(Received 19 March 2018; revised manuscript received 8 August 2018; published 29 August 2018)

We study Mn substitution for Ti in BaTiO<sub>3</sub> with and without compensating oxygen vacancies using density functional theory (DFT) in combination with dynamical mean-field theory (DMFT). We find strong charge and spin fluctuations. Without compensating oxygen vacancies, the ground state is found to be a quantum superposition of two distinct atomic valences,  $3d^4$  and  $3d^5$ . Introducing a compensating oxygen vacancy at a neighboring site reduces both charge and spin fluctuations due to the reduction of electron hopping from Mn to its ligands. As a consequence, valence fluctuations are reduced, and the valence is closely fixed to the high spin  $3d^5$  state. Here we show that inclusion of charge and spin fluctuations is necessary to obtain an accurate ground state of transition metal-doped ferroelectrics.

## I. INTRODUCTION

Multiferroics respond to both electric and magnetic fields, and their coupling is an exciting field of research for both understanding their fundamental physics and for potential device applications. One promising route to magnetoelectric materials is to dope ferroelectrics with magnetic ions [1–4]. Such materials are of interest for electronics that can integrate data processing and memory operation in a single solid state device [1,2,5,6]. Many commercial transducer materials are doped with transition metal impurities to improve piezoelectric properties, mechanical quality factor, and coercive field, and to decrease electrical conductivity [1–3,5–15], but the exact role of the doped impurities is unclear. Defect dipoles formed by transition metal dopants with oxygen vacancy neighbors can greatly enhance electromechanical coupling [16–20]. Thus, the electronic structure of transition metal dopants is of great interest in general, and in particular in multiferroics and dilute magnetic semiconductors [21,22].

When a transition metal ion is doped into a classic ferroelectric material like BaTiO<sub>3</sub>, whether the impurity would be an acceptor or a donor of electrons depends on the number of valence electrons and  $3d$  occupation, i.e., oxidation state. Valence, charge, or oxidation state are concepts commonly used in chemistry. Oxidation state is an ill-defined quantity in quantum mechanics, although it has proven extremely useful in chemical intuition [23–29]. Oxidation state can be a point of confusion as very often the charge or oxidation state of a cation differs significantly from the Born transverse effective charges, or the static charges computed by projection onto local or Wannier orbitals or from orbital occupations [24–28]. The  $d$  occupation remains invariant in charge order driven metal-insulator transitions [24], but does depend on the choice of orbitals. The  $d$  occupation is also related to the ion magnetic moment.

Mn commonly has three different oxidation states ( $\text{Mn}^{4+}$ ,  $\text{Mn}^{3+}$ ,  $\text{Mn}^{2+}$ ) in perovskites.  $\text{Mn}^{4+}$  and  $\text{Mn}^{2+}$  have an electronic configuration of  $d^3$  and  $d^5$ , respectively, or half-filled  $t_{2g}$  or  $t_{2g} + e_g$  manifolds in octahedral symmetry. Which states of valence the paramagnetic ions are incorporated into the BaTiO<sub>3</sub> and other perovskites is an open and long standing problem [7–15]. The magnetic moment of Mn substituting for Ti on the B site in Mn-doped BTO without any compensating oxygen vacancy is  $3 \mu_B$  ( $\text{Mn}^{4+}$ ) [18,30] in conventional DFT and DFT+U. Electron paramagnetic resonance (EPR) and x-ray photoelectron spectroscopic measurements on Mn-doped BTO show that Mn can exist in various charge states in BTO; some EPR measurements performed on Mn-doped BTO nanoparticle show a high spin state of Mn with the moment of  $5 \mu_B$  ( $\text{Mn}^{2+}$ ) [6], whereas  $\text{Mn}^{4+}$  with  $3 \mu_B$  is also found [7]. The oxidation state of the Mn depends on the oxygen fugacity during growth or annealing, and depends on the concentration of compensating oxygen vacancies or other impurities and defects. Using density functional calculations, Nossá *et al.* found that depending on the oxygen vacancy, Mn ions in BaTiO<sub>3</sub> can exist either on high spin ( $\text{Mn}^{2+}$ ) or low spin state ( $\text{Mn}^{4+}$ ) [18].

In this paper, we carefully investigate electronic structure of Mn-doped BTO with and without compensating O vacancies in the paramagnetic phase of Mn. Using a *state-of-the-art* DFT+DMFT method, we focus on understanding the charge and spin states Mn exhibits in these prototypical systems in order to combine both  $d^0$  states and partially occupied  $d$  states to unite ferroelectricity and magnetism in one material. We compare our results with conventional DFT and DFT+U in the ferromagnetic phase of Mn. We then describe the effects of oxygen vacancies on the charge and spin fluctuations of Mn and explore the change in local magnetic moment of Mn.

## II. METHODS AND STRUCTURAL DETAILS

To understand better the electronic structure of transition metal dopants in dielectrics, in general, and  $\text{Mn}_{\text{Ti}} \pm \text{V}_\text{O}$  in

\*smandal@mtu.edu

BaTiO<sub>3</sub> in particular, we use dynamical mean-field theory (DMFT) [31], a sophisticated method, which includes quantum dynamical effects, and takes into account both valence and spin fluctuations. In contrast, DFT includes only average interactions, and DFT+U includes only a single configuration, ignoring multiplet effects. DFT+DMFT has been very successful in describing strongly correlated materials like high temperature superconductors, Mott insulators, and several transition metal bearing compounds [32–41]. In DFT+DMFT, the self-energy that samples all local skeleton Feynman diagrams is added to the DFT Kohn-Sham Hamiltonian [31,42]. This implementation is fully self-consistent [34,42]. The iterations stop after full convergence of the charge density, the impurity level, the chemical potential, the self-energy, and the lattice and impurity Green’s functions. The lattice is represented using the full potential linear augmented plane wave (LAPW) method, implemented in the Wien2k [43] package in its generalized gradient approximation (Wu-Cohen-GGA) [44]. The continuous time quantum Monte Carlo method is used to solve the quantum impurity problem and to obtain the local self-energy due to the correlated Mn 3*d* orbitals. The self-energy is analytically continued from the imaginary to real axis using an auxiliary Green’s function to obtain the partial density of states. A fine *k*-point mesh of at least  $4 \times 4 \times 4$  *k* points in Monkhorst-Pack *k*-point grid and a total 40 million Monte Carlo steps for each iteration are used for the paramagnetic phase of the Mn-doped BTO at  $T = 300$  K. The Coulomb interaction *U* and Hund’s coupling *J<sub>H</sub>* are fixed at 6.0 and 0.8 eV, respectively [45], and we have tested varying these parameters. We use the fully localized limit (FLL) double counting [46], as well as “exact” double counting [47]. For DFT and DFT+U we use the all electron LAPW method as implemented in WIEN2K [43]. The same *U* and *J<sub>H</sub>* of 6.0 and 0.8 eV are used for DFT+U computations, respectively.

We study a paramagnetic Mn dopant in a supercell with (Mn<sub>Ti</sub>V<sub>O</sub>) and without (Mn<sub>Ti</sub>) a neighboring compensating oxygen vacancy using DFT-DMFT [48] computation at room temperature. Two  $2 \times 2 \times 2$  supercell structures are considered here; one structure with one Mn-replacing Ti atom, and the other structure is with Mn-replacing Ti with an oxygen vacancy next to the Mn atom along the *c* axis. These structures were optimized using DFT+U as implemented in ABINIT [49,50] and also used in Ref. [18] to understand the role of Mn doping

FIG. 1. (a) Schematic representation of the structure for Mn-doped (at Ti site) BaTiO<sub>3</sub> without any compensating oxygen vacancy. Isosurface plot of electron density difference between (b) DFT and DFT+U, (c) DFT and DFT+DMFT, and (d) DFT+U and DFT+DMFT methods. The green or red means increase or decrease of  $0.85 \times 10^{-3} \text{ e}/\text{\AA}^3$  upon the DMFT calculation.

in BTO. For DFT computations, we consider ferromagnetic order with a single Mn atom in the supercell.

### III. RESULTS AND DISCUSSIONS

Firstly, we describe the effects of a Mn impurity without any compensating oxygen vacancy (Mn<sub>Ti</sub>). The charge density  $\rho(r)$  is computed using spin-polarized DFT, DFT+U, and DFT+DMFT (Fig. 1). The difference in  $\rho(r)$  in DFT and DFT+U shows that DFT places more charge on the Mn atoms compared to DFT+U [Fig. 1(b)]. DFT+DMFT always places more charge on the Mn atom than other two methods.

To better understand these differences, we compare the total and the partial densities of states (DOS) for spin-polarized DFT, DFT+U, and DFT+DMFT (Fig. 2). The partial DOS

TABLE I. Computed magnetic moment (in  $\mu_B$ ), occupation of Mn *d* orbital, and band gap (eV) for Mn in BaTiO<sub>3</sub> with and without O vacancy obtained within nonmagnetic (NM) DFT, spin-polarized (SP) DFT with ferromagnetic order, DFT+U, and DFT+DMFT methods. Here DFT+DMFT is performed in paramagnetic phase of the materials and the magnetic moments in DFT+DMFT represent the average fluctuating local moment; the occupations in DFT and DFT+U are obtained by integrating the projected DOS to the Fermi energy.

| Method   | System                          | Magnetic moment ( $\mu_B$ ) | Occupation           | Band gap (eV) |

FIG. 2. Spin decomposed total and projected densities of states (DOS) computed in (a) DFT, (b) DFT+U, and (c) DFT+DMFT methods for Mn substitution of Ti in BaTiO<sub>3</sub> without any compensating oxygen vacancy (Mn<sub>Ti</sub>). (d) Computed spin density ( $\rho_{\uparrow} - \rho_{\downarrow}$ ) with DFT and DFT+U for the same system.

shows that most of the contribution around  $E_F$  is from O atoms [Figs. 2(a)–2(c)]. The 3d occupation is consistent with Mn<sup>4+</sup> in both DFT and DFT+U, as found in previous DFT-based studies [18,30] (Table I). Although the nonmagnetic DFT predicts the occupation to be 4.65, it puts the Mn *d* orbital at  $E_F$ , and results a metallic solution [30]. The magnetic moment in DFT+U is 2.67  $\mu_B$  inside the Mn muffin-tin sphere, 0.24  $\mu_B$  for the interstitial, and 0.09  $\mu_B$  inside the other spheres, giving a total moment of 3.00  $\mu_B$  (Table I). The equal magnetic moment in DFT and DFT+U can also be obtained from the integration of the spin density [Fig. 2(d)] of the *d* orbital until  $E_F$ .

The computed Mn 3d occupation in DFT+DMFT is 4.44, and the average fluctuating local moment is 2.90  $\mu_B$ . We compare our results with different double counting (DC) schemes; a fully localized limit form of double counting or FLL as introduced in Ref. [46], “nominal” DC as introduced in [42,51] and “exact” double counting [47]. We use both density-density form of the Coulomb repulsion (Ising) and the full Coulomb repulsion (Full) in rotationally invariant Slater form (Table II) [52]. Changing *U* does not affect the *d* occupation significantly. Keeping  $J_H = 0.8$  eV and varying *U* from 2 to 6 eV, the occupation changes from 4.74 to 4.78. Also keeping *U* fixed at 6 eV and varying  $J_H$  from 0 to 1.2 eV, the occupation changes from 4.30 and 4.40 and reaches its maximum value of 4.77 for  $J_H = 0.8$  eV.

We next discuss the results for Mn-doped BTO with a compensating oxygen vacancy along the *z* direction (Mn<sub>Ti</sub>V<sub>O</sub>) [18]. For DFT and DFT+U, we find the moment to be 4.47 and 5.00  $\mu_B$ , respectively, for the entire cell. In DFT+U, the moment in the Mn muffin-tin sphere is 4.28  $\mu_B$ , in the interstitial is 0.51  $\mu_B$ , and the other spheres have a moment of 0.21  $\mu_B$ , giving a total of 5.00  $\mu_B$  for the cell. Whereas the magnetic mo-

ment computed in DFT and DFT+U are for the ferromagnetic phase, for DFT+DMFT we compute the average fluctuating moment ( $\langle m_z \rangle$ ) in the paramagnetic phase of Mn using the formula  $\langle m_z \rangle = 2 \sum_i P_i |S_z|_i$ , where  $P_i$  is the probability of the *i*th multiplet in the CTQMC impurity solver and  $|S_z|_i$  is the absolute value of the corresponding moment. In DFT+DMFT the magnetic moment is mostly concentrated on the magnetic ion; the induced moments on the interstitial charge or other nonmagnetic ions in the unit cell are very small. Hence we can compare DFT+DMFT local moment with the total moment of the cell within DFT and DFT+U calculations (Table I).

We now discuss the valence fluctuations of Mn in DFT+DMFT, where the ground-state wave function is not restricted to being a single multiplet, as in DFT+U. On a single atom, there are 1024 different possible multiplets for *d* electrons, characterized by different valences, orbital occupations, and spins [34]. The histograms in Fig. 3 describe the probability of finding a Mn atom in the solid in each

TABLE II. DFT+DMFT computed occupation of the *d* orbital in Mn<sub>Ti</sub> using different double counting and Coulomb schemes [42,46,47,51,53].

| DC      | Coulomb | $n_d$ |
|---------|---------|-------|
| Exact   | Ising   | 4.44  |
| Exact   | Full    | 4.39  |
| Nominal | Ising   | 4.75  |
| FLL     | Full    | 4.76  |
| FLL     | Ising   | 4.77  |

FIG. 3. DFT+DMFT computed atomic histogram of the Mn  $3d$  shell for Mn substituted  $\text{BaTiO}_3$  (left) without ( $\text{Mn}_{\text{Ti}}$ ) and (right) with ( $\text{Mn}_{\text{TiVO}}$ ) compensating oxygen vacancy: (a) and (b) Decomposed in number of particles  $N$  and (inset) spin-state ( $S_z$ ); probability distribution for all  $2^{10}$  ( $=1024$ ) atomic configurations sorted for each  $N$  (c) and (d) and for each spin state (e) and (f).  $N$  and  $S_z$  values are denoted with various colors.

multiplet, and show that any method that considers only a single multiplet, such as even single determinant group state quantum Monte Carlo, will only be approximate. We find many occupied multiplets, such as  $3d^3$ ,  $3d^4$ , and  $3d^5$  with a maximum occupation of  $3d^4$  for  $\text{Mn}_{\text{Ti}}$  and  $3d^5$  for  $\text{Mn}_{\text{TiVO}}$  [Figs. 3(a) and 3(b)]. Without compensation, we find only about 5% weight in the most probable configurations. With a compensating vacancy, the fluctuations are smaller, but still there is only about 20% weight in the most likely multiplets. In  $\text{Mn}_{\text{Ti}}$  the sum of the probabilities are found to be 0.43, 0.34, and 0.09, respectively, for  $N = 4, 5$ , and  $6$ . Thus the system is in a mixed valence state with an average  $d$  occupation of  $\sim 4.4$ . For  $\text{Mn}_{\text{TiVO}}$ , the sum of the probabilities are 0.28, 0.57, and 0.11 for  $N = 4, 5$ , and  $6$ , respectively. The difference in probabilities between  $N = 4$  and  $N = 5$  reduces with compensating oxygen vacancy in  $\text{Mn}_{\text{TiVO}}$  [Fig. 3(b)]; the probability for  $N = 5$  increases and becomes the most probable state. This leads to an increase in average  $3d$  occupation from 4.4 to 4.8 with compensating O vacancy.

The histograms of the CTQMC [inset of Figs. 3(a) and 3(b)] show the largest probability for the spin state  $S_z = 1.5$  for  $\text{Mn}_{\text{Ti}}$  and  $S_z = 2.5$  for  $\text{Mn}_{\text{TiVO}}$ . The histograms also show strong spin fluctuations. To identify the associated spin state for each eigenstate, we present them in various colors in Figs. 3(e) and 3(f). Here the first (last) few states with a particular  $N$  show the high (low) spin state [Figs. 3(c)–3(f)]. For  $\text{Mn}_{\text{Ti}}$  we clearly see the spikes in probability for the high spin states ( $S_z = 2, 2.5$ ) at the beginning of the constant  $N$  interval as well as for the low spin states ( $S_z = 0, 0.5$ ), at the end of the constant  $N$  interval [Figs. 3(c) and 3(e)]. For  $\text{Mn}_{\text{TiVO}}$  we see spikes in probability for high spin states ( $S_z = 2, 2.5$ ) are dominated than that for the low spin states ( $S_z = 0, 0.5$ ) [Figs. 3(d) and 3(f)] for  $N = 4$  and  $N = 5$ . The overall probability distribution changes significantly with oxygen vacancy and peaks mainly for  $N = 5$  and  $S_z = 2.5$ . Thus both the charge and spin fluctuations are reduced in  $\text{Mn}_{\text{TiVO}}$  since the hopping of the electrons from Mn to neighboring oxygen is reduced due to the compensating vacancy. The dominance of the  $S_z = 2.5$  configuration implies that Mn in BTO has a predominantly high spin state in  $\text{Mn}_{\text{TiVO}}$ .

FIG. 4. DFT+DMFT computed squared fluctuating local moment or the averaged spin-spin correlation function (a) for Mn substituted BaTiO<sub>3</sub> without (Mn<sub>Ti</sub>) and (b) with compensating oxygen vacancy (Mn<sub>Ti</sub>VO).

The increase in magnetic moment with O vacancy, as found in Table I, can be explained from the DFT+DMFT computed time averaged spin-spin correlation function [ $\langle S(\tau = 0)S(\tau = 0) \rangle$ ] or the squared fluctuating local moment (Fig. 4), where we find an increase in the local moment in Mn<sub>Ti</sub>VO. Reduced fluctuation and increased probability for an electron to spend more time in the high spin states with O vacancy gives rise to the increase in average fluctuating local moment.

#### IV. CONCLUSIONS

Unlike previous density functional based studies yielding either a high (Mn<sup>2+</sup>) or low spin (Mn<sup>4+</sup>) state of Mn in BaMn<sub>1-x</sub>Ti<sub>x</sub>O<sub>3</sub>, with and without, compensating oxygen va-

cancy, respectively, DFT+DMFT predicts a mixed valence state of Mn in either system. Without compensating oxygen vacancies, the ground state in DFT+DMFT is found to be a quantum superposition of two distinct atomic valences, 3d<sup>4</sup> and 3d<sup>5</sup>. Introducing a compensating oxygen vacancy at a neighboring site of Mn reduces hopping of electron from Mn to its ligand. This results in reduction of both charge and spin fluctuations. We conclude that the charge and valence fluctuations in 3d-transition metal-doped BTO are strong, and are not captured by conventional DFT or DFT+U. DFT+DMFT predicted average valence of Mn in BTO is 3d<sup>2+</sup> and 3d<sup>3.5+</sup> with and without compensating oxygen vacancy, respectively. The most important results presented here are the extreme fluctuations predicted, with only a small fraction in any given multiplet, and very different from DFT+U which assumes a single multiplet to be occupied. Even very accurate methods such as diffusion Monte Carlo generally consider only a single Slater determinant for solids. DFT+DMFT gives a new insight into the fluctuating states in correlated solids, which is presently challenging to represent by other standard methods. Our predictions of valence fluctuations in transition metal-doped ferroelectrics can be verified, as was done in a heavy Fermion system through hard x-ray photoemission study [54], in topological Kondo insulators through muon spin relaxation studies [55,56], and in perovskite through Mossbauer spectroscopy [57] and NMR [58].
