Abstract: Topographic depressions in upland soils experience anaerobic conditions conducive for iron (Fe) reduction following heavy rainfall. These depressional areas can also accumulate reactive Fe compounds, carbon (C), and nitrate, creating potential hot spots of Fe-mediated carbon dioxide (CO₂) and nitrous oxide (N₂O) production. While there are multiple mechanisms by which Fe redox reactions can facilitate CO₂ and N₂O production, it is unclear what their cumulative effect is on CO₂ and N₂O emissions in depressional soils under dynamic redox. We hypothesized that Fe reduction and oxidation facilitate greater CO₂ and N₂O emissions in depressional compared to upslope soils in response to flooding. To test this, we amended upslope and depressional soils with Fe(II), Fe(III), or labile C and measured CO₂ and N₂O emissions in response to flooding. We found that depressional soils have greater Fe reduction potential, which can contribute to soil CO₂ emissions during flooded conditions when C is not limiting. Additionally, Fe(II) addition stimulated N₂O production, suggesting that chemodenitrification may be an important pathway of N₂O production in depressions that accumulate Fe(II). As rainfall intensification results in more frequent flooding of depressional upland soils, Fe-mediated CO₂ and N₂O production may become increasingly important pathways of soil greenhouse gas emissions.

Keywords: iron; redox; carbon dioxide; nitrous oxide; chemodenitrification; Feammox; dissimilatory iron reduction; upland soils; flooding; global change

1. Introduction

Rainfall intensification as a result of global climate change has resulted in the increased ponding of ecosystems that exhibit topography [1–3]. Even the ponding of shallow topographic depressions in upland soils can deplete soil O₂ by inhibiting the diffusive resupply of O₂ consumed by microbial respiration [4,5]. These anaerobic periods allow for the occurrence of anaerobic biogeochemical reactions, such as iron (Fe) reduction and oxidation, that are typically overlooked in non-flooded environments. Iron redox reactions can be coupled to C and N transformations in upland soils via multiple mechanisms (Figure 1) [6,7], contributing to emissions of carbon dioxide (CO₂) and nitrous oxide (N₂O), two potent greenhouse gases. These reactions could become more prevalent as rainfall intensification increases the ponding extent and duration in upland soils. However, it is unknown if Fe redox cycling could be more important in depressional areas that are more prone to ponding. While Fe redox reactions are known to occur in upland soils, it is unclear how they contribute to CO₂ and N₂O emissions in upslope and depressional soils in response to ponding following heavy rainfall.

Figure 1. Conceptual diagram showing the four main Fe mediated C and N transformations considered in this study: Dissimilatory Fe reduction, abiotic reactive oxygen species (ROS) formation, anaerobic ammonium oxidation coupled to Fe reduction (Feammox), and chemodenitrification. While C is not directly lost via ROS production, ROS can stimulate the abiotic degradation of soil organic matter (SOM). Arrows originate at the starting reactant and end at the product. Colors correspond to different reactions coupling Fe reduction or oxidation with C and N transformations.

The reduction and oxidation of Fe minerals has the potential to drive C mineralization to a greater degree in depressional compared to upslope soils via multiple mechanisms. Dissimilatory Fe reduction is an anaerobic respiration pathway in which microbes couple Fe reduction with C oxidation [6,8,9], potentially contributing up to 40% of soil C mineralization in upland soils [10]. Iron reduction potential could be greater in depressional soils compared to upslope soils due to legacy effects from more frequent ponding in depressions. For example, Fe-reducing bacterial taxa such as *Geobacter* and *Anaeromyxobacter* can be more abundant in depressions compared to nearby upslope soils [11], suggesting higher genetic potential for Fe reduction in depressional soils. Fluctuations in soil O₂ concentrations can also facilitate the buildup of poorly-crystalline Fe compounds that are more susceptible to microbial reduction [12–14], leading to higher concentrations of poorly crystalline Fe(III) minerals in depressional soils that more frequently experience fluctuations in soil O₂ [11,15]. If Fe reduction rates are Fe-limited, then this could directly stimulate Fe reduction in depressional soils compared to upslope soils. If Fe reduction rates are C-limited, then this could indirectly stimulate Fe reduction in depressional soils that can receive labile C inputs from a variety of sources. For example, C protected from mineralization by complexation with Fe-oxyhydroxides under aerobic conditions [16–18] can be released as the Fe is reduced under anaerobic conditions [18–20]. Topographic depressions can also accumulate C as a result of erosion or downslope transport of dissolved organic carbon (DOC) in hydrological flow [21–23]. When upland soils drain and return to aerobic conditions, abiotic Fe(II) oxidation can create reactive oxygen species (ROS) that breakdown recalcitrant soil organic matter (SOM) via Fenton reactions [24]. More frequent fluctuations in soil O₂ concentrations in depressional soils compared to upslope soils can lead to more episodes of Fe(II) oxidation [15], potentially fueling more abiotic soil organic matter (SOM) mineralization in depressional soils. Some or all of these mechanisms could contribute to greater potential for Fe-coupled C mineralization in depressional soils compared to upslope soils, but the contribution of Fe redox cycling to microtopographic variation in upland soil CO₂ and N₂O emissions has not previously been explored.

The reduction and oxidation of Fe minerals may also contribute to N₂O production in upland soils via multiple mechanisms. Under anaerobic conditions, the microbially mediated process of Feammox can couple Fe(III) reduction to ammonium (NH₄⁺) oxidation [25,26]. The most energetically favorable end product of Feammox is dinitrogen gas (N₂) [25], but the reaction can also produce NO₃[−] or NO₂[−] that can subsequently be reduced to N₂O via biotic denitrification or chemodenitrification. Chemodenitrification can abiotically produce N₂O via oxidation of Fe(II) coupled to reduction of NO₃[−],

nitrite (NO_2^-), or nitric oxide (NO) [7,27,28]. Some microorganisms can also couple Fe(II) oxidation with NO_3^- or NO_2^- reduction for energy yield or NO_2^- detoxification, but these reactions occur more slowly compared to chemodenitrification [28–31]. While the importance of chemodenitrification and Feammox in driving soil N cycling from upland soils is increasingly recognized [7,25,26,32], these reactions are not often considered as major sources of N_2O production from upland soils. However, they may be important drivers of soil N_2O emissions in upland ecosystems that experience soil redox fluctuations, and especially in depressional soils that experience these fluctuations more frequently than upslope soils.

In this study, we tested the hypothesis that oxidation and reduction of reactive Fe compounds facilitate greater CO_2 and N_2O emissions in depressional compared to upslope soils in response to flooding and drainage. In a laboratory experiment, we measured CO_2 and N_2O emissions as well as Fe(II) accumulation in upslope and depressional soils in response to a flooding and drainage cycle with and without amendment of substrates (either Fe(III), Fe(II), or labile C). This was done to gain insight into which Fe reduction and oxidation processes contribute to soil trace gas emissions. We predicted that if dissimilatory Fe reduction contributes to CO_2 emissions, or if Feammox indirectly contributes to soil N_2O emissions, then added Fe(III) minerals should stimulate CO_2 and N_2O production, respectively. We also predicted that if Fe(II) oxidation contributes to SOM decomposition via the creation of ROS, or N_2O production via chemodenitrification, then addition of Fe(II) should stimulate CO_2 and N_2O production, respectively. Finally, we predicted that if C availability as an electron donor rather than electron acceptor availability limits anaerobic respiration, then C addition should stimulate CO_2 emissions in flooded soils. By assessing C amendment effects on Fe reduction rates, we can determine the potential importance of Fe reduction as an anaerobic respiratory pathway generating CO_2 . These predictions assume that the treatment amendments will only stimulate the processes of interest if the processes are limited by the added substrates rather than other substrates or factors such as microbial community composition.

2. Methods

2.1. Study Site

This study was conducted on soils collected from three agricultural fields managed in conventional maize-soybean rotations across Champaign County, Illinois (40.2139° N, 88.2461° W): South Farms, Energy Farm, and Cardinal Road. When the soils were collected during the summer of 2018, the Energy Farm and Cardinal Road fields were planted in maize while the South Farms field was planted in soybean. Depressional soils were identified within each of these fields based on visual observations of ponding following rain events of at least 30 mm in a 24-h period. Upslope areas were chosen as relatively elevated areas within 100 m of the depressional area in the same field. All depressional soils were classified as silty clay loams from the Drummer soil series. Upslope soils from South Farms and Cardinal Road fields were silt loams from the Flanagan soil series, and the upslope soils from the Energy Farm field were fine-silty soils from the Dana series.

The mean annual air temperature in Champaign County is 10 °C, and the mean annual precipitation is 1008 mm [33]. For the early season experiment, soils were collected in May after planting of crops and fertilization of only the maize fields. For the late season experiment, soils were collected in July when the crops were at peak growth. The mean air temperature in May was 16.7 °C and the mean monthly precipitation was 105 mm. The mean temperature in July was 23.1 °C and the mean monthly precipitation was 114 mm [33]. Soils were collected when no rain had fallen in at least 4 days to minimize effects from antecedent soil moisture differences between topographic positions.

2.2. Experimental Design

A laboratory experiment was designed to elucidate the role of Fe reduction and oxidation on CO_2 and N_2O emissions from depressional and upslope soils collected from three agricultural fields

in Champaign County, Illinois. The experiment was conducted twice, once in May and once in July, to account for potential changes in soil properties and microbial community composition over the course of the growing season. To determine the role of Fe reduction and oxidation on soil GHG emissions, CO₂ and N₂O emissions were measured from soil cores in response to flooding and drainage over the course of a nine-day lab incubation, and Fe(II) concentrations were measured on the final day of the flooding period in the late season experiment. A nine-day incubation period was chosen to replicate a four-day flooding period followed by four days of drainage, which is typical in depressional upland soils in response to heavy rainfall. To gain insight into which specific pathways were responsible for CO₂ or N₂O production from these soils, the soil cores were treated with either Fe(III), Fe(II), or C. If any of the Fe redox reactions detailed in the introduction (Figure 1) were limited by Fe(III), Fe(II), or C, then these treatments should stimulate CO₂ or N₂O production compared to unamended control cores.

2.3. Soil Collection and Initial Characterization

Approximately one week prior to initiating experimental treatments, seven 0–10 cm deep surface soil cores were collected from each topographic position within each of the three sites. The cores were collected within 5 m from the center of each plot using a 10 cm diameter auger. The cores were stored in gallon Ziploc bags at ambient temperature and immediately transported back to lab at the University of Illinois at Urbana-Champaign where cores from each topographic position within each site were homogenized and passed through an 8 mm sieve. Soils were homogenized to limit spatial variability and allow for the detection of treatment effects in the lab. The homogenized soil was analyzed for initial gravimetric soil moisture by drying five 10 g subsamples at 105 °C for two days and measuring water loss. Initial HCl extractable Fe(II) and Fe(III) concentrations were measured by adding 1.0 g of dry soil equivalent to 30 mL of 0.5 N HCl and shaking vigorously on an orbital shaker for 24 h. These samples were then centrifuged at 10,000 rcf for 10 min, and the supernatant was immediately analyzed for Fe(II) and Fe(III) concentrations using a modified ferrozine method [34]. Soil pH was measured in a 1:1 deionized water to dry soil mass mixture. These measurements were performed on five replicate subsamples from each of the homogenized soil samples originating from the six sampling locations. Three 10 g subsamples of air-dried and ground soil from each sampling location for the late season experiment were also analyzed for total organic C (TOC) concentrations using a Vario Micro Cube elemental analyzer (Elementar, Hanau, Germany).

2.4. Experimental Methods

The experiment was conducted on re-packed soil cores that could be flooded and drained in the laboratory. For each core, a 150 g subsample of homogenized soil from a given sampling location was packed to approximate field bulk density ($\sim 1.0 \text{ g cm}^{-3}$) in a plastic cylinder that was 11 cm tall and 5 cm in diameter. Each plastic cylinder had 0.5 mm mesh window screening glued to the bottom of the cylinder with a watertight plastic cap fitted over top of the window screening. This allowed the cores to retain water when capped at the bottom and to drain water without losing soil when the cap was removed. Five replicate cores were packed with soil from each sampling location for each treatment, for a total of 120 cores. Each core was placed into a 1 L canning jar filled with 150 g of silica sand to allow water to drain away from the bottom of the soil cores. The silica sand was heated at 550 °C for four hours in a muffle furnace to burn off any C compounds and sterilize the sand.

Net CO₂ and N₂O fluxes were measured from each of the jars five times over the course of the nine day incubation. A pre-treatment measurement was made on field moist soils within one week of collection. All of the cores were then flooded with 80 mL of deionized (DI) water the day after the pre-treatment trace gas flux measurement. For the treatment soils receiving amendments, Fe(III), Fe(II), or acetate was dissolved in the added DI. Water was added by injecting 20 mL of water four times vertically throughout the core using a 10 cm long spinal tap needle. This process left approximately 0.5 cm of standing water above the soil surface and saturated the soil core. Dissolved O₂ was not purged from the DI prior to flooding the cores, and the jar was left open to room air in between trace

gas flux measurements. Trace gas fluxes from all cores were measured 24 h after flooding, and again 72 h after flooding. The watertight plastic caps were removed from all of the cores the day after the 72-h flooded measurement to allow the soil cores to drain. Standing water was no longer present on any cores within 12 h of removing the cap. Trace gas fluxes were measured from each core 24 h after removing the cap and again 72 h after removing the cap.

The Fe(III), Fe(II), and C treatment solutions for the experiment were prepared based on previous data from the study sites. The Fe(III) amendment corresponded to observed differences in Fe(III) concentrations between depressional and upslope soils at these sites [11,15]. For the Fe(III) treatment, hydrous ferrous oxide (HFO) synthesized from ferric chloride hexahydrate [35] was added to increase Fe(III) concentrations by 113 ug Fe g^{-1} dry soil to each soil core for the first experiment and by 165 ug Fe g^{-1} dry soil for the second experiment. Stoichiometric calculations of 4 moles Fe reduced for every mole C oxidized [10] suggest that this was of sufficient magnitude to sustain $0.08\text{--}0.12 \text{ ug C-CO}_2 \text{ g}^{-1} \text{ h}^{-1}$ of CO_2 production coupled to dissimilatory Fe reduction over the course of the 72 h flooding period. For the Fe(II) treatment, Fe(II) was added to correspond to differences in Fe(II) concentrations previously observed between depressional versus upslope soils in these sites under ponded conditions [11,15]. To do this, approximately $125 \text{ ug Fe-FeCl}_2 \text{ g}^{-1}$ dry soil was added to each soil core. The Fe(II) solution was made by dissolving FeCl_2 into DI water under an anoxic headspace. It is difficult to calculate an expected effect size for the Fe(II) treatment since the abiotic breakdown of SOM by ROS does not have a set stoichiometric ratio. This Fe(II) addition amount could potentially fuel the production of $139 \text{ ng N-N}_2\text{O g}^{-1} \text{ h}^{-1}$ via chemodenitrification over the course of the 72 h flooding period assuming six moles of Fe oxidized for every one mole N_2O produced [7]. For the C treatment, the C amendment rate was designed to stimulate up to $0.37 \text{ ug C-CO}_2 \text{ g}^{-1} \text{ h}^{-1}$ CO_2 efflux over the course of the nine-day experiment, assuming 30% carbon use efficiency. This response size is similar to previously observed differences in CO_2 efflux between upslope and depressional soils under flooded conditions [15]. By adding 80 mL of 7.2 mM sodium acetate to each soil core in both experiments, the C concentration of each core was increased by approximately 0.12 mg C g^{-1} dry soil.

To measure net CO_2 and N_2O fluxes from the soil cores, each canning jar was sealed with a metal lid fitted with a rubber septum and the change in CO_2 and N_2O concentrations was measured over four hours. Immediately after sealing each jar, a 15 mL gas sample was collected by inserting a needle fitted to a 20 mL syringe and a two-way stopcock through the rubber septum, mixing the jar headspace by slowly pumping the syringe three times, and then removing a 15 mL gas sample. The gas sample was stored in a 10 mL pre-evacuated vial sealed with a thick rubber septum (Geo-Microbial Technologies, Inc., Ochelata, OK, USA) and an aluminum crimp (Wheaton Industries Inc., Millville, NJ, USA). Another gas sample was collected from each jar four hours after the initial gas sample. A four-hour incubation was chosen to ensure accumulation of CO_2 and N_2O in the jar headspace so that a change in trace gas concentrations could be detected. It is possible that the accumulation of N_2O in the jar headspace could stimulate soil N_2O consumption and result in an underestimation of net N_2O emissions [36]. All gas samples were analyzed on a Shimadzu GC-2014 gas chromatograph fitted with an electron capture device and a thermal conductivity detector for N_2O and CO_2 analysis, respectively (Shimadzu Scientific Instruments, Columbia, MD, USA). Net CO_2 and N_2O fluxes were calculated as the change in CO_2 and N_2O concentrations over the four-hour incubation. A minimum detectable flux was calculated based on the standard deviation of three standard gas samples (1001 ppm CO_2 and 1.08 ppm N_2O) run on the GC. The calculated detection limit for N_2O was $0.0025 \text{ ppm h}^{-1}$ and for CO_2 was 2.41 ppm h^{-1} . Net fluxes under this limit were considered not detectable and estimated as zero. Since the soil cores were homogenized and water was evenly distributed throughout the cores, fluxes were expressed per soil mass. This assumes that gas production was even throughout the core and that diffusion was minimally limited.

Concentrations of Fe(II) were measured from each soil core on Day 5 of the experiment using the modified ferrozine method described above [34]. To calculate net rates of Fe reduction, the average initial Fe(II) concentration of soils collected from each topographic position within each site were

subtracted from the Fe(II) concentrations measured from corresponding soil cores on Day 5 of the late season experiment, after cores had been flooded for 72 h. This number was divided by the total amount of time that each core had been flooded to calculate the net rate of Fe reduction within each core.

2.5. Statistical Analyses

All statistical analyses were performed using R version 3.5.2 [37]. Two way analysis of variance (ANOVA) was used to assess differences in initial SOC, pH, Fe(III), and Fe(II) concentrations using the ANOVA function in the car package [38]. Separate ANOVAs were run for each soil property with site and topographic position as independent variables. Type III sums of squares were used to test for the presence of an interaction, and type II sums of squares were used if no interaction was present. This same analysis was done to compare net Fe reduction rates in response to all treatments on day 5 of the experiment. A separate ANOVA was run for each site with treatment and topographic position included as independent variables. Tukey-corrected multiple comparisons were used to assess differences in Fe rates between all treatments and topographic positions within each site using the lsmeans package [39]. Statistical significance was assessed as $p < 0.05$.

Mixed effects models were used to determine the effect of topographic position and day of experiment on soil CO₂ and N₂O emissions from unamended control soil cores. The control cores were analyzed separately to isolate the effect of topographic position on soil CO₂ and N₂O emissions without amendments. Separate models were run on CO₂ and N₂O emissions from soils collected from each site. In each model, topographic position and day of experiment were included as fixed independent variables, while soil core ID was included as a random variable to account for repeated measures of each soil core over time. This was done using the lme function from the nlme package in R [40]. N₂O emissions were log transformed to meet assumptions of normality; a constant of 5 was added prior to log transformation to avoid taking the log of values below 1. The anova.lme function was then used to determine which variables explained the most variance in either CO₂ or N₂O emissions.

To gain insight into the processes driving the responses to soil flooding and drainage, we assessed the difference in CO₂ or N₂O emissions between treatment cores that received amendments and corresponding unamended soil cores that served as controls. This was done by subtracting the mean control CO₂ or N₂O efflux ($n = 5$) from the mean CO₂ or N₂O efflux from any given treatment. Standard errors were calculated using Gaussian error propagation to assess the variability of this treatment effect. Linear mixed effects models were also used to assess treatment and day of experiment effects on soil CO₂ and N₂O efflux over the course of the incubation, as described above. Soil cores receiving each of the three treatments as well as the control were included in these models to assess treatment effects on soil CO₂ and N₂O emissions compared to control soils over the course of the incubation. Prior to running these models, CO₂ and N₂O emissions were log transformed to meet assumptions of normality. Separate models were run for soils collected from each topographic position (upslope versus depressional) within each site. All linear mixed effects models were run using the lme function from the nlme package in R [40]. To assess the significance of the treatment and day of experiment effects, ANOVAs were run on each model using the anova.lme function in the nlme package [40].

3. Results

3.1. Background Soil Properties

Soil organic C concentrations, pH, Fe(III), and Fe(II) concentrations differed significantly between upslope and depressional soils and among sites (Figure 2). Soil organic C concentrations were significantly higher in depressional compared to upslope topographic positions (Figure 2a; $F_{1,14} = 41$, $p < 0.001$). Overall, SOC concentrations were highest at Cardinal Road and lowest at the Energy Farm ($F_{2,14} = 97$, $p < 0.001$). Soil pH was higher in depressions compared to upslope positions ($F_{2,26} = 50$, $p < 0.001$, Figure 2b); it was lowest in the Energy Farm soils and highest in Cardinal Road soils ($F_{1,26} = 459$, $p < 0.001$). Concentrations of 0.5 N HCl extractable Fe(III) were significantly higher

in depressional soils (Figure 2c; $F_{1,26} = 7.0$, $p = 0.01$), but did not differ significantly among sites ($F_{2,26} = 2.7$, $p = 0.09$). Finally, 0.5 N HCl extractable Fe(II) concentrations were higher in depressional soils compared to upslope soils (Figure 2d; $F_{1,26} = 32$, $p < 0.001$), and were highest in Cardinal Road soils ($F_{2,26} = 3.8$, $p = 0.03$).

Figure 2. Soil organic carbon concentration (a), soil pH (b), 0.5N HCl-extractable Fe(III) concentration (c), and 0.5N HCl-extractable Fe(II) concentration (d) from upslope and depressional soils from the South Farms (SF), the Energy Farm (EF), and Cardinal Road (CR) ($n = 3$ for C, $n = 5$ for pH, Fe(II), and Fe(III)). Colors represent the topographic position where soils were collected from within each site. The line in each box represents the mean, the upper and lower portions of each box correspond to the 25th and 75th percentiles, the whiskers extend to the upper and lower inter-quartile range, and dots represent outliers.

3.2. Redox Fluctuation Effects on Trace Gas Emissions

Trace gas emissions responded to a redox fluctuation caused by flooding and drainage of soils similarly in the early- and late growing seasons. Therefore, only late season data are presented throughout the results whereas early season data are reported in the supplemental material (Figures S1–S4, Tables S1 and S2). Flooding inhibited CO_2 emissions from all soils, and drainage stimulated CO_2 emissions above pre-flooding levels (Figure 3). This effect was evident from both upslope and depressional soils from all three sites, but the degree to which CO_2 emissions spiked as soils drained differed between upslope and depressional soils at each site. Specifically, the day of experiment significantly interacted with the topographic position at the South Farms ($F_{4,32} = 5.3$, $p = 0.002$) and Cardinal Road ($F_{4,32} = 54$, $p < 0.001$) soils (Figure 3a,c). While Energy Farm soils did not exhibit this interaction effect (Figure 3b), topographic position and day of experiment each significantly affected soil CO_2 emissions ($F_{1,8} = 18$, $p = 0.003$; $F_{4,32} = 31$, $p < 0.001$; respectively). In contrast to the consistent direction of response to flooding for the two topographic positions, upslope and depressional

soils did not respond the same to soil drainage in all sites. Upslope soils from the South Farms had higher CO₂ emissions compared to depressional soils during drainage, while depressional soils in the Energy Farm and Cardinal Road had higher CO₂ emissions as soils drained (Figure 3). This was most pronounced in soils collected from Cardinal Road, where CO₂ emissions from depressional soils reached $0.60 \pm 0.03 \text{ ug C-CO}_2 \text{ g}^{-1} \text{ h}^{-1}$ on the last day of the experiment.

Figure 3. Soil CO₂ emissions (mean $\pm$ SE, $n = 5$) from unamended control soils from the South Farms (a), the Energy Farm (b), and Cardinal Road (c) over the course of the late season experiment. Solid lines represent emissions from depressional soils, and dotted lines represent emissions from upslope soils. Shaded areas represent when the soil cores were flooded. Results from ANOVAs run on linear mixed effects models are presented within each panel. Interaction effects are presented when significant interactions were detected. Otherwise, significant main effects are presented.

Flooding stimulated N₂O emissions from all soil cores (Figure 4). There was a significant interaction effect between the topographic position and the day of experiment on N₂O emissions from all three sites ($p \leq 0.001$, Figure 4). Soil N₂O emissions were higher from upslope soils compared to depressional from all three sites on the first day of flooding. Soil N₂O emissions returned to near undetectable levels for most soils after day 5 of the experiment. This was not the case for upslope soils from the Energy Farm, where N₂O emissions climbed to $40.7 \pm 2.32 \text{ ng N-N}_2\text{O g}^{-1} \text{ h}^{-1}$ by Day 9 of the experiment (Figure 4b).

Figure 4. Soil N₂O emissions (mean $\pm$ SE, $n = 5$) from unamended control soils from the South Farms (a), the Energy Farm (b), and Cardinal Road (c) over the course of the late season experiment. Solid lines represent emissions from depressional soils, and dotted lines represent emissions from upslope soils. Shaded areas represent when the soil cores were flooded. Results from ANOVAs run on linear mixed effects models are presented within each panel. Interaction effects are presented when significant interactions were detected. Otherwise, significant main effects are presented.

3.3. Amendment Effects on Trace Gas Emissions and Fe Reduction

Of all amendment treatments, labile C had the strongest and most consistent effect on soil CO₂ emissions in response to flooding and drainage in the late growing season (Figure 5). Carbon amendment stimulated soil CO₂ emissions from all sites and topographic positions during both flooding and drainage (Table 1, Figure 5, $p \leq 0.05$ for all treatment * day of experiment interaction effects). During flooded conditions on days 2 through 5 of the experiment, the treatment effect size relative to unamended controls soils was as large as 0.39 ug C-CO₂ g⁻¹ h⁻¹, comparable to the expected response based on the amount of acetate added and assumed 30% carbon use efficiency (Figure 5). Amendment of Fe(II) stimulated CO₂ emissions as both upslope and depressional soils from Cardinal Road drained, but had no effect on CO₂ emissions from the South Farms and Energy Farm soils (Figure 5). Soil CO₂ emissions did not exhibit a consistent response to the Fe(III) treatment throughout the experiment (Figure 5).

Figure 5. Effect size of treatments on soil CO₂ emissions from upslope (a–c) and depressional (d–f) soils from the South Farms (a,d), the Energy Farm (b,e), and Cardinal Road (c,f) during the late season experiment. The treatment effect was calculated as the difference between net CO₂ emissions from soil receiving a given treatment amendment compared to unamended control soils. Error bars represent propagated standard error ($n = 5$) of the difference between the control and treatment means. Colors represent each treatment. Gray shading indicates when soils were flooded.

Table 1. Results from ANOVAs run on mixed effects models examining the interaction effect between treatment and date on soil CO₂ emissions during the late season lab experiment.

Site	Drainage Class	Degrees of Freedom (n,d)	F Statistic	p Value
South Farms	upslope	9,47	3.2	0.004
South Farms	depressional	9,48	2.1	<0.05
Energy Farm	upslope	9,48	4.6	<0.001
Energy Farm	depressional	9,46	3.8	0.001
Cardinal Road	upslope	9,45	9.2	<0.001
Cardinal Road	depressional	9,47	3.5	0.002

Log transformed CO₂ emissions were included as the dependent variable, treatment was the independent variable, and date was included as a random variable.

Soil N₂O emissions from depressional and upslope soils from all three sites also responded to both C and Fe(II) additions in the late growing season (Figure 6). Carbon and Fe(II) addition stimulated N₂O emissions starting on the first day of flooding (Table 2, Figure 6, $p < 0.05$ for all treatment * day of experiment interaction effects). Carbon addition led to the largest treatment effects. Carbon addition stimulated N₂O emissions on the first day of flooding in soils from the South Farms and the Energy Farm (Figure 6). The addition of Fe(II) also consistently stimulated N₂O emissions during flooding of both depressional and upslope soils from most sites, with an average increase of 4.41 ± 0.82 ng N-N₂O g⁻¹ h⁻¹ above emissions from unamended control soils on the third day of the experiment (Figure 6). Assuming a ratio of 6 mole Fe oxidized for every 1 mole N₂O produced via chemodenitrification [7], the oxidation of just 1.4 µg Fe(II) g⁻¹ soil could drive this observed treatment effect over 24 h flooded period prior to the day 3 measurement, which is less than 2% of the Fe(II) added to the cores. Similar treatment effects on soil N₂O emissions were observed on soils collected during the early growing season (SI data).

Figure 6. Effect size of treatments on soil N₂O emissions from upslope (a–c) and depressional (d–f) soils from the South Farms (a,d), the Energy Farm (b,e), and Cardinal Road (c,f) during the late season experiment. The treatment effect was calculated as the difference between net N₂O emissions from soil receiving a given treatment amendment compared to unamended control soils. Error bars represent propagated standard error ($n = 5$) of the difference between the control and treatment means. Colors represent each treatment. Gray shading indicates when soils were flooded.

Table 2. Results from ANOVAs run on mixed effects models examining the treatment effect on soil N₂O emissions during the late season lab experiment.

Site	Drainage Class	Degrees of Freedom (n,d)	F Statistic	p value
South Farms	upslope	9,47	46	<0.001
South Farms	depressional	9,48	6.9	<0.001
Energy Farm	upslope	9,48	7.6	<0.001
Energy Farm	depressional	9,46	8.7	<0.001
Cardinal Road	upslope	9,45	7.1	<0.001
Cardinal Road	depressional	9,47	3.1	0.006

Log transformed N₂O emissions were included as the dependent variable, treatment was the independent variable, and date was included as a random variable.

Carbon addition resulted in higher Fe reduction rates compared to unamended control soils during the 72-h flooding treatment in depressional soils but not upslope soils. Across all sites, treatment and topographic position significantly interacted to affect Fe reduction rates (Table 3, Figure 7). In C-amended depressional soils, average Fe reduction rates from all three sites ranged between 3.51 and 5.07 $\mu\text{g Fe g}^{-1} \text{h}^{-1}$ compared to between -0.14 and $0.55 \mu\text{g Fe g}^{-1} \text{h}^{-1}$ in upslope soils (Figure 7). Tukey-corrected multiple comparisons showed that Fe reduction rates were significantly higher from C-amended depressional soils compared to all other treatments in depressional or upslope soils across all sites ($p < 0.01$, Figure 7).

Table 3. Results from ANOVAs explaining variation in soil Fe reduction rates during the late season lab experiment.

Site	Degrees of Freedom (n,d)	F Statistic	p Value
South Farms	3,32	17	<0.001
Energy Farm	3,32	172	<0.001
Cardinal Road	3,32	6.1	0.002

Figure 7. Net Fe reduction rates in depressional and upslope areas at the South Farms (a), the Energy Farm (b), and Cardinal Road (c) during the late season experiment (mean $\pm$ SE, $n = 5$). Colors represent different treatments.

Soil Fe reduction rate is the dependent variable for each model and the interaction between treatment and topographic position is the independent variable.

4. Discussion

We demonstrated that the potential for Fe reduction and oxidation to drive CO₂ and N₂O emissions is greater in depressional versus upslope soils, in support of our hypothesis. Flooding initially suppressed CO₂ emissions from all soils but triggered a pulse in CO₂ production as soils drained. While there were no consistent differences in CO₂ emissions between upslope and depressional soils (Figure 3), acetate addition stimulated CO₂ emissions under flooded conditions (Figure 5), suggesting that anaerobic respiration in upland soils may be limited by C availability and not access to alternative terminal electron acceptors (TEAs). However, depressional soils had higher rates of Fe reduction compared to upslope soils following the C amendment treatment (Figure 7). Thus, downslope transport of DOC from upslope to depressional areas following heavy rainfall may fuel hot spots of anaerobic CO₂ production from dissimilatory Fe reduction. Additionally, high Fe(II) production rates in depressional soils can stimulate N₂O and CO₂ emissions via chemodenitrification and abiotic ROS production, respectively. While abiotic Fe(II) oxidation can contribute to the pulse in CO₂ emissions that we observed as soils drain, other mechanisms such as the physical release of C from aggregates [41–43] or microbial necromass could also be important [44]. Together, these results suggest that Fe reduction

and oxidation can contribute to CO₂ and N₂O production in upland soils, especially from depressional soils that have higher Fe reduction potential and experience accumulation of DOC and NO₃[−] as a result of hydrologic flow.

Conventional understanding of moisture-soil respiration relationships suggests that O₂ limitation following inundation should inhibit soil CO₂ emissions [45,46], yet anaerobic respiration using alternative TEAs such as Fe contributes to soil CO₂ emissions under flooded conditions. Although flooding inhibited CO₂ efflux, acetate addition stimulated CO₂ emissions from flooded soils (Figure 5), suggesting that anaerobic microbial respiration is more limited by concentrations of low molecular weight C compounds than access to alternative TEAs [5]. Depressional soils from Cardinal Road had the highest SOC concentrations (Figure 2a) and were the only soils where Fe reduction was observed under control conditions (Figure 7c), further supporting limitation of Fe reduction by C availability. Because of this, greater poorly crystalline Fe(III) concentrations in depressional soils, and Fe(III) addition to both depressional and upslope soils, did not result in higher rates of CO₂ production. While Fe reduction can drive soil CO₂ emissions in response to short anaerobic periods in C-rich tropical soils [10], it is likely that greater labile C availability is necessary to stimulate CO₂ production via dissimilatory Fe reduction in tilled agricultural fields with lower SOC concentrations. Additionally, longer anaerobic periods may be necessary for the reductive dissolution of C-bearing Fe-oxyhydroxide compounds [47]. However, when acetate was added to the soil cores, depressional soils had higher Fe reduction rates compared to upslope soils (Figure 7). Observed rates of Fe reduction could produce CO₂ at a rate ranging from 0.15 and 0.25 $\mu\text{g C-CO}_2 \text{ g}^{-1} \text{ h}^{-1}$ via dissimilatory Fe reduction over the 72 h flooding period, which is of similar magnitude to the pulse in CO₂ emissions that was observed with acetate amendment. As such, dissimilatory Fe reduction has the potential to drive higher soil CO₂ emissions from depressional areas that accumulate DOC from hydrologic flow following rainfall compared to upslope areas. This is contingent upon the composition of the DOC, as more complex compounds may not stimulate Fe reduction to the same degree as acetate [48,49].

We speculate that release of DOC into soil solution following soil drainage triggers pulses in CO₂ emissions. Soil CO₂ emissions increased as soils drained (Figure 3), suggesting either that the act of drainage stimulated the release of labile C, or that reactive C compounds accumulated during flooded periods and were aerobically respired as O₂ diffused into the soil. This pulse in CO₂ emissions was greatest from depressional soils collected from Cardinal Road (Figure 3c). Control depressional soils from Cardinal Road had higher Fe reduction rates compared to control upslope soils during the flooding period (Figure 7c), suggesting that Fe reduction could have contributed to the release of more DOC via the dissolution of solid Fe-oxyhydroxide compounds, as has been demonstrated in soils that experience prolonged anaerobic periods [16,47]. Depressional soils from the South Farms and the Energy Farm did not have higher Fe reduction rates compared to their upslope counterparts during the flooding treatment, and CO₂ emissions from these soils did not consistently differ between depressional and upslope areas (Figure 5a,b). At these sites, other mechanisms such as physical breakdown of soil aggregates [41–43] or release of labile C from microbial necromass [44] could have increased C availability to fuel C mineralization in drained soils. We also observed evidence that abiotic Fe(II) oxidation may have been coupled to SOM degradation following soil drainage, as the addition of Fe(II) stimulated CO₂ emissions from the drained Cardinal Road soils. These soils had the highest pH (Figure 2c) and it is possible that a decrease in soil pH following Fe(II) oxidation freed C from physical protection [19]. Iron reduction and oxidation can contribute to CO₂ production as soils drain, but the relative importance of these mechanisms varies by site.

High Fe(III) reduction potential in depressional soils may support anaerobic C mineralization when labile C is abundant. Acetate addition, but not Fe(III) addition, stimulated Fe reduction in depressional soils (Figure 7). This treatment effect occurred only in depressional soils, indicating that depressional soils have higher Fe reduction potential than upslope soils. Greater abundance of genera capable of Fe reduction, such as *Geobacter* and *Anaeromyxobacter*, found in depressions within fields exhibiting microtopography [11] could lead to higher potential for Fe reduction to occur under

favorable conditions. Higher Fe reduction rates in poorly-drained compared to nearby well-drained soils has previously been observed [50], suggesting that this phenomenon may be widespread. This is also consistent with studies showing increased abundance of Fe reducing microbes and higher rates of Fe reduction in tropical soils that experience repeated fluctuations in soil redox potential [10,12,13]. While CO₂ emissions were not consistently higher from unamended depressional soils that were flooded (Figure 3), the stimulation of both CO₂ and Fe(II) production with acetate addition indicate that anaerobic respiration using Fe(III) as a TEA was limited by soil labile C availability. During prolonged ponding in the field, higher abundance of Fe reducing microbes in depressional soils may facilitate continued CO₂ production via dissimilatory Fe reduction after other more favorable TEAs, such as NO₃[−], are locally depleted. As such, greater Fe reduction potential in depressional soils may enable these areas to act as hotspots of Fe-mediated CO₂ production under extended anaerobic periods.

An abundant supply of Fe(II) from high Fe reduction rates could support N₂O production via chemodenitrification in depressional soils under flooded conditions. During the first day of flooding, Fe(II) additions stimulated N₂O emissions from all soils (Figure 6). The abiotic oxidation of less than 2% of the Fe(II) amendment amount could sustain this level of N₂O production over 24 h. It is possible that rapid chemodenitrification occurred immediately after flooding the soil cores and that we did not capture this initial pulse and subsequently underestimated the contribution of chemodenitrification to N₂O emissions. While both biotic and abiotic reactions have been shown to produce N₂O when Fe(II) oxidation is coupled to the reduction of inorganic N compounds [27,28,30,31,51,52], it is likely that abiotic Fe(II) oxidation was the dominant process since it is significantly faster than biotic Fe(II) oxidation [7,27]. However, it is possible that biotic pathways also contribute, either by directly oxidizing Fe(II) for energy or NO₂[−] detoxification, or by denitrifying other inorganic N compounds produced by abiotic Fe(II) oxidation [27,30]. The increase in N₂O emissions in response to acetate and Fe(II) treatments was smaller from Cardinal Road soils, potentially due to higher pH in these soils favoring the reduction of N₂O to N₂ [36]. Addition of Fe(III) compounds did not have any consistent effects on soil N₂O emissions, suggesting that Feammox coupled to denitrification did not contribute to N₂O production in these soils. These results highlight the potential for Fe(II) oxidation to drive high rates of N₂O production, warranting further exploration of this process in upland soils. This may be especially important in depressional soils that experience accumulation of Fe(II) as a result of high rates of Fe reduction and from transport of dissolved Fe(II) in hydrologic flow from upslope areas of the field following large rain events.

In conclusion, we demonstrate that the reduction and oxidation of Fe compounds has the potential to drive microtopographic variation in CO₂ and N₂O emissions in upland soils, with these Fe-coupled reactions occurring more readily in depressional areas. In the laboratory experiment, CO₂ efflux did not consistently differ between unamended depressional and upslope soils. However, depressional soils had higher Fe reduction potential with C amendment, suggesting that greater C mineralization via dissimilatory Fe reduction could occur with downslope transport of C to depressional areas under field conditions. Additionally, higher Fe reduction rates in depressional soils may supply sufficient Fe(II) to stimulate N₂O production via chemodenitrification. Iron redox reactions are not often accounted for in upland soils but have the potential to significantly contribute to both CO₂ and N₂O emissions as soil redox potential fluctuates in response to large rain events. As climate change induced rainfall intensification results in greater extent and duration of flooding of depressional upland soils [1], Fe-mediated C and N transformations may become increasingly important pathways of soil greenhouse gas emissions that can feed back on climate change.
