Abstract

We conduct a comparative study of the Jacobian-free linearly implicit Rosenbrock–Wanner (ROW) methods, the explicit first stage, singly diagonally implicit Runge–Kutta (ESDIRK) methods, and the second-order backward differentiation formula (BDF2) for the high-order flux reconstruction/correction procedure via reconstruction solution of the unsteady Navier–Stokes equations. Pseudo-transient continuation is employed to solve the nonlinear equation at each stage of ESDIRK (excluding the first stage) and each step of BDF2. A Jacobian-free implementation of the restarted generalized minimal residual method solver is employed with a low storage element-Jacobi preconditioner to solve the linear system at each stage of ROW and each pseudo time iteration of ESDIRK and BDF2. Several numerical experiments, including both laminar and turbulent flow simulations, are conducted to carry out the comparison. We observe that the multistage ROW2 and ESDIRK2 are more efficient than the multistep BDF2, and higher-order implicit time integrators are more efficient than lower-order ones. In general, the ESDIRK method allows a larger physical time step size for unsteady flow simulation than the ROW method when the element-Jacobi preconditioner is employed, especially for wall-bounded flows; and the ROW method can be more efficient than the ESDIRK method when the time step size is refined.

Keywords Rosenbrock–Wanner · ESDIRK · BDF2 · Jacobian-free GMRES · Flux reconstruction/correction procedure via reconstruction · High-order spatiotemporal methods · Unsteady flows

1 Introduction

High-order computational fluid dynamics (CFD) methods have been attracting much research attention in past decades due to their high-resolution and low-dissipation properties that

enable high-fidelity simulation of intricate flows. High-order spatial discretization methods, such as discontinuous Galerkin (DG) methods [1–3] and FR/CPR methods [4–7], have shown their capabilities of dealing with turbulent flows [8–15]. Usually, the high-order explicit strong stability preserving Runge–Kutta (SSPRK) methods [16] are used to integrate the semi-discretized governing equations for unsteady flow simulation. Due to the Courant–Friedrichs–Lewy (CFL) number constraint, explicit time integration methods may not be the optimal choice for efficient numerical simulation of stiff flow problems, such as wall-bounded turbulent flows at high Reynolds numbers. To circumvent the CFL restriction, an implicit time integration method can be employed. Recent work [17–19] has confirmed that time integration methods can have significant impact on unsteady flow simulation with high-order spatial formulations. This motivates the present study to conduct a systematic comparison of accuracy and efficiency among several widely used implicit time integration methods.

One family of the implicit time integrators is the multistep method [20]. In this family, the standard BDF method is popular in the CFD community arguably due to its ease of implementation. Since a BDF method is not A -stable when the order of accuracy exceeds two, the second-order BDF2 is widely used for large-scale simulations instead of higher-order BDF methods [21–23]. One direction to search for high-order A -stable multistep methods is to “throw in additional stages, off-step points, super-future points and the like, which leads into the large field of general linear methods” [20], such as the modified extended BDF (MEBDF) [24], the split Adams–Moulton formula (SAMF) [25], and two implicit advanced step-point (TIAS) method [26,27]. Interested readers are referred to the work by Carpenter et al. [22] on a comparative study of implicit time integrators including the fourth-order MEBDF4, and the work by Nigro et al. [28,29] on the application of MEBDF and TIAS to Navier–Stokes equations discretized by the high-order DG method.

An alternative family of the implicit time integrators is the multistage implicit Runge–Kutta (IRK) method [30]. We note that fully coupled IRK methods are not widely used in the CFD community due to the complication of solving fully coupled nonlinear systems. Solution strategies based on the dual time stepping procedure [31] have recently been reported by Jameson [32] and several fully coupled IRK methods have been evaluated for unsteady flow simulation. To decrease computational complexity, diagonally implicit Runge–Kutta (DIRK) and singly diagonally implicit Runge–Kutta (SDIRK) methods can be used. A comprehensive review of DIRK methods by Kennedy and Carpenter can be found in [33]. Vermeire and Vincent have analyzed the dispersion and dissipation properties of fully-discrete high-order FR methods with two SDIRK schemes, and provided insights on their suitability for implicit large eddy simulation [18]. As a special case of SDIRK, the ESDIRK method reduces the degree of the nonlinear systems of SDIRK by one. Comparisons of BDF and ESDIRK methods have been performed in [21,23]. ESDIRK methods are found to be more efficient than BDF methods. We note that for BDF and DIRK, a nonlinear system needs to be solved at each step or each stage.

For the linearly implicit Rosenbrock method, only one linear system is to be solved at each stage. Besides, the Jacobian matrix is only evaluated once at the first stage. All these features can potentially make a Rosenbrock method more computationally efficient than a DIRK method when they have the same number of stages and order of accuracy. In a traditional Rosenbrock method, the exact Jacobian matrix [34,35] is critical to ensure accuracy. However, in many stiff flow problems, the analytical Jacobian matrices are not easy to obtain; and the matrix-based implementation can consume tremendous memory, thus impeding efficient simulation of large-scale flow problems. The ROW method [36–38] can preserve the nominal order of accuracy with an approximate Jacobian matrix. This flexibility makes it possible to implement a Jacobian-free Krylov subspace solver. The Rosenbrock–Krylov (ROK) method

[39] reformulates the Rosenbrock/ROW method such that stage vectors are obtained from the Krylov subspace using the modified Arnoldi iteration. The ROK method naturally favors the matrix-free implementation. We notice that the Rosenbrock method can suffer from order reduction for moderately stiff problems and improvements have been developed in [40]. Recent results on the performance of several Rosenbrock methods on solving Navier–Stokes equations with high-order DG-type schemes have been reported in a series of works [41–44].

When the Jacobian-free implementation is used, the advantage that the Jacobian matrix of the Rosenbrock method only needs to be evaluated once for each time step does not hold anymore. In fact, the performance of ROW and ESDIRK highly depends on how the linear and nonlinear systems are solved. Blom et al. [45] have shown that ROW is not necessarily more efficient than ESDIRK when a second-order central finite volume method is used. Liu et al. [42] has conducted a comparative study of several third-order ROW methods and a third-order ESDIRK (ESDIRK3) [21] method with a third-order hierarchical WENO (weighted essentially non-oscillatory) reconstructed discontinuous Galerkin (rDG) method. They observed that the third-order ROW methods tested are more efficient than ESDIRK3. Sarshar et al. [46] conducted a comparative study of various matrix-free implicit time-stepping methods on solving two-dimensional (2D) Navier–Stokes equations including SDIRK, Rosenbrock, ROW, and ROK using a second-order spatial discretization. It is found that ROK can be a competitive method compared to other implicit time integrations.

Contributions. In this work, we conduct comparison of the Jacobian-free ROW (second-, third- and fourth-order schemes), ESDIRK (second-, third- and fourth-order schemes) and BDF2 for the high-order FR solution of the unsteady compressible Navier–Stokes equations. The nonlinear systems in ESDIRK and BDF2 are solved by means of pseudo-transient continuation. The restarted GMRES solver [47] with the element-Jacobi preconditioner serves as the linear solver. The Jacobian-free implementation decreases the tremendous memory consumption of matrix-based implementation. The accuracy and efficiency of different implicit time integrators are compared using several laminar and turbulent flows, including 2D isentropic vortex propagation, 2D laminar flow over a cylinder, three-dimensional (3D) Taylor–Green vortex evolution, and the 3D transitional flow over the SD7003 wing at the chord-based Reynolds number of 60000.

Article Organization. The rest of the paper is organized as follows. The FR discretization of the 3D compressible Navier–Stokes equations is reviewed in Sect. 2. Section 3 introduces all the time integration methods tested in this study as well as the matrix-free implementation of the iterative methods. Numerical results and corresponding discussions are documented in Sect. 4. We summarize this work in the last section.

2 The Flux Reconstruction Method

2.1 Governing Equations

The 3D unsteady compressible Navier–Stokes equations can be written as

$$\frac{\partial \mathbf{q}}{\partial t} + \nabla \cdot \mathbb{F} = 0, \quad (1)$$

where $\mathbf{q} = (\rho, \rho u_j, E)^\top$, $j = 1, 2, 3$, is the vector of conserved variables, and \mathbb{F} is the corresponding flux tensor. Specifically, ρ is the fluid density, u_j , $j = 1, 2, 3$, are the velocities in three orthogonal directions, and $E = \frac{p}{\gamma-1} + \frac{1}{2}\rho \sum_{k=1}^3 (u_k u_k)$ is the total energy per unit volume, where $p = \rho R T$ is the pressure, T is the temperature, $R = c_p - c_v$ is the ideal

gas constant, γ is the specific heat ratio defined as $\gamma = c_p/c_v$, and c_p and c_v are specific heat capacities at constant pressure and volume, respectively. In this study, γ is set as 1.4. The flux tensor \mathbb{F} consists of the inviscid part and viscous part, which can be expressed as $\mathbb{F} = \mathbb{F}_{inv}(\mathbf{q}) - \mathbb{F}_{vis}(\mathbf{q}, \nabla \mathbf{q})$. Note that $\mathbb{F}_{inv}(\mathbf{q})$ and $\mathbb{F}_{vis}(\mathbf{q}, \nabla \mathbf{q})$ can be rewritten in a vector format as: for any j , $j \in \{1, 2, 3\}$,

$$\mathbb{F}_{inv,j}(\mathbf{q}) = \begin{pmatrix} \rho u_j \\ \rho u_1 u_j + \delta_{1j} p \\ \rho u_2 u_j + \delta_{2j} p \\ \rho u_3 u_j + \delta_{3j} p \\ u_j(E + p) \end{pmatrix}, \text{ and } \mathbb{F}_{vis,j}(\mathbf{q}, \nabla \mathbf{q}) = \begin{pmatrix} 0 \\ \tau_{1j} \\ \tau_{2j} \\ \tau_{3j} \\ \sum_{k=1}^3 u_k \tau_{kj} - K_j \end{pmatrix}, \quad (2)$$

where δ_{ij} is the Kronecker delta, τ_{ij} is the viscous stress defined as

$$\tau_{ij} = \mu \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) - \frac{2}{3} \mu \sum_{k=1}^3 \frac{\partial u_k}{\partial x_k} \delta_{ij} \text{ with } i = 1, 2, 3,$$

and following Fourier's law, the heat flux K_j is defined as $K_j = -\kappa \partial T / \partial x_j$. In this study, the thermal conductivity κ is calculated from the Prandtl number Pr as $\kappa = \mu c_p / Pr$. The fluid viscosity μ and the Prandtl number Pr are treated as constants.

2.2 The Spatial Discretization

To achieve an efficient implementation of the FR method, we transfer the Navier–Stokes equations Eq. (1) from the physical domain (x, y, z) to the computational domain (ξ, η, ζ) . Thus Eq. (1) can be expressed as

$$\frac{\partial \mathbf{Q}}{\partial t} + \frac{\partial \mathbf{F}}{\partial \xi} + \frac{\partial \mathbf{G}}{\partial \eta} + \frac{\partial \mathbf{H}}{\partial \zeta} = 0, \quad (3)$$

where

$$\begin{cases} \mathbf{Q} = |\mathbf{J}| \mathbf{q}, \\ \mathbf{F} = |\mathbf{J}| (f \xi_x + g \xi_y + h \xi_z), \\ \mathbf{G} = |\mathbf{J}| (f \eta_x + g \eta_y + h \eta_z), \\ \mathbf{H} = |\mathbf{J}| (f \zeta_x + g \zeta_y + h \zeta_z), \end{cases} \quad (4)$$

and

$$\mathbf{J} = \frac{\partial(x, y, z)}{\partial(\xi, \eta, \zeta)}, \text{ and } |\mathbf{J}| = \det(\mathbf{J}). \quad (5)$$

Herein, $\mathbf{f} = \mathbb{F}_1$, $\mathbf{g} = \mathbb{F}_2$, and $\mathbf{h} = \mathbb{F}_3$ are flux vectors in the x , y , and z directions of a Cartesian coordinate system. $\partial \xi_i / \partial x_j$, $i, j = 1, 2, 3$, are metrics in the coordinate transformation.

The reconstructed flux polynomial in the FR method consists of two parts. One is the local flux polynomial and the other one is the correction polynomial. On solving Eq. (3), the reconstructed polynomials $\tilde{\mathbf{F}}$, $\tilde{\mathbf{G}}$ and $\tilde{\mathbf{H}}$ of \mathbf{F} , \mathbf{G} and \mathbf{H} can be expressed as

$$\begin{cases} \tilde{\mathbf{F}} = \mathbf{F}^l + \mathbf{F}^c, \\ \tilde{\mathbf{G}} = \mathbf{G}^l + \mathbf{G}^c, \\ \tilde{\mathbf{H}} = \mathbf{H}^l + \mathbf{H}^c, \end{cases} \quad (6)$$

where the superscript ‘ l ’ stands for the local flux and ‘ c ’ stands for the correction flux. Consequently, Eq. (1) can be rewritten as

$$\frac{\partial \mathbf{q}}{\partial t} + \frac{\partial \mathbf{f}^l}{\partial x} + \frac{\partial \mathbf{g}^l}{\partial y} + \frac{\partial \mathbf{h}^l}{\partial z} + \frac{1}{|\mathbf{J}|} \left(\frac{\partial \mathbf{F}^c}{\partial \xi} + \frac{\partial \mathbf{G}^c}{\partial \eta} + \frac{\partial \mathbf{H}^c}{\partial \zeta} \right) = 0. \quad (7)$$

For a hexahedral element, \mathbf{F}^c , \mathbf{G}^c and \mathbf{H}^c can be explicitly expressed as

$$\begin{cases} \mathbf{F}^c(\xi, \eta, \zeta) = (\tilde{\mathbf{F}}(-1, \eta, \zeta) - \mathbf{F}^l(-1, \eta, \zeta))g_L(\xi) \\ \quad + (\tilde{\mathbf{F}}(1, \eta, \zeta) - \mathbf{F}^l(1, \eta, \zeta))g_R(\xi), \\ \mathbf{G}^c(\xi, \eta, \zeta) = (\tilde{\mathbf{G}}(\xi, -1, \zeta) - \mathbf{G}^l(\xi, -1, \zeta))g_L(\eta) \\ \quad + (\tilde{\mathbf{G}}(\xi, 1, \zeta) - \mathbf{G}^l(\xi, 1, \zeta))g_R(\eta), \\ \mathbf{H}^c(\xi, \eta, \zeta) = (\tilde{\mathbf{H}}(\xi, \eta, -1) - \mathbf{H}^l(\xi, \eta, -1))g_L(\zeta) \\ \quad + (\tilde{\mathbf{H}}(\xi, \eta, 1) - \mathbf{H}^l(\xi, \eta, 1))g_R(\zeta), \end{cases} \quad (8)$$

where $g_{L/R}$ are the correction polynomials. In this study, we employ the Radau polynomials to recover the nodal FR-DG method. $\tilde{\mathbf{F}}$, $\tilde{\mathbf{G}}$ and $\tilde{\mathbf{H}}$ at the element interface are referred as numerical fluxes \mathbf{F}^{num} , \mathbf{G}^{num} and \mathbf{H}^{num} . The inviscid common fluxes can be obtained from approximate Riemann solvers. In this study, the Roe approximate Riemann solver [48] is used to calculate the common fluxes at the cell interface in the normal directions as

$$\mathbf{f}_{n,inv}^{com} = \frac{\mathbf{f}_{n,inv}^+ + \mathbf{f}_{n,inv}^-}{2} - \mathbf{R}|\mathbf{\Lambda}|\mathbf{R}^{-1} \frac{\mathbf{q}^+ - \mathbf{q}^-}{2}, \quad (9)$$

where superscripts ‘ $-$ ’ and ‘ $+$ ’ denote the left and right side of the current interface, the subscript $\mathbf{n} = (n_x, n_y, n_z)^\top$ is the unit normal direction from left to right, $\mathbf{f}_{\mathbf{n}} = f n_x + g n_y + h n_z$ is the flux projection in the \mathbf{n} direction, $\mathbf{\Lambda}$ is a diagonal matrix consisting of the eigenvalues of the Jacobian $\partial \mathbf{f}_{\mathbf{n}} / \partial \mathbf{q}$, and \mathbf{R} consists of the corresponding right eigenvectors evaluated with the Roe-averaged variables. Numerical common fluxes can be obtained as

$$\begin{cases} \mathbf{F}^{num} = |\mathbf{J}| |\nabla \xi| \mathbf{f}_{\mathbf{n}}^{com} \text{sign}(\mathbf{n} \cdot \nabla \xi), \\ \mathbf{G}^{num} = |\mathbf{J}| |\nabla \eta| \mathbf{f}_{\mathbf{n}}^{com} \text{sign}(\mathbf{n} \cdot \nabla \eta), \\ \mathbf{H}^{num} = |\mathbf{J}| |\nabla \zeta| \mathbf{f}_{\mathbf{n}}^{com} \text{sign}(\mathbf{n} \cdot \nabla \zeta). \end{cases} \quad (10)$$

The common viscous fluxes are $\mathbf{f}_{n,vis}^{com} = \mathbf{f}_{vis}(\mathbf{q}^+, \nabla \mathbf{q}^+, \mathbf{q}^-, \nabla \mathbf{q}^-)$ at the cell interface. Here we need to define the common solution \mathbf{q}^{com} and common gradient $\nabla \mathbf{q}^{com}$ at the cell interface. By simply taking the average of the conserved variables, we get

$$\mathbf{q}^{com} = \frac{\mathbf{q}^+ + \mathbf{q}^-}{2}. \quad (11)$$

The common gradient is computed as

$$\nabla \mathbf{q}^{com} = \frac{\nabla \mathbf{q}^+ + \mathbf{r}^+ + \nabla \mathbf{q}^- + \mathbf{r}^-}{2}, \quad (12)$$

where \mathbf{r}^+ and \mathbf{r}^- are the corrections to the gradients on the interface. The second approach of Bassi and Rebay (BR2) [8] is used to calculate the corrections. For the hexahedral element, the correction terms are defined as

$$\mathbf{r} = \gamma(\mathbf{q}^{com} - \mathbf{q}_{L/R})\mathbf{n}, \text{ and } \gamma = |\nabla \varpi| g'_{L/R}(\varpi) \text{sign}(\mathbf{n} \cdot \nabla \varpi), \quad (13)$$

where $\varpi \in \{\xi, \eta, \zeta\}$, and $\mathbf{q}_{L/R}$ is the local solution on the interface. If the interface is the left boundary of the element, then the local solution \mathbf{q}_L is used, and ϖ is -1 ; if the interface

is the right boundary of the element, then the local solution \mathbf{q}_R is used, and ϖ is 1. In this study, $g(\pm 1) = \pm(P+1)(P+2)/2$ is used to stabilize the FR method [49], where P is the polynomial degree of the solution.

3 Implicit Time Integrators and Iterative Methods

3.1 Implicit Time Integrators

We rewrite Eq. (7) in a semi-discretized form as

$$\frac{\partial \mathbf{q}}{\partial t} = \mathbf{R}(\mathbf{q}), \quad (14)$$

for convenience of notation. We use the method of lines approach to solve this equation: the partial differential equation is first discretized in space with the FR formulation in Sect. 2, and then is marched in time. In this study, three different types of implicit or linearly implicit time integration methods are studied.

The BDF Method. The first one is the backward differentiation formula. A general formulation of the s -th order BDF method for solving Eq. (14) can be expressed as

$$\mathbf{q}^{n+1} = \Delta t \omega \mathbf{R}(\mathbf{q}^{n+1}) + \sum_{j=1}^s a_j \mathbf{q}^{n+1-j}, \quad (15)$$

A BDF method is not A -stable when the order of accuracy exceeds two. In this study, we only consider the BDF2 method for comparison. For BDF2, $s = 2$, $\omega = 2/3$, $a_1 = 4/3$ and $a_2 = -1/3$. BDF2 is not able to start by itself. Therefore, at the first time step the backward Euler method or BDF1 is used.

The ESDIRK Method. The second one is the explicit first stage, single diagonally implicit Runge–Kutta method, which reads

$$\begin{cases} \mathbf{q}^{n+1} = \mathbf{q}^n + \Delta t \sum_{i=1}^s b_i \mathbf{R}(\mathbf{q}_i), \\ \mathbf{q}_i = \mathbf{q}^n + \Delta t \sum_{j=1}^i a_{ij} \mathbf{R}(\mathbf{q}_j), \quad i = 1, \dots, s, \end{cases} \quad (16)$$

where s is the number of stages. The second-order, three-stage ESDIRK2 [33], third-order, four-stage ESDIRK3 [21] and fourth-order, six-stage ESDIRK4 [21] methods are studied in this paper. All the ESDIRK methods investigated in this study have the feature that

$$a_{ii} = \begin{cases} 0, & i = 1, \\ \omega, & i \neq 1. \end{cases} \quad (17)$$

Therefore, we can rewrite Eq. (16) as

$$\begin{cases} \mathbf{q}^{n+1} = \mathbf{q}^n + \Delta t \sum_{i=1}^s b_i \mathbf{R}(\mathbf{q}_i), \\ \mathbf{q}_1 = \mathbf{q}^n, \\ \mathbf{q}_i = \Delta t \omega \mathbf{R}(\mathbf{q}_i) + \mathbf{q}^n + \Delta t \sum_{j=1}^{i-1} a_{ij} \mathbf{R}(\mathbf{q}_j), \quad i = 2, \dots, s. \end{cases} \quad (18)$$

The ROW Method. The last one is the linearly implicit Rosenbrock–Wanner method. The general form of a s -stage Rosenbrock method can be written as [20]

$$\begin{cases} \mathbf{q}^{n+1} = \mathbf{q}^n + \sum_{j=1}^s b_j \mathbf{K}_j, \\ \mathbf{K}_i = \Delta t \mathbf{R} \left(\mathbf{q}^n + \sum_{j=1}^{i-1} \alpha_{ij} \mathbf{Y}_j \right) + \Delta t \frac{\partial \mathbf{R}}{\partial \mathbf{q}} \sum_{j=1}^i \gamma_{ij} \mathbf{K}_j, \quad i = 1, 2, \dots, s. \end{cases} \quad (19)$$

The above equations are reorganized to avoid the matrix-vector product of the Jacobian matrix and the summation of stage vectors [20,41], following

$$\begin{cases} \mathbf{q}^{n+1} = \mathbf{q}^n + \sum_{j=1}^s m_j \mathbf{Y}_j, \\ \left(\frac{\mathbf{I}}{\omega \Delta t} - \frac{\partial \mathbf{R}}{\partial \mathbf{q}} \right)^n \mathbf{Y}_i = \mathbf{R} \left(\mathbf{q}^n + \sum_{j=1}^{i-1} a_{ij} \mathbf{Y}_j \right) + \frac{1}{\Delta t} \sum_{j=1}^{i-1} c_{ij} \mathbf{Y}_j, \quad i = 1, 2, \dots, s. \end{cases} \quad (20)$$

Similarly, $\omega = \gamma_{ii}$ is defined for the Rosenbrock method. Herein, $\mathbf{K}_i = \frac{1}{\omega} \mathbf{Y}_i - \sum_{j=1}^{i-1} c_{ij} \mathbf{Y}_j$, $(m_1, \dots, m_s) = (b_1, \dots, b_s) \mathbf{\Gamma}^{-1}$, $(a_{ij})_{i,j=1}^s = (\alpha_{ij})_{i,j=1}^s \mathbf{\Gamma}^{-1}$, $(c_{ij})_{i,j=1}^s = \frac{1}{\omega} \mathbf{I} - \mathbf{\Gamma}^{-1}$ and $\mathbf{\Gamma} = (\gamma_{ij})_{i,j=1}^s$ [20,41]. The Rosenbrock–Wanner method has the flexibility of evaluating the Jacobian matrix approximately while preserving the accuracy. In this study, we restrict our attention to three popular Rosenbrock–Wanner methods, namely, the second-order, three-stage ROS2PR [37], the third-order, four-stage ROS34PW2 [36], and the fourth-order, six-stage RODASP [38]. We note that it has been shown in [40] that ROS34PW2 and RODASP can suffer from order reduction. For simplicity, we use ROW2, ROW3 and ROW4 to denote them, respectively.

The coefficients of all ESDIRK and ROW methods can be found in the “Appendix”.

3.2 Iterative Methods

For BDF2 and ESDIRK, one needs to solve the nonlinear equations in Eqs. (15) and (18). We can rewrite them as

$$\mathbf{F}(\mathbf{q}^*) = 0, \quad (21)$$

where \mathbf{q}^* is \mathbf{q}^{n+1} for BDF and \mathbf{q}_i for ESDIRK, respectively. For BDF2, $\mathbf{F}(\mathbf{q}^*)$ reads

$$\mathbf{F}(\mathbf{q}^{n+1}) = \left(\frac{1}{\omega \Delta t} \mathbf{q}^{n+1} - \mathbf{R}(\mathbf{q}^{n+1}) \right) - \frac{1}{\omega \Delta t} \sum_{j=1}^2 a_j \mathbf{q}^{n+1-j}. \quad (22)$$

For ESDIRK methods,

$$\mathbf{F}(\mathbf{q}_i) = \left(\frac{1}{\omega \Delta t} \mathbf{q}_i - \mathbf{R}(\mathbf{q}_i) \right) - \frac{1}{\omega \Delta t} \left(\mathbf{q}^n + \Delta t \sum_{j=1}^{i-1} a_{ij} \mathbf{R}(\mathbf{q}_j) \right), \quad (23)$$

where $i = 2, \dots, s$. In this work, the pseudo-transient continuation is employed [21,31,32]. The pseudo-transient continuation is an inexact Newton’s method to solve the steady state equation $\mathbf{F}(\mathbf{q}^*) = 0$ iteratively as

$$\frac{\mathbf{q}^{k+1,*} - \mathbf{q}^{k,*}}{\Delta \tau} = -\mathbf{F}(\mathbf{q}^{k+1,*}). \quad (24)$$

Herein, k is the iteration step for the pseudo-transient continuation. Eq. (24) can be linearized as

$$\left(\frac{\mathbf{I}}{\Delta \tau} + \frac{\partial \mathbf{F}}{\partial \mathbf{q}} \right)^k \Delta \mathbf{q}^{k,*} = -\mathbf{F}(\mathbf{q}^{k,*}). \quad (25)$$

For a steady problem, as $k \rightarrow \infty$, $\tau \rightarrow \infty$ and $\Delta \mathbf{q}^k \rightarrow 0$. Therefore, $\mathbf{F}(\mathbf{q}^{k,*}) \rightarrow \mathbf{F}(\mathbf{q}^*)$. The Jacobian matrix for fully implicit methods can be expressed as

$$\left(\frac{\partial \mathbf{F}}{\partial \mathbf{q}} \right)^k = \left(\frac{\mathbf{I}}{\omega \Delta t} - \frac{\partial \mathbf{R}}{\partial \mathbf{q}} \right)^k. \quad (26)$$

Substitute the Jacobian matrix into Eq. (25) to obtain the final form of the linear system in the pseudo-transient continuation procedure as follows

$$\left(\frac{\mathbf{I}}{\Delta\tau} + \frac{\mathbf{I}}{\omega\Delta t} - \frac{\partial \mathbf{R}}{\partial \mathbf{q}} \right)^k \Delta \mathbf{q}^{k,*} = -\mathbf{F}(\mathbf{q}^{k,*}). \quad (27)$$

The pseudo-transient continuation procedure requires an adaptation algorithm of the pseudo time step size to complete the method. In this study, we employ the successive evolution relaxation (SER) algorithm [50] as

$$\tau^0 = \tau_{init}, \quad \Delta\tau^{k+1} = \min \left(\Delta\tau^k \frac{\|\mathbf{F}\|_{L_2}^{k-1}}{\|\mathbf{F}\|_{L_2}^k}, \Delta\tau_{max} \right). \quad (28)$$

As the pseudo time marches forward, a series of linear equations (27) is successively solved until convergence. Ideally, we would expect that when $\Delta\tau$ approaches $\Delta\tau_{max} = \infty$, the residual of the pseudo-transient procedure will gradually converge to machine zero. However, in our practice of simulating wall-bounded flows with elements clustered in near wall regions, we have to choose a moderately large $\Delta\tau_{max}$ to ensure that the residual of the linear solver can at least drop by one order of magnitude when $\Delta\tau$ equals to $\Delta\tau_{max}$. Once the linear solver fails, we would reject the current pseudo-transient continuation iteration and decrease $\Delta\tau_{max}$ by half to continue. In this study, if not specifically mentioned, $\Delta\tau_{init} = \Delta t$ and $\Delta\tau_{max} = 10^{20}$.

Restarted GMRES is employed to solve Eq. (27) as well as the linear system in Eq. (20). All linear systems can be expressed as

$$\mathbf{A}\mathbf{X} = \mathbf{b}, \quad (29)$$

where

$$\mathbf{A} = \mathbf{D}(\Delta t, \Delta\tau) - \frac{\partial \mathbf{R}}{\partial \mathbf{q}}. \quad (30)$$

The first term $\mathbf{D}(\Delta t, \Delta\tau)$ on the right-hand side of the above equation is a diagonal matrix related to Δt and $\Delta\tau$. The GMRES method approximates the exact solution by a vector $\mathbf{x}_n \in \mathbf{K}_n$ that minimizes the Euclidean norm $\|\mathbf{A}\mathbf{x}_n - \mathbf{b}\|$ where \mathbf{K}_n is the n -th Krylov subspace

$$\mathbf{K}_n = \text{span}\{\mathbf{b}, \mathbf{A}\mathbf{b}, \mathbf{A}^2\mathbf{b}, \dots, \mathbf{A}^{n-1}\mathbf{b}\}. \quad (31)$$

The sparse matrix $\frac{\partial \mathbf{R}}{\partial \mathbf{q}}$ in \mathbf{A} only appears in the matrix-vector product. For an unknown vector \mathbf{X} , the matrix-vector product can be approximated as

$$\left(\frac{\partial \mathbf{R}}{\partial \mathbf{q}} \right) \mathbf{X} = \frac{\mathbf{R}(\mathbf{q} + \varepsilon \mathbf{X}) - \mathbf{R}(\mathbf{q})}{\varepsilon} + O(\varepsilon). \quad (32)$$

$\varepsilon = 10^{-8}$ is employed in this study. Interested readers are referred to [51] for more discussions on this approximation. We take advantage of the framework of the restarted GMRES solver in PETSc [52] with user-defined functions to perform the matrix-vector product approximation and left preconditioning.

The performance of the Newton–Krylov method substantially depends on the preconditioner. In the context of the Jacobian-free implementation, the element-Jacobi preconditioner is arguably the simplest one with acceptable performance for many applications among the low-storage preconditioners, such as the matrix-free LU-SGS (Lower-Upper Symmetric-Gauss-Seidel) preconditioner [53], and p -multigrid preconditioner [54]. In this study, only the element-Jacobi preconditioner is considered and it is updated at the starting stage of each

physical time step. The restart number of the GMRES solver is set as 60. The maximum number of iterations for GMRES are specifically designated for different numerical experiments in this work.

4 Numerical Results

All the simulations presented in this section are performed on the high performance computing facility (HPCF) of the University of Maryland, Baltimore county (UMBC). All nodes used in this work have two Intel E5-2650v2 Ivy Bridge (2.6 GHz, 20 MB cache) processors with eight cores apiece, for a total of 16 cores per node. A quad data rate (QDR) Infiniband switch connects all the nodes. Ideally the system can achieve a latency of $1.2 \mu\text{sec}$ to transfer a message between two nodes, and can support a bandwidth of up to 40 gigabits per second (40 Gbps). Every node possesses 64 GB RAM. All nodes are running Red Hat Enterprise Linux 6.4. We employ g++ (GCC) 4.8.4 with mpich-3.1.4 to compile the code for parallel simulation.

4.1 Vortex Propagation

The 2D isentropic vortex propagation problem is employed as a benchmark to investigate the accuracy and efficiency of different time integrators in this subsection. The free stream flow conditions are set as $(\rho, u, v, \text{Ma})^T = (1, 1, 1, 0.5)^T$ and the ideal gas constant R is set as 1.0 for this case. The perturbation is defined as [41]

$$\begin{cases} \delta u = -\frac{\alpha}{2\pi}(y - y_0)e^{\phi(1-r^2)}, \\ \delta v = \frac{\alpha}{2\pi}(x - x_0)e^{\phi(1-r^2)}, \\ \delta T = -\frac{\alpha^2(\gamma-1)}{16\phi\gamma\pi^2}e^{2\phi(1-r^2)}, \end{cases} \quad (33)$$

where $\phi = \frac{1}{2}$ and $\alpha = 5$ are parameters that define the vortex strength, and $r = (x - x_0)^2 + (y - y_0)^2$ is the distance to the center of the vortex $(x_0, y_0) = (0, 0)$ at $t = 0$. The periodic domain is defined as $\Omega = [-10, 10]^2$. We use 16 CPU processes to simulate this problem on a uniform mesh of 50×50 elements with the P^6 (i.e. 7th order) FR method for one period $t_p = 20$. The time step size Δt is refined from $t_p/100$ to $t_p/800$. The error of any variable s is defined as

$$\text{Error}(s) = \sqrt{\frac{\int_{\Omega} (s_{\text{exact}} - s_{\text{num}})^2 dV}{V}}, \quad (34)$$

where s_{exact} is the exact value, s_{num} is the numerical value, and V is the volume of the domain Ω .

Two convergence criteria are discussed in this section. The first one is the tolerance for the relative residual of the pseudo-transient continuation $\text{tol}_{\text{rel}, \text{nonlinear}}$ and the second one is that for the relative residual of the GMRES solver $\text{tol}_{\text{rel}, \text{linear}}$. Herein, the subscript 'rel' stands for 'relative'. On solving Eq. (21), $\text{tol}_{\text{rel}, \text{nonlinear}}$ will determine the error level of the pseudo-transient continuation, which will affect the order of accuracy of ESDIRK and BDF2 and $\text{tol}_{\text{rel}, \text{linear}}$ is more related to the efficiency and robustness of the pseudo-transient continuation [55]. On solving Eq. (29), $\text{tol}_{\text{rel}, \text{linear}}$ will determine the order of accuracy of ROW directly. The maximum number of iterations of the GMRES solver is 200, which is

sufficiently large for the GMRES solver to converge to the designated tolerances for this problem.

4.1.1 Effect of the Nonlinear and Linear Convergence Criteria on ESDIRK and BDF2

The pseudo-transient continuation does not require an exact solution of the linear system at each iteration. We first employ a relatively large tolerance $tol_{rel,linear} = 10^{-1}$ for GMRES to investigate the effect of $tol_{rel,nonlinear}$ on accuracy and efficiency of fully implicit methods. The convergence study of ESDIRK and BDF2 using different $tol_{rel,nonlinear}$, namely, 10^{-2} , 10^{-4} , 10^{-6} and 10^{-8} , is presented in Table 1. We observe that when $tol_{rel,nonlinear}$ is refined from 10^{-2} to 10^{-4} , all ESDIRK methods studied here will preserve the nominal order of accuracy except that ESDIRK4 shows slightly order reduction when Δt is refined from $t_p/400$ to $t_p/800$ (due to insufficient $tol_{rel,nonlinear}$); when $tol_{rel,nonlinear}$ is refined from 10^{-4} to 10^{-6} , no order reduction shows up. We also note that overrefined $tol_{rel,nonlinear}$, such as 10^{-8} , will not improve simulation accuracy, but only increase the computational cost (i.e. run time; in this study, run time is the wall clock time spent by parallel simulations). ESDIRK methods have shown better accuracy and efficiency than BDF2. Generally, the higher the order of accuracy of ESDIRK is, the more efficient ESDIRK is (see Fig. 1b).

The impact of $tol_{rel,linear}$ on efficiency is investigated when $tol_{rel,nonlinear} = 10^{-6}$ is employed. $tol_{rel,linear}$ spans $\{10^{-1}, 10^{-2}, 10^{-4}, 10^{-6}\}$. The run time results are presented in Table 2. For this specific problem, all values of $tol_{rel,linear}$ lead to the same numerical errors as expected since the accuracy of ESDIRK and BDF2 solely depends on the convergence of pseudo-transient continuation. As documented in Table 2, the computational cost will keep on increasing when we refine the tolerance $tol_{rel,linear}$. This indicates that in order to save computational cost, $tol_{rel,linear}$ for ESDIRK and BDF2 can be relaxed.

4.1.2 Effect of the GMRES Convergence Criterion on ROW

A comparison of different convergence criteria $tol_{rel,linear}$ of the restarted GMRES solver is conducted to study its impact on the accuracy and efficiency of the ROW time integrators. The results are presented in Table 3. It is observed that when the convergence criterion is not tight enough, such as $tol_{rel,linear} = 10^{-2}$ and 10^{-4} , the ROW methods cannot preserve the nominal order of accuracy. This is not a surprise considering that the residual convergence is directly related to the accuracy of the solution in ROW. When $tol_{rel,linear}$ is sufficiently small, such as $tol_{rel,linear} = 10^{-6}$ and 10^{-8} , all ROW methods can preserve the nominal order of accuracy, excepted that ROW4 shows order reduction [40] when the time step is refined from $t_p/400$ to $t_p/800$. We also notice that when $tol_{rel,linear}$ is refined from 10^{-6} to 10^{-8} , no significant differences in errors are observed. Another observation is that when $tol_{rel,linear}$ is overrefined, the run time of the simulation is noticeably increased. In general, we do not recommend machine zero convergence criterion for $tol_{rel,linear}$. A relatively tight value such as 10^{-6} is sufficient to preserve the accuracy of high-order Rosenbrock methods for this problem.

4.1.3 Comparison of Different Time Integrators

The order of accuracy study of ESDIRK and BDF2 and linearly implicit ROW are summarized in Fig. 1. For ESDIRK and BDF2, $tol_{rel,nonlinear}^{ESDIRK,BDF2} = 10^{-6}$ and $tol_{rel,linear}^{ESDIRK,BDF2} = 10^{-1}$. $tol_{rel,linear}^{ROW} = 10^{-6}$ is employed for ROW.

Figure 1b presents the run time versus errors of different time integrators with different convergence criteria. As illustrated in Fig. 1b, all multistage methods are significantly more efficient than BDF2. We notice that ROW2 and ESDIRK2 intersect with ROW3 and ESDIRK3. However, as the error threshold is decreased, higher-order methods will be more efficient. When $tol_{rel,nonlinear}^{ESDIRK}$ is the same as $tol_{rel,linear}^{ROW}$, ROW methods are more efficient than ESDIRK methods. However, ROW methods cannot preserve the nominal order of accuracy when the convergence criterion is not tight, and even suffer from severe order reduction [40]. Instead, $tol_{rel,nonlinear} = 10^{-4}$ can make ESDIRK methods preserve the nominal order of accuracy (0.46 order reduction at most). It is observed that when $tol_{rel,linear}^{ROW} = 10^{-6}$ and $tol_{rel,nonlinear}^{ESDIRK} = 10^{-4}$ are employed, the ESDIRK method is more efficient than the ROW method when they have the same order of accuracy and number of stages. This indicates that the ESDIRK method tends to be over-solved more easily than the ROW method if the nonlinear convergence criterion $tol_{rel,nonlinear}^{ESDIRK}$ is not set up judiciously. We also note that ESDIRK can be more robust than ROW. As documented in Tables 1 and 3, when the tolerance criteria are set to 10^{-2} , ESDIRK2 can show optimal convergence rate, while ROW cannot; when $\Delta t = t_p/100$, ROW2 even fails to converge.

4.2 Laminar Flow Over a Circular Cylinder

In this subsection, we employ laminar flow over the circular cylinder as an example to study the performance of different time integrators. This case has been tested in various literature [21,45]. The Reynolds number of the inflow with respect to the diameter of the cylinder is $Re_d = 1200$, and the Mach number is $Ma = 0.1$. The diameter of the cylinder is $d = 1$, and the computational domain is $[-100, 200] \times [-100, 100]$. The mesh in the near wall region and the wake region, and an instance of the vortex shedding are presented in Fig. 2. There are 5690 elements in the mesh. The height of the first layer of the mesh is roughly 0.0033. The P^3 FR method is employed for spatial discretization. 16 processes are used for this case. $\Delta\tau_{init} = 0.01$ and $\Delta\tau_{max} = 1.0$ are used for all numerical experiments in this section. $tol_{rel,linear}^{ROW} = tol_{rel,nonlinear}^{ESDIRK,BDF2} = 10^{-6}$, and $tol_{rel,linear}^{ESDIRK,BDF2} = 10^{-1}$. The maximum

number of iterations for GMRES is 500. As aforementioned, for ESDIRK and BDF2, if the linear solver fails to drive the residual to drop by one order of magnitude, the current iteration in the pseudo-transient continuation procedure will decrease $\Delta\tau_{max}$ by half and restart.

The flow is initialized with the steady solution when $Re = 40$. Then, we use ESDIRK4 to run this simulation until $t = 180$ with $\Delta t = 0.001$ to obtain the initial conditions for the convergence and efficiency study. For the convergence and efficiency study, we run all simulations for ten convective time units. The time step size Δt is refined from 0.2 to 0.00625. We use the numerical results of explicit SSPRK3 with a small time step $\Delta t = 5 \times 10^{-6}$ as the reference. The drag coefficient C_d is used for the error estimation. The error is calculated as

$$Error(C_d) = \sqrt{\frac{\sum_{n=1}^N (C_{d,n} - C_{d,ref,n})^2}{N}}, \quad (35)$$

where $C_{d,ref,n}$ is the reference value from SSPRK3, and N is the number of time steps. The results from convergence and efficiency study are presented in Fig. 3a, b, respectively. As the time step size Δt is refined, all second- and third-order methods will converge at the nominal convergence rate. For both ROW4 and ESDIRK4, we have observed order reduction. The order reduction of ROW4 is more severe than that of ESDIRK4. In terms of run time, when $\Delta t = 0.2$, unexpected computational cost is observed for ESDIRK and BDF2. Many iterations in the pseudo-transient continuation are rejected due to the poor performance of the element-Jacobi preconditioner. However, all ROW methods fail when $\Delta t = 0.2$ and ROW2 even fails when $\Delta t = 0.1$. At a relatively large error level, such as 10^{-3} , second-order methods take the least amount of time. However, to reach a lower error level, higher-order methods are more efficient. We have noticed that the abnormal increase in run time for ROW4 when $\Delta t = 0.05$ and $\Delta t = 0.025$. This is due to the fact that the residual of the restarted GMRES solver with an element-Jacobi preconditioner sometimes cannot converge to the designated $tol_{rel,linear}^{ROW}$ when the maximum number of iteration is reached. From this study,

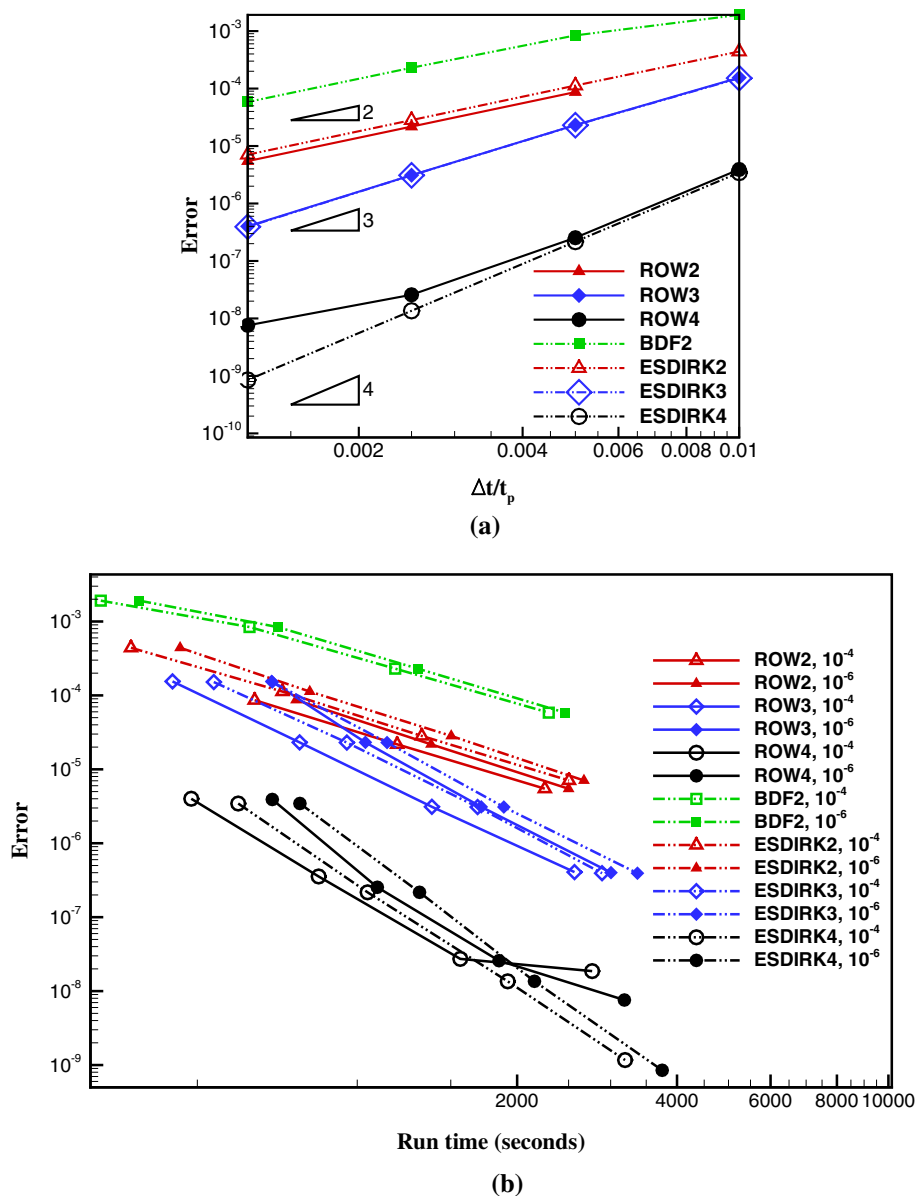

Fig. 1 **a** The convergence study of different time integrators and **b** efficiency study of different time integrators for the vortex propagation

we find that the performance of schemes from the ESDIRK family is more consistent than that of ROW methods when simulating unsteady flows over walls. Due to the limitation of the element-Jacobi preconditioner, ROW is only found to be consistently more efficient when the time step size Δt is small enough such that the GMRES solver can converge to the designated $tol_{rel,linear}^{ROW}$ within the maximum number of iterations.

4.3 Taylor–Green Vortex

The Taylor–Green vortex is a benchmark to test the accuracy and performance of high-order methods on the direct numerical simulation of a 3D periodic and transitional flow defined by initial conditions [42]

$$\begin{cases} u = V_0 \sin(x/L) \cos(y/L) \cos(z/L), \\ v = -V_0 \cos(x/L) \sin(y/L) \cos(z/L), \\ w = 0, \\ p = p_0 + \frac{\rho_0 V_0^2}{16} (\cos(2x/L) + \cos(2y/L)) (\cos(2z/L) + 2). \end{cases} \quad (36)$$

The domain is $\Omega = [-\pi L, \pi L]^3$. The Reynolds number of the flow is defined as $Re = \frac{\rho_0 V_0 L}{\mu}$ and is equal to 1600. For this study, we consider the flow with weak compressibility and the perfect gas law holds, i.e., $p = \rho RT$. The Prandtl number is $Pr = \frac{\mu c_p}{\kappa} = 0.71$. We assume that the gas has zero bulk viscosity $\mu_v = 0$. The Mach number $Ma = \frac{V_0}{c_0} = 0.1$, where c_0 is the speed of sound corresponding to p_0 . The characteristic convection time is defined as $t_c = \frac{L}{V_0}$. The maximum dissipation occurs at $t \approx 8t_c$. A uniform 64^3 mesh is employed and the P^3 FR methods is used for the spatial discretization. 512 processes are employed to

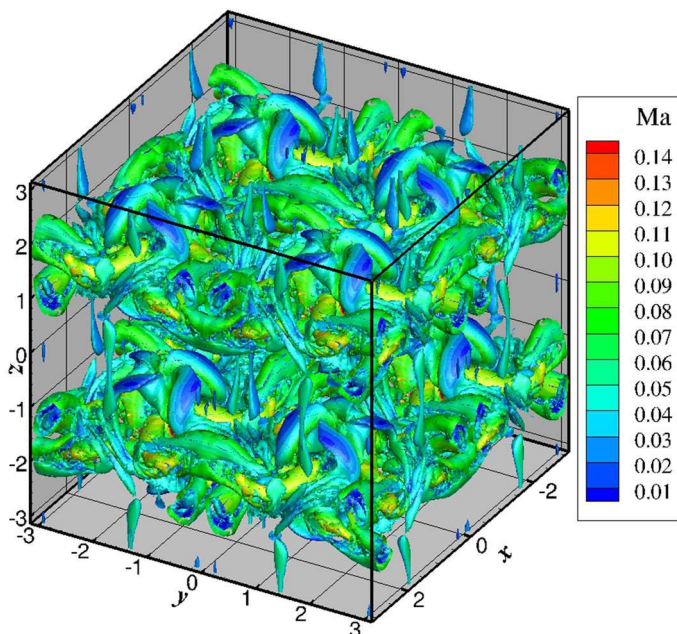

Fig. 4 The isosurface of the Q criterion, where $Q_{\text{criterion}} = 1$, colored by Ma at $t = 8t_c$ for Taylor–Green vortex evolution

conduct the numerical experiments. The numerical simulation is conducted until $t = 10t_c$. Figure 4 presents the isosurface of the Q criterion, where $Q_{\text{criterion}} = 1$, colored by Ma at $t = 8t_c$.

We employ the error of kinetic energy dissipation rate for the accuracy and efficiency study. The kinetic energy dissipation rate of compressible flows is the summation of three parts as $\epsilon = \epsilon_1 + \epsilon_2 + \epsilon_3$:

$$\epsilon_1 = 2 \frac{\mu}{\rho_0} \frac{1}{V} \int_{\Omega} S^d : S^d dV, \quad (37)$$

where S^d is the deviatoric part of the strain rate tensor, and V is the volume of the domain Ω ,

$$\epsilon_2 = \frac{\mu_v}{\rho_0} \frac{1}{V} \int_{\Omega} (\nabla \cdot \mathbf{v})^2 dV, \quad (38)$$

where $\mu_v = 0$, and

$$\epsilon_3 = -\frac{1}{\rho_0} \frac{1}{V} \int_{\Omega} p \nabla \cdot \mathbf{v} dV. \quad (39)$$

The numerical results of SSPRK3 method with $\Delta t = 2 \times 10^{-4} t_c$ is adopted as the reference data for error evaluations. We define the error of the kinetic energy dissipation rate as

$$\text{Error}(\epsilon) = \sqrt{\frac{\sum_{n=1}^N (\epsilon_n - \epsilon_{\text{ref},n})^2}{N}}, \quad (40)$$

where $\epsilon_{\text{ref},n}$ is the reference value from SSPRK3, and N is the number of time steps.

As discovered in previous sections, the convergence criteria have significant effect on the efficiency of ROW, ESDIRK and BDF2. In this section, we only consider $\text{tol}_{\text{rel,linear}}$

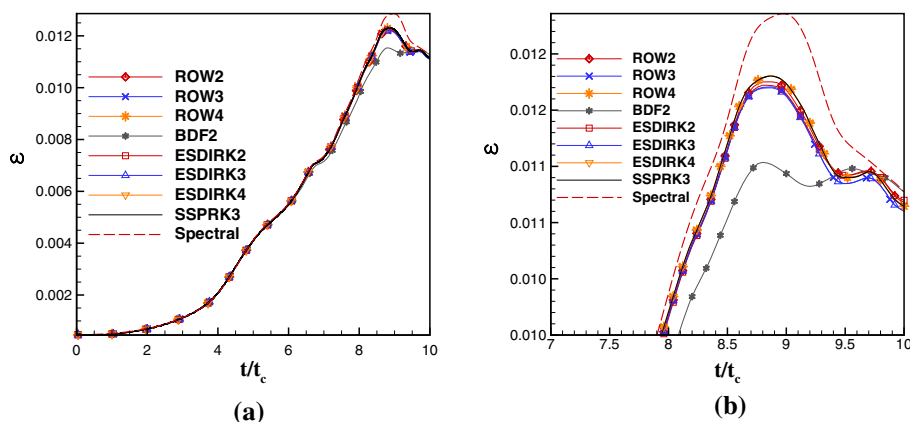

Fig. 5 The kinetic energy dissipation rate history of Taylor–Green vortex decaying. **a** A full view when $t/t_c \in [0, 10]$, **b** a close-up view when $t/t_c \in [7, 10]$

of ROW is the same as $tol_{rel, nonlinear}$ of ESDIRK and BDF2. Herein, $tol_{rel, linear}^{ROW} = tol_{rel, nonlinear}^{ESDIRK, BDF2} = 10^{-6}$. For the inexactly linear-solving part of ESDIRK and BDF2, we employ $tol_{rel, linear}^{ESDIRK, BDF2} = 10^{-1}$ to save computational cost. The maximum number of iterations for GMRES is 600, which is large enough to guarantee that GMRES can converge to the designated tolerance for all implicit time integrators.

The time step size Δt is refined from $t_c/25$ to $t_c/100$. The kinetic energy dissipation rate history when $\Delta t = t_c/25$ is presented in Fig. 5a. A close-up view within $t/t_c \in [8.5, 10]$ is illustrated in Fig. 5b. The numerical results from the spectral method on a 512^3 mesh is also presented for reference [56]. Our observation is that the results of ROW4 and ESDIRK4 almost coincide with that of SSPRK3. BDF2 is much more dissipative than ROW2 and ESDIRK2. The convergence study is presented in Fig. 6. Figure 6a shows the error vs. time step size $\Delta t/t_c$ and Fig. 6b shows the error vs. run time. From Fig. 6a, the convergence features of ROW and ESDIRK are almost the same. As is shown in Fig. 6b, BDF2 is not as efficient as ROW2 and ESDIRK2 as expected. When $tol_{rel, linear}^{ROW} = tol_{rel, nonlinear}^{ESDIRK, BDF2} = 10^{-6}$, ROW methods are found to be more efficient than ESDIRK methods. From Fig. 5, we find that for turbulent simulation, compared to the results from SSPRK3 with very small time steps, all time integrators with excessively large time step size will lead to numerical dissipation of the kinetic energy dissipation rate except ROW4 and ESDIRK4. This reveals that the dissipation due to the temporal discretization should also be taken into account for turbulent simulation. We refers interested readers to Refs. [18,19] for more discussions.

4.4 Transitional Flow Over the SD7003 Wing

The transitional flow over the SD7003 wing is studied when the Reynolds number of the inflow with respect to the chord length of the wing is $Re_c = 60000$ and the angle of attack (AoA) of the inflow is 8° . The Mach number is $Ma = 0.1$. The geometry is obtained from the 1st International Workshop on High-Order CFD Methods [57]. The chord length is $c = 1$ with the sharp trailing edge rounded by an arc of radius $r \approx 0.0004c$. The unstructured mesh near the SD7003 wing is illustrated in Fig. 7. The height of the first layer close to the wall is $0.0003c$. The 3D mesh is obtained by extruding a 2D mesh along the z -direction for 20 layers

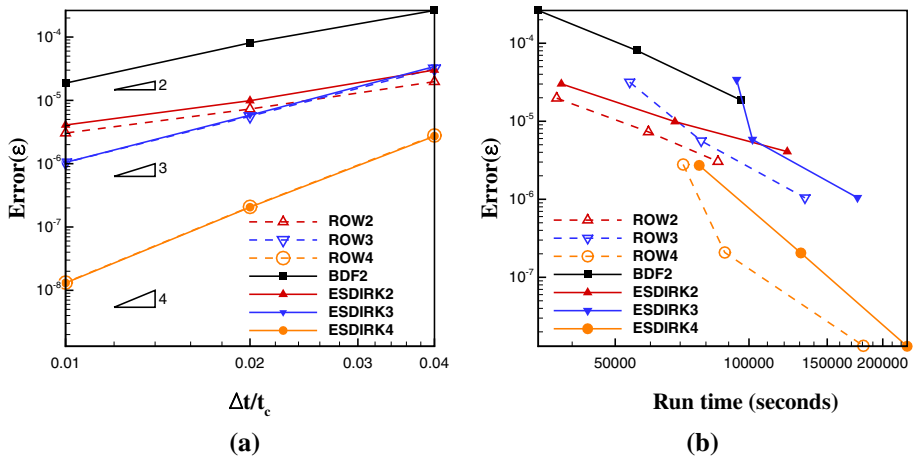

Fig. 6 The convergence and efficiency study for Taylor–Green vortex evolution. **a** Error vs. time step size $\Delta t/t_c$ and **b** error vs. run time

and each layer has a thickness of $0.01c$. There are 109540 quadric hexahedral elements. The third-order FR method is employed for spatial discretization. 252 processes are used for the parallel simulation in this section.

We compare the computational cost of BDF2, ESDIRK2, ROW2 and the explicit SSPRK3. We run all simulations until $t_{end} = 32$ and the instantaneous solutions in $t \in (26, 32]$ are averaged for statistics. For BDF2 and ESDIRK2, $\Delta t = 0.002$ is used and the flow field is initialized uniformly with the inflow conditions. ROW2 fails when the time step Δt equals to 0.002. Therefore, we use a smaller time step size $\Delta t = 0.001$ for ROW2. In this section, $tol_{rel,linear}^{ROW} = tol_{rel,nonlinear}^{ESDIRK,BDF2} = 10^{-4}$ and $tol_{rel,linear}^{ESDIRK,BDF2} = 10^{-1}$. $\Delta\tau_{init} = 0.0002$ and $\Delta\tau_{max} = 0.004$ are used for ESDIRK2 and BDF2. The maximum number of iterations for the GMRES solver is 200. We use SSPRK3 to run this simulation for 32 convective time units with $\Delta t = 2 \times 10^{-6}$, which is slightly smaller than the allowed maximum time step size, as a reference. Note that the time step for the explicit SSPRK3 method is about three orders of magnitude smaller than that for the implicit methods due to the highly anisotropic mesh near the wing.

The instantaneous isosurface of Q criterion, where $Q_{criterion} = 500$, and the averaged field of the velocity component in the x -direction are plotted in Fig. 8a, b, respectively. Numerical predictions, namely, the time-averaged lift coefficient C_l , drag coefficient C_d , the separation point x_s , and the reattachment point x_{re} , are documented in Table 4. The predictions of different time integration methods are close to each other. Compared to previous numerical and experimental results, a decent agreement has been observed. Run time of all methods is also provided. Due to the difficulty of determining the accuracy of different time integration methods via inspecting the averaged values, we examine the run time only. It is observed that all implicit time integration methods are significantly faster than the explicit method. Up to 82.36% computational cost can be saved by employing an implicit time integrator instead of using an explicit one. Not surprisingly, BDF2 takes the largest amount of run time to finish the simulation. Even though ROW2 diverged when $\Delta t = 0.002$, it can still outperform BDF2 with a smaller $\Delta t = 0.001$ and is only slightly more expensive than ESDIRK2. Note that the total number of time steps of ROW is twice as that of ESDIRK2 and BDF2. This indicates that when the time step size is refined to a suitable level, i.e., the linear solver can easily

Fig. 7 Unstructured meshes near the SD7003 wing

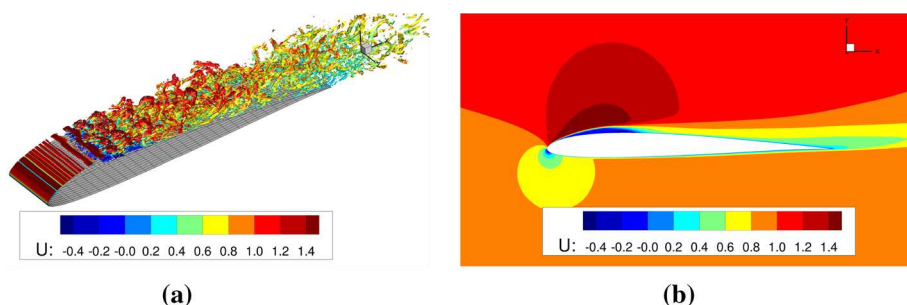

Fig. 8 **a** The isosurface of Q criterion, where $Q_{criterion} = 500$, at $t = 32$ and **b** averaged velocity component in the x -direction using ESDIRK2

converge to preserve the accuracy of ROW, the performance of ROW is comparable with that of ESDIRK.

5 Conclusions

In this work, we compare the accuracy and efficiency of ROW and ESDIRK (from second order to fourth order) and BDF2 for unsteady flow simulation with the high-order FR formulation. We find that ROW2 and ESDIRK2 are more computationally efficient than BDF2. To achieve an accurate estimation, i.e., the target error is small, higher-order implicit time integrators are more efficient than lower-order ones.

The efficiency of ROW and ESDIRK highly depends on the convergence criteria of solving nonlinear and linear equations. For most of the case, when $tol_{rel,linear}^{ROW} = tol_{rel,nonlinear}^{ESDIRK}$ and the time step size is refined, ROW is more efficient since it only needs to solve one linear system at each stage. However, the tolerance $tol_{rel,linear}^{ROW}$ needs to be sufficiently small to preserve the order of accuracy of ROW. With a large time step size, to drive the residual of GMRES to a trivial value is expensive with the element-Jacobi preconditioner for wall-bounded flows; this may degrade the advantage of ROW over ESDIRK. Besides, the ROW method is more prone to suffer from order reduction. On the contrary, the tolerance $tol_{rel,nonlinear}^{ESDIRK}$ for the pseudo-time iterations in ESDIRK can be relatively larger than $tol_{rel,linear}^{ROW}$ to preserve the nominal

Table 4 A summary of flow statistics from long-time simulation of the transitional flow over SD7003

Time marching	Ma	C_l	C_d	x_s	x_{re}	Run time (h)

The abbreviation *Inc.* stands for incompressible and *Exp.* stands for experiment

order of accuracy. Therefore, when $tol_{rel, nonlinear}^{ESDIRK}$ is allowed to be larger than $tol_{rel, linear}^{ROW}$, ESDIRK can be more efficient. The inexact Newton's method, i.e., the pseudo-transient continuation, gives ESDIRK the edge that the stiffness of the linearized system can be controlled with the pseudo time step size. A relaxed GMRES tolerance, such as $tol_{rel, linear}^{ESDIRK} = 10^{-1}$, can be used to accelerate simulation. This feature makes ESDIRK more robust and allow for a larger time step size than ROW.

We note that the preconditioner has a significant impact on the performance of implicit time integrators. In this work, only the element-Jacobi preconditioner is considered. Future work will be to develop low-storage preconditioners, such as the p -multigrid preconditioner, to improve the efficiency of implicit time marching methods.
