43 **Abstract**

44 An essential human skill is our capacity to monitor and execute a sequence of tasks in the service  
45 of an overarching goal. Such a sequence can be as mundane as making a cup of coffee or as  
46 complex as flying a fighter plane. Previously we showed that during sequential control the  
47 rostralateral prefrontal cortex (RLPFC) exhibits activation that ramps steadily through the  
48 sequence and is necessary for sequential task execution using fMRI in humans (Desrochers et al.,  
49 2015). It remains unknown what computations may underlie this ramping dynamic. Across two  
50 independent fMRI experiments, we manipulated three features that were unique to the sequential  
51 control task to determine if and how they modulated ramping activity in the RLPFC: 1) sequence  
52 position uncertainty, 2) sequential monitoring without external position cues (i.e. from memory),  
53 and 3) sequential monitoring without multi-level decision making (i.e. task execution). We  
54 replicated the ramping activation in RLPFC and found it to be remarkably robust, regardless of  
55 the level of task abstraction or engagement of memory functions. Therefore, these results both  
56 replicate and extend previous findings regarding the function of the RLPFC. They suggest that  
57 sequential control processes are integral to the dynamics of RLPFC activity. Advancing  
58 knowledge of the neural bases of sequential control is crucial for our understanding of the  
59 sequential processes that are necessary for daily living.

60

61 **Significance Statement**

62 We perform sequences of tasks every day, but little is known about how they are controlled in  
63 the brain. Previously we found that ramping activity in the rostrolateral prefrontal cortex  
64 (RLPFC) was necessary to perform a sequence of tasks. We designed two independent fMRI  
65 experiments in human participants to determine which features of the previous sequential task  
66 potentially engaged ramping in the RLPFC. We found that any demand to monitor a sequence of  
67 state transitions consistently elicited ramping in the RLPFC, regardless of the level of the  
68 decisions made at each step in the sequence or engagement of memory functions. These results  
69 provide a framework for understanding RLPFC function during sequential control, and  
70 consequently, daily life.

71

72 **Introduction**

73       Whether it's making your morning cup of coffee or cooking a complex ten-course meal,  
 74 sequential tasks are common in our daily lives. Such sequences require not only maintaining the  
 75 end goal (make coffee), but also monitoring and performing multiple subgoals (e.g., grind beans,  
 76 pour water). The rostrolateral prefrontal cortex (RLPFC), also referred to as (lateral) frontal polar  
 77 cortex (Brodmann Area 10) or anterior prefrontal cortex (aPFC), has been implicated in many  
 78 tasks that share processing demands with sequential control tasks. The functions implicated in  
 79 these non-sequential tasks include managing abstract contexts (Badre and D'Esposito, 2007);  
 80 cognitive tracking of multiple items or "branching" (Koechlin et al., 1999; Chahine et al., 2015);  
 81 integration of multiple information sources (Nee et al., 2014); and temporal abstraction  
 82 (Bahlmann et al., 2015b; Nee and D'Esposito, 2016). Though these tasks were not explicitly  
 83 sequential, these functional observations led to the general hypothesis that RLPFC might be  
 84 necessary for sequential cognitive control.

85       Desrochers et al. (2015) tested this hypothesis directly in a sequential task. When  
 86 participants were asked to repeatedly perform four-item sequences of simple tasks (e.g. color,  
 87 shape, shape, color), fMRI activation in the RLPFC increased progressively ("ramped") from the  
 88 first to last item in the sequence. Further, two, separate transcranial magnetic stimulation (TMS)  
 89 experiments using the same task showed that stimulating the RLPFC, and not other frontal  
 90 control regions, produced an increasing number of errors as the sequence progressed, mirroring  
 91 the observed ramping activation. These results showed that RLPFC is necessary for intact  
 92 performance of a sequential control task, particularly near the terminal boundary of a sequence.

As ramping in RLPFC had not been previously observed in non-sequential tasks, a key open question concerns what aspect of this sequential control task drove the ramping activity dynamic in RLPFC. Understanding the conditions needed for this dynamic can provide insight into the functioning of the RLPFC. The Desrochers et al. (2015) task included at least four unique features relative to prior non-sequential tasks. First and foremost, the task was sequential. There was a series of transitions through task “states” that had a defined beginning, end, and directed order throughout. Second, there were no task or positional cues beyond the initial instruction screen. As a consequence, the current sequence position had to be monitored internally in order to perform the task sequence correctly. Third, also following from the absence of external cues, uncertainty regarding current sequence position could grow as one progressed through the sequence to be maximal at the end of the sequence. Finally, the task required managing at least two levels of context-dependent decisions simultaneously: both the task-level choice (i.e., color or shape task) and the stimulus-level categorization.

We hypothesized that only the sequential demands of the task were critical for the ramping dynamic observed in RLPFC. We therefore designed experiments to manipulate the other unique elements of the Desrochers et al. (2015) task and observe whether doing so modulated the ramping dynamic in RLPFC. Specifically, across two separate human fMRI experiments involving a sequential task, we manipulated uncertainty, the levels of context required, and the availability of external cues to sequence position. In the first experiment, we tested whether providing clues to the position within the sequence would manipulate positional uncertainty and so break the potential correlation between increasing uncertainty through the sequence and sequence position. In the second experiment, we removed the two-level decision

115 and only required monitoring of the sequence. Further, we manipulated whether the sequence  
 116 must be monitored from memory to engage ramping in the RLPFC.

117 Across these experiments, we replicated the ramping pattern in RLPFC in each sequential  
 118 task. Importantly, however, we provide novel evidence that ramping in the RLPFC was robust to  
 119 all the manipulations that we tested, as long as a demand was in place to monitor a sequence of  
 120 state changes. These results further our understanding of the functional role of RLPFC in  
 121 sequential tasks, and consequently, daily human behaviors.

122

## 123 **Materials and Methods**

### 124 **Experimental Design and Statistical Analysis**

125 A total of 27 people participated in Experiment 1. One participant was excluded from  
 126 analyses because of excessive movement (>3 mm, multiple times within individual runs) in the  
 127 scanner resulting in 26 (19 female) right-handed adults (ages 19-30, mean 22) being included in  
 128 final analyses for Experiment 1. A total of 50 right-handed adults initially participated in  
 129 Experiment 2. Prior to analysis, ten participants were excluded: two participants were excluded  
 130 for excessive movement in the scanner (>3 mm, multiple times within individual runs), two  
 131 participants were excluded for sleeping (one completed zero runs of the task, the other completed  
 132 only two runs with >90% error rate), and the remaining six participants were excluded due to the  
 133 lack of data available to produce reliable estimates of brain activation and/or > 30% error rate on  
 134 the task. Error rate and available data for analysis are related because only correct blocks were  
 135 analyzed. The criteria for lack of data were as follows. Runs were only included for analysis if  
 136 they contained more than two complete, correctly-monitored 4-item sequences for each condition  
 137 (>8 trials). If this criterion resulted in the exclusion of a single run for a participant, then that

138 participant was included (3 participants with single runs excluded). If, however, this criterion  
 139 resulted in more than one run being excluded, then the participant was excluded from analysis.  
 140 The remaining 40 (25 female) right-handed adults (ages 18-29, mean 21) were included in all  
 141 analyses for Experiment 2. All participants were screened for central nervous system affecting  
 142 drugs or conditions, contraindications for MRI, and had normal or corrected-to-normal vision.  
 143 All behavioral testing and scanning was conducted according to procedures approved by the  
 144 Human Research Protections Office of Brown University. All participants gave informed,  
 145 written consent and were compensated for their participation.

146 Statistical design for the behavioral analyses and fMRI analyses can be found for each  
 147 experiment under the appropriate subheading below.

148

## 149 **Experiment 1**

### 150 *Exp. 1: Behavioral Procedure*

151 The core behavioral task, timing, and block structure remain the same as in (Desrochers  
 152 et al., 2015), briefly summarized here. Experiment control scripts were programed using the  
 153 Psychophysics Toolbox (RRID:SCR\_002881) in Matlab (Mathworks, RRID:SCR\_001622) and  
 154 were displayed using an Apple computer running Mac OSX. On each trial, participants classified  
 155 a simple shape according to either its color or shape by pressing one of four response buttons  
 156 (MR compatible four-button response pad, Mag Design and Engineering, RRID:SCR\_009600)  
 157 within 4s. The buttons corresponded to “Red”, “Blue”, “Circle”, or “Square” and their specific  
 158 assignment (i.e. which finger pressed each response) was counterbalanced across participants.  
 159 After the participant responded, the fixation cross was shown and the jittered intertrial interval  
 160 (ITI) began (0.25-8s, mean 2s).

161 Participants repeatedly performed four-item sequences of color and shape judgments for  
 162 each block of 24-27 trials. The sequence was displayed (4s) at the beginning of each block (e.g.  
 163 the words color, color, shape, shape). As in Desrochers et al. (2015), participants performed two  
 164 kinds of sequences: simple and complex. Simple sequences contained only one internal task  
 165 switch (e.g. color, color, shape, shape), whereas complex sequences contained two internal task  
 166 switches (e.g. color, shape, shape, color). Importantly, the overall number of switches and  
 167 repeats were balanced between blocks of simple and complex sequences because the first  
 168 position in a simple sequence was also a task switch when the sequence was repeated. Each  
 169 block could terminate on any of the four positions in the sequences, and participants were asked  
 170 to report which position in the sequence they would next perform to encourage them to perform  
 171 the judgments as a sequence. Each of the six total runs consisted of four blocks: two simple and  
 172 two complex with the order of color and shape judgments within each sequence counterbalanced.

173 The key difference between the Desrochers et al. (2015) task and Experiment 1 was the  
 174 addition of “clue” trials that provided additional information to participants and thus potentially  
 175 manipulated the uncertainty about sequence position. Clue trials disambiguated which judgment  
 176 (shape or color) should be performed by presenting a stimulus where one of the judgments would  
 177 require an answer that was not available. For example, if a green square was presented then  
 178 participants should indicate the shape of the stimulus, as “green” was not an available response.  
 179 Green and triangle were used as clues in the color and shape dimension, respectively.

180 Clue trials comprised approximately 25% of the trials within a block. The first four trials  
 181 (first sequence iteration) in a block were always excluded from analysis and therefore they never  
 182 contained clues. The variable 0-3 additional trials at the end of the block also never contained  
 183 clues. Therefore, out of the minimum 20 trials that were used in analysis for each block,

184 approximately six trials were clue trials. Clue trials were randomly distributed across positions 2-  
 185 4 in each sequence; the first position in each sequence was never a clue trial because we assume  
 186 that the first position is defined by the participant, and so is not subject to uncertainty about  
 187 sequence position (see Desrochers et al., 2015 for discussion).

188 We took a hidden Markov model approach to predict the uncertainty about the position in  
 189 the sequence for a subject's particular series of clue and no clue trials. Specifically, we assumed  
 190 that participants were tracking the latent variable "order", which corresponds to sequence  
 191 position and conditioned an inference about the current task. The inferred current task then itself  
 192 constrained the chosen action (conditioned on the observed stimulus). We specify this graphical  
 193 model here:

194 Let  $O_t$  in  $\{1:4\}$  be the latent random variable describing the trial order at  $t$ . We assume  
 195 that participants track uncertainty about the current trial  $t$  order according to:

$$196 \quad P(O_{t+1} = i) = \sum_{j=1:4} P(O_{t+1} = i | O_t = j) P(O_t = j)$$

197  $P(O_{t+1} = i | O_t = j) = Tr_{ij}$  defines a transition matrix describing the process by which  
 198 participants keep track of position/order. We assume that in the absence of a clue at trial  $t+1$ ,  
 199 participants are equally likely to accidentally skip or repeat a count in their tracking of order, as  
 200 captured by parameter  $\tau$ , but that there is also a small likelihood  $\varepsilon$  that they will transition to any  
 201 of the three possible wrong orders. This is formalized by transition matrix

$$202 \quad Tr = Noise \times Count = \begin{pmatrix} 1-\varepsilon & \varepsilon/3 & \varepsilon/3 & \varepsilon/3 \\ \varepsilon/3 & 1-\varepsilon & \varepsilon/3 & \varepsilon/3 \\ \varepsilon/3 & \varepsilon/3 & 1-\varepsilon & \varepsilon/3 \\ \varepsilon/3 & \varepsilon/3 & \varepsilon/3 & 1-\varepsilon \end{pmatrix} \times \begin{pmatrix} \tau/2 & 1-\tau & \tau/2 & 0 \\ 0 & \tau/2 & 1-\tau & \tau/2 \\ \tau/2 & 0 & \tau/2 & 1-\tau \\ 1-\tau & \tau/2 & 0 & \tau/2 \end{pmatrix}.$$

203 In the presence of a clue, we assume that the transition probability matrix *Count*'s values are  
 204 collapsed to 0 for order values  $O_{t+1}$  that do not respect the current cue, and that *Count* is

205 accordingly renormalized. This is mathematically equivalent to inferring through Bayes rule that  
 206 some order values are impossible conditioned on observing a cue.

207 Next, we assume that participants' choice at time  $t$  is conditioned on their inferred order  
 208  $O_t$  and stimulus  $s_t$ , and is  $\eta$ -greedy, with a bias  $b$  for within task errors, specifically:

$$\begin{aligned}
 209 \quad P(a_t=i|s_t, O_t) &= 1 - \eta && \text{if } i \text{ is the correct action for the task specified by } O_t \text{ and } s_t \\
 210 &= \eta \times b && \text{if } i \text{ is the other correct action for the task specified by } O_t \\
 211 &= \eta \times (1-b)/2 && \text{for other actions } i
 \end{aligned}$$

212 This graphical model captures our assumptions of how participants track position order to make  
 213 choices, and their uncertainty about the current position. It allows us to infer participants'  
 214 uncertainty from their behavior (see Behavioral Analysis).

215 Finally, to optimize the design for fMRI, multiple clue trial distributions were generated  
 216 for a block and then the correlation between position and a measure of position uncertainty was  
 217 calculated for each potential clue trial distribution. Uncertainty was operationalized as the  
 218 entropy over the current position's probability. Clue trial distributions where the trial-by-trial  
 219 uncertainty values were least correlated with position itself were chosen for inclusion in the  
 220 scanning experiment.

221

## 222 *Exp. 1: Behavioral Analysis*

223 As in Desrochers et al. (2015), the following trials were excluded from analysis: the first  
 224 four trials of every block (96 trials per participant), trials with reaction times  $< 100$  ms (zero  
 225 trials across all participants), and trials where the participant had "lost" their place in the  
 226 sequence ( $\geq 2$  trials incorrect in a 4-trial moving window, terminated with 4 correct trials; mean  
 227 1.7% of trials per participant). Reaction time (RT) analyses excluded error trials. Analyses were

228 collapsed across variants within a sequence type (e.g. color, color, shape, shape; and shape,  
 229 shape, color, color for simple sequences). For some error rate analyses differences in baseline  
 230 chance levels between clue (50% chance) and no clue (25% chance) were accounted for by  
 231 dividing error rates by two and four, respectively. Repeated measures analysis of variance (RM-  
 232 ANOVA) and paired t-tests were used to assess differences where applicable.

233 We used computational modeling to infer from subjects' trial-by-trial choices their  
 234 uncertainty about the task sequence (**Figure 1d-g**). For these analyses we used all trials, and did  
 235 not exclude trials due to error, RT, or being "lost". To fit the model to the data, we used the  
 236 Viterbi algorithm (Viterbi, 1967) to identify the most likely sequence of latent orders for a given  
 237 block, conditioned on parameters. We used this sequence to compute the log likelihood of the  
 238 observed sequence of choices. We then used standard model fitting techniques to identify  
 239 parameters that explained the participants' choices best: specifically, we used Matlab's fmincon  
 240 procedure to optimize parameters ( $\tau, \epsilon, \eta$  and  $b$ ) under constraints in  $[0, 1]^4$ . Fit parameter values  
 241 supported the behavioral results that participants performed well in the task: all noise parameters  
 242 were very low, with mean  $\tau=0.003$  (range  $[0\ 0.01]$ ),  $\epsilon=0.001$  ( $[0\ 0.02]$ ),  $\eta=0.01$  ( $[0\ .06]$ ); and the  
 243 bias parameter favored order knowledge ( $b=.7, [0\ 1]$ ). The model captured the data well:  
 244 Average likelihood per trial was .85 (std .09, range  $[\ .52\ -\ .99]$ ). The fit parameters and path  
 245 inferred by Viterbi algorithm over orders ( $O_t$ ) were used to compute the sequence of  $P(O_t), t=1:T$   
 246 for each block. At each trial, we extracted the entropy of the probability over the possible orders.

247

#### 248 *Exp. 1: fMRI Procedure*

249 A Siemens 3T Trio Tim MRI system with a 32-channel head coil was used for whole-  
 250 brain imaging. Anatomical scans consisted of a T1-MPRAGE (repetition time, TR, 2200 ms;

251 echo time, TE, 1.54, 3.36, 5.18, 7.01 ms; flip angle, 7°; 144 sagittal slices;  $1.2 \times 1.2 \times 1.2$  mm)  
 252 and a T1 in-plane (TR, 350 ms; TE 2.5 ms; flip angle, 70°; 38 interleaved transversal slices;  $1.5$   
 253  $\times 1.5 \times 3$  mm). Functional images were acquired using a fat-saturated gradient-echo echo-planar  
 254 sequence (TR, 2 s; TE, 28 ms; flip angle, 90°; 38 interleaved axial slices;  $3 \times 3 \times 3$  mm). A mean  
 255 of 209 functional scans were acquired per run.

### 257 *Exp. 1: fMRI Data Analysis*

258 As stated previously, one participant was excluded from analysis because of excessive  
 259 movement (>3 mm, multiple times within individual runs) in the scanner. Analyses were  
 260 performed using SPM 12 (<http://www.fil.ion.ucl.ac.uk/spm>, RRID:SCR\_007037). Data were  
 261 slice time and motion corrected, normalized to Montreal Neurological Institute (MNI) stereotaxic  
 262 space, and smoothed (8mm isotropic Gaussian kernel).

263 Within-subject statistical models were constructed under the assumptions of the general  
 264 linear model (GLM). For all models, regressors were generated by convolving with the canonical  
 265 hemodynamic response function (HRF) and included the temporal derivative. The following  
 266 were included as nuisance regressors for all participants in all models: first four trials in a block,  
 267 error trials, “lost” trials (see Behavioral Analysis section), the six motion parameters (translation  
 268 and rotation), linear drift over the course of each run, block instructions, and sequence position  
 269 questions.

270 Regressors were estimated using a subject-specific fixed-effects model. Whole brain  
 271 estimates of subject-specific effects were entered into second-level analyses that treated subject  
 272 as a random effect. One-sample t-tests (contrast value vs. zero,  $p < 0.001$ ) were used to assess  
 273 significance. These effects were corrected for multiple comparisons when examining whole brain

274 group voxel-wise effects using extent thresholds at the cluster level to yield family-wise error  
 275 (FWE) correction ( $p < 0.05$ ). Group contrasts were rendered on an inflated MNI canonical brain  
 276 using Caret (Van Essen et al., 2001; RRID:SCR\_006260).

277 Six GLMs were applied to the data as follows:

278 Onsets Model: To assess the univariate effects of clue trials, we constructed a model using  
 279 instantaneous stimulus onset regressors based on the crossing of sequence type (simple/complex)  
 280 x sequence position (1-4) x clue (clue/no clue).

281 Parametric Sequence Position Ramp Model: This model tests for ramping activation that  
 282 increased with sequence position as in Desrochers et al. (2015). Onset regressors were  
 283 constructed by crossing sequence type (simple/complex) x clue (clue/no clue). A parametric  
 284 regressor of sequence position (1-4) was added as a modulator of trial onsets for all positions (i.e.  
 285 separate regressors were not constructed for each position as in the Onsets Model above). The  
 286 temporal derivatives of the parametric regressors were also included in the model. Parametric  
 287 regressors are implemented hierarchically in the GLM; therefore, variance explained by the  
 288 parametric regressors is above and beyond what can be explained by the onsets alone. Note that  
 289 clue trials did not exist at position 1, therefore the parametric sequence position values would  
 290 only be 2, 3, or 4 for clue trials.

291 Parametric Increasing and Decreasing Sequence Position Ramp Model: This model is to provide  
 292 a contrast for the solo increasing parametric modulator. The model was constructed the same as  
 293 the Parametric Sequence Position Ramp Model, with the addition of a second parametric  
 294 regressor that decreased as the four positions in the sequence increased (4, 3, 2, 1). We did not  
 295 orthogonalize the increasing and decreasing parametric regressors to allow them to compete for  
 296 variance.

297 Parametric Sequence Position Ramp Model excluding Position 1: This model was used as a  
 298 control. It was constructed the same as the Parametric Sequence Position Ramp Model above,  
 299 but with position 1 only modeled as an onset (without a parametric) for both clue and no clue  
 300 trials.

301 Sustain vs. Unique Ramp Model: To directly assess whether variance could be better accounted  
 302 for by sustained or ramping activation, we constructed a pair of models to allow Sustain and  
 303 Ramp regressors to compete for variance within the same model. These models contained  
 304 Sustain and Ramp regressors (separated for each sequence type and clue presence) in addition to  
 305 a single regressor for the stimulus onsets at all positions. These regressors started at the stimulus  
 306 onset of each sequence position 1 and ended at the stimulus offset (response) of sequence  
 307 position 4. As the Sustain and Ramp functions share variance, we sought to identify what  
 308 variance was uniquely explained by each function. This first of the pair of models sought to  
 309 determine the variance uniquely explained by the Ramp regressor. We orthogonalized  
 310 (spm\_orth.m) the Sustain and Ramp regressors within each sequence type to remove the shared  
 311 variance from the Ramp regressors (and assign it to the Sustain regressors).

312 Unique Sustain vs. Ramp Model: This second model of the pair sought to identify any variance  
 313 uniquely explained by the Sustain regressor (independent of Ramp). Specifically, we removed  
 314 the shared variance from the Sustain regressor (and assigned it to the Ramp regressor). All other  
 315 aspects of the model were the same as the Sustain vs. Unique Ramp model above.

316 Parametric Task Entropy Model: This model tests for variance that can be explained by  
 317 uncertainty, operationalized as entropy obtained from the hidden Markov model. As in the  
 318 Parametric Sequence Position Ramp Model, onset regressors were constructed by crossing

319 sequence type (simple/complex) x clue (clue/no clue). Entropy values from the behavioral model  
 320 fits were added parametrically as a modulator of trial onsets for all positions.

321 Regions of interest (ROIs) were constructed from clusters of activation in the Parametric  
 322 Ramp > Baseline contrast in Desrochers et al. (2015) and from clusters of activation in the same  
 323 contrast in the present study. The ROI defined by the cluster of activation in the RLPFC for the  
 324 Parametric Ramp > Baseline contrast in Desrochers et al. (2015) will be referred to as the “D15”  
 325 ROI (center of mass xyz = -28, 56, 4; volume 1,432 mm<sup>3</sup>; max/min x = -38/-18, y = 46/62, z = -  
 326 10/18). The RLPFC cluster in the Parametric Ramp > Baseline contrast, defined across  
 327 conditions and irrespective of the sequence type and whether or not the trial contained a clue, in  
 328 the Parametric Sequence Position Ramp Model for Experiment 1 will be referred to as the  
 329 “Clue” ROI (center of mass xyz = -29, 50, 21; volume 2,160 mm<sup>3</sup>; max/min x = -34/-24, y =  
 330 38/60, z = 12/30). To compare ramping activation across models and regions, the mean beta  
 331 values for the parametric ramp regressor across all voxels in the ROI (taken using MarsBar SPM  
 332 toolbox, RRID:SCR\_009605) were compared using RM-ANOVA or paired t-tests where  
 333 appropriate. The time course of activity across positions was extracted using an 8-time point  
 334 (16s) finite impulse response (FIR) model (MarsBar, RRID:SCR\_009605) that contained the  
 335 same regressors as the Onset Model.

336

## 337 **Experiment 2**

### 338 *Exp. 2: Behavioral Procedure*

339 For the sequence monitoring task in Experiment 2, participants had to monitor a repeated  
 340 series of four stimuli (based on Allen et al., 2014). On each trial, an image was presented for 1s.  
 341 The participant released the response button if the item was out of sequence (OutSeq), otherwise

342 the item was considered in sequence (InSeq) and the response button was continuously held.

343 Stimuli were serially presented in blocks that were further divided into mini-blocks.

344 Each mini-block was as follows. A solid color screen was presented at the beginning of  
 345 the block as a “get ready” signal when the participant had to start holding the response button to  
 346 progress (minimum 0.5s). The participants continued to hold the response button during the  
 347 instruction period, during which the four items to be monitored were sequentially presented  
 348 (0.75s each) in the correct order. The identity of the stimuli that followed the instruction stimuli  
 349 differed according to sequence type: visible or occluded. For the visible sequence type, all the  
 350 stimuli that followed were members of the original instruction stimuli. During occluded trials, a  
 351 single placeholder image that was constant throughout the entire experiment was presented in  
 352 place of items from the sequence. Participants had to monitor the sequence as if the instructed  
 353 stimuli were still occurring, but were “hidden” by the placeholder image.

354 After each stimulus presentation, a fixation cross was shown during the jittered intertrial  
 355 interval (0.25-8s, mean 2s). Visible mini-blocks terminated with an OutSeq item that was a  
 356 member of the instruction set, presented at the incorrect position (e.g. stimulus instructed at  
 357 position 1 was shown at position 3). Occluded mini-blocks ended with the presentation of an  
 358 instruction set stimulus (rather than the occluder image) that was either InSeq (participant had to  
 359 hold) or OutSeq (release) with a 50% probability. A large check (correct) or “X” (error) was  
 360 shown (0.5s) as feedback after the last stimulus. Each mini-block could end with equal  
 361 probability on any of the four positions in the sequence. If the participant released the button  
 362 incorrectly to an InSeq item prematurely, the mini-block would proceed immediately to feedback  
 363 and the rest of the stimuli in the mini-block would not be displayed.

364           Blocks contained one of each of three possible mini-block lengths: 8, 12, or 16 minimum  
 365 trials in counterbalanced order. The first mini-block of each block had a red get ready screen to  
 366 signal that the four instruction stimuli would follow and that the sequence could be different  
 367 from the previous block. Subsequent mini-blocks within the block (mini-blocks 2 and 3) had a  
 368 green get ready screen to indicate the participant should continue to monitor for the same  
 369 sequence that was instructed at the beginning of the block (during the first mini-block), but start  
 370 again with the first item.

371           Four blocks made up a single run. Each block (and its component mini-blocks) was a  
 372 single sequence type. Each participant performed two different sequences during the experiment.  
 373 Each run contained sequence 1 visible and occluded, and sequence 2 visible and occluded with  
 374 the order of blocks counterbalanced across run. The 9 stimuli that composed the two sequences  
 375 and the occluder image were drawn randomly from a pool of 109 everyday objects for each  
 376 participant. Prior to scanning, participants were trained on the sequence monitoring task using  
 377 example letter stimuli and then were exposed to example blocks of both sequence types using the  
 378 same stimuli they would subsequently see in the scanner. Some participants received additional  
 379 practice while lying in the scanner but prior to scanning acquisition to become accustomed to the  
 380 response buttons. Participants were asked to complete six total runs.

381

## 382 *Exp. 2: Behavioral Analysis*

383           When participants performed the sequence monitoring task in Experiment 2, we  
 384 determined that there were at least two sources of error that were not due to a failure of the  
 385 participants to monitor the sequence. To avoid unnecessary data loss, we accounted for these  
 386 errors in the following two ways.

387 Because participants were nearly continuously holding a sensitive button, occasionally a  
 388 slight shift of the participant's pressure on the button or mechanical oscillation between the  
 389 "pressed" and "released" state would mistakenly trigger the detection of a release. Participants  
 390 also often indicated that they did not release the button in these instances by verbal report at the  
 391 next break. These mistakes also happened at times when a release was highly unlikely and the  
 392 button state had just changed, i.e. in the first four stimulus presentations of the mini-block after  
 393 the get ready screen or instruction stimuli. The out of sequence item was never present those first  
 394 four items. We therefore identified releases that occurred in the first four stimulus presentations  
 395 of each mini-block and coded those mini-blocks as "button errors" (mean 0.7% total trials or  
 396 5.4% mini-blocks across participants). Button error mini-blocks were excluded from all  
 397 subsequent analyses.

398 A second source of error was that participants' release reaction times shifted to be  
 399 slightly slower in the scanner than in pre-scanning piloting or training. This resulted in the  
 400 slower tail of the distribution of correct release reaction times to be cut off by the 1 s response  
 401 deadline. We therefore "re-coded" these mini-blocks (mean 6.5% across participants) as correct  
 402 (mean re-coded RT = 1.176 s) and included them in all subsequent analyses as correct mini-  
 403 blocks.

404 After excluding button error mini-blocks and including re-coded trials, as described  
 405 previously, runs were only included for analysis if there were greater than two 4-item sequences  
 406 (>8 trials) of each condition (visible/occluded block type crossed with sequence position, 3  
 407 participants with one run excluded). If this criterion resulted in the elimination of more than one  
 408 run or a participant's overall error rate based on correct mini-block performance was greater than  
 409 30%, then they were excluded from further analyses (6 participants excluded).

410 Behavior on the mini-block level was a limited description of the behavior (but necessary  
 411 because the only “response” was the release at the end of each mini-block), as there were  
 412 relatively few mini-blocks (72 per participant) in comparison to the total number of stimulus  
 413 presentations (1,044 possible per participant). We therefore categorized trials according to the  
 414 detection of an OutSeq item. The four detection types were as follows.

415 Hit: A release in response to an OutSeq item. These items are considered correct.

416 Correct Rejection: A hold in response to an InSeq item. All successful holds during visible mini-  
 417 blocks prior to the OutSeq item were classified as correct rejections. Conversely, in occluded  
 418 mini-blocks, trials where the occluder image was displayed were not counted as correct  
 419 rejections because the stimulus was not one of the items in the sequence and could be  
 420 unambiguously identified as irrelevant. These items were also considered correct.

421 Miss: A hold in response to an OutSeq item. These items are considered errors.

422 False Alarm: A release in response to an InSeq item. These items are considered errors.

423 Using these trial types, the sensitivity index was calculated as follows:

$$424 \quad d' = Z(\text{hit rate}) - Z(\text{false alarm rate})$$

425 where  $Z(p)$ ,  $p \in [0,1]$ , is the inverse of the normal cumulative distribution function (Macmillan  
 426 and Creelman, 2004). To prevent an infinite  $d'$ , extreme rates of zero or one were converted to  
 427  $1/(2N)$  and  $1-1/(2N)$ , respectively, where  $N$  is the number of trials on which the rate is based  
 428 (Macmillan and Creelman, 2004).

429

#### 430 *Exp. 2: fMRI Procedure*

431 Experiment 2 was scanned at the same facility as Experiment 1, but after the scanner was  
 432 upgraded to a Siemens 3T PRISMA system, with a 64-channel head coil. Anatomical scans

433 consisted of a T1-MPRAGE (TR, 1900 ms; TE, 3.02 ms; flip angle, 9°; 160 sagittal slices;  $1 \times 1$   
 434  $\times 1$  mm) and a T1 in-plane that was the same as in Experiment 1 (TR, 350 ms; TE 2.5 ms; flip  
 435 angle, 70°; 38 interleaved transversal slices;  $1.5 \times 1.5 \times 3$  mm). Functional images were acquired  
 436 using the same fat-saturated gradient-echo echo-planar sequence as in Experiment 1 (TR, 2 s;  
 437 TE, 28 ms; flip angle, 90°; 38 interleaved axial slices;  $3 \times 3 \times 3$  mm). A mean of 313 functional  
 438 scans were acquired per run.

439

#### 440 *Exp. 2: fMRI Data Analysis*

441 As stated previously, two participants were excluded from analysis because of excessive  
 442 ( $> 3$  mm) movement in the scanner. Preprocessing and general model construction was the same  
 443 for Experiment 2 as in Experiment 1. All analyses were performed in SPM 12  
 444 (RRID:SCR\_007037). If any trial in the mini-block was incorrect (release to an InSeq item or  
 445 failure to release to an OutSeq item), then the entire mini-block was coded as an error because it  
 446 was unknown if the participant was correctly monitoring the sequence. For the purposes of these  
 447 models, all the trials within mini-blocks classified as “button-error” were also coded as error  
 448 trials (see Exp. 2: Behavioral Analysis).

449 The same Parametric Sequence Position Ramp Model was constructed as in Experiment 1  
 450 to explicitly test for ramping activation over sequence position, with separate onset regressors for  
 451 visible and occluded trials that the parametric for sequence position (1-4) was added to. The  
 452 companion control Parametric Increasing and Decreasing Sequence Position Ramp Model was  
 453 also formed. An Onsets Model was constructed that separated the four positions in the sequence  
 454 and visible and occluded trials. Similarly, the same pair of models to test whether variance could  
 455 be better accounted for by sustained or ramping activation, Sustain vs. Unique Ramp model and

456 Unique Sustain vs. Ramp model, were constructed with separate Ramp and Sustain regressors  
 457 for visible and occluded trial types. Regions of interest (ROI) were constructed from clusters of  
 458 activation in the Parametric Ramp > Baseline contrast as in Experiment 1. The RLPFC cluster in  
 459 the Parametric Ramp > Baseline contrast in the Parametric Sequence Position Ramp Model for  
 460 Experiment 2 will be referred to as the “Monitoring” ROI (center of mass xyz = -32, 42, 27;  
 461 volume 6,568 mm; max/min x = -40/-20, y = 26/62, z = 12/46). The time course of activity  
 462 across positions was extracted using an 8-time point (16s) finite impulse response (FIR) model  
 463 (MarsBar, RRID:SCR\_009605) that contained the same regressors as the Onset Model.

464       We completed an initial analysis of the fMRI data after acquiring 30 participants.  
 465 Specifically, we originally hypothesized that there would be a difference in parametric ramping  
 466 activation betas in the RLPFC between the visible and occluded sequence types. With the 30-  
 467 participant sample, we found a marginal, but not statistically significant effect of sequence type.  
 468 To determine if collecting further participants would yield sufficient power to observe this effect,  
 469 we selected ten participants at random (due to the lack of an independent pilot data set on this  
 470 task) and calculated that with 80% power, 39 participants would be necessary to observe a  
 471 difference between visible and occluded ramping betas in the RLPFC. We therefore collected 10  
 472 more participants, for a total of 40 participants included in Experiment 2. We intended to correct  
 473 for using a two-stage process by using a Bonferroni correction on the expected type I error rate,  
 474 i.e. dividing 0.05 by two total “peeks” for a type I error rate of 0.025 at the second stage.  
 475 However, subsequent simulations revealed that our total experienced chance of type I error  
 476 across the two stages was  $p = 0.0548$ . We emphasize that even though the experienced chance of  
 477 type I error was greater than originally planned, this fact did not fundamentally change any of

our inferences or conclusions about the data. We included our full methods here in the interest of scientific rigor and transparency.

## **Results**

### **Experiment 1**

In the first experiment, we tested if manipulating uncertainty would modulate ramping activation in the RLPFC during sequential task performance. Previously, we hypothesized that an accumulation of uncertainty as sequences progress away from the initiation may be responsible for ramping dynamics observed in the RLPFC (Desrochers et al., 2015). However, uncertainty was not separable from sequence position in that initial set of experiments; both steadily increased through the sequence. We designed a task based on the previous sequential task to manipulate the amount of uncertainty that participants experienced at each position in the sequence by providing “clues” throughout their performance of a sequence of tasks (**Figure 1**). These clues were designed to explicitly decouple increases in sequence position from increases and decreases in uncertainty.

The behavioral results replicated those found previously (Schneider and Logan, 2006; Desrochers et al., 2015), with reaction times (RTs) providing evidence for sequence level control and that participants performed the sequences of tasks in four item sets as instructed. On trials that did not contain clues, RT at the first position in the sequence was slowed in comparison to the same trial type (switch or repeat) in the interior of the sequence (position 3), regardless of whether it was a switch or a repeat (simple sequence position 1 (switch) and position 3 (switch) vs. complex sequence position 1 (repeat) vs. position 3 (repeat),  $F(1,25) = 83.3$ ,  $p = 1.96 \times 10^{-9}$ , main effect of position in ANOVA, **Figure 2a**). Because this sequence initiation cost is over and

above costs expected from task switching/repeating alone, it can only be due to crossing the unsignalled sequence boundary between position 4 of the previous sequence, and position 1 of the next sequence. Consistent initiation costs were not observed in error rate on non-clue trials (sequence type x position 1 and 3,  $F(1,25) = 0.76$ ,  $p = 0.39$ , main effect of position in ANOVA, **Figure 2b**).

Clues did not have an effect on RT overall or by position (sequence type x clue x position 2-4,  $F(1,25) = 0.26$ ,  $p = 0.61$ , main effect of clue in ANOVA, **Figure 2a**). We did observe a decrease in error rate on clue trials, but this was expected because clues effectively eliminated the incorrect options (sequence type x clue x position 2-4,  $F(1,25) = 9.72$ ,  $p = 0.0045$ , main effect of clue in ANOVA, **Figure 2b**). When we normalized the error rate for baseline differences in chance in clue and no clue trials, we no longer observed a reliable difference between the trial types (sequence type x clue x position 2-4,  $F(1,25) = 0.47$ ,  $p = 0.5$ , main effect of clue in ANOVA, **Figure 2c**). In the normalized error rates, the effect of clue on error rate differed by sequence position ( $F(2,50) = 3.52$ ,  $p = 0.037$ , ANOVA), such that the reduction in error rate was greatest at position 3. This finding is possibly consistent with a greater benefit later in the sequence due to the resolution of increased uncertainty, but inconclusive due to a lack of a similar effect at position 4.

Given the changes in task from the original sequential task used in Desrochers et al. (2015), namely the addition of clue trials and a potential reduction in response conflict due to spreading out the possible responses over four buttons (instead of two), we next examined ramping activity in the RLPFC in this task. The following analyses also collapsed across Clue and No Clue conditions to focus on ramping dynamics that are common to both conditions and potentially more general to the sequential task as a whole. First, we conducted a whole-brain

voxelwise analysis that tested a parametric ramping function that reset at each position 1 and increased to position 4. This analysis yielded a network of regions including RLPFC, dorsal premotor cortex (PMd), supplementary motor area (SMA), and the precuneus (**Figure 3a, Table 1**), with the RLPFC and PMd clusters overlapping with those observed in Desrochers et al. (2015).

Next, to determine whether variance in RLPFC could be better accounted for by ramping or sustained activation, we constructed a pair of models that pitted ramp and sustain regressors against each other and examined the variance in MR signal from RLPFC that could uniquely be accounted for by each regressor, in turn (see Methods). In the ROI defined by the parametric ramping cluster in RLPFC from Desrochers et al. (2015) (center of mass xyz = -28, 56, 4), hereafter the “D15” ROI, we found that variance was better accounted for by ramping, over and above what could be accounted for by a sustained function ( $F(1,25) = 26.4$ ,  $p = 0.018$ , ANOVA). As an additional control, we found that variance was better accounted for by an increasing, rather than a decreasing parametric ramp function in the D15 ROI ( $F(1,25) = 11$ ,  $p = 0.003$ ). We therefore replicated ramping activity in the RLPFC during a sequential task, despite the occasional presentation of clues, in this sequential task.

Because clue trials do not exist at position 1, we also constructed a parametric ramping model that excluded the parametric at position 1 for both clue and no clue trials (position 1 was included as an onset regressor only). To determine if RLPFC ramping was consistent across the models, we examined the same D15 ROI. Ramping activation in the D15 ROI remained reliable in this parametric model that excluded position 1 (not shown,  $t(25) = 3.48$ ,  $p = 1.86 \times 10^{-3}$ , t-test) and did not differ between the two models ( $F(1,25) = 0.03$ ,  $p = 0.86$ , ANOVA).

547 Despite the lack of evidence for the effect of clues on RT, we observed differences in  
 548 activation across the caudal to mid-lateral fronto-parietal network, in clue compared to no clue  
 549 trials (**Figure 3b**). This provided evidence that clues were at least registered by the control  
 550 system as distinct from the more common no-clue trials.

551 Theoretically, clues reduced uncertainty and therefore the need for increased RLPFC  
 552 activation. To determine if there was an effect of clues on ramping activation in the RLPFC, we  
 553 compared the variance explained by parametric ramping (mean parametric betas in the GLM) in  
 554 the previously defined D15 ROI in clue and no clue trials. In this D15 ROI, there was significant  
 555 ramping activation in the clue task when collapsing across conditions ( $t(25) = 3.28$ ,  $p = 0.003$ ,  $t$ -  
 556 test vs. zero) and when considering them separately (clue trials:  $t(25) = 2.7$ ,  $p = 0.01$ ; no clue  
 557 trials:  $t(25) = 3.0$ ,  $p = 0.0066$ ;  $t$ -tests vs. zero). Further, there were no differences based on  
 558 sequence type ( $F(1,25) = 0.27$ ,  $p = 0.61$ , ANOVA) or the presence or absence of a clue ( $F(1,25)$   
 559  $= 2.63$ ,  $p = 0.12$ , ANOVA, **Figure 3c**). And, if anything, the trend is for more rather than less  
 560 activation on Clue trials (when uncertainty is reduced). These results were also illustrated by the  
 561 activity across the positions in the D15 ROI when modeling each position separately and  
 562 collapsing across sequence type (**Figure 3d**).

563 Because clue trials may appear at varied positions in the sequence, and position in the  
 564 sequence may influence uncertainty, the above analysis does not take into account potential  
 565 history or position effects in the activity observed in response to clues in the brain. We therefore  
 566 took a straightforward approach to accounting for potential positional effects in the uncertainty  
 567 signal by fitting participants' choices with a model that estimated the uncertainty at each position  
 568 in the sequence (see Methods). This model has the advantage of de-correlating uncertainty and  
 569 sequence position, as the clues would cause uncertainty decreases at the highest positions (e.g.

position 4), rather than uncertainty and position being at the highest point at the same position in the sequence, under the assumptions we make. However, modeling uncertainty this way (see Methods) did not yield any reliable correlations with activation in RLPFC or elsewhere in the brain. In a model that included a parametric regressor for uncertainty on individual position regressors, the parametric > baseline contrast did not yield any suprathreshold clusters ( $p < 0.001$  unc., data not shown). Further, beta values extracted from that contrast were not significantly different from zero in the D15 ROI ( $t(25) = -0.78$ ,  $p = 0.44$ , t-test). Thus, we do not find evidence to support the hypothesis that trial-to-trial uncertainty, as operationalized in this task, underlies ramping activation in the RLPFC. Rather, we again observe ramping activation during sequential task control in this region.

## Experiment 2

In Experiment 2, we assessed whether task (i.e., subgoal) performance at each step in the sequence was an essential task component to engage ramping in the RLPFC. We used a simplified task that eliminated the categorization decisions on each trial based on sequence position, and rather asked participants to simply monitor the sequential order of presented images either as presented (visible) or internally tracked (occluded) (adapted from Allen et al., 2014).

RT was assessed on trials when the participant released the button. Though here during a release rather than a press, we again found increased RTs at the first position in the sequence (sequence type x position 1 and 2-4,  $F(1,39) = 21.2$ ,  $p = 4.26 \times 10^{-5}$ , ANOVA, **Figure 5a**). There was no effect of sequence type (visible or occluded) on RT ( $F(1,39) = 0.84$ ,  $p = 0.36$ , ANOVA). There was again no evidence of increased ER at sequence initiation (sequence type x position 1 and 2-4,  $F(1,39) = 0.16$ ,  $p = 0.69$ , ANOVA, **Figure 5b**). However, there were significantly more

errors, regardless of sequence position, in occluded sequences ( $F(1,39) = 11.0$ ,  $p = 0.002$ , ANOVA).

To further examine the difference in error rate between occluded and visible sequence types, we analyzed trials according to the detection of an OutSeq item. We found that  $d'$  was greater for visible than occluded blocks ( $t(39) = -20.0$ ,  $p = 4.43 \times 10^{-22}$ , paired t-test, **Figure 5c**). This was primarily due to an increase in false alarms (release to an InSeq item) in occluded blocks ( $t(39) = 12.5$ ,  $p = 3.37 \times 10^{-15}$ , paired t-test, **Figure 5d**), as the hit rate did not differ between occluded and visible blocks ( $t(39) = -1.51$ ,  $p = 0.14$ , paired t-test, **Figure 5e**). Thus, even though the error rate was different between the sequence types, the participants were equally able to correctly release in response to an OutSeq item.

To determine if task execution was required to engage ramping in the RLPFC, we first performed a whole-brain voxelwise contrast of parametric ramping activity across both sequence types. Ramping activation was evident in the RLPFC and extended caudal and dorsally along the middle frontal gyrus (**Figure 6a, Table 2**). As in Experiment 1, to determine whether variance in RLPFC could be better accounted for by ramping or sustained activation, we constructed a pair of models that pitted ramp and sustain regressors against each other and examined the variance that could uniquely be accounted for by each regressor, in turn. In the D15 ROI from the Desrochers et al. (2015) study, we found that variance was better accounted for by ramping, over and above what could be accounted for by a sustained function ( $F(1,39) = 39.8$ ,  $p = 1.92 \times 10^{-7}$ , ANOVA). As an additional control, we found that variance was also better accounted for by an increasing, rather than a decreasing parametric ramp function in the D15 ROI ( $F(1,39) = 7.2$ ,  $p = 0.01$ ).

615 We next contrasted parametric ramping activity separately in the visible and occluded  
 616 sequence types. We found a greater number of areas, including the RLPFC, that survived  
 617 statistical correction in the occluded parametric ramp > baseline contrast (**Figure 6b**) than in the  
 618 visible parametric ramp > baseline contrast (**Figure 6c**). However, a direct contrast of parametric  
 619 ramping in the occluded over the visible sequence types yielded only one suprathreshold cluster  
 620 in the left superior parietal lobule (SPL, **Figure 6d**).

621 Follow up ROI analyses were consistent with the above results. We tested the beta values  
 622 associated with the parametric ramp regressors in this monitoring task in the D15 ROI.  
 623 Significant ramping betas in the monitoring task overall were evident in this ROI ( $t(39) = 2.54$ ,  $p$   
 624  $= 0.015$ , t-test). Further, though the ramping betas were quantitatively larger in the D15 ROI for  
 625 the occluded task, the difference between the visible and occluded conditions in this ROI did not  
 626 reach statistical significance ( $t(39) = 1.43$ ,  $p = 0.16$ , paired t-test, **Figure 6e**). We likewise  
 627 observed the same trend and lack of statistical significance between visible and occluded when  
 628 the ROI was defined directly on the overall parametric ramp contrast from Exp. 2 (“Monitoring”  
 629 ROI,  $t(39) = 1.35$ ,  $p = 0.18$ , paired t-test). Thus, these results cannot provide conclusive evidence  
 630 for or against the hypothesis that the occluded condition activated RLPFC more or showed  
 631 greater ramping than when the sequence was visible, and merit further experimentation.

632 Finally, there was limited evidence that the ramping activation in the visible task alone  
 633 may preferentially be located more caudally than in the Desrochers et al. (2015) task. Even  
 634 though when considering the visible and occluded tasks together the ramping betas in the D15  
 635 ROI were significant overall and not statistically different from each other in the two conditions,  
 636 as discussed above, in the visible task only, ramping betas in the D15 ROI were not significantly  
 637 different from zero ( $t(39) = 0.82$ ,  $p = 0.42$ , t-test, **Figure 6e** “Vis”). However, in the more caudal

Monitoring ROI the ramping betas for the visible task only were reliable ( $t(39) = 2.79$ ,  $p = 0.008$ ,  
 t-test), and there was a significant difference between the two ROIs ( $t(39) = 2.08$ ,  $p = 0.04$ ,  
 paired t-test). Further analyses regarding potential differences in ramping location will be  
 presented below. The ramping in the occluded condition and the relative non-ramping in the  
 visible condition in the D15 ROI were also illustrated by the activity across the positions when  
 modeling each position separately (**Figure 6f**). In summary, we again found ramping activation  
 in RLPFC over the course of a sequence that was robust across all conditions of the monitoring  
 task.

#### Comparisons Across Tasks

Including the previously published study by Desrochers et al. (2015), we have now  
 observed ramping activation in the RLPFC during sequential tasks across three independent data  
 sets (Total N=94). However, the plot of the parametric ramp > baseline contrast from all three  
 experiments reveals that though the networks are similar, the proximity/overlap of the ramping  
 activation clusters in the RLPFC shows some small differences in spatial locus (**Figure 7a**). For  
 example, there did appear to be a trend that clusters derived from sequential tasks that required  
 task execution were both more anterior in their location (**Figure 7b**) and showed greater ramping  
 activation when sequences required task execution.

To directly address whether these differences among the rostral frontal cortex clusters  
 reflect small cross-study differences in peaks across variable samples versus a meaningful  
 difference in activation patterns, we examined the ramping activation (betas associated with the  
 parametric ramp > baseline contrast) from three cluster-based ROIs defined in RLPFC from the

parametric ramp contrast from each study (**Figure 7b**; D15 center of mass xyz = -28, 56, 4; Clue center of mass xyz = -29, 50, 21; Monitoring center of mass xyz = -32, 42, 27).

We did not find conclusive evidence of overall differences in ramping activation among the three ROIs in any of the three tasks. Specifically, we did not have strong statistical evidence of a difference by ROI on ramping activation betas across the three clusters in the Desrochers et al. (2015) task sequences experiment ( $F(2,54) = 2.50$ ,  $p = 0.092$ , ANOVA, **Figure 7c**), Experiment 1 ( $F(2,50) = 2.23$ ,  $p = 0.118$ , ANOVA, **Figure 7d**), or Experiment 2 ( $F(2,78) = 3.04$ ,  $p = 0.054$ , ANOVA, **Figure 7e**). However, the differences among the ROIs are trending in the more abstract Desrochers et al. experiment to be greater in more anterior regions, and in the less abstract Experiment 2 are trending to be greater in more posterior regions. These trends may further support a rostral-to-caudal gradient observed in the locations of the clusters of ramping activation in the RLPFC (**Figure 7b**). When divided by condition, the only difference in ramping betas among the ROIs was between the D15 and Monitoring ROIs in the visible condition of Experiment 2, as noted in the previous section. Though we cannot conclusively rule out differences across conditions on the basis of these results, we do show consistent ramping activation in the RLPFC across all three datasets.

## **Discussion**

Across two separate experiments, we have replicated and extended the prior observation that ramping activation in the RLPFC accompanies sequential task performance. We provide novel evidence that three features of sequential task control need not be present in order to engage RLPFC: task-state uncertainty, multi-level decision making, and internal maintenance of context. Experiment 1 observed that RLPFC ramping is not affected by the appearance of less

683 frequent clue stimuli that could reduce uncertainty. Experiment 2 showed that RLPFC exhibits  
 684 ramping even during a simplified sequential monitoring task that does not require subtask  
 685 sequencing and performance within the sequence. Further, in this experiment, we found that  
 686 ramping in the RLPFC was engaged during sequential monitoring in the absence of external cues  
 687 (i.e. from memory). This remarkable consistency indicates that the ramping dynamic in RLPFC  
 688 observed in these experiments, and thus likely its functional role, is minimally tied to the  
 689 sequential nature of these tasks, specifically that they involve monitoring a predictable series of  
 690 state transitions toward a bound.

691 The necessity of RLPFC for sequential task control was established in previous combined  
 692 fMRI and TMS studies (Desrochers et al., 2015). However, several features of the task used in  
 693 this previous experiment distinguished it from other non-sequential studies and so could have  
 694 accounted for the novel ramping activation observed in RLPFC.

695 First, progress through a sequence might result in increased uncertainty under the  
 696 assumptions that (a) sequence starting position can be arbitrarily defined and so is not uncertain,  
 697 and (b) after initiation, there is a non-zero probability that one can transition from one task state  
 698 to another that is out of sequence (i.e., make a sequential error). Thus, progressively increasing  
 699 position uncertainty might necessitate an increasing contribution from RLPFC over the course of  
 700 the sequence to overcome uncertainty (Desrochers et al., 2015; see also White and Monosov,  
 701 2016).

702 In Experiment 1, we provided clue trials in order to break this confound between  
 703 sequence position and uncertainty. However, despite replicating ramping activation in the  
 704 RLPFC, we did not obtain evidence that activation in RLPFC was affected by a reduction in  
 705 uncertainty from these clue trials. Indeed, RLPFC became more rather than less activated when

706 clues were presented. We do note that, though the brain clearly responded to the less-frequent  
 707 clues, the reduced errors on clue trials provided only limited behavioral evidence that  
 708 participants used the clue information to reduce uncertainty. Thus, it is conceivable that we did  
 709 not manipulate uncertainty sufficiently to impact the ramping pattern. Nevertheless, we did not  
 710 find evidence that activation in RLPFC tracks trial-to-trial position uncertainty.

711 Experiment 2 tested a second unique feature of the sequential control task used by  
 712 Desrochers et al. (2015): multi-level decision making. Numerous studies have implicated RLPFC  
 713 in processes that are common to sequential control including representing high-level, abstract,  
 714 hierarchical information and integration (Badre and D'Esposito, 2007; Nee et al., 2014; Rahnev  
 715 et al., 2016), multiple courses of action (e.g., Koechlin et al., 1999; Braver and Bongiolatti, 2002;  
 716 Badre et al., 2012), integration of verbal and spatial working memory (Chahine et al., 2015), and  
 717 temporal control (Nee and D'Esposito, 2016). However, the TMS result from Desrochers et al.  
 718 (2015) is inconsistent with the idea that RLPFC plays a role in trial-to-trial episodic or temporal  
 719 control throughout the sequence. These demands are constant throughout the sequence, whereas  
 720 RLPFC was more necessary near the terminal sequence bound.

721 Experiment 2 extended this observation by testing two specific proposals regarding  
 722 RLPFC. First, prior cognitive control research has highlighted RLPFC as potentially important  
 723 during tasks that require higher order decisions, either with greater relational integration or more  
 724 complex rules (i.e., higher policy abstraction) (Koechlin et al., 1999; Badre and D'Esposito,  
 725 2007; Nee and Brown, 2013; Parkin et al., 2015). Experiment 2 removed multi-level decision  
 726 making or abstraction across rules/contexts, and nevertheless observed ramping (collapsed across  
 727 the conditions) in the RLPFC.

728           Second, RLPFC has been associated with episodic or temporal control (Koechlin et al.,  
 729   2003; Badre and D'Esposito, 2007; Nee et al., 2014; Bahlmann et al., 2015b, 2015a; Nee and  
 730   D'Esposito, 2016), which refers to our ability to control behavior based on an internal  
 731   representation of a temporal context or episode. Experiment 2 manipulated the demand on this  
 732   type of control by allowing sequences to be monitored either via a presented stimulus or via a  
 733   remembered representation of the sequence. Ramping in the RLPFC more broadly was engaged  
 734   even in the presence of external cues (visible condition), when it was not necessary to track an  
 735   internal episode representation, though this result is specific to the more caudal Monitoring and  
 736   Clue ROIs. It should be noted, however, that across all ROIs examined in the RLPFC, ramping  
 737   activation was quantitatively greater in the condition without external position cues (occluded),  
 738   though this difference was not statistically significant. Thus, we do not find evidence in support  
 739   of or contrary to a difference between visible and occluded items, and it is clear that occlusion is  
 740   not essential to engage ramping activity in RLPFC. Further experiments will be necessary to  
 741   determine if there is an interaction between sequential control and internally guided behavior.

742           We have focused on RLPFC in this work primarily because this region has been the focus  
 743   of considerable debate regarding its function, and it has been widely hypothesized to be involved  
 744   in the kind of temporal control needed for sequential control. It is important to emphasize,  
 745   however, that RLPFC is not acting as an independent module. Rather, the activations observed in  
 746   RLPFC are part of a larger network of areas exhibiting ramping activation across these  
 747   sequential tasks. Among these broader networks, only two areas of ramping activation  
 748   overlapped across all three experiments: left RLPFC and right PMd (**Fig. 7a,b** white areas). This  
 749   finding again underscores the consistency in RLPFC ramping activation across the tasks. Other  
 750   network areas show ramping activation that are unique to each of the three experiments. While it

751 is outside the scope of these experiments to speculate on the unique function of each (**Fig. 7a,b**  
752 red, green, and blue areas), these areas of unique ramping activation may be related to task  
753 specific demands that differ among the experiments. Therefore, while RLPFC functions in a  
754 network, it may be consistently involved in these sequential tasks relative to other areas. Future  
755 experiments will be necessary to elucidate the potential relationship among these ramping  
756 signals.

757         An important future direction will be to test the hypothesis of whether such ramping  
758 activation is dependent on the sequential information being task relevant. It is also possible that  
759 when there is sequential information, the monitoring or tracking of it is automatic, regardless of  
760 the task relevance. There are paradigms in both the auditory (e.g., Wang et al., 2015) and visual  
761 domain (e.g., Hsieh and Ranganath, 2015; Jiang et al., 2018) where the sequential information  
762 provided is not necessary for the performance of the task. Crucially, these experiments did not  
763 test for the presence of ramping activation in the RLPFC. Therefore, this significant question  
764 remains unresolved.

765         In conclusion, ramping activation in RLPFC was found to be robust across multiple tasks  
766 requiring monitoring predictable, sequential state transitions. This pattern was not reliably  
767 modulated by the presence of informative stimuli, the removal of multi-level task structure, or  
768 the presence of external position cues. The critical feature in common among these experiments  
769 is that they involve monitoring a sequence of states that occur in a repeated and fixed order. It  
770 remains possible that RLPFC may be engaged when memory must be referenced in order to  
771 make serial control decisions or it may track progress towards a goal or sequence bound.  
772 Numerous other studies have associated activity in the RLPFC with various boundary conditions  
773 (e.g., Dobbins et al., 2002; Gilbert et al., 2005; Burgess et al., 2007; Farooqui et al., 2012) and it

774 is possible that RLPFC may play a role in the progress of ongoing temporal events, along with  
775 preparing for what is to come next. However, it seems clear from previous work (Desrochers et  
776 al., 2015) that RLPFC function is not equally necessary or engaging throughout a sequence. In  
777 this regard, we should note that as we did not conduct TMS in this experiment, the necessity of  
778 RLPFC during simpler sequential tasks such as in Experiment 2 have not yet been established.  
779 Nevertheless, it is clear that adding sequential structure to a task is crucial to modulate activity in  
780 RLPFC. The goal of future work will be to further specify the functional role played by these  
781 sequential signals, and their potential impact on human behavior.

852 **Figure 1.** Clue task used in Experiment 1. **a**, Example single trial. **b**, Example block with the  
 853 task that should be executed on each trial indicated below each screen. **c**, Simple and complex  
 854 sequence types. Color and Shape categorization tasks are generalized to A's and B's. Simple  
 855 sequences contain one switch (bold) in the interior of the sequence, whereas complex sequences  
 856 contain two switches (bold). Underlined task switches illustrate that the total number of switches  
 857 and repeats are balanced when considering the two sequence types across repetitions. **d**, Example  
 858 block from a single participant illustrating uncertainty (operationalized as entropy) estimates  
 859 resulting from the model (see Methods). The model-inferred order captures the pattern of errors  
 860 made by the participant in this block and shows that their internal order has shifted. **e-g**, Entropy  
 861 averaged across all participants. **e**, Entropy increases with order number before the first clue in a  
 862 block, as expected. **f**, Entropy increases with time within the block before the first clue in a  
 863 block, as expected. **g**, The presence of a clue diminishes uncertainty for both sequence order and  
 864 task. Task entropy re-increases directly after a clue, because knowing that the current task is A is  
 865 not informative about whether the next task will be A or B.

866

867 **Figure 2.** Experiment 1 behavioral results. **a**, Mean reaction time (RT) across sequence position.  
 868 Note that clue and no clue RTs nearly perfectly overlap. **b**, Mean error rate (ER) across sequence  
 869 position. The generic task designation (A or B) is indicated at each data point, color-coded  
 870 according to the sequence type. **c**, ER normalized for baseline levels of chance across sequence  
 871 position.

872

873 **Figure 3.** Experiment 1 fMRI results. **a**, Ramping activation in clue task shown with the  
 874 voxelwise contrast of the parametric ramp regressor > baseline in the parametric sequence  
 875 position ramp model (see Materials and Methods). Black outline is the location of the D15 ROI.  
 876 FWE cluster corrected  $p = 0.05$  (height  $p = 0.001$ , extent = 176 voxels). **b**, Voxelwise contrast of  
 877 clue > no clue trials for sequence positions 2-4 (there were no clues presented at position 1) in  
 878 the onsets model (see Materials and Methods). Positive contrast shown in reds and negative  
 879 contrast shown in blues. Coronal slices shown contained no supra-threshold negative contrast  
 880 values. Familywise error (FWE) cluster corrected  $p = 0.05$  (height  $p = 0.001$ , extent = 156  
 881 voxels). **c**, Mean parametric ramp regressor beta values in the parametric sequence position ramp  
 882 model for the D15 ROI. **d**, Mean percent signal change ( $\pm$ SEM) from the peak (6 s) of the finite  
 883 impulse response (FIR) in the D15 ROI.

884

885 **Figure 4.** Monitoring task used in Experiment 2. **a**, Example single trial. **b**, Two example mini-  
 886 blocks of the sequence monitoring task. Upper row illustrates the Visible sequence type where  
 887 the instructed sequential stimuli are visible all through the block. Bottom row illustrates the  
 888 Occluded sequence type where the place holder “occluder” image is shown after the instruction,  
 889 and are monitored as if the instructed stimuli were present on each screen, but occluded by the  
 890 place holder. The last image of the block is one of the instructed stimuli, and participants must  
 891 hold or release according to whether it is InSeq or OutSeq. Example feedback is illustrated as a  
 892 check mark (correct) or “X” (error). **c**, Complete example Occluded block consisting of three  
 893 mini-blocks followed by the first mini-block of a Visible block. The red screen and four  
 894 instruction images are only shown during the first mini-block of each block. The subsequent two

mini-blocks within a block only show a green screen and monitoring stimuli are presented immediately following it. **d**, Example run. Each run consists of one of each sequence identity and type with the order counter-balanced across runs and participants.

**Figure 5.** Experiment 2 behavioral results. **a**, Mean RT across sequence position. **b**, Mean ER across sequence position. **c**, Mean sensitivity index ( $d'$  or d-prime) across sequence types. **d**, Mean probability of false alarm (pFA). **e**, Mean probability of hit (pHit).

**Figure 6.** Experiment 2 fMRI results. **a**, Ramping activation in the monitoring task shown with the voxelwise contrast of the parametric ramp regressor > baseline in the parametric sequence position ramp model (see Materials and Methods). Black outline is the location of the D15 ROI. FWE cluster corrected  $p = 0.05$  (height  $p = 0.001$ , extent = 181 voxels). **b**, Same as **a**, but only occluded sequence type (height  $p = 0.001$ , extent = 191 voxels). **c**, Same as **a**, but only visible sequence type (height  $p = 0.001$ , extent = 185 voxels). **d**, Same as **a**, but occluded > visible (height  $p = 0.001$ , extent = 196 voxels). **e**, Mean parametric ramp regressor beta values for the D15 ROI in the parametric sequence position ramp model. Note the small scale. **f**, Mean percent signal change ( $\pm$ SEM) from the peak (6 s) of the FIR in the D15 ROI.

**Figure 7.** Comparison across experiments. **a**, Overlay of the voxelwise contrast of the parametric ramp regressor > baseline in the parametric sequence position ramp model from three different experiments. Red depicts the original task sequence experiment (Desrochers et al., 2015). The Experiment 1 clue task is shown in green, and the Experiment 2 monitoring task is shown in blue. Overlap is shown by the colors indicated in the Venn diagram. **b**, Same as **a**, but only

918 showing the left RLPFC cluster from each experiment. These are the three ROIs used  
919 throughout. **c**, Conjunction across parametric ramp > baseline contrasts in all three experiments  
920 ( $p < 0.001$  unc., conjunction null). **d**, In the task sequence experiment (Desrochers et al., 2015),  
921 mean parametric ramp regressor beta values in the parametric sequence position ramp model  
922 across the three ROIs illustrated in b. **e**, Same as d, but in the clue Experiment 1. **f**, Same as d,  
923 but in the monitoring Experiment 2.

927

928 **Table 1.** Experiment 1, clue task. All peaks greater than 8 mm apart in the parametric ramp >  
929 baseline contrast shown in **Figure 3a** (cluster-corrected  $p = 0.05$  FWE, height  $p = 0.001$ , extent =  
930 176 voxels). Extent is the cluster size in voxels and is only listed once for each group of peaks  
931 belonging to the same cluster. BA = Brodmann's Area, RLPFC = rostralateral prefrontal cortex,  
932 PMd = dorsal premotor cortex, SMA = supplementary motor area.
