Key Points:

- Long term carbon sources and sinks are likely larger than traditional envisioned
- There is significant silicate weathering in the marine as well as terrestrial settings
- Ocean oxygenation and evolution of a biotic Si cycle forced a drop in reverse weathering rates and an increase in marine weathering rates

Abstract The existence of stabilizing feedbacks within Earth's climate system is generally thought to be necessary for the persistence of liquid water and life. Over the course of Earth's history, Earth's atmospheric composition appears to have adjusted to the gradual increase in solar luminosity, resulting in persistently habitable surface temperatures. With limited exceptions, the Earth system has been observed to recover rapidly from pulsed climatic perturbations. Carbon dioxide (CO₂) regulation via negative feedbacks within the coupled global carbon-silica cycles are classically viewed as the main processes giving rise to climate stability on Earth. Here we review the long-term global carbon cycle budget, and how the processes modulating Earth's climate system have evolved over time. Specifically, we focus on the relative roles that shifts in carbon sources and sinks have played in driving long-term changes in atmospheric pCO₂. We make the case that marine processes are an important component of the canonical silicate weathering feedback, and have played a much more important role in pCO₂ regulation than traditionally imagined. Notably, geochemical evidence indicate that the weathering of marine sediments and off-axis basalt alteration act as major carbon sinks. However, this sink was potentially dampened during Earth's early history when oceans had higher levels of dissolved silicon (Si), iron (Fe), and magnesium (Mg), and instead likely fostered more extensive carbon recycling within the ocean-atmosphere system via reverse weathering—that in turn acted to elevate ocean-atmosphere CO₂ levels.

1. Introduction

Liquid water is essential for life as we know it (Dole, 1964). Although water is present on multiple bodies within our solar system, only one planet—Earth—has sustained liquid water at the surface for the majority of its history (Mojzsis et al., 2001; Wilde et al., 2001). Despite large changes in solar luminosity (Gough, 1981; Hoyle, 1957), ocean chemistry, and the rock cycle over time (Berner, 2004; Holland, 1984, 2002; Mackenzie & Garrels, 1971), processes within Earth's system have naturally regulated greenhouse gas levels so as to maintain relatively invariant planetary temperatures (Berner et al., 1983; Hart, 1978; Kasting, 1987; Sagan & Mullen, 1972). This climate stability has allowed for the persistent inhabitation and proliferation of complex life over billions of years, and is typically taken as strong evidence for the existence of stabilizing feedbacks on Earth (e.g., Berner & Caldeira, 1997; Kasting, 2019; Lovelock & Whitfield, 1982). Classically, climate regulation on Earth is viewed to be tied foremost to the regulation of atmospheric carbon dioxide (CO₂) levels, via processes such as terrestrial silicate weathering that control the rate of carbon removal from the ocean-atmosphere system. Within this system, steady-state and transient variations to a range of carbon sources and sinks have been proposed to drive major changes in pCO₂ and thus Earth's climate. Collectively, the robustness and character of Earth's climate regulating mechanisms have been proposed to play a significant role in governing its long-term habitable life span (Caldeira & Kasting, 1992; Li et al., 2009; Lovelock & Whitfield, 1982). In this light, a mechanistic understanding of Earth's climate feedbacks can help guide our views on planetary habitability beyond our solar system.

Here, we review key concepts and changes to traditional views of the long-term carbon cycle (section 2), its budget (section 3), and its evolution through time (section 4). Rather than providing an overview of all aspects of the long-term climate controls, we review the main processes leading to climate regulation and focus our discussion on potential deviations from the standard view (e.g., Berner, 2004).

Figure 1. Simplified cartoon illustrating the inorganic portion of the global long-term carbon cycle. Red arrows indicate carbon entering and leaving the ocean-atmosphere system. Blue and green arrows indicate weathering and reverse weathering processes respectively, that alter the species of carbon (between CO_2 and carbonate alkalinity) within the ocean-atmosphere system.

2. Climate Regulation Through the Carbon Cycle

2.1. Silicate Weathering

Carbon enters the ocean-atmosphere reservoir through solid Earth degassing of CO_2 and is lost through the sequestration of carbon as carbonate (XCO_3 , here and elsewhere X represents a divalent cation, typically Ca^{2+} , Mg^{2+} , or Fe^{2+}) or biomass (CH_2O) (Figure 1) (Chamberlin, 1899; Högbom, 1894; Urey, 1952). The pathways leading to the release and drawdown of carbon have long been recognized and can be simply expressed as two fundamental reactions that highlight the inorganic (equation (1)) and organic (equation (2)) portions of the long-term carbon cycle.

This so-called Urey equation (equation (1)) is the simplest description of the inorganic carbon cycle. In the forward (left to right) direction, the weathering of a silicate mineral (XSiO_3) is coupled to the removal of carbon as carbonate and silicon as chert (SiO_2). The reverse direction (right to left) illustrates CO_2 degassing as a result of thermal decarbonation reactions during metamorphism.

Equation (2) represents the organic portion of the carbon cycle. Here, the forward (left to right) direction describes carbon fixation, releasing oxygen (O_2) in the process, while the reverse (right to left) accounts for the oxidation of organic matter. Although water (H_2O) is not the only electron donor (i.e., anoxygenic photosynthesis reactions exist), and similarly, oxygen not the only oxidizing agent available, these represent the predominant pathways of organic matter synthesis and remineralization in the modern oceans.

It is important to note that the organic portion of the global carbon cycle is classically not viewed to play a substantial role in regulating climate stability given that oxygen sources and sinks are likely to balance each other due to the presence of strong negative feedbacks on atmospheric O_2 (e.g., Berner, 2004; Laakso & Schrag, 2014; Ozaki et al., 2019). For instance, enhanced organic carbon production elevates free O_2 and increases organic matter oxidation. However, there are exceptions to this view (e.g., France-Lanord & Derry, 1997; Galy et al., 2007; Galy et al., 2010).

The size of the ocean-atmosphere carbon reservoir (Table 1) at any given interval in Earth's history is controlled by a balance between rates of carbon input (F_{in}), and the ease with which carbon leaves the system (i.e., the efficiency of carbon sequestration for a given Earth state). All else being equal, an increase in

Table 1
Modern Earth Surface Carbon Reservoirs

Carbon reservoirs	Mass (10^{18} mol)
Ocean	2.8
Atmosphere	0.06
Soil	0.3
Terrestrial biosphere	0.06
Marine biosphere	0.05
Upper continental crust	6,250
(Carbonate C in rocks)	(5,000)
(Organic C in rocks)	(1,250)

Note. Source: Berner, 2004.

degassing rates or an Earth environment more resistant to carbon removal (decrease weatherability or increase reverse weathering) will lead to an increase in atmospheric $p\text{CO}_2$ (Figures 1–3). Solid Earth processes (e.g., arc volcanism, mid-ocean ridge spreading rates, and metamorphic decarbonation) govern the rates of new carbon being introduced (discussed in section 3.1). Carbon removal, on the other hand, involves two steps, first the conversion of CO_2 to carbonate alkalinity (HCO_3^- and CO_3^{2-}), and second the removal of carbonate alkalinity as carbonate rock (XCO_3). The ease to which CO_2 is converted to carbonate alkalinity is determined by Earth's susceptibility to silicate weathering, a property commonly referred to as the “weatherability” of Earth's surface environment (Figures 2 and 3). Although the concept of weatherability is most commonly applied only to terrestrial silicate weathering, silicate weathering

in the marine realm (in marine sediments and oceanic crust) ought to be included when referring to the weatherability of the Earth surface system as a whole. Numerous factors have been proposed to control Earth's surface weatherability in terrestrial environments, including crustal composition (lithology), tectonics (e.g., uplift rates, topography), continental configuration (paleogeography), and hydrology and biological alteration (effect of land plants and soil biomass) (Kump & Arthur, 1997). On the other hand, the weatherability of the marine environment depends on the rate of formation of new oceanic crust, its bulk composition, abyssal sedimentation rate, and the saturation state of seawater with respect to silicate phases—all of which have likely evolved over the course of Earth's history.

Figure 2. Key principles of the global carbon cycle and atmospheric CO_2 . The effect of (a) outgassing, (b) strength of the silicate weathering feedback, (c) organic carbon and carbonate sequestration, (d) weatherability, (e) reverse weathering, and (f) ratio of marine to terrestrial weathering on long-term stable state atmospheric $p\text{CO}_2$ levels. Carbon input is the total new carbon flux added into the ocean-atmosphere system, and output is the total carbon flux removed from the system (which equals input at steady state).

Figure 3. Controls on weatherability. For a set carbon input, any increase in weatherability would lead to a drop in stable state $p\text{CO}_2$ levels (a). Factors that have been proposed to regulate weatherability include uplift rates (b), the composition of the weatherable crust (c), and the degree of biological alteration (d). Higher uplift rates and increasing the fraction of exposed of basalts (shifting mafic/felsic ratio) act to increase weatherability. Higher uplift rates lead to a higher proportion of fresh weatherable primary mineral phases (and a shorter soil residence time) within the weathering horizon at Earth's surface (e.g., Lee et al., 2015; Maher & Chamberlain, 2014). In panel (b), more intense colors indicate a higher fraction of weatherable minerals within the weathering horizon. Note that the effects of uplift are more well established than increasing basalt area.

There has been a longstanding debate about the locus of silicate weathering at Earth's surface (e.g., Kump et al., 2000). The view that silicate weathering occurred predominantly in terrestrial environments became the dominant view in the 1980s to 1990s, but recent work has stressed the importance of the weathering of silicate minerals in the marine environment (Coogan & Gillis, 2018; Wallmann et al., 2008). Marine weathering can be categorized into two distinct marine environments and lithologies: (1) oceanic crust and (2) marine sediments (section 3.2.2).

2.2. Reverse Weathering

The formation of authigenic silicate minerals consumes alkalinity and generates acidity, a process classically referred to as reverse weathering (Garrels, 1965; Mackenzie & Garrels, 1966a; Sillén, 1961). As the name suggests, this process has, in essence, the opposite effect of silicate weathering:

Clay authigenesis (equation (3) from left to right) consumes dissolved cations and converts carbonate alkalinity back into CO₂. This CO₂ now has to facilitate another round of silicate weathering (equation (1)) before it can be removed as carbonate rock. Reverse weathering in essence recycles carbon within the ocean-atmosphere reservoir. This process makes carbon export from the system less efficient by increasing the amount of silicate weathering required to sequester an equal amount of carbon relative to a system with less extensive reverse weathering (Isson & Planavsky, 2018). Thus, all else being equal, an increase in reverse weathering will elevate the amount of carbon in the ocean-atmosphere reservoir and thus baseline $p\text{CO}_2$

Figure 4. Global carbon cycle box model demonstrating that carbon input must equal output (steady state) on geologic time scales (adapted from Berner & Caldeira, 1997). In the absence of a stabilizing feedback, sustained imbalances (excess input or output) will very rapidly lead to either runaway icehouse or greenhouse conditions. Color bar indicates % imbalance between input and output of carbon from the ocean-atmosphere system. Blue indicates excess output and red excess input.

levels (Figures 1 and 2). It is important to note, however, that although reverse weathering is a source of CO₂, it is not a source of new carbon and thus does not alter the total steady-state flux of carbon entering (or leaving) the ocean-atmosphere system. Reverse weathering does, however, act as a net sink for ocean alkalinity. Similar to silicate weathering, the process of reverse weathering encompasses an extensive suite of reactions—reflecting the diversity of clay mineral species and flexible mineral stoichiometries that can form under different chemical conditions. Clays in the marine realm can form directly from dissolved constituents or through cation enrichment of preexisting clays.

2.3. Mass Balance and Stabilizing Feedbacks

The mass of the ocean-atmosphere carbon reservoir is small compared to that of geologic reservoirs, implying that short-term mass imbalances can easily occur. In a classic thought experiment, Berner and Caldeira (1997) highlighted with a simple box model that small carbon imbalances will very rapidly (on $<10^6$ years) trigger CO₂ runaway into extreme icehouse or hothouse conditions (Figure 4). In other words, it is not possible for chemical weathering rates to be substantially out of balance with the supply of CO₂ from volcanic and metamorphic sources for extended intervals without catastrophic consequences. While rapid temperature shifts have been observed throughout Earth's history, these occurrences are rare, and where they have been observed to take place, Earth's system has without failure responded by reestablishing relatively clement conditions. In other words, with limited exceptions—foremost the Snowball Earth Events (Hoffman et al., 2017)—none of Earth's climate perturbations were a threat to sustained habitability. This suggests that although mass imbalance may persist on the short term ($<10^6$ years), the total amount of carbon removal from the ocean-atmosphere reservoir (F_{out}) must be nearly equal to new carbon input (F_{in}) in the long term ($>10^6$ years). It is therefore reasonable to assume that negative or stabilizing feedbacks must exist for a system to consistently achieve mass balance. At the core of these feedbacks is a link between the rate-limiting step of CO₂ drawdown and CO₂ levels. There are three stabilizing feedbacks that have been commonly discussed (Figure 5):

1. **Terrestrial silicate weathering feedback.** The view that the terrestrial silicate weathering feedback is the main factor regulating temperatures on Earth has been deeply entrenched in our view of climate stability on Earth. The basic idea of this feedback is that any increases in CO₂ lead to increased surface temperatures, acceleration of the hydrological cycle, and larger fluxes of silicate chemical weathering,

Figure 5. Schematic of the processes that give rise to Earth's thermostat. Three main stabilizing feedbacks associated with the global carbon cycle: terrestrial silicate weathering (blue), marine silicate weathering (red), and reverse weathering (green).

leading to greater CO₂ removal from the ocean-atmosphere system through continental weathering (Berner et al., 1983; e.g., Urey, 1952; Walker et al., 1981).

2. **Marine silicate weathering feedback.** Recent work has highlighted that rates of silicate mineral dissolution within mafic oceanic crust are sensitive to bottom-water temperatures, essentially establishing a negative feedback with CO₂ given that sea surface and bottom water temperatures are intimately coupled (Brady & Gislason, 1997; e.g., Coogan & Dosso, 2015). Silicate dissolution within marine sediments has also been noted to contribute to global alkalinity fluxes (Solomon et al., 2008; Wallmann et al., 2008). Here, release of CO₂ during organic matter decomposition drives silicate mineral dissolution (e.g., Aloisi et al., 2004). Additionally, the production of dissolved organic humic and fulvic acid anions that complex cations (e.g., Al³⁺) is proposed to enhance mineral dissolution through further undersaturation of primary silicate phases. Rates of primary productivity (and the myriad factors affecting water column organic carbon remineralization) have therefore been proposed to exert a control on weathering rates (Wallmann et al., 2008). There are links between organic matter delivery to sediments and temperature—however, these associations have not yet been demonstrated to clearly give rise to a stabilizing feedback. Direct bottom-water temperature and pH controls on mineral dissolution rates ought to establish a negative feedback with atmospheric CO₂ levels as well, but the chemistry of porewaters (and waters within fractured oceanic crust) can evolve significantly with depth, and do not necessarily reflect surface water conditions.
3. **Reverse silicate weathering feedback.** The flux of CO₂ to the ocean-atmosphere system derived from reverse weathering is sensitive to marine pH conditions and thus pCO₂ (Isson & Planavsky, 2018; Sillén, 1961, 1967). This link results in a stabilizing climate feedback. For instance, an increase in pCO₂ levels (decrease in marine pH) will lead to decreased reverse weathering, in turn acting to lower pCO₂ levels. Because increasing temperatures will act to elevate rates of reverse weathering (reactions are more rapid at higher temperatures), the pH kinetic effect must outweigh the temperature effect. Reverse weathering has been demonstrated to be sensitive to pH in the most detailed clay experimental work done thus far (e.g., Tosca et al., 2011; Tosca et al., 2016), though it should be noted that there is a dearth of clay kinetic data.

Table 2
Modern Global Carbon Cycle Budget

Source/sink	Flux (10^{12} mol/year)	Reference
CO ₂ sources		
Collisional metamorphism	0.5–7.0	Becker et al. (2008) and Stewart and Ague (2018)
Subduction metamorphism (diffuse)	0.3–>1.0	Kelemen and Manning (2015)
Arc volcanism	1.5–3.5	Dasgupta and Hirschmann (2010), Hilton et al. (2002), and Marty and Tolstikhin (1998)
Mid-ocean ridge	1.0–5.0	Chavrit et al. (2014), Dasgupta and Hirschmann (2006, 2010), Hirschmann (2018), Marty and Tolstikhin (1998), Matthews et al. (2017), and Saal et al. (2002)
Ocean Island	0.12–3.0	Dasgupta and Hirschmann (2010) and Marty and Tolstikhin (1998)
Reverse weathering (Alk:Si = 1–2)	0.5–10.0	Rahman et al. (2016) and Tréguer and De La Rocha (2013)
HCO ₃ [−] sources		
Terrestrial weathering (not including groundwater)	11.5–23	Gaillardet et al. (1999) and Li and Elderfield (2013)
Oceanic crust weathering	0.2–3.75	Coogan and Gillis (2018)
Marine sediment weathering	5–20	Wallmann and Aloisi (2012) and Wallmann et al. (2008)
HCO ₃ [−] sinks		
Biogenic carbonate	14–25	Wallmann and Aloisi (2012)
Authigenic carbonate (sediment)	0.5–1.5	Sun and Turchyn (2014)
Authigenic carbonate (oceanic crust)	1.5–2.4	Coogan and Gillis (2018)

All three of these stabilizing feedbacks operate together as a unified global silicate weathering feedback, although with varied response times for each individual feedback. With a shift away from a stable state in the carbon cycle and climate (e.g., with a change in CO₂ outgassing rates) the change in atmospheric $p\text{CO}_2$ is set by the strength of the global silicate weathering feedback. A stronger silicate weathering feedback yields a smaller change in $p\text{CO}_2$ level for an equivalent forcing. Controls on the strength of the silicate weathering feedback traditionally include the amount of fresh silicate material exposed at Earth's surface undergoing water-rock interactions, the composition of Earth's weatherable shell, and the role of the terrestrial biosphere in mediating weathering rates (see Kump et al., 2000). Below we develop the idea that marine chemistry—and in particular marine Si concentrations—will also play a role in controlling the strength of the global silicate weathering feedback.

3. Global Carbon Cycle Budget

3.1. Carbon Sources

3.1.1. Modern Degassing Estimates

CO₂ is released from the solid Earth into surface reservoirs via both volcanic and metamorphic processes (equation (1), from right to left; Table 2). Volcanic fluxes have long been considered the primary contribution to global degassing, and, as such, there is a substantial body of work dedicated to constraining their magnitudes. Modern mid-ocean ridge volcanism is estimated to contribute ~1.0 to ~5.0 Tmol CO₂/year (for reference 1 Tmol C is approximately 0.012 Pg C) (Chavrit et al., 2014; Dasgupta & Hirschmann, 2006, 2010; Hirschmann, 2018; Le Voyer et al., 2017; Marty & Tolstikhin, 1998; Matthews et al., 2017; Saal et al., 2002). While this range is quite significant, it is possible that this upper limit remains conservative, given the lack of consideration of other factors such as bubble loss (e.g., Chavrit et al., 2014). Further, explosive volcanism along ridges provide evidence for melt inclusions with extremely high CO₂ content, suggesting that the CO₂ content of mid-ocean ridge basalt may be much more heterogeneous than previously thought (Helo et al., 2011; Ilyinskaya et al., 2018).

Arc volcanic degassing estimates range from ~1.5 to ~3.2 Tmol CO₂/year (Dasgupta & Hirschmann, 2010; Hilton et al., 2002; Marty & Tolstikhin, 1998). However, there is work suggesting that arc magmas may be more CO₂ rich than previously thought, and that the arc volcanic CO₂ flux may be correspondingly higher (Blundy et al., 2010). A large portion of the carbon emitted by these volcanoes may be derived from

reworking of crustal carbonate rocks in the upper plate (Mason et al., 2017). Further, metamorphism in contact aureoles around magmatic intrusions also drives decarbonation reactions (D'Errico et al., 2012; Lee et al., 2013). We are not aware of any quantitative estimate of the global contact metamorphic flux (flux estimates from observations of atmospheric plumes above volcanoes should integrate this CO₂ with magmatic CO₂). For example, Nesbitt et al. (1995) estimate that 1.5 to 7.8 Tmol CO₂/year were released by Cenozoic contact metamorphism in the North American Cordillera. Lee et al. (2013) suggest that contact metamorphism in continental arcs has been a major control on atmospheric CO₂ throughout the Phanerozoic. Intraplate volcanism is less well studied, but Dasgupta and Hirschmann (2010) suggest a range of ~0.12 to ~3.0 Tmol CO₂/year degassed from ocean island basalts and Lee et al. (2013) calculate a flux of ~0.8 to ~2.4 Tmol CO₂/year from continental rift volcanism.

Metamorphic decarbonation in mixed carbonate-silicate rocks has been shown to be an equally important source of CO₂ (Bickle, 1996; Kerrick & Caldeira, 1993, 1999; Kerrick & Caldeira, 1998; Stewart et al., 2019). While it has been suggested that metamorphic decarbonation is negligible except at very high temperatures (e.g., Dasgupta, 2013), these calculations ignore the critical effect of fluid infiltration. A rock that is in contact with a water-bearing fluid during metamorphism in an open system will begin to decarbonate at much lower temperatures (Ferry, 1988) and may release more than 500% more CO₂ than metamorphism of the same rock in a closed system (Stewart & Ague, 2018). The extent to which the Urey reactions can work in reverse depend on the supply of Si either from impurities in the rock or transported in a fluid (Ague, 2003). As noted by Stewart and Ague (2018), multiple independent calculations of degassing during regional metamorphism agree on an area-normalized flux of ~0.5 × 10⁶ to ~7 × 10⁶ mol CO₂·year⁻¹·km⁻² (Becker et al., 2008; Chiodini et al., 2000; Kerrick & Caldeira, 1998; Skelton, 2011). These studies estimate the flux via both thermodynamic modeling of metamorphism at depth (Kerrick & Caldeira, 1998; Skelton, 2011; Stewart & Ague, 2018) and surface measurements of degassing in modern mountain belts (Becker et al., 2008; Chiodini et al., 2000), suggesting that most of the devolatilized CO₂ does escape to the surface environment. Multiplying this areal flux by the area of present-day orogenesis (~10⁶ km², dominated by the Himalayas) (Becker et al., 2008), we arrive at a modern regional metamorphic flux of 0.5 to 7.0 Tmol CO₂/year.

Carbon dioxide is also released via metamorphic decarbonation in subducting oceanic crust. Based on closed-system thermodynamic modeling, it was believed that this decarbonation was minimal and that most CO₂ is retained within the subducting slab to depths of more than ~100 km (Dasgupta & Hirschmann, 2010; e.g., Kerrick & Connolly, 2001). However, recent work by Kelemen and Manning (2015) suggests that subduction zones are highly inefficient at shuttling carbon into the convecting mantle. There are several possible explanations for this discrepancy. As with regional metamorphism, subduction-related decarbonation may also be facilitated by fluid infiltration (Gorman et al., 2006), thus accounting for the presence of a water-bearing fluid increases flux estimates. In addition, congruent dissolution of carbonate minerals during subduction may release even more CO₂ from the slab (Ague & Nicolescu, 2014). Some amount of CO₂ is also released during partial melting of carbonate-bearing rocks (e.g., Duncan & Dasgupta, 2014; Grassi & Schmidt, 2011; Poli, 2015). Furthermore, mechanical processes such as sediment diapirism may transfer CO₂ from the subducting slab to the overriding plate (Kelemen et al., 2003). In an apparent contradiction to the “what goes down mostly comes back up” world view (Kelemen & Manning, 2015), global geochemical arguments (specifically relating to CO₂/Ba ratios) may indicate that 35–80% of outgassed CO₂ must be returned to the mantle, presumably via subduction (Hirschmann, 2018). Moreover, CO₂ released via decarbonation and dissolution may be reincorporated into the slab by carbonation reactions driven by migrating fluids (e.g., Piccoli et al., 2016; Scambelluri et al., 2016). Finally, the amount of CO₂ and organic carbon delivered to subduction zones varies considerably in both space and time (Plank & Manning, 2019). The storage of CO₂ in the lithosphere is a major uncertainty in both models. Thus, the efficiency of CO₂ subduction remains an area of ongoing research and debate, and more work is needed to reconcile these disparate models.

Once released, CO₂ from the slab may escape to the surface as part of the arc volcanic flux or it may form a separate, diffuse CO₂ flux. Kelemen and Manning (2015) estimate this diffuse subduction flux as ~0.3 to ~1.0 Tmol CO₂/year but go on to speculate that it may be much higher. It is also probable that some slab-derived CO₂ is precipitated in the overlying crust for long-term storage (up to ~3.9 Tmol CO₂/year from Kelemen & Manning, 2015), rather than being released to the surface. The proportion of CO₂ that follows each of these paths remains as a major uncertainty in our understanding of global carbon cycling.

3.2. Carbon Sinks

3.2.1. Terrestrial Weathering

As outlined above, the weathering of silicate minerals in terrestrial settings contributes alkalinity to the marine environment (Table 2). Carbonate weathering coupled to the eventual precipitation of carbonate rock from seawater, however, has no long-term net effect as a source or sink of carbon unless these fluxes are out of balance—implying a change to the composition of Earth's sedimentary reservoir. Further, changes to the composition of the upper continental crust have been suggested to influence the weatherability of Earth's surface and hence atmospheric $p\text{CO}_2$ (Gaillardet et al., 1999; Hartmann et al., 2014; e.g., Suchet et al., 2003). Today, the upper continental crust exposes ~65–71% sedimentary rock (Hartmann et al., 2014; Hartmann & Moosdorf, 2012; Li, 2000; Suchet et al., 2003) (Figure 6). The nonsedimentary fraction comprises ~16% basic (e.g., basalts and gabbros), ~8% intermediate, and 26% acidic (e.g., rhyolites and granites) igneous rocks, with metamorphic rocks making up the remaining ~50% (Hartmann et al., 2014). On average, the main components of granite are K-feldspar, sodic plagioclase and quartz (in roughly equal proportions), while basalts are high in calcic plagioclase (~60%), pyroxene (~30%), and olivine (~10%) (Mason & Moore, 1982). The sedimentary reservoir comprises roughly 51 wt.% shale, 23 wt.% sandstone, 25 wt.% carbonate, and 1% evaporate (Li, 2000). It should be noted that the metamorphic rock classification is compositionally broad (i.e., can refer to a rock of virtually any composition) and basically describes any rock with a crystalline texture interpreted to have been subject to elevated pressure and/or temperature sometime after initial formation of the rock (Hartmann & Moosdorf, 2012). Metamorphic rocks are ~90% metasedimentary, with metaigneous rocks comprising the remaining ~10% (Ronov et al., 1990), which bolsters the case that the Earth's weatherable shell is dominated by sedimentary (and metasedimentary) rocks (e.g., Bluth & Kump, 1991; Bluth & Kump, 1994).

In the modern oceans, calcium (Ca) is the main cation involved in the removal of carbon as carbonate. Shales and silts are, however, on average, depleted in Ca relative to crystalline rocks. This does not mean that the weathering of shales and silts does not contribute to the formation of carbonate rock. The weathering of shales and silts has to be linked to either: (1) the formation of dolomite (Ca-Mg carbonate), which, although uncommon today, was far more prominent during other intervals in Earth's history when dolomite was the dominant carbonate phase (Lowenstein et al., 2003) and/or (2) hydrothermal exchange of Mg (derived from shales or silt weathering) for Ca eventually sequestered as calcium carbonate.

Tremendous effort has been put into understanding the factors controlling terrestrial silicate weathering rates (e.g., Brantley, 2008; Kump et al., 2000; Li et al., 2017). Arguments center on the relative importance of soil biome, temperature, denudation rates, tectonics, and hydrologic controls on chemical weathering: This debate is nuanced, even though the basic idea of how each one influences weathering is straightforward. Mineral dissolution rates increase with temperature, organic acid levels, denudation, and increased water flux through the weathering zone (e.g., Brantley, 2008; Chen & Brantley, 1997; Maher & Chamberlain, 2014). On a broad scale, if denudation rates are higher, there is more fresh material to weather, and thus, silicate weathering rates are likely to increase. Similarly, if more water is fluxed through the weathering zone, minerals will be further from equilibrium and dissolution rates will increase (Maher & Chamberlain, 2014).

3.2.2. Transport Versus Weathering Limitation

There are two end member views for thinking about controls on chemical silicate weathering in terrestrial environments—supply-limited and weathering-limited regimes (Kump et al., 2000; Stallard, 1985; Stallard & Edmond, 1981, 1983). In a supply-limited system, rates of CO_2 drawdown are limited by the amount of material exposed to weathering, and changes to atmospheric $p\text{CO}_2$ levels (and surface temperature) do not influence weathering rates. In this end member view, it is the extent of tectonic uplift and hence the supply of fresh material that regulates atmospheric $p\text{CO}_2$ levels—essentially negating the terrestrial silicate weathering feedback. In contrast, a weathering-limited regime has an “excess” of material available for water-rock interactions, and rates of CO_2 consumed through silicate weathering are limited by both temperature and the supply of CO_2 (coupled to factors such as soil pH and mineralogy). In this world view, there is an active terrestrial silicate weathering feedback, where an increase in atmospheric CO_2 levels and global temperature will increase CO_2 delivery to and consumption within the weathering realm.

There is compelling evidence to suggest that global silicate weathering today is not supply-limited. Global data sets indicate that an increase in runoff is met by an increase in silicate weathering rates (e.g., Maher

Figure 6. Composition of the modern upper continental crust (Suchet et al., 2003). Rock exposure at Earth's surface is dominated by sedimentary rock. This includes the metamorphic component, which is estimated to consist of ~90% metasedimentary rock.

& Chamberlain, 2014), implying that more intense hydrology always increases CO_2 neutralization, and so Earth as a whole cannot be supply-limited (Figure 7). Quantifying the extent of physically eroded but chemically unweathered material accumulating in river deltas can be used to assess the extent of local supply limitation on chemical weathering rates. In addition, the expression of immature soils rich in primary silicate phases at Earth's surface, particularly in highland areas, represent an excess of silicate material available for weathering. Furthermore, geochemical and mineralogical evidence suggest that shifts in global temperatures across hyperthermal events are often coupled to accelerated rates of silicate weathering (e.g., Penman, 2016; Von Strandmann et al., 2013).

Figure 7. Global geochemical river data sets indicate that Earth's system as a whole is not supply limited. In a supply limited Earth system, an increase in rainfall (more intense hydrology) will not be met by an increase in chemical weathering rates. Earth's river system however, indicates a strong correlation between the acceleration of the hydrological cycle and chemical weathering rates (data from Maher & Chamberlain, 2014).

Earth's system as a whole is generally viewed to sit somewhere in between these two end member regimes, with some environments sitting closer to one end member than another denoting local scale heterogeneity to Earth's weatherable environment. The Amazon watershed, for instance, sits closer to the supply-limited end member regime relative to the Great Himalayan Watershed (Hartmann et al., 2014). Such supply-limited environments are characterized by thicker, more mature (chemically depleted) soils largely devoid of primary silicate minerals (e.g., feldspars, olivine, and hornblende), and are composed mostly of secondary mineral phases (e.g., clay minerals and oxides) depleted in soluble cations (Ca^{2+} , Mg^{2+} , Na^+ , and K^+). In contrast, watersheds that sit closer to the weathering limited environment have a less mature, higher primary silicate mineral content (less chemically depleted).

The globally averaged weathering state has the potential to slide between these two end member regimes. In particular, there are intervals in Earth's history where Earth as a whole is suggested to have shifted toward the supply limited end member regime. These include the (1) end-Permian to early Triassic interval where the amount of CO_2 injected into the ocean-atmosphere system is suggested to have come close to "exhausting" Earth's weatherable shell so as to provide an explanation for the delayed climate recovery during this interval (Kump, 2018) and (2) end-Cretaceous through early Eocene time periods (Misra & Froelich, 2012). It is perhaps important to note that although Earth's system as a whole is not supply limited, this does not mean that Earth's climate system is

insensitive to tectonic changes. All else being equal, an increase in tectonic uplift rates will elevate both weathering fluxes globally, and the weatherability of Earth's surface environment and thus the strength of the silicate weathering feedback (e.g., Caves et al., 2016; Kump & Arthur, 1997; Rugenstein et al., 2019; Zhang & Planavsky, 2019b). Rates of uplift bring fresh silicate material into the weatherable portion of Earth's surface environment. In essence, an increase in uplift will decrease the integrated maturity of soil profiles globally.

3.2.3. Terrestrial Sources of Acid for Weathering

Continental weathering reactions are tied to the neutralization of CO₂. Carbon dioxide is supplied predominantly through direct diffusion between the atmosphere and terrestrial fluids, the partitioning of CO₂ into rainwater, and/or the supply and oxidation of organic matter in soils (e.g., through respiration) (Figure 8). An increase in the biological supply of CO₂ to the soil environment has the potential to alter the pH of soil porewater and thus mineral dissolution rates. On this basis, there have been arguments concerning the role that biology (microbiota and vascular plants) has played in altering both weathering rates and the weatherability of Earth's terrestrial environment and in turn atmospheric pCO₂ (and O₂) levels.

Perhaps most notably, it has been commonly proposed that the emergence and diversification of vascular land plants during the Silurian and Devonian (~420 million years ago) could have led to a drawdown of pCO₂ levels through a transient enhancement of terrestrial weathering rates (Algeo et al., 1995; Berner, 1997, 1998). It is suggested that this transient weathering enhancement could occur through several mechanisms including (1) increasing water retention in soils, (2) root and heterotrophic respiration of plant debris, (3) production of organic acids from plant roots, (4) root physical erosion, and (5) stabilization of soils (Berner, 1992; Drever, 1994; Gibling & Davies, 2012; Griffiths et al., 1994; Winnick & Maher, 2018). Support for this argument typically involve calling upon both laboratory (e.g., Quirk et al., 2015) and field data (e.g., Bormann et al., 1998; Moulton & Berner, 1998) that indicate enhanced chemical weathering in systems with land plants as compared to barren surfaces or ones covered with moss/lichen (i.e., no significant root penetration) (Lenton, 2001). In contrast, recent steady-state carbon cycle modeling work indicate that the rise of land plants potentially decreased (instead of increase) silicate weathering rates, and that any drop in CO₂ levels was instead linked to an increase in the strength of the silicate weathering feedback (D'Antonio et al., 2019).

The link between vascular plants and atmospheric CO₂ levels through the Paleozoic has, however, remained contentious for several reasons. First, the earlier evolving bryophytes (liverworts; in the Ordovician) (Quirk et al., 2015) have also been shown to accelerate weathering rates, and direct comparison of these with the effect of vascular plants (with more deeply penetrating roots) has proven challenging. Further, integrating these biologically enhanced weathering rates derived from short lived experiments ("instantaneous" relative to the time scale of soil formation) into long-term global biogeochemical cycle models that operate on the multimillion-year time scales has the potential to drastically overestimate the integrated weathering rate. Silicate weathering rates decrease as a soil horizon matures given that primary phases become more depleted (Figure 9). In areas with limited denudation, integrated or long-term weathering rates with and without land plants will be closer than the observed initial difference. Although both field and experimental data that highlight biotic enhancement of weathering (sometimes by several orders magnitude), rate enhancements at such high levels are likely not sustainable on longer time scales. When weathering fluxes are integrated on time scales similar to or longer than that of soil formation (and maturation), the net weathering effect with or without vascular plants becomes significantly less or even indistinguishable (Figure 9). This framework was put into question by Keller and Wood (1993), where they used a reactive transport model to make a case that vascular plants are likely not required to maintain low soil pH. Instead, they propose that terrestrial chemical weathering rates were more likely equally intense before and after the rise of vascular plants. Specifically, they posit that because CO₂ loss from soils is a slow process, only a small amount of microbial soil respiration is required to maintain high CO₂ (low pH) porewaters. On the empirical side, terrestrial cyanobacterial biofilms have been found to significantly increase silicate weathering rates (Seiffert et al., 2014).

Sulfuric acid (H₂SO₄) derived from the oxidation of pyrite:

also accounts for a portion of the acid that facilitates weathering in the terrestrial environment (~5% of

Figure 8. Sources of acidity for terrestrial silicate weathering: contributions from rain and soil respiration. Results from a simple water rock mass balance model exploring the amount of rain required to generate a global terrestrial weathering alkalinity flux of 10 Tmol/year through terrestrial silicate weathering. New CO_2 input into the system is set at 10 Tmol/year, and all infiltrating CO_2 is assumed to be neutralized. We specify that 50% of CO_2 neutralization occurs through the weathering of carbonate rock, meaning that 20 Tmol/year of CO_2 has to be delivered to the terrestrial environment. Red circle indicates preindustrial values of rainfall = 1 m/year, temperature = 12 °C, and atmospheric $p\text{CO}_2$ = 280 ppm. This model assumes quantitative neutralization of rainwater through weathering. The model outputs indicate that at $p\text{CO}_2$ levels of 280 ppm, 10 m/year of rainfall is required to neutralize volcanic CO_2 if there was no soil respiration. This is roughly an order of magnitude higher than modern average annual rainfall estimates. To achieve an annual rainfall estimate of ~1 m/year, this requires that rain supplies only 3 Tmol/year of CO_2 for silicate weathering (right panel). The remaining 7 Tmol/year of CO_2 can be accounted for by acid generation in terrestrial porewaters through soil respiration. This simple model indicates that rainfall is not the dominant source of CO_2 for weathering today (red circle does not sit on the red line). However, at high $p\text{CO}_2$ conditions the amount of rainfall needed to deliver enough CO_2 to the critical zone to ensure a balanced carbon cycle (silicate weathering equal to CO_2 outgassing) is significantly less (left panels). Under these conditions, rainfall becomes the dominant source of CO_2 , and changes in soil respiration will play a smaller role. The gray region indicates possible temperature and CO_2 combinations assuming different climate sensitivities (2–4.5 °C) at modern solar luminosity.

Figure 9. (a, b) The effect of land plants on weathering during soil maturation. Laboratory and field work both indicate that vascular plants accelerate chemical weathering of bedrock over the short time scales in which these experiments are conducted (<1 year). It is important to note that the observed weathering rates are not likely sustainable over the time scale of soil formation (on a time scale of typically thousands of years). As soil profiles mature, they become more chemically depleted (in alkalinity and in fresh material) and therefore the rate of chemical weathering will be dampened. (c) Results from a reaction transport model showing the relationship between the material age or soil residence time (horizontal axis) and fresh mineral concentration (X_s/X_r) (Maher & Chamberlain, 2014). The upper and lower bracketing lines represent sensitivity analysis to the weathering rate constant (K_{eff}) of $K_{\text{eff}}/2$ and $K_{\text{eff}} \times 2$ from the best fit value, respectively, with all model run results falling between these upper and lower brackets.

silicate dissolution and 10% of carbonate dissolution) (Brantley, 2008; Torres et al., 2014). Iron oxidation likely accounts for a smaller portion of the acid that facilitates weathering, although this flux is poorly constrained.

3.2.4. Groundwater Alkalinity Fluxes

There have been extensive studies of river input to the ocean and its influence on global biogeochemical cycling (e.g., Berner & Berner, 2012; Gaillardet et al., 1999; Meybeck, 1987; Milliman & Farnsworth, 2011), but we still have a relatively nascent understanding of groundwater discharge and element fluxes to the ocean (Taniguchi et al., 2002). However, there is mounting evidence that groundwater discharge is a critical component of the water and nutrient budget in the land-ocean system (e.g., Burnett et al., 2003; Kwon et al., 2014; Moore et al., 2008). Further, there is evidence that groundwater plays a significant role in coastal ecosystem evolution (Moosdorf & Oehler, 2017; Paytan et al., 2006). Groundwater contains, on average, significantly higher bicarbonate concentrations than overlying surface waters, indicating that weathering occurs not only in soil horizons but also deeper within the crust (Zhang & Planavsky, 2019a). In terms of the global carbon cycle, continental groundwater discharge serves as a pathway for dissolved carbon fluxes to the ocean where carbonate eventually precipitates, and may therefore likely provide a significant but previously underappreciated carbon sink (Zhang & Planavsky, 2019a).

Groundwater discharge to the ocean is usually called submarine groundwater discharge (SGD), which is defined as “any and all flow of water on continental margins from the seabed to the coastal ocean” (Burnett et al., 2003). Since groundwater flow in a coastal region can be driven by both terrestrial and marine forces, SGD therefore comprises two sources—terrestrially derived fresh water (fresh SGD) that is originally produced by rainwater infiltration on land, and modified seawater (saline SGD) that penetrates through the

land-ocean interface and is recirculated back to the ocean. When these two sources are mixed, SGD is called mixed or brackish SGD. There are several approaches to estimate SGD, depending on the spatial extent of interest. On a local scale, seepage meters can measure mixed SGD at specific locations directly. On a regional scale, chemical tracers (e.g., radium and radon) can be used to quantify the mixed SGD fluxes integrated over continental shelves. On a global scale, hydrological modeling and water balance methods can both be applied for estimation of fresh SGD (Mulligan & Charette, 2009; Taniguchi, 2002). Unfortunately, flux estimates from these approaches are typically significantly different (see discussion in Zhang & Planavsky, 2019b).

Compared with river systems that are well gauged and monitored throughout the world, direct quantification of global SGD is extremely difficult since it mainly occurs as unseen diffusive flow on continental margins and varies significantly over temporal and spatial scales. The installation of seepage meters lacks global coverage, and upscaling of seepage measurement remains a challenge. The chemical tracer approach seems to be more fruitful in quantifying large-scale SGD. Using ^{228}Ra as a tracer, Moore et al. (2008) concluded that the magnitude of SGD in coastal region of the Atlantic Ocean is comparable to the corresponding river flux. Combining global observations of ^{228}Ra and an inverse model, Kwon et al. (2014) argued that the SGD along the coastlines between 60°S and 70°N is around 3 times greater than the river discharge. After correcting the salinity effect, Cho and Kim (2016) stated that instead of 3 to 4 times, global SGD is approximately 1–1.5 times the river discharge. In terms of element fluxes, it is reported by Cho et al. (2018) that dissolved inorganic nitrogen, phosphorus, and silicon derived from SGD are comparable with the river fluxes to the global ocean.

For dissolved inorganic carbon (DIC) and alkalinity, several studies argued that SGD-derived fluxes exceed regional river input and in some cases are 1 order of magnitude larger (Liu et al., 2014; Stewart et al., 2015). It should be noted that a large portion of SGD is thought to belong to saline SGD (Kwon et al., 2014; Taniguchi et al., 2006). Consequently, fresh SGD might be significantly less than river discharge (Taniguchi, 2002), and the element flux (including dissolved carbon) derived from fresh SGD might be diminished. Given the fact that DIC concentration in groundwater is typically higher than rivers in the same region (Stewart et al., 2015; Szymczycha & Pempkowiak, 2015), even a relatively small magnitude of fresh SGD could potentially make a nonnegligible contribution to the total dissolved carbon flux to the ocean. It was recently estimated that between 20% and 250% of chemical silicate weathering globally occurred in groundwaters (Zhang & Planavsky, 2019a). This estimate highlights foremost that large uncertainties exist for estimating fresh SGD and the extent of groundwater mediated silicate weathering. However, it has become clear over the past decade that this flux is likely a significant part of the global carbon cycle.

3.2.5. Weathering of Marine Sediments

The emerging perspective from recent studies is that silicate mineral dissolution within marine environments contributes to global alkalinity and thus carbon sequestration (Figure 1), suggesting that the terrestrial to marine transition is better viewed as a continuum rather than two distinct environments.

The physical erosion of rocks in terrestrial environments delivers detrital silicate materials (e.g., feldspar, olivine, pyroxene, volcanic ash, and clays) to the marine environment where they can make up a significant portion of marine sediments. Here, recent work provides compelling geochemical evidence for potentially substantial rates of silicate dissolution in marine sediments (e.g., Kim et al., 2016; Maher et al., 2004; Maher et al., 2006; Scholz et al., 2013; Solomon et al., 2008; Wallmann et al., 2008). This is perhaps unsurprising as seawater and porewaters are generally undersaturated with respect to primary silicate minerals, and thus, their dissolution plays a role in buffering pore fluid pH and chemistry. Geochemical evidence for marine weathering deviates from the traditional framework, which specifies that silicate mineral dissolution is largely limited to terrestrial environments. Through the same Urey reaction pathway invoked for continental silicate weathering (equation (1)), the generation of alkalinity and cations during the weathering of marine sediment plays a potentially large role in global carbon sequestration when coupled to carbonate formation.

Techniques used to fingerprint silicate mineral dissolution within sedimentary systems include the application of isotope tracers (e.g., $^{87}\text{Sr}/^{86}\text{Sr}$ (Kim et al., 2016); $^{234}\text{U}/^{238}\text{U}$ (Maher et al., 2004; Maher et al., 2006)) and the identification of “anomalous” alkalinity or cation (e.g., Mg^{2+} and Ca^{2+}) fluxes (Scholz et al., 2013; Solomon et al., 2008; Wallmann et al., 2008) within porewaters. Unexpectedly high alkalinity fluxes can

be used as tracers for silicate weathering by first establishing background in situ porewater alkalinity levels through the application of diagenetic reaction transport modeling (e.g., Scholz et al., 2013; Solomon et al., 2008; Wallmann et al., 2008).

Silicate dissolution has been observed to take place throughout the sediment column within virtually all redox zones (oxic, suboxic, sulfidic, and methanic). Further, silicate weathering rates have been observed to evolve with depth into the sediment pile and laterally between depositional environments. Both the availability of primary silicate minerals and porewater chemistry ultimately determine the rate of silicate dissolution. Silicate mineral availability varies depending on the local tectonic regime, bottom water temperature, and proximity to the shoreline. For instance, in situ weathering rates have been observed to vary by up to 4 orders in magnitude between the deep sea site Ocean Drilling Program Site 984 in the North Atlantic and slope sediments on the Sakhalin Slope, Sea of Okhotsk (Maher et al., 2006; Wallmann et al., 2008). Critically, porewater chemistry evolves with depth, most notably between redox zones tied to the oxidation of organic matter, and has the potential to alter the saturation state (and thus dissolution rate) of silicate phases. Some of the most rapid rates of silicate weathering have been observed to occur within the methanogenic zone of the sediment pile (Wallmann et al., 2008). On the basis that methanogenesis is responsible for the generation of $\sim 5\text{--}20$ Tmol/year of CO_2 (and an equal amount of CH_4) globally (Hinrichs & Boetius, 2002; Reeburgh, 1993; Wallmann et al., 2012) and the assumption that all this CO_2 is neutralized through silicate mineral dissolution in marine sediments (Wallmann et al., 2008), it has been proposed that roughly a third of this alkalinity is precipitated in marine sediments as authigenic carbonate, and the rest fluxed into overlying seawater (Wallmann et al., 2008; Wallmann & Aloisi, 2012).

3.2.6. Weathering of Oceanic Crust

Oceanic crust that is continually accreted along the global mid-ocean ridge network covers more than half of Earth's surface. The uppermost layer of this crust is made up of high-porosity and permeability lavas through which seawater continually circulates. The difference between measured conductive heat flow at the seafloor and that predicted by thermal models of the cooling of the oceanic lithosphere—the “missing heat”—indicates that fluid flow through the upper oceanic crust transports $\sim 8\text{--}11$ TW globally (Hasterok, 2013; Stein & Stein, 1994). Fluid temperatures within the upper oceanic crust are typically $5\text{--}10^\circ\text{C}$ higher than that of bottom water during the first $10\text{--}20$ Myr after crustal accretion when most fluid-rock reaction occurs (Coogan & Gillis, 2018). At these temperatures, fluid fluxes of $\sim 0.6\text{--}1.7 \times 10^{16}$ kg/year (roughly $10\text{--}50\%$ of the river flux) are required to transport the “missing heat”. At modern seawater DIC levels of ~ 2.3 mmol/kg, this equates to $\sim 1.5\text{--}4 \times 10^{13}$ moles of C passing through off-axis hydrothermal systems annually.

Fluid-rock reactions within the uppermost crust lead to dissolution of basaltic phases (e.g., glass, feldspar, and pyroxene) and precipitation of secondary minerals such as clays, zeolites, and calcite (or aragonite), providing a sink for ocean DIC (carbon from the ocean-atmosphere system). Because finding and sampling fluids exiting off-axis hydrothermal systems is technically challenging, most observational constraints on the role of seafloor weathering in the long-term carbon cycle come from studies of rocks altered in such systems. Staudigel et al. (1989) presented the first detailed study of C uptake during seafloor weathering focusing on three closely spaced drill cores from the western Atlantic showing that the lavas in these holes had taken up substantial seawater C in the lava section (~ 2.9 wt% CO_2 , equivalent to $\sim 2.9 \times 10^{12}$ mol/year if these were globally representative). The only way to have such a large C uptake by the crust ($\sim 10\%$ of the C that passes through the crustal aquifer) appears to be through alkalinity generation during seafloor weathering reactions (Coogan & Gillis, 2013; Spivack & Staudigel, 1994). Francois and Walker (1992) proposed that this seafloor weathering C-sink depended on bottom water pH and DIC and that it provided the dominant negative feedback on the long-term carbon cycle. However, at the near-neutral pH of seawater, the pH dependence of weathering rates is limited, leading Caldeira (1995) to suggest that this feedback mechanism was unlikely to be effective.

Nonetheless, observations from a larger number of ocean crust drill cores have now shown that the total CO_2 uptake by the lava section of the oceanic crust through time is variable and was significantly higher for crust formed in the late Mesozoic than late Cenozoic (Alt & Teagle, 1999; Gillis & Coogan, 2011). Further, most upper oceanic crust carbonate is precipitated within the first 20 Myr after crustal accretion (Coogan et al., 2016; Coogan & Dosso, 2015; Staudigel & Hart, 1985), suggesting that this difference in CO_2 content reflects

something intrinsically different about the system between these times—the most likely candidates being differences in ocean temperature and composition. A significant temperature dependence of seafloor basalt alteration was proposed by Brady and Gíslason (1997) based on basalt-seawater experiments and is supported by modeling Sr-isotope systematics in these systems (Coogan & Dosso, 2015) and by global C-cycle models (Krissansen-Totton & Catling, 2017). Additionally, O-isotope thermometry shows that both the minimum and average temperature of precipitation of carbonate in the upper oceanic crust track bottom water temperature, being higher in the late Mesozoic than late Cenozoic (Coogan & Gillis, 2018; Gillis & Coogan, 2011). These observations lead to a simple model for the role of seafloor weathering of basalts in the long-term carbon cycle in which increased atmospheric CO₂ gives rise to an increased global mean surface temperatures and in turn increase in bottom water temperature of the same magnitude (Krissansen-Totton & Catling, 2017). Thus, the temperature of seawater-basalt reactions in the upper oceanic crust increases leading to elevated CO₂ consumption (alkalinity generation) and a stabilizing feedback on the C cycle.

3.3. Internal Carbon Recycling (Reverse Weathering)

To our knowledge, the notion of reverse weathering (and marine weathering) can be traced back to a seminal paper by Sillén (1961), where clay minerals are proposed to act as a buffer of seawater pH. In this contribution and subsequent publications, Sillén questioned the traditional view of a carbonate system operating as the sole regulator of seawater pH, highlighting that significant amounts of seawater alkalinity could be released (marine weathering) and/or consumed (reverse weathering) by silicate mineral phases (Sillén, 1961, 1967). Multiple articles followed within the decade, predominantly focused on highlighting the importance of reverse weathering for the budgets of multiple major cations, alkalinity and H⁺ (Garrels, 1965; Holland, 1965; Mackenzie & Garrels, 1965, 1966a, 1966b). Perhaps most notably, Mackenzie and Garrels constructed a mass balance for river water inputs, such that the major constituents were precipitated from seawater as mineral phases commonly found in marine sediments—balancing their budgets required for Na, Mg, K and Si removal through clay authigenesis (Mackenzie & Garrels, 1966a, 1966b).

Subsequently, both field (e.g., Baldermann et al., 2013; Baldermann et al., 2015; Ehlert et al., 2016; Ku & Walter, 2003; Mackenzie et al., 1981; Mackin & Aller, 1984, 1986; März et al., 2015; Michalopoulos et al., 2000; Michalopoulos & Aller, 1995, 2004; Presti & Michalopoulos, 2008; Rahman et al., 2016, 2017; Ristvet, 1978; Solomon et al., 2008; Tatzel et al., 2015; Wallmann et al., 2008) and laboratory studies (Loucaides et al., 2010; Michalopoulos & Aller, 1995) investigating the mineralogy and porewater chemistry of modern marine sediments and their evolution with depth have provided convincing evidence for the operation of this process in the natural environment, prompting greater acceptance within the broader community. Most recently, studies of stable Si (Ehlert et al., 2016), cosmogenic Si (Rahman et al., 2016, 2017) and beryllium (Be) (Bernhardt et al., 2020) isotopes have been developed as a tracer for fingerprinting Si uptake during authigenic clay formation in marine sediments. Similar to marine weathering, reverse weathering has been observed to take place in both marine sediments (e.g., Ehlert et al., 2016) and oceanic crust (e.g., Chan et al., 1992; Chan et al., 2002; Chan & Kastner, 2000). Note that the latter should not be confused with cation exchange between fluids and primary mineral phases in oceanic crust (Berner & Berner, 2012), which have no direct effect on the global marine alkalinity balance.

On the basis that silica forms the framework of all clay minerals, the global silica cycle provides for a useful method of keeping track of reverse weathering fluxes. Largely based on extrapolations from work carried out in the proximal Amazon delta (Michalopoulos & Aller, 2004), dissolved silica sequestration as authigenic clay phases globally was initially estimated at ~1 to 1.5 Tmol/year (Holland, 2005; Laruelle et al., 2009; Tréguer & De La Rocha, 2013). For reference, the total amount of new Si introduced into the ocean system is estimated at ~10.9 Tmol/year (Tréguer & De La Rocha, 2013). However, recent work adopting the use of cosmogenic ³²Si suggest that this flux could be significantly higher at ~4.5 to 4.9 Tmol/year globally in coastal and deltaic systems (Rahman et al., 2017). In this novel contribution, ³²Si is applied as a tracer for studying Si release during biogenic silica dissolution and its recapture by authigenic phases in marine sedimentary porewaters (Rahman et al., 2017). The capture of cosmogenic ³²Si (generated by cosmic ray spallation of ⁴⁰Ar in the atmosphere) by biogenic silica (e.g., diatoms) upon entering the ocean, delivers the ³²Si to the sediment-water interface after the organism dies. Elevated 10Be/9Be ratios in marine relative to riverine clay mineral sediment fractions provide further supporting evidence for the capture of Si (derived from biogenic opal) during authigenic clay formation. These estimates do not account for (1) shelf, slope, upwelling,

and deep sea environments and (2) any amount of Si capture that was derived from direct diffusion with marine bottom waters and/or Si released via dissolution of primary silicate minerals (marine weathering) that do not host ^{32}Si and, therefore, can be viewed as conservative.

Reverse weathering can involve a variety of different dissolved cation species (e.g., Li^+ , K^+ , Mg^{2+} , and Fe^{2+}), and so keeping track of this process through any of these individual cycles will provide an incomplete view of its impact on the global carbon and alkalinity budgets. Similarly, the global export of Si does not translate directly to a flux of carbon being recycled through reverse weathering. However, with knowledge of the alkalinity (Alk):silica (Si) consumption ratio associated with clay authigenesis, which is determined by the composition (clay species) of the globally integrated clay mineral assemblage, the reverse weathering flux of CO_2 can be estimated. A clay mineral species/assemblage with a higher Alk:Si ratio will have a larger impact on global carbon recycling (Isson & Planavsky, 2018). The formation of kaolinite, for instance, does not consume soluble cations and thus alkalinity and so has no impact on the global carbon cycle. Alk:Si ratios of standard clay compositions (note that many have flexible stoichiometries) span a large range between kaolinite and up to 4.0. For instance, sepiolite has an Alk:Si = 1.33, greenalite = 3.0, berthierine = 4.0. The activities of dissolved cations, silica, H^+ , and temperature all play a role in regulating the saturation state and thus rate of formation of an authigenic clay mineral phase. The dependence (A, B, and C) of each one is set by the stoichiometry of the clay mineral (for instance, if $\text{X}_A\text{Si}_B\text{O}_5(\text{OH})_4$, and $\text{C} = \text{A}$ for a monovalent cation and $\text{C} = \text{A} \times 2$ for a divalent cation):

$$K_{\text{sp}} = \frac{\alpha_{\text{cation}}^A + \alpha_{\text{SiO}_2(\text{aq})}^B}{\alpha_{\text{H}^+}^C}$$

Organic matter remineralization reactions have the potential to alter marine porewater chemistry and pH levels and their evolution with depth in the sediment pile, which have the potential to influence rates of reverse weathering (and forward marine weathering). Hydrogen ion and alkalinity budgets evolve with depth in marine sediments. Specifically, the oxidation of organic matter tied to aerobic respiration and methanogenesis generates acidity, while iron and sulfate reduction consumes acidity. Thus, all else being equal, the chemistry of the upper portion of an anoxic marine sediment pile above the sulfate-methane transition zone would be expected to produce conditions that favor reverse weathering type reactions (increase saturation state of silicate minerals) and favor marine weathering below it (section 3.2.5).

4. Evolution of the Global Carbon Cycle

4.1. Controls on Degassing and its Evolution

All of the major carbon dioxide outgassing sources can potentially vary dramatically through time. There are likely unidirectional changes in the history of outgassing, tied to Earth's long-term thermal and tectonic evolution and superimposed on this shorter-term cyclic changes on the order of several million years linked to tectonic processes. Historically, a long-term drop in mantle heat flow is assumed to drive a progressive decline in mid-ocean ridge spreading rates and thus ridge CO_2 fluxes. But this rapid spreading rate model clashes strongly with empirical observations and first-principle geophysical modeling, which provide strong evidence that the early Earth was instead characterized by slow rates of ocean ridge spreading (Korenaga, 2018). This, however, does not imply that there has been no decline in outgassing rates through Earth's history. Most importantly, there is compelling evidence from modeling the ^{142}Nd isotope and zircon records that crustal recycling rates have declined through Earth's history—with the most precipitous decline in the Archean (Korenaga, 2018; Rosas & Korenaga, 2018). These enhanced rates of continental crustal recycling would have driven enhanced CO_2 outgassing in the Precambrian, providing part of the solution to the faint young Sun paradox. Rates of outgassing are also likely to have varied during “supercontinent” cycles which occur on a roughly 15 Myr time scale, and during magmatic flare ups that typically occur on a several million-year time scale or less (e.g., Burgess et al., 2014).

There is little debate that outgassing fluxes have likely varied through Earth history, but it is difficult to provide constraints on outgassing evolution. This is not surprising, given that there are large uncertainties even in modern outgassing fluxes (see section 3.1). An exception to this rule is continental arc systems, that have the potential to contribute large fluxes of CO_2 to the atmosphere associated with the recycling of carbon

preserved in the upper plate (Lee et al., 2013; Lee & Lackey, 2015; Mason et al., 2017). Detrital zircon U-Pb ages extracted from clastic sedimentary rocks provide a means to assess regional continental magmatism in deep geologic time. Zircon is an accessory mineral commonly produced in silicic magmas (e.g., Lee & Bachmann, 2014), which are produced in large volumes along continental arc systems. Mafic rocks can certainly contain zircons; however, they are far less abundant than in the higher silicic content rocks. Zircons can remain in upper crustal rocks for extended intervals of time because of the mineral's resilience to physical and chemical degradation (e.g., Gehrels, 2014). Thus, zircon can survive multiple episodes of sedimentary recycling (i.e., burial, exhumation, erosion, and reburial). This explains why a sandstone may contain a wide variety of zircons with crystallization ages billions of years older than the depositional age of the rock—even modern river sands can yield Archean aged zircon (Campbell & Allen, 2008). Clastic sediments deposited along continental margins with arc systems, however, tend to contain large abundances of zircon with crystallization ages close to the depositional age of the sediment (Cawood et al., 2012), which are likely first-cycle zircons sourced from volcanic or rapidly exhumed plutonic rocks produced by the arc system. Sediment collected in close proximity to the arc will generally be dominated by relatively young arc-derived zircons, whereas zircon collected further away from the arc will likely contain mixed zircons from older bedrock sources and with the abundance of the young grains being reduced (Blum & Pecha, 2014; Capaldi et al., 2017).

The marine environment has changed dramatically with the advent of deep sea carbon burial in the Mesozoic (Ridgwell, 2005), and this shift in the carbonate factory could have changed CO₂ outgassing. Specifically, this would have increased the amount of carbonate on average associated with subducting slabs globally, which (in the standard view) would in turn elevate the amount of carbonate recycled and degassed as CO₂ in arc systems (e.g., Edmond & Huh, 2003). Interestingly, however, there is currently no evidence for a step increase in surface temperatures associated with the emergence of deep-sea carbon burial, although it should be noted that the Cretaceous and Cenozoic are anomalously warm and cool periods respectively. There is increasing evidence for CO₂ degassing from metacarbonate rock in the overriding plate when there is fluid infiltration (Stewart & Ague, 2018). In this case, the arc systems before and after the onset of extensive deep sea carbon burial may have, on average, had roughly similar ratios of CO₂ outgassed to new zircons produced. Regardless, of this uncertainty, it is reasonable to assume that careful assessment of detrital zircon age-data may provide first-order insights into global continental magmatism and CO₂ outgassing through time.

Recent studies have utilized global detrital zircon U-Pb data to track the spatial distribution of arc systems at various time scales (McKenzie et al., 2014; McKenzie et al., 2016). A general problem in studies utilizing zircon age compilations is the unevenness of data available, which biases composite global age distributions from being truly “global”—most distributions are biased toward regions which contribute a substantial amount of data (Campbell & Allen, 2008; Voice et al., 2011). McKenzie et al. (2016) attempted to circumvent these sampling issues by binning their data by geographic region and depositional age, which allowed the regional data to be normalized prior to incorporation into temporal composites. There are likely more sophisticated ways to avoid sampling biases, and as databases increase there will certainly need to be future assessment of these records. But at present, this simple normalization process provides a reasonable means of assessing how global zircon production has changed throughout time.

The sedimentary record of zircon production from the Cryogenian to the present (i.e., the past ~720 million years of Earth history) demonstrates a correlation with icehouse-greenhouse transitions. This suggests a causative link between arc activity and climate transitions—when volcanism was reduced Earth moved into an icehouse state, whereas when volcanic arcs expanded, Earth transitioned into a greenhouse climate (McKenzie et al., 2016). Correlation—even when there is an obvious mechanistic link—does not, necessitate causation. However, the current sedimentary zircon record points toward carbon outgassing history playing a critical role in shaping Earth's climate. Future work attempting to tease apart the effects of production versus preservation on the sedimentary zircon record and test the framework that this record can faithfully track arc activity would be of great interest to the community.

Conclusions about outgassing from the zircon record can be tested to a degree by (1) considering how continents have migrated and amalgamated throughout time (i.e., supercontinent breakup and formation) and/or (2) mapping the known distribution of ancient volcanic systems. Continental breakup requires the establishment of rift systems and the opening of new ocean basins, which also requires the establishment of subduction zones to accommodate oceanic spreading. Therefore, as plates break up and migrate,

volcanic arc systems will be more prevalent, whereas the collision of continental blocks shuts down and reduces arc systems. Extensive continental arc systems existed throughout the Ediacaran and early Paleozoic to form Gondwana, during the mid-Paleozoic to form Pangea, and the Mesozoic to early Cenozoic following the breakup of Pangea. These intervals correspond with greenhouse climates, whereas the final collisions that formed Gondwana, Pangea, and the closure of the Tethys ocean (Cawood & Buchan, 2007; Lee et al., 2013) all correspond with icehouses (McKenzie et al., 2014; McKenzie et al., 2016). Mapping of arc systems in deep time is presently hindered by inconsistencies in reconstructing the extent and nature of magmatism along ancient margin configurations and problems with pre-Pangean plate configurations (e.g., Evans, 2013). Nonetheless, recent attempts to use paleogeographic maps to estimate arc length and outgassing have demonstrated similar results to that of the zircon record (Cao et al., 2017; Mills et al., 2017; Van Der Meer et al., 2014). Estimating the areal extent of regions undergoing low-, middle-, and high-grade metamorphic alteration, which can also be a major CO₂ source (e.g., Stewart & Ague, 2018; Stewart et al., 2019; Zhang et al., 2018), is similarly hindered by inconsistent geologic reconstructions. But collectively, multiple lines of data from recent studies are demonstrating a consistent relationship between outgassing estimates and major shifts in climate (Cao et al., 2017; McKenzie et al., 2014; McKenzie et al., 2016; Mills et al., 2017; Van Der Meer et al., 2014). Therefore, empirical records support the idea that carbon sources have played a major role in controlling Earth's climate and provide a simple explanation as to why Earth has toggled between icehouse-greenhouse intervals. Large igneous provinces have been linked to short-term climate shifts (foremost the end Permian mass extinction and temperature spike; Burgess & Bowring, 2015) but cannot be linked to longer-term climate swings and shifts given their limited active lifespan.

4.2. Links Between the Oxygen, Iron, Sulfur, and Carbon Cycles

The iron and sulfur cycles both have the potential to drive significant variations in atmospheric carbon dioxide levels. There are multiple burial channels for iron and sulfur—sulfur can be buried as pyrite or sulfate evaporites, and iron can be buried as Fe clays, Fe carbonates, pyrite, or oxides. At steady state, the cycling of these elements does not impact the global carbon cycle. On the other hand, shifts in the iron and sulfur weathering and burial terms can drive transient yet geologically meaningful shifts in pCO₂ tied to long-term imbalances in the global marine alkalinity budget. This idea builds on the same principles introduced for silicate weathering and reverse weathering—numerous iron and sulfur reactions either produce acidity or alkalinity. Sulfide and ferrous iron oxidation produce acidity while ferric iron and sulfate reduction produce alkalinity—potentially altering the ocean-atmosphere carbonic acid system balance and thus the ocean's capacity to hold inorganic carbon.

There are numerous scenarios whereby changes in the iron and sulfur cycles could have driven a rise or decline in atmospheric carbon dioxide levels. However, there are two scenarios that have been the most thoroughly explored and are most likely to have impacted Earth's climate on a several million-year time scale (Bachan & Kump, 2015; Torres et al., 2014). An increase in pyrite weathering coupled to carbonate weathering can drive a jump in atmospheric carbon dioxide levels as long as the resulting sulfate accumulates in the ocean or is deposited as evaporite (Torres et al., 2014). In contrast, enhanced sulfide oxidation directly coupled to enhanced pyrite burial does not have a direct effect on the global carbon cycle. This transient, sulfur-driven CO₂ source likely played an important role in shaping Cenozoic climate, where there was a marked and progressive increase in marine sulfate concentrations (e.g., Wortmann & Paytan, 2012).

The progressive oxidation of iron in the upper continental crust can also result in a net release of carbon dioxide. Foremost, oxidation of continental crust rich in siderite and the deposition of sediments rich in ferric iron can result in a net CO₂ release. Bachan and Kump (2015) proposed that this process was likely important during the Archean-Paleoproterozoic transition, which saw Earth's first notable rise in atmospheric oxygen levels. Although there is strong evidence that the crust contained abundant Fe carbonates in the Archean—there is also abundant evidence for the deposition of Fe silicates (e.g., Johnson et al., 2018; Rasmussen et al., 2017) and Fe oxides (e.g., Bekker et al., 2014). Further, the oceans appear to have remained anoxic through most of the Precambrian and potentially even in the early Phanerozoic. Therefore, atmospheric oxygenation may not lead to a jump in ferric/ferrous ratio of marine sediments. Better constraints on the evolution of sedimentary iron speciation are needed to further evaluate this problem.

Figure 10. Cartoon summarizing the modern and Precambrian carbon cycle sources and sinks. Elevated rates of degassing have been predicted from geophysical models for the Precambrian relative to the modern (e.g., Holland, 2009; O'Neill et al., 2014; Tajika & Matsui, 1992), and on this basis carbonate export tied to silicate weathering must be proportionally larger. Higher dissolved silica and iron levels that are hallmark features of the Precambrian ocean gave rise to conditions that favored enhanced rates of reverse weathering, and dampened marine weathering rates (Isson & Planavsky, 2018). By this framework, it follows that the ratio of terrestrial to marine silicate weathering rates would have been higher in the Precambrian.

4.3. Reverse Weathering Through Time

Reverse weathering could have evolved dramatically through time (Figure 10). In particular, it was recently proposed that reverse weathering rates were likely elevated in early Precambrian oceans, directly linked to the higher dissolved Si, Fe, and Mg levels that are traditionally viewed to be characteristic features of this time period (Isson & Planavsky, 2018). In this view, enhanced carbon recycling during this time could have sustained a significantly elevated $p\text{CO}_2$ baseline, providing a solution to the faint young Sun paradox that does not necessitate invoking a significant reduction to the weatherability of Earth's surface. The subsequent radiation of siliceous organisms (sponges, radiolarians, and most recently diatoms) from the latest Precambrian through the Phanerozoic forced a drop in dissolved marine Si levels and thus the extent of carbon recycling through reverse weathering and in turn baseline $p\text{CO}_2$ levels. Marine authigenic clay mineral assemblages are likely to have evolved through time. While authigenic clays have long been recognized to make up a significant portion of the mineralogical and textural makeup of marine sediments (e.g., Hazen et al., 2013), a wide variety of species have been reported (for example, palygorskite, montmorillonite, glauconite, saponite, berthierine, greenalite, and minnesotaite) (Baldermann et al., 2015; e.g., Bhattacharyya, 1983; Hazen et al., 2013; Johnson et al., 2018; Pletsch, 2001; Rasmussen et al., 2015; Rasmussen et al., 2013; Rasmussen et al., 2017). For instance, Fe-rich clays with higher Alk:Si consumption ratios (e.g., greenalite, berthierine, and chamosite) appear to be more abundant in anoxic Precambrian marine sediments than observed in the modern oceans characterized by lower Alk:Si consumption ratios such as montmorillonite. The drop in atmospheric $p\text{CO}_2$ levels since the Precambrian (Kasting, 1987) can, to a significant degree, be explained by this evolution of clay mineral assemblage and Alk:Si.

5. Future Directions

Although there have been major steps forward in our understanding of the global carbon cycle in the past decade, many advances have resulted in more questions than answers. We make a case that marine processes (marine weathering and reverse weathering) are likely more important controls on long-term climate than traditionally envisioned (e.g., in contrast to Berner, 2004). However, there is an obvious need for better constraints on the extent and evolution of these processes. In large part, this will center on improving our understanding of global cation mass balances. For the Mg cycle, this entails working toward a better constraint on the balance of clay to dolomite formation, and how the flux of Mg to the oceans has changed through time as the composition of the upper continental crust and weathering intensities have evolved. Mg isotopes provide a promising means to track these fluxes (e.g., Higgins & Schrag, 2015). Similarly,

recent work has highlighted the need for better estimates on the extent of iron burial that consumes alkalinity (Baldermann et al., 2015; Bhattacharyya, 1983; Rasmussen et al., 2015; Tosca et al., 2016) and there are poor empirical constraints on how iron fluxes to the oceans have changed through time. There is a need for a better basic understanding of the fate of Na and K in the ocean, particularly constraints on the fraction of these elements that are lost in alkalinity consuming versus producing reactions (e.g., reverse weathering reactions versus seafloor weathering of feldspars). The Ca cycle, with a single output term, is typically considered to be the best constrained cation geochemical cycle. However, counter to the standard view, it has been suggested—and not yet refuted—that hydrothermal Ca fluxes dominate the Ca input to the oceans (Caro et al., 2010).

In sum, there are still major uncertainties in the sources and sinks of all major cations even in the modern oceans, and the evolution of cation budgets through Earth's history are even more poorly understood. A multifaceted approach—more well-grounded models, more experimental data, and better constraints from the rock record—is needed to move forward our understanding of evolution of cation budgets. However, an increase in the amount of kinetic data for marine reactions (e.g., clay formation) might lead to the most significant steps forward in the short term. The amount of kinetic data for conditions relevant to basalt alteration and marine porewaters is well short of that for terrestrial soils.

Better constraints on outgassing fluxes are also essential to move forward our understanding of the long-term carbon cycle. Although there have been several recent large-scale efforts (e.g., Trail by Fire project) to better constrain volcanic outgassing rates, several fluxes are still highly speculative. Foremost, the diffuse outgassing flux is poorly constrained (Kelemen & Manning, 2015). This should not be a surprise since diffuse fluxes are of course more difficult to constrain than point sources. Given the importance of fluid infiltration in determining CO₂ fluxes (Stewart & Ague, 2018), more mechanistic models of fluid flow in subduction zones and metamorphic terranes are also potentially promising targets.

Lastly, exoplanet research is rapidly developing as a field and future space-based telescope missions provide a strong impetus to translate our understanding of Earth's carbon cycle into a general theory for carbon cycling on terrestrial planets. Moving toward a more generally accepted view of the factors that have allowed for Earth to remain persistently inhabited for billion year time scales is a critical step toward understanding how terrestrial planets evolve. The “habitable zone” for exoplanets—where liquid water can exist—is typically delineated by assuming the maximum greenhouse gas capacity of a planet (Kasting et al., 1993). Therefore, a well-grounded general theory of carbon cycling on terrestrial planets is essential to predict how likely a planet within the habitable zone will sustain the evolution and persistence of life. Further, coupling astronomical data with carbon cycle modeling may even help us pinpoint exoplanets most likely to harbor life (i.e., ideal target for exoplanet atmospheric characterization).

6. Summary

Earth has been a habitable planet for over 4 billion years because of the persistence of stabilizing feedbacks in the global carbon and silicon cycles. Terrestrial silicate weathering was traditionally assumed to give rise to this negative feedback. Indeed, work over the last few decades suggests the presence of a terrestrial silicate weathering feedback (e.g., Von Strandmann et al., 2013). However, there are major uncertainties in the processes controlling terrestrial silicate weathering rates and the balance between terrestrial and marine silicate weathering. The extent of silicate weathering in groundwater has likely been underappreciated. Similarly, marine weathering—both within the sediment pile and during oceanic crust alteration—is also likely a more important part of the global carbon cycle than was traditionally envisioned (Coogan & Gillis, 2018; e.g., Gillis & Coogan, 2011; Wallmann et al., 2008). In other words, terrestrial silicate weathering in the critical zone only accounts for part of the carbon removal from the ocean-atmosphere system and global silicate weathering fluxes are much higher than those reconstructed from riverine alkalinity budgets. New evidence for higher modern weathering rates than traditionally envisioned does not imply that the carbon cycle is dramatically out of steady state; carbon source terms have likely also been underestimated. Foremost, carbon dioxide fluxes from diffuse metamorphic outgassing are almost certainly higher than in traditional balanced long-term carbon cycles budgets (e.g., Berner, 2004).

Authigenic clay formation in the oceans—reverse weathering—is a relatively minor part of the modern global carbon cycle, but it is likely to have been more important earlier in Earth's history (Isson & Planavsky,

2018). The switch to a biologically controlled Si cycle—where the majority of SiO_2 fluxes in the oceans are biogenic—caused a dramatic drop in dissolved marine Si concentrations (Siever, 1992). This drop in dissolved marine Si concentrations would have decreased the saturation state of clay minerals—leading to relatively less extensive reverse weathering and more intense marine weathering, and thus a decline in baseline CO_2 levels due to less extensive carbon recycling within the ocean-atmosphere system. Reverse weathering, the rates of which are pH dependent, also stabilizes the climate system—through the reverse weathering feedback. Si biomineralization, a major biotic innovation, would have therefore destabilized Earth's climate system, adding to one of the central dogmas of the original Gaia hypothesis, that life as a part of a global Earth system can give rise to both positive and negative climate feedbacks (Lovelock & Kump, 1994; Lovelock & Margulis, 1974).

Given that there is still debate about the modern carbon cycle mass balance, it is unsurprising that there is not a clear consensus about the factors that have driven long-term shifts in Earth's climate. This debate is often distilled down into arguments about whether the sources or sinks of carbon sources have driven climate shifts. There is a strong correlation between outgassing tracers and climate records over the last 800 million years (e.g., McKenzie et al., 2016; Mills et al., 2017), tentatively suggesting that carbon sources were the main drivers of climate oscillations. However, shifts in weatherability (carbon sinks) have also been linked to major climate shifts (e.g., Cenozoic cooling; Caves et al., 2016; Jagoutz et al., 2016; Zhang & Planavsky, 2019b). Resolving the factors controlling climate shifts and working toward a more well-defined global carbon mass balance are critical areas of future research.
