\text{br}} \approx \text{few}$ is the Lorentz factor of the material at the breakout shell). As more and more matter becomes transparent, the prompt luminosity released at breakout, evolves smoothly to the cooling signal described below. The exact temporal evolution depends on the velocity distribution of the material behind the breakout shell. Using the parametrization adopted above, we get $L \propto \eta(t)t^{-2}$ (this can be shown by comparing equation 14 with equation 16 below)

where $\eta(t_{\text{peak}}) \equiv \eta_{\text{br}} \ll 1$ and at later times $\eta(t)$ depends on the shock profile (eventually reaching $\eta(t_{\text{thin}}) = 1$).

The cocoon ejecta cools due to adiabatic energy losses until it becomes optically thin and the remaining energy $E_{\text{cool}} < E_{\text{Th}}$ is radiated away. This will happen when the time-scale for the diffusion of photons from the cocoon becomes comparable to the dynamical time-scale. At this point, the cocoon radius is vt_{thin} and the energy E_{cool} is given by:

$$E_{\text{cool}} = E_{\text{Th}} \frac{t_{\text{peak}}}{t_{\text{thin}}} = \begin{cases} 6 \times 10^{45} E_{50}^{1/2} v_{.5}^{3/2} t_{e,3} \kappa_{0.1}^{-1/2} \text{ erg} & E_{\text{cr}} \leq E_{\text{j}} \leq 30E_{\text{cr}} \\ 9 \times 10^{42} E_{50}^{-1} v_{.5}^{3/2} \theta_{0.1}^3 t_{e,3} \kappa_{0.1}^{-1/2} \text{ erg} & E_{\text{j}} > 30E_{\text{cr}}, \end{cases} \quad (15)$$

where $t_{e,3} \equiv t_e/0.3$ s. This energy is radiated away on a time-scale of t_{thin} . The cooling luminosity associated with this phase is then given by:

$$L_{\text{cool}} = \frac{E_{\text{cool}}}{t_{\text{thin}}} = \begin{cases} 4 \times 10^{42} v_{.5}^3 t_{e,3} \kappa_{0.1}^{-1} \text{ erg s}^{-1} & E_{\text{cr}} \leq E_{\text{j}} \leq 30E_{\text{cr}} \\ 3 \times 10^{40} E_{50}^{-1} v_{.5}^3 \theta_{0.1}^2 t_{e,3} \kappa_{0.1}^{-1} \text{ erg s}^{-1} & E_{\text{j}} > 30E_{\text{cr}}, \end{cases} \quad (16)$$

Notice that the cooling luminosity is very sensitive to the velocity of the outflow ($L_{\text{cool}} \propto v^3$). Since this radiation is fully thermalized, and originates from a radius of vt_{thin} , we can estimate its blackbody temperature as:

$$T_{\text{Th}} = \left(\frac{L_{\text{cool}}}{4\pi\sigma v^2 t_{\text{thin}}^2} \right)^{1/4} = \begin{cases} 5 \times 10^4 E_{50}^{-1/4} v_{.5} t_{e,3}^{1/4} \kappa_{0.1}^{-1/2} \text{ K} & E_{\text{cr}} \leq E_{\text{j}} \leq 30E_{\text{cr}} \\ 4 \times 10^4 E_{50}^{-1/4} v_{.5} t_{e,3}^{1/4} \kappa_{0.1}^{-1/2} \text{ K} & E_{\text{j}} > 30E_{\text{cr}}, \end{cases} \quad (17)$$

Therefore, we expect the cooling emission from the cocoon to peak at the UV band (see also Nakar & Piran 2017). For a limiting *Swift*-UVOT *B*-band flux of $\sim 5 \times 10^{-3}$ mJy in 1000 s (Gehrels 2004), and $v = 0.5c$ the derived luminosities from equation (16) imply that

this emission should be detectable for future NS merger events up to ~ 900 Mpc if $E_{\text{cr}} \leq E_j \leq 30E_{\text{cr}}$ and up to ~ 80 Mpc if $E_j > 30E_{\text{cr}}$. This of course, is provided that these events can be localized rapidly enough, in time to catch this signal (see also equation 13). This can be a challenging prospect. As an example, the EM counterpart of GW170817, was only first detected 0.5 d after the GW detection (Coulter et al. 2017).

5 DISCUSSION

The first discovery of GW from an NS merger allowed us to significantly improve our understanding of sGRB jets. Assuming all sGRBs arise from NS–NS (or NS–BH) mergers, the intrinsic rate of sGRBs should be at most comparable to the merger rate inferred by advanced LIGO/Virgo. This implies that if sGRB jets have a universal, luminosity independent structure, their typical opening angles should be $\theta_0 \gtrsim 0.07$ (see Section 2.3). At the same time, the observed population of sGRBs with *Swift* in the last 14 yr places a lower limit of ~ 250 Mpc on the distance from which we have observed an on-axis sGRB. This leads to an upper limit on the rate of local on-axis sGRBs and therefore on their typical opening angles $\theta_0 \lesssim 0.1$. These limits on the opening angle are consistent with values inferred for GRB170817 from afterglow modelling and from the measurements of superluminal motion. Furthermore, they imply that the NS merger rate is comparable to that of sGRBs and reveals that a fraction of order unity of NS mergers must lead to sGRBs. In other words, sGRB jets typically manage to breakout of the NS merger ejecta, in contrast to collapsar GRB jets.

The large fraction of successful sGRB jets and the typical opening angles of $\theta_0 \sim 0.1$ are consistent with a critical breakout luminosity (estimated from hydrodynamical simulations of the interaction between the sGRB jet and the NS merger ejecta) being close to the ‘canonically’ assumed minimal luminosity of the sGRB luminosity function, namely $L_{\text{min}} \approx 5 \times 10^{49}$ erg s $^{-1}$. This consideration demonstrates that the role of failed jets in shaping the observed luminosity function of sGRBs cannot be significant (see Section 2.2.1). At the same time, we have also shown here that the angular structure of sGRBs is challenged to reproduce the observed luminosity function, given that the required structure is very shallow in contention with observational indications from GRB170817 (see Section 2.2.2). If this is the case, the implication is that the broken PL luminosity function of sGRBs has an intrinsic origin and that the inferred break of the luminosity function, at an isotropic γ -ray luminosity of $L_* \approx 2 \times 10^{52}$ erg s $^{-1}$ (corresponding to a beaming corrected jet mechanical power of $\sim 10^{51}$ erg s $^{-1}$) reveals an intrinsic characteristic luminosity of sGRB jets. One possible interpretation that holds for magnetic jets, powered by the Blandford–Znajek mechanism (Blandford & Znajek 1977), is that the value of L_* reflects a characteristic accretion rate, below which the accretion disc is advection dominated (ADAF), and above which it becomes dominated by neutrino cooling (NDAF, Giannios 2007). Indeed, Kawanaka, Piran & Krolik (2013) have shown that a sharp change in the jet power may occur due to this transition at accretion rates $\dot{M} \approx 0.003\text{--}0.01 M_\odot \text{ s}^{-1}$, consistent with the beaming corrected jet luminosity mentioned above, assuming $L \approx 0.1 \dot{M} c^2$.

While the joint discovery of GW170817 and GRB170817 has helped to constrain the fraction of successful GRB jets, their opening angles, and their luminosity function as discussed above, the angular structure of GRB jets and the nature of their γ -ray emission are still uncertain. In this paper, we considered different off-axis emission models, motivated by the analysis above and by observations of GRB170817. We showed that 90 per cent–99 per cent of future GW

Table 2. Expected number of NS mergers detectable in GWs in the case of: no *Fermi*/GBM detection, an on-axis GRB detection, and an off-axis GRB detection. The numbers (with their 1σ statistical errors, Gehrels 1986) are obtained from our simulations for a limiting distance of 220 Mpc and a 10-yr period, assuming a merger rate $R_{\text{merg}} = 1540 \text{ Gpc}^{-3} \text{ yr}^{-1}$. For the assumed parameters, ~ 192 NS mergers are expected.

Model	Parameters	<i>Fermi</i>		
		undetected	On-axis	Off-axis
PL	$\delta = 3$ and $\theta_0 = 0.05$	180.8 ± 13.4	< 1.8	$9.6^{+3.5}_{-3.5}$
PL	$\delta = 4.5$ and $\theta_0 = 0.1$	178.9 ± 13.4	$1.1^{+2.1}_{-1.0}$	$11.5^{+3.9}_{-3.8}$
PL	$\delta = 5.5$ and $\theta_0 = 0.1$	182.7 ± 13.5	$1.1^{+2.1}_{-1.0}$	$7.7^{+3.1}_{-3.3}$
PL	$\delta = 10$ and $\theta_0 = 0.1$	177.0 ± 13.3	$5.8^{+2.6}_{-2.9}$	$9.6^{+3.5}_{-3.5}$
GS	$\theta_0 = 0.05$	188.5 ± 13.7	< 1.8	$3.8^{+2.1}_{-2.5}$
GS	$\theta_0 = 0.1$	178.9 ± 13.4	$1.5^{+1.8}_{-1.4}$	$11.5^{+3.9}_{-3.8}$
GS	$\theta_0 = 0.2$	146.2 ± 12.2	$5.8^{+2.6}_{-2.9}$	$38.5^{+6.7}_{-6.6}$
CL	$\eta_{\text{br}} = 10^{-3}$ and $\theta_0 = 0.05$	190.4 ± 13.8	< 1.8	< 1.8
CL	$\eta_{\text{br}} = 10^{-3}$ and $\theta_0 = 0.1$	190.4 ± 13.8	$1.1^{+2.1}_{-1.0}$	$1.0^{+2.3}_{-0.8}$
CL	$\eta_{\text{br}} = 10^{-3/2}$ and $\theta_0 = 0.1$	188.5 ± 13.7	$1.1^{+2.1}_{-1.0}$	$1.9^{+1.4}_{-1.7}$
CL	$\eta_{\text{br}} = 10^{-3}$ and $\theta_0 = 0.2$	184.6 ± 13.6	$5.8^{+2.6}_{-2.9}$	$1.9^{+1.4}_{-1.7}$

events accompanied by a successful GRB jet and detected up to a distance of 220 Mpc, should not be accompanied by any detectable prompt GRB signal. In the comparatively rare cases of a joint GRB and GW detections, we find that for each GRB observed on-axis $\sim 1\text{--}10$ GRBs should be observed at angles beyond the jet core.

The distribution of prompt luminosities and observation angles from joint GRB and GW detections can help to distinguish between off-axis prompt emission models (see Fig. 4). For example, let us assume an NS merger rate of $R_{\text{merg}} = 1540 \text{ Gpc}^{-3} \text{ yr}^{-1}$, a ratio of failed to successful GRB jets $r_{\text{fail}} = 1$, and $\theta_0 = 0.1$. Then, angular structure models with $L(\theta > \theta_0) \propto \theta^{-\delta}$ and $\delta = 4.5$ lead to ~ 19.2 GW detectable mergers per year (up to 220 Mpc), out of which ~ 18 without *Fermi*/GBM γ -ray detection, 0.1 with an on-axis GRB detection, and 1.1 with an off-axis GRB detection. Alternatively, for cocoon models with a breakout efficiency of $\eta_{\text{br}} = 10^{-3}$ (and $\theta_0 = 0.1$), we have ~ 19 events per year with no accompanying GRB, and 0.1 with on-axis or off-axis GRBs. Table 2 summarizes the expected number of events within a period of 10 yr for the emission models discussed in Section 3.1. Inspection of the table shows that the detection rates of off-axis GRBs accompanying GW-detected mergers are the key for differentiating between the models. For example, the lack of any other prompt GRB detections from NS mergers within the next 10 yr (for the assumed parameters), would be in strong tension with the predictions of the SJ model. The thermal energy in the cocoon may also be observed via its cooling emission that is expected to lead to a UV thermal signal at $\sim 10^3$ s after the trigger (see equations 13 and 16). Provided that the NS merger can be located rapidly enough, the cooling emission of the cocoon may be detectable up to a distance of ~ 900 Mpc. It turns out that events similar to GRB170817 are rare. This is a combination of the small distance and observation angle of GRB170817 and the high inferred luminosity at the core of that event compared to typical sGRBs.

In conclusion, the discovery of the first GRB associated with an NS merger, GRB170817, has already significantly improved our knowledge of short GRB jets. None the less, the nature of the prompt

signal that is seen by observers far from the jet cores remains unclear. The association of a γ -ray signal with a GW event could allow us to detect orders of magnitude fainter signals associated with GRBs, which would otherwise be undetected for cosmological events (see also Beniamini et al. 2018). This, coupled with the relatively large detection rate of NS mergers as inferred from GW170817, implies that the existing models could be differentiated observationally within the next several years, opening up the window towards a more detailed understanding and future studies of short GRB jets.

ACKNOWLEDGEMENTS

The authors would like to thank the referee for a constructive report, and Tsvi Piran, Ehud Nakar, Pawan Kumar, Omer Bromberg, and Kenta Hotokezaka for helpful discussions. RBD thanks Danielle Taylor for useful discussions. MP acknowledges support from the Lyman Jr. Spitzer Postdoctoral Fellowship and NASA grant 80NSSC18K1745. DG acknowledges support from NASA grants NNX16AB32G and NNX17AG21G. RBD and DG acknowledge support from the National Science Foundation under grants 1816694 and 1816136.
