# Identification of toxicity effects of Cu<sub>2</sub>O materials on *C. elegans* as a function of environmental ionic composition†

Catherine J. Munro,<sup>‡a</sup> Michelle A. Nguyen,<sup>‡a</sup> Christian Falgons,<sup>ab</sup> Sana Chaudhry,<sup>b</sup> Mary O. Olagunju,<sup>a</sup> Addys Bode,<sup>b</sup> Carla Bobé,<sup>ab</sup> Manuel E. Portela,<sup>ab</sup> Marc R. Knecht,<sup>‡\*\*a</sup> and Kevin M. Collins<sup>‡\*b</sup>

Previous work has shown that spherical CuO nanomaterials show negative effects on cell and animal physiology. The biological effects of Cu<sub>2</sub>O materials, which possess unique chemical features compared to CuO nanomaterials and can be synthesized in a similarly large variety of shapes and sizes, are comparatively less studied. Here, we synthesized truncated octahedral Cu<sub>2</sub>O particles and characterized their structure, stability, and physiological effects in the nematode worm animal model, *Caenorhabditis elegans*. Cu<sub>2</sub>O particles were found to be generally stable in aqueous media, although the particles did show signs of oxidation and leaching of Cu<sup>2+</sup> within hours in worm growth media. The particles were found to be especially sensitive to inorganic phosphate (PO<sub>4</sub><sup>3−</sup>) found in standard NGM nematode growth medium. Cu<sub>2</sub>O particles were observed being taken up into the nematode pharynx and detected in the lumen of the gut. Toxicity experiments revealed that treatment with Cu<sub>2</sub>O particles caused a significant reduction in animal size and lifespan. These toxic effects resembled treatment with Cu<sup>2+</sup>, but measurements of Cu leaching, worm size, and long-term behavior experiments show the particles are more toxic than expected from Cu ion leaching alone. These results suggest worm ingestion of intact Cu<sub>2</sub>O particles enhances their toxicity and behavior effects while particle exposure to environmental phosphate precipitates leached Cu<sup>2+</sup> into bioavailable phosphate salts. Interestingly, the worms showed an acute avoidance of bacterial food with Cu<sub>2</sub>O particles, suggesting that animals can detect chemical features of the particles and/or their breakdown products and actively avoid areas with them. These results will help to understand how specific, chemically-defined particles proposed for use in polluted soil and wastewater remediation affect animal toxicity and behaviors in their natural environment.

## Environmental significance

In this manuscript, we have identified key components of material toxicity using the model animal, *Caenorhabditis elegans*. For these studies, we focused on materials composed of Cu<sub>2</sub>O, which is a highly important photocatalyst for a variety of applications, including environmental remediation of toxic pollutants. Beyond simple composition, we have explored the effects of the sample environment on material toxicity. *C. elegans* was selected as it is well studied and can be easily monitored for a variety of toxicological effects of material exposure. Our results demonstrated that the Cu ion leaching from the Cu<sub>2</sub>O materials is controlled as a function of the growth medium for the animal model; however, the toxicity of the particles is more than just simply from the release of Cu ions. This suggests that the particles themselves have a degree of toxicity that must be considered in their use in the environment. Such results demonstrate unique capabilities of this model system for understanding short- and long-term toxicological effects of potentially important materials for environmental applications.

## Introduction

The rational design of nanomaterials has yielded new technologies that have revolutionized diverse applications from biomedical diagnostics to catalysis. One specific example is the application of nanomaterials towards environmental remediation protocols, such as wastewater treatment or contaminant removal *via* catalytic processes.<sup>1,2</sup>

‡ Equal contribution.

In these approaches, oftentimes catalytic nanomaterials are dispersed into the environment to drive the catalytic degradation of known pollutants such as polychlorinated biphenyls, polybrominated diphenyl ethers, polychlorinated dibenzo-*p*-dioxins, and dibenzofurans;<sup>3–7</sup> however, the effects of nanomaterials released into the environment remain remarkably unknown where their own toxicity could rival or even surpass the toxicity of the original pollutant.

Metal oxide semiconductor photocatalysts are attractive materials for environmental remediation due to their reliance on renewable solar light as the main energy source to drive the reaction. In particular, Cu<sub>2</sub>O has gained increasing interest as a material for the photocatalytic degradation of environmental pollutants due to its narrow band gap of 2.17 eV,<sup>8</sup> allowing it to exploit visible light absorption, a significantly greater portion of the solar spectrum. It has been demonstrated that Cu<sub>2</sub>O has the ability to break down aromatic dyes that are known to be difficult to degrade.<sup>6,9,10</sup> This reaction occurs through the generation of reactive oxygen species at the metal oxide surface, leading to pollutant degradation.<sup>11–13</sup> Additionally, metal-containing nanoparticles can release toxic metal ions, such as Ag<sup>+</sup>, Cu<sup>2+</sup>, and Zn<sup>2+</sup>, *via* dissolution in aquatic environments.<sup>14,15</sup> However, toxicity effects will undoubtedly vary depending on numerous parameters, such as metal oxidation state, particle size, surface properties, including the effects of any ligands that may be integrated into the material during synthesis that could also be leached into the environment.<sup>16</sup> Metal-containing nanoparticles are likely to have dramatically different stability and catalytic properties in varying environments, for example at high or low ionic strength, at different pH, availability of salt-inducing counter ions, and in abiotic *vs.* biotic environments. Particle size and shape are anticipated to be highly important determinants of biocompatibility; smaller, hydrophilic particles are more likely to interact with or be taken up by organisms, leading to potential physiological effects.

In this study, *C. elegans* worms were used as a model organism to assess the short- and long-term toxicological and physiological impacts of newly synthesized truncated cuboctahedral Cu<sub>2</sub>O microcrystals.<sup>16</sup> Previous work has shown that Ag, Au, Cu, and Si nanoparticles, but not Zn or Ce cause *C. elegans* feeding behaviour defects and premature lethality.<sup>15,17–20</sup> In general, the toxicity of metal oxide nanomaterials has been found to be less than release of an equivalent amount of metal ions alone.<sup>21</sup> Previous studies looking specifically at Cu-based nanoparticles were limited to small (30 nm) CuO particles with a spherical shape,<sup>19</sup> raising the question whether particle toxicity is a general feature of all Cu materials or specific to particular oxidation states, particle shapes, sizes, and/or surface chemistries. Here we show that truncated octahedral Cu<sub>2</sub>O crystals, like CuO spherical nanoparticles, are toxic to the *C. elegans* animal model. This toxicity depended crucially on the ionic environment, with phosphate-containing growth medium causing enhanced particle degradation, reducing their

bioavailability and physiological effects. In phosphate-deficient media, the Cu<sub>2</sub>O particles were more stable and the particles were more toxic to worms than an equivalent amount of Cu<sup>2+</sup> ion, suggesting the particle structure provides additional environmental stability and catalytic features. Because worms also avoid areas with Cu<sub>2</sub>O particles, their toxicological consequences are expected to be blunted further when encountered in the environment.

## Materials and methods

### Chemicals

CuSO<sub>4</sub>·5H<sub>2</sub>O, and 95% ethanol were obtained from BDH Chemicals, while glucose, cholesterol, CaCl<sub>2</sub>·2H<sub>2</sub>O, potassium chloride, and sodium hydrogen phosphate were acquired from Alfa Aesar. Sodium hypochlorite was purchased from Clorox. Sodium hydroxide, sodium carbonate, and nitric acid were from EMD Millipore. Bacto-tryptone was acquired from BD Biosciences. Sodium chloride and MgSO<sub>4</sub>·7H<sub>2</sub>O were obtained from Amresco. 5-Fluoro-2'-deoxyuridine (FUDR) was purchased from BioWorld. Finally, polyvinylpyrrolidone (PVP; MW ~29 000 g mol<sup>−1</sup>), potassium phosphate dibasic, potassium phosphate monobasic, and sodium citrate were from Sigma Aldrich. All chemicals were used as received without further purification. Milli-Q water (18 MΩ cm) was used for all experiments.

### Synthesis of Cu<sub>2</sub>O particles

Cu<sub>2</sub>O truncated octahedra (1.1 μm) were fabricated according to synthetic protocols established by Sui *et al.*<sup>22</sup> Specifically, 1.5 mM of PVP was dissolved in 17 mL of an aqueous 38 mM CuSO<sub>4</sub> solution. Upon complete dissolution of the PVP, 1 mL of an aqueous solution containing both 0.37 M sodium citrate and 0.60 M sodium carbonate was added drop-wise with continuous stirring. This was followed by the addition of 1 mL of an aqueous 1.4 M glucose solution, which was again added drop-wise with continuous stirring. The reaction vessel was then placed in a 70 °C water bath for 2 h. Once complete, the dark red precipitate was filtered through a 0.1 μm polycarbonate membrane, thoroughly washed with water and ethanol, and dried under vacuum at 60 °C for at least 12 h.

### Materials characterization

Scanning electron microscopy (SEM) was performed using a FEI/Philips XL-30 Field Emission SEM. To prepare the sample, the Cu<sub>2</sub>O materials were dispersed in ethanol *via* sonication, after which 10 μL of the sample was drop-casted onto an aluminium stub. Particle size distribution was determined by measuring ≥100 individual particles from multiple images of the synthesized material. UV-vis DRS analysis was completed on a Shimadzu Model UV-2600 system, scanning from 200–800 nm, using a 2 mm quartz cuvette as the sample holder. To analyse the materials after incubation with different worm growth media, the particles

were dispersed in 95% ethanol (200 mg mL<sup>-1</sup>) and diluted 50-fold in water (4 mg mL<sup>-1</sup>). From this, 200 µL of the suspension was applied to each of four agar plates of each media type (see below) seeded with OP50 bacteria.<sup>23</sup> After incubation for 24 h at 25 °C, the particles were recovered from the plates by washing into 2 mL of water. The particles were then sedimented by centrifugation (170 × g; 1 min), resuspended in 1 mL of sterile Milli-Q water, and recentrifuged. This resuspension procedure was repeated twice after which the aqueous supernatant was removed, leaving ~100 µL of water and particles. The particles were then diluted with 1 mL of 95% ethanol and re-centrifuged (1000 × g; 1 min). Most of the supernatant was removed, and the remaining particles were resuspended in the residual ethanol (~100 µL) and applied to aluminium stubs and dried overnight at 25 °C for SEM analysis.

### Cu<sup>2+</sup> leaching experiments

Cu<sub>2</sub>O particles (4 mg mL<sup>-1</sup>; or ~3.5 mg mL<sup>-1</sup> Cu equivalents) were resuspended in either distilled water, B-broth only (per liter: 10 g Bacto-tryptone, 5 g NaCl), or liquid nematode growth medium (NGM), K medium, or low K medium after inoculation with OP50 bacteria culture grown overnight in B-broth (1 : 100 dilution of the OP50/B-broth culture into each media type). Reactions (3 replicates for each incubation time) were run in microcentrifuge tubes with 1470 µL of water, the indicated medium, or B broth. 30 µL of a 200 mg L<sup>-1</sup> Cu<sub>2</sub>O particle suspension in ethanol was diluted, sealed, and vortexed for 5 s before it was left undisturbed for a given period (0 h, 1 h, 2 h, 8 h, 24 h, and 7 days). At the end of the reaction the time, the microcentrifuge tube was centrifuged at 8000 rpm for 1 min before 750 µL of the supernatant was extracted and diluted into 10% HNO<sub>3</sub> prior to being run for elemental analysis on Agilent 4200 MP-AES.

### *Caenorhabditis elegans* worm culture and treatment with particles

*C. elegans* Bristol N2 wild-type animals were maintained as hermaphrodites at 20 °C on nematode growth medium (NGM) agar plates seeded with *Escherichia coli* OP50 food grown in B broth as described.<sup>23</sup> NGM contained (per liter): 25 mM K<sub>3</sub>PO<sub>4</sub> pH 6, 51.37 mM NaCl, 1 mM CaCl<sub>2</sub>, 1 mM MgSO<sub>4</sub>, 5 mg cholesterol, 2.5 g Bacto-peptone, and 17 g Bacto-agar. To test the effects of inorganic phosphate and ionic strength, K medium was prepared, as described,<sup>24</sup> along with a derivative, low K medium, that has reduced ionic strength. K medium is equivalent to NGM except 25 mM K<sub>3</sub>PO<sub>4</sub> is replaced with 25 mM KCl. Low K medium is K medium with 10 mM KCl, 0 mM NaCl. Lawns of OP50 bacteria grown in NGM were at pH 6.0, while those in K medium and low K medium agar plates were at pH 7.5.

Mixed stage, gravid adult worms grown on NGM were synchronized by bleaching and hatching of eggs in M9 buffer. Hatched L1 larvae were then dispensed onto the indicated media (NGM, K, and low K) for ~48 h until they

reached the L4 stage, after which they were treated with either vehicle control (2% ethanol), Cu<sub>2</sub>O particles, or CuSO<sub>4</sub> solution. The concentrations indicated represent the total concentration of free copper ions (in mg mL<sup>-1</sup>) available for release assuming 100% ionization. For example, we assumed a molar weight of 143 g per mole for the Cu<sub>2</sub>O particles of which ~89% of the mass is copper. As such, 4 mg mL<sup>-1</sup> Cu<sub>2</sub>O particles have ~3.5 mg mL<sup>-1</sup> total ionizable copper, comparable to the ~3.2 mg mL<sup>-1</sup> copper ion present in an equal volume of 50 mM CuSO<sub>4</sub>·5H<sub>2</sub>O solution. Dried particles were resuspended in 95% ethanol at a concentration of 200 mg mL<sup>-1</sup> and bath sonicated for 5 min. Particle suspensions in ethanol were found to be stable for weeks. Serial dilutions of nanoparticle stock solutions were performed in 95% ethanol. For behaviour assays, sonicated particles (or ethanol alone) were freshly diluted 50-fold with sterile Milli-Q water, vortexed, and 200 µL of the diluted suspension, vehicle, or CuSO<sub>4</sub>·5H<sub>2</sub>O solution at the indicated concentrations was applied to each plate containing worms and bacteria. All behaviour assays were performed using age-matched adult hermaphrodites 24–40 h past the late L4 stage.

### Survival

Long-term viability assays were performed as described.<sup>33</sup> Animals were synchronized through bleaching of gravid adults followed by hatching of eggs in M9 buffer. Approximately 30–40 arrested L1 larvae were deposited onto each of three 60 mm NGM, K medium, or low K medium plates seeded with OP50 bacterial food and grown for ~48 h until they reached the late L4 stage. The bacterial lawn was then overlaid with 100 µL of 10 mg mL<sup>-1</sup> FUDR, as described, to prevent overgrowth of the plate with worm progeny during the subsequent long-term incubations.<sup>25–27</sup> After the FUDR soaked into the plates, the L4 animals were overlaid with 200 µL of the freshly diluted aqueous particle suspensions, 2% ethanol vehicle control, or CuSO<sub>4</sub> at the indicated concentrations and incubated at 20 °C. Animals were tested for viability every 2–3 days by gentle prodding with a platinum worm pick.<sup>28</sup> An animal was considered dead if it showed no movement or pharyngeal pumping after mechanical stimulation.

### Body length and worm recordings

Worms were recorded using a FLIR Grasshopper 3 USB3 camera (41C6NIR-C) with 2 by 2 binning through a Leica M165FC stereomicroscope using a PLAN APO 1.0× or 5.0× (0.5NA) objective, as described.<sup>25</sup> Ingestion and gut transport of particles was recorded at 30–60 frames per second. Average worm length was determined using FIJI software.<sup>29</sup> Briefly, a segmented line with ~10 points was drawn through the worm mid-body. Approximately 30 individuals per treatment condition were measured.

### Particle avoidance

Plates with OP50 bacteria overlaid with diluted vehicle, particles, or CuSO<sub>4</sub> were prepared as above. A worm was

considered on food if she was within one body length of the bacterial lawn, where  $\geq 29$  animals per treatment condition were measured.

### Statistical procedures

Prism 7.0d (GraphPad) was used for statistical analyses of the biological studies. A  $p$  value of  $\leq 0.05$  was considered significant. Individual  $p$  values and statistical tests can be found in the figure legends. All tests were corrected to account for multiple comparisons.

## Results and discussion

We have previously shown that *C. elegans* worms can consume nanomaterials derivatized with novel fluorescent moieties, allowing for studies of their localization and optical properties *in vivo*.<sup>30,31</sup> In this contribution, we examine the uptake and toxicity of synthesized  $\text{Cu}_2\text{O}$  particles using established criteria of viability and health.<sup>16</sup> The  $\text{Cu}_2\text{O}$  composition was chosen for two specific reasons. First, it is becoming an important metal oxide photocatalyst with potential applications for environmental remediation, thus understanding its effects on biological systems is important. Second, a variety of known synthetic methods are available to control the particle size and shape of  $\text{Cu}_2\text{O}$ .<sup>8,22</sup> This will allow for a holistic understanding of how composition, size, and shape contribute to the toxicological and physiological effects under different environmental conditions, specifically ionic strength and composition.

In the initial work described here, we focus specifically on the effects of ionic strength and composition using a single  $\text{Cu}_2\text{O}$  particle type, that of a truncated octahedra. The  $\text{Cu}_2\text{O}$  particles were generated by reducing a copper-citrate complex with glucose in the presence of PVP at 70 °C.<sup>22</sup> For this synthetic method, PVP acts as the stabilizing polymer to control the shape of the materials as the particle morphology is dictated by the amount of PVP. To achieve  $\text{Cu}_2\text{O}$  truncated octahedra, the copper-citrate complex was reduced by glucose with 1.5 mM PVP in the reaction mixture. Note that after synthesis, the particles were fully purified by washing with water followed by ethanol, thus any free polymer in the system is readily removed. SEM analysis of the prepared particles indicated predominantly truncated octahedra (Fig. 1a). Size histograms showed a width of  $1.1 \pm 0.3 \mu\text{m}$  (Fig. 1b). The UV-vis absorbance properties of the materials were evaluated using UV-vis DRS, and the absorption spectra of the  $\text{Cu}_2\text{O}$  particles are presented in Fig. 1c. The materials exhibited strong absorption in the visible region, where the onset of visible light absorption started at  $\sim 650 \text{ nm}$ . From this analysis, the band gap was determined using a Tauc plot,<sup>32</sup> which was found to be 2.09 eV (Fig. 1d). Such a value is comparable to other  $\text{Cu}_2\text{O}$  materials previously reported.<sup>6,8</sup> Together, these results show the preparation of a uniform truncated octahedral particles with robust visible light absorption with a narrow band gap.

**Fig. 1** Comprehensive characterization of truncated octahedra  $\text{Cu}_2\text{O}$  micro crystals (a) SEM images of the  $\text{Cu}_2\text{O}$  particles. (b) Histogram of the particle size distribution. Particle sizes represent the average over at least 100 particles  $\pm$  one standard deviation. (c) UV-vis absorption spectra of the truncated octahedra  $\text{Cu}_2\text{O}$  material. (d) Tauc plot of the  $\text{Cu}_2\text{O}$  particles studied.

Having established the structural and optical properties of the particles, we next tested whether and how they affect the health and viability of the animal model, *Caenorhabditis elegans*, as they would be expected to interact with these particles introduced into the environment. Previous work indicates that that  $\mu\text{g mL}^{-1}$  and  $\text{mg mL}^{-1}$  levels of  $\text{Cu}^{2+}$  and  $\sim 30 \text{ nm}$  spherical  $\text{CuO}$  nanoparticles, respectively, caused adverse physiological effects in laboratory and wild strains *C. elegans*.<sup>19,24,33,34</sup> In these prior studies, nanoparticle toxicity was greater than an equivalent amount of copper ion.<sup>27</sup> In contrast, a recent meta-analysis of nanoparticle toxicity showed that the particle form is typically less toxic to biological systems than similar levels of the dissolved metal ion.<sup>21</sup> To determine whether the larger ( $1.1 \mu\text{m}$ )  $\text{Cu}_2\text{O}$  particles prepared here cause toxic effects on *C. elegans*, we used the truncated octahedra as a model material for these studies.

We first tested the stability of the  $\text{Cu}_2\text{O}$  particles in culture media used for worms and the *E. coli* bacteria they consume.

We observed no significant copper release from 4 mg mL<sup>-1</sup> particles over seven days in purified Milli-Q water (Fig. 2a). When the particles were incubated in NGM, K medium lacking inorganic phosphate, or low ionic strength K medium (low K medium) inoculated with OP50 bacteria, elemental analyses indicated a significant amount of copper was released within hours. To this end, for the K and low K media, the copper release concentration reached a value of ~0.5 mg mL<sup>-1</sup> by 24 h; however, a lower value of 0.14 mg mL<sup>-1</sup> copper was solubilized for the materials in phosphate-containing NGM. The copper release reached ~1 mg mL<sup>-1</sup>

after 7 days of incubation for K and low K media (Fig. 2a), representing about one third of the total copper present in the particles in the starting dilution (~3.5 mg mL<sup>-1</sup>). For the NGM medium, notable copper release was achieved after 7 days, reaching a value of 0.61 mg mL<sup>-1</sup> soluble copper, which is lower than that observed for the phosphate free media. Copper release was significantly lower in worm growth media compared to B broth used for growth of the OP50 bacterial food consumed by *C. elegans*. Incubation in B broth caused nearly complete copper release from the particles after seven days (Fig. 2a). These elemental analyses indicate that the synthesized Cu<sub>2</sub>O particles are generally stable in culture media used for the worm growth and behaviour experiments (which require ~1 to 25 days of analyses), although the particles do undergo time- and media-dependent release of soluble copper that might negatively affect *C. elegans*.

We observed that free, soluble copper levels were markedly lower after incubation in NGM compared to either K or low K media (Fig. 2a), suggesting the Cu<sub>2</sub>O particles were more stable on NGM. To our surprise, we noticed that on NGM plates, the standard growth media for *C. elegans*, the previously brick-red Cu<sub>2</sub>O particles changed to a blue-green colour, consistent with oxidation of the particles (Fig. 2b). Interestingly, the particles did not show this acute colour change when applied to growth media lacking added inorganic PO<sub>4</sub><sup>3-</sup> (K or low K media) where the 25 mM K<sub>3</sub>PO<sub>4</sub> was replaced with KCl (Fig. 2b). The blue-green colour of the NGM-particles was consistent with particle oxidation and precipitation of Cu<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>, and the blue green precipitate could be replicated by application of aqueous CuSO<sub>4</sub> solutions to NGM plates (data not shown). We examined the integrity of the particles in each growth medium, and we found that red K- and low K-particles were stable for days while blue NGM-particles had become less visible (Fig. 2c). Additionally, we used SEM to examine the morphology of the particles after incubation in each growth medium for 24 h. As expected for the particles in K and low K growth media, they generally retained the truncated octahedral shape and size of the original structures; however, their surfaces were rougher and a degree of pitting was observed (Fig. 2d). This suggests that oxidation is happening in these media, leading to release of Cu ions to solution. Interestingly, the Cu<sub>2</sub>O materials incubated in NGM had substantially less defined shapes, as compared to the original structures (Fig. 2d), consistent with the loss of particle integrity observed by light microscopy on NGM but not K or low K media plates (Fig. 2c). Such results are consistent with the observed leaching of Cu species to solution (Fig. 2a). For all three media, release of Cu from the Cu<sub>2</sub>O material is evident; however, for NGM our data suggest that the presence of PO<sub>4</sub><sup>3-</sup> also leads to the precipitation of highly insoluble Cu<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>. For the media without PO<sub>4</sub><sup>3-</sup> (K and low K), the Cu ions are released to solution as well, but do not precipitate. As such, higher Cu solution concentrations are anticipated from the K and low K media, consistent with the results of Fig. 2a.

**Fig. 2** Chemical stability of Cu<sub>2</sub>O particles. (a) Chemical determination of copper ion release from 4 mg mL<sup>-1</sup> Cu<sub>2</sub>O materials incubated in uninoculated B broth (filled red squares), NGM (blue open circles), K medium (red open squares), low K medium (open orange triangles) inoculated with OP50 bacteria, or distilled water alone (filled blue circles), at 25 °C for 7 days. (b) Particles (4 mg mL<sup>-1</sup>) were applied to phosphate-containing NGM (top right), phosphate-free K medium (left), or low K medium (lower right) agar plates seeded with OP50 bacteria. Particles in NGM became blue-green after incubation at 25 °C for 24 h, while particles in K or low K medium remained brick red. Scale bar, 20 mm. (c) Brightfield micrographs of increasing concentrations of Cu<sub>2</sub>O particles applied to each media type after incubation at 25 °C for 24 h. Scale bar, 20 μm. (d) SEM analysis of particles before (control) and after incubation at 25 °C for 24 h in NGM (blue), K medium (red), or low K medium (orange). Bar, 2 μm.

Worms were found to readily eat particles encountered with bacterial food on the surface of NGM and other growth media (Fig. 3a and ESI† Movie S1). Ingested NGM particles were then detectable inside the gut lumen (Fig. 3b and ESI† Movie S2). Previous experiments studying the size exclusion of particles in the worm pharynx suggested the 1.1  $\mu\text{m}$  particles studied here are within the range of consumption and transport into the gut.<sup>11</sup> We have previously shown that fluorescent nanocarriers between 20 nm to 3  $\mu\text{m}$  are also consumed by worms with food and deposited into gut.<sup>30,31</sup> These results indicate that the  $\text{Cu}_2\text{O}$  particles can be internalized by feeding into the worms as they consume similarly sized bacteria food.

$\text{Cu}_2\text{O}$  particles were found to be deleterious to worm health and viability. On average, particle-treated worms were smaller and had a starved appearance compared to control worms (Fig. 3c and d). As shown in Fig. 4, we measured the overall worm length after 24 h of particle (left) and  $\text{Cu}^{2+}$  treatments (right) in different growth media and found the treated worms failed to reach the same size as age-matched control animals treated with the ethanol vehicle (Fig. 4a–c; compare to Fig. 3c and d). Higher concentrations of particles were required to cause a significant effect on worm length in NGM compared to  $\text{Cu}^{2+}$  treatment (Fig. 4a). This was not observed in K and low K media where particles and  $\text{Cu}^{2+}$  caused similar reductions in worm growth (compare Fig. 4a–c). This is consistent with our

**Fig. 3** *C. elegans* worms consume  $\text{Cu}_2\text{O}$  particles. Animals were incubated at 20 °C for 24 h with 2% ethanol vehicle alone or 4  $\text{mg mL}^{-1}$   $\text{Cu}_2\text{O}$  particles on top of lawns of OP50 bacterial food in NGM. Red arrowheads indicate visible particles. Still images from video recordings show particle uptake into the pharynx (a) and movement within the gut (b). Yellow dotted line provides a worm landmark of the gut to highlight relative movement of the ingested particle aggregate. See also ESI† Movies S1 and S2. Micrographs of worms after incubation for 24 h with (c) 2% ethanol vehicle alone or (d) with 4  $\text{mg mL}^{-1}$   $\text{Cu}_2\text{O}$  particles on top of lawns of OP50 bacterial food. Arrowheads indicate particles visible on the surface of the food; bar, 100  $\mu\text{m}$ .

**Fig. 4**  $\text{Cu}_2\text{O}$  particle treatment reduces worm length. Scatterplots showing length of worms grown in NGM (a, blue), K medium (b, red) or low K medium (c, orange) after incubation with the indicated concentrations of particles for 24 h. Individual points indicate the length of a single worm ( $n \geq 22$  animals per treatment). Lines/symbols indicate average length  $\pm 95\%$  confidence intervals. Asterisks indicate significant differences in length compared to vehicle treatment alone within a media and treatment group ( $p < 0.05$ , one-way ANOVA with Bonferroni correction for multiple comparisons); n.s. indicates means not significant ( $p > 0.05$ ). (d) Normalized changes in worm length by added particles in NGM (blue hexagons), K medium (red squares), and low K medium (orange triangles). Mean length without particles (vehicle only) was set to 100%. Error bars indicate 95% confidence intervals. Grey boxes indicate changes in normalized worm length at comparable levels of soluble Cu released by particles into K and low K medium after 24 h, as previously determined in Fig. 2a.

observation that  $\text{Cu}_2\text{O}$  particles were more stable in phosphate-free media, which likely prolonged any adverse physiological and behavioural effects. Particles caused a similar reduction in worm length after 24 h as an equivalent level of total Cu in all media types except NGM (Fig. 4), raising the question of whether Cu ion leaching from particles in K or low K media could be causative of the enhanced  $\text{Cu}_2\text{O}$  particle toxicity. As shown in Fig. 4d, worms treated for 24 h with  $4 \text{ mg mL}^{-1}$  particles were considerably shorter than vehicle-treated animals (K medium:  $68.0 \pm 2.6\%$ ; low K medium:  $76.5 \pm 2.4$ ). Because  $\sim 0.5\text{--}1 \text{ mg mL}^{-1}$  Cu is released from  $4 \text{ mg mL}^{-1}$  particles after 24 h (Fig. 2a), the detrimental effect of  $\text{Cu}_2\text{O}$  particles on worm

length was stronger than treatment with  $0.5$  or  $1.0 \text{ mg mL}^{-1}$   $\text{Cu}^{2+}$  alone (K medium:  $84.4 \pm 2.8\%$ ; low K medium:  $90.3 \pm 3.1\%$ ) (Fig. 4c and d, compare grey boxes). As a result, we conclude that levels of  $\text{Cu}^{2+}$  leached from  $\text{Cu}_2\text{O}$  particles into the growth media are insufficient to explain the observed reduction of worm length, although oxidation and release of other toxic Cu species, particularly after concentration in the lumen of the worm intestine, cannot be excluded.

We next tested the consequences of long-term incubation with the  $\text{Cu}_2\text{O}$  particles using survival assays. Median lifespan of animals grown and treated in NGM (Fig. 5a), the phosphate-containing growth medium in which we see the

**Fig. 5**  $\text{Cu}_2\text{O}$  particles have enhanced long-term toxicity compared to  $\text{Cu}^{2+}$  ions alone. Adult *C. elegans* worms grown in (a and d) NGM (blue hexagons or circles), (b and e) K medium (red squares), or (c and f) low K medium (yellow triangles) with OP50 bacterial food overlaid with the indicated concentrations of  $\text{Cu}_2\text{O}$  particles (a–c) or  $\text{CuSO}_4$  measured in  $\text{mg mL}^{-1}$  Cu added (d–f) (filled symbols) or a vehicle control (open symbols). Worm viability of each treatment group was examined every 2–4 days for ~4 weeks. Asterisks indicate significant differences in median survival times (g) compared to vehicle-treated controls from the same growth media type ( $p < 0.0005$ ; Mantel-Cox Log-rank test with Bonferroni correction). (h) Median survival normalized as a percent of vehicle-treated animals (set to 100%) after treatment with  $\text{Cu}_2\text{O}$  particles or  $\text{Cu}^{2+}$  ion on each media type. (i) Normalized median survival of animals treated with  $4 \text{ mg mL}^{-1}$  particles or  $1 \text{ mg mL}^{-1}$   $\text{Cu}^{2+}$ , an equivalent level of Cu leached from  $4 \text{ mg mL}^{-1}$  particles after ~7 days.

lowest levels of soluble Cu released, was only affected at the highest doses of particles tested, 4 mg mL<sup>-1</sup> (Fig. 5a and g). In contrast, animals grown in K and low K media showed adverse effects at 1 mg mL<sup>-1</sup> (Fig. 5b) and 0.125 mg mL<sup>-1</sup> (Fig. 5c), respectively. As summarized in Fig. 5g, animals treated with Cu<sub>2</sub>O particles showed a significant reduction in lifespan (median 10 days after reaching adulthood) compared to untreated control animals (17 days). This reduction in lifespan depended critically upon the growth media with worms grown on K or low K media showing enhanced sensitivity to Cu<sub>2</sub>O particle exposure (Fig. 5g).

To determine whether Cu leaching could be causative of the observed particle toxicity, we compared the survival of animals treated with Cu<sub>2</sub>O particles to those treated with soluble Cu<sup>2+</sup>. Median (50%) survival of worms treated with 4 mg mL<sup>-1</sup> Cu<sub>2</sub>O particles, which we have previously shown release ~1 mg mL<sup>-1</sup> soluble Cu after 7 days on all three media types, was ~10 days while survival of worms treated with 1 mg mL<sup>-1</sup> free Cu<sup>2+</sup> was 14 days. As such, it took 4 mg mL<sup>-1</sup> Cu<sup>2+</sup> to cause a quantitatively similar decrease in worm survival as seen for 4 mg mL<sup>-1</sup> Cu<sub>2</sub>O particles (Fig. 5h). Because Cu leaching from 4 mg mL<sup>-1</sup> particles is ~1 mg mL<sup>-1</sup> by this timepoint (Fig. 2a), we interpret this result as

indicating Cu<sub>2</sub>O particles are more toxic than expected if Cu<sup>2+</sup> leaching into the surrounding growth media was their primary mode of toxicity (Fig. 5i). Because Cu oxidation and leaching from particles occurs on the order of days in K and low K media, while Cu<sup>2+</sup> exposure was initiated on day 0, these results are likely underestimating the toxicity of Cu<sub>2</sub>O particles relative to Cu<sup>2+</sup>. Thus, Cu<sub>2</sub>O particle toxicity is distinct from Cu<sup>2+</sup> leaching, although leaching of other toxic forms of Cu and/or their combined toxic effects with the particulate form could be synergistic. For example, because the Cu<sub>2</sub>O particles are similar in size to the worm's bacterial food, accumulation of the particles into the gut during feeding may lead to an increase in particle concentration relative to the external environment.<sup>35</sup> Mechanical disruption of the particles is also expected as the food passes into the pharyngeal grinder which might accelerate particle dissolution in the gut lumen, enhancing toxicity.<sup>36</sup> Our results further suggest that inorganic phosphate present in NGM reduces particle and Cu<sup>2+</sup> toxicity by decreasing the bioavailability of leached Cu<sup>2+</sup> by the precipitation of insoluble phosphate salts.

These experiments indicate that Cu<sub>2</sub>O particles have significant detrimental consequences on worm viability when

**Fig. 6** Worms avoid Cu<sub>2</sub>O particles. Darkfield micrographs of worms on lawns of bacterial food treated with either (a) vehicle control or (b) 2 mg mL<sup>-1</sup> Cu<sub>2</sub>O particles; worms are indicated in white. Percent of animals found within one worm body length of the food (yellow dotted line) after treatment with particles (c) or Cu<sup>2+</sup> alone (d) were measured in either NGM (blue hexagons or circles), K medium (red squares), or low K medium (orange triangles). 4 mg mL<sup>-1</sup> Cu<sub>2</sub>O particles (c, open grey box) leach ~0.5–1 mg mL<sup>-1</sup> Cu ion after 24 h (Fig. 2a), a comparable level indicated by the filled grey box in (d). Error bars indicate the mean proportion ± 95% confidence intervals ( $n \geq 39$  animals). Asterisks indicate significant differences in the proportion of animals found on 0.25 mg mL<sup>-1</sup> (and greater) particle-treated lawns or 2 mg mL<sup>-1</sup> Cu<sup>2+</sup> treated lawns compared to the vehicle-only control of the same media type ( $p < 0.0015$ ), except for low K medium which was not found to be significantly different until 0.5 mg mL<sup>-1</sup>; n.s. indicates  $p > 0.05$  (Fisher exact test with Bonferroni correction).

the animals were given no alternate food source or opportunity to escape. Worms typically spend most of their time in the lawns of *E. coli* bacterial food, showing only infrequent trips away from the lawn (Fig. 6a). However, we found worms avoided food containing Cu<sub>2</sub>O particles after 24 h (Fig. 6b). We measured the proportion of animals found off food treated with the different levels of particles (Fig. 6c). Worms began avoiding lawns of bacteria with particles even at low concentrations (0.25 mg mL<sup>-1</sup>), with complete avoidance observed at the highest particle levels, 4 mg mL<sup>-1</sup>. Particle avoidance at 24 h was largely recapitulated by Cu<sup>2+</sup> ion, with ~50% of worms showing avoidance at 2 mg mL<sup>-1</sup> Cu<sup>2+</sup> applied, independent of media type (Fig. 6d). Levels of Cu ion leached from 4 mg mL<sup>-1</sup> particles after 24 h reaches only ~0.5 mg mL<sup>-1</sup> (Fig. 2a), a level of Cu<sup>2+</sup> which by itself only causes modest avoidance effects (Fig. 6d, filled grey box). Together, these results suggest that Cu<sup>2+</sup> leaching is not responsible for worm avoidance of the Cu<sub>2</sub>O particles.

These results show that Cu<sub>2</sub>O particles are generally aversive to worms, with worms detecting and avoiding food areas containing particles. Why do worms exposed to Cu<sub>2</sub>O particles die? Because of the phenotypic similarities between Cu<sub>2</sub>O and Cu<sup>2+</sup> treatment, our data are consistent with one mode of Cu<sub>2</sub>O particle toxicity occurs *via* particle oxidation and leaching of toxic Cu<sup>2+</sup> ions. Contamination of bacterial food could affect *C. elegans* viability both acutely and after long-term exposure. Cu<sup>2+</sup> is aversive to *C. elegans*, typically activating nociceptive sensory neurons and leading to the avoidance behaviour we observe.<sup>37</sup> The shortened lifespan and reduction of animal growth could be a direct result of starvation. Metals like Cu<sup>2+</sup> are also taken up into *C. elegans* and cells *via* the transporters expressed in the gut and other tissues, and loss of these transporters reduces metal uptake and acute toxicity.<sup>38</sup> Metals are detoxified by ABC transporters that efflux accumulated metal ions, and loss of these transporters enhances metal toxicity by preventing their removal.<sup>39</sup> Once inside cells, heavy metals like Cu<sup>2+</sup> have long-established toxic effects, interacting with thiol containing molecules in cells and increasing reactive oxygen species.<sup>40,41</sup> Our results are consistent with previous results with CuO nanoparticles which show enhanced toxicity in the particle form,<sup>19</sup> and toxicity results for both particle types may relate to their size and/or sensitivity to oxidation. Phosphate-containing media led to the formation of insoluble Cu<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub> salts and a reduction in toxicity. As such, the Cu<sub>2</sub>O particles in phosphate-free media have the potential to deliver more of the toxic Cu<sup>2+</sup> form through particle oxidation. In the absence of PO<sub>4</sub><sup>3-</sup>, these copper ions remain in solution, leading to animal exposure. We propose that mechanical disruption of ingested particles during passage through the pharyngeal grinder will increase their surface area, facilitating oxidation and copper ion dissolution. Such concentrated uptake should elevate Cu<sup>2+</sup> levels in the gut lumen to levels much higher than equimolar concentrations of CuSO<sub>4</sub> in the medium. It might also trigger pharyngeal spitting or learned sensory avoidance behaviours.<sup>37,42,43</sup> Alternatively, nanosized

materials may have additional mechanical consequences on *C. elegans* feeding and other behaviours separate from the catalytic properties of the materials.<sup>44</sup> These could contribute to our observation that worms avoid Cu<sub>2</sub>O particles more than Cu<sup>2+</sup> alone. Future work will test whether particles of different size or shape have altered stability and toxicity in different growth conditions and ionic environments. Use of defined *C. elegans* mutants with predicted defects in Cu<sup>2+</sup> avoidance behaviour or alterations in metal ion uptake should reveal whether the reduced viability we observe is caused by starvation or metal uptake. Additional measurements of metal toxicity, including morphological defects of neuron development, could help explain how Cu<sub>2</sub>O nanomaterials affect animal viability.<sup>19,20</sup> Such results illustrate that while these materials demonstrate promise for environmental remediation applications, they might degrade to soluble toxic or insoluble non-toxic materials. This indicates that while great effort should be made to fully examine catalytic materials for clean-up of toxic sites, the long-term effects of release of nanomaterials must also be examined to determine their inherent toxicity and environmental effects.

## Conclusions

Here we document the synthesis and functional characterization of truncated octahedral Cu<sub>2</sub>O crystals and their effects on an animal model. We show using the nematode worm, *Caenorhabditis elegans*, that Cu<sub>2</sub>O particles have both acute and long-term toxic effects, reducing animal feeding and viability. Indeed, the worms actively choose to avoid areas that are contaminated with particles. Cu<sub>2</sub>O particle toxicity is enhanced at reduced ionic strength and reduced in the presence of inorganic phosphate, suggesting environmental factors affect particle stability and catalytic perdurance. These results show that Cu<sub>2</sub>O particles may provide a safe alternative to treatment of environmental pollutants if their oxidation and release of toxic Cu<sup>2+</sup> ions can be eliminated.
