Abstract The Proterozoic-Phanerozoic evolution of the Tarim and North China cratons is integral to the construction of the Eurasian continent. Throughout the Paleozoic, these continents were bound by the Paleo-Asian and Tethyan Oceans to the north and south, respectively, and, thus, their paleogeography is critical to reconstructions of the oceanic domains. Specifically, it remains uncertain whether the Tarim and North China cratons were contiguous during the Paleozoic. Geologic observations from the Qilian Shan and Longshou Shan of western China provide valuable information regarding the paleotectonic relationships of these continents. Here we present detailed field, geochronological, and geochemical observations from key locations in the Qilian Shan and Longshou Shan to decipher complex relationships between the Kunlun-Qaidam, North China, and Tarim continents. Paleoproterozoic deformation might have been associated with the northern North China orogen, whereas a Neoproterozoic collisional orogen occurred between the Kunlun-Qaidam-South Tarim and the North China-North Tarim. Subsequent late Neoproterozoic rifting led to the opening of the Qilian ocean as an embayed marginal sea, and the Paleo-Asian Ocean developed along the northern margin of the North China craton. South-dipping subduction, arc magmatism, slab rollback, and convergence between Kunlun-Qaidam and North China continued throughout the Early Silurian, which were recorded in the Qilian Shan and Longshou Shan regions. Our updated geotectonic framework requires reevaluation of previously published paleogeographic models, including ones that suggest the North China craton was affixed to Gondwana in the early Paleozoic. It is further considered a possible connection between the North China and southern Africa at ca. 2.05 Ga.

1. Introduction

The assembling of the Eurasian continent occurred from the Proterozoic to the Mesozoic over a time span of nearly one billion years (Scotese & McKerrow, 1990; Şengör & Natal'in, 1996; Sone & Metcalfe, 2008; Yin & Nie, 1996). It was accomplished primarily by the closure of the Paleo-Asian and Tethyan ocean systems, involving cratonal blocks separated from the supercontinents Columbia, Rodinia, and Pangea (e.g., Badarch et al., 2002; Biske & Seltmann, 2010; Heubeck, 2001; Kusky et al., 2007; S. Li et al., 2018; Rogers & Santosh, 2002; Şengör & Natal'in, 1996; Stampfli & Borel, 2002; C. Wu et al., 2016a; Yin & Nie, 1996; G. C. Zhao et al., 2018; Zonenshain et al., 1990; Zuza & Yin, 2017) (Figure 1). The Paleo-Asian and the Tethyan oceanic domains are separated by the Tarim and North China cratons whose geologic histories are critical for deciphering the interactions of the two orogenic systems to the north and south. A major obstacle for establishing the geologic history of Tarim and North China cratons is that the two tectonic entities are currently bounded by Cenozoic structures along the southern margin of the Tian Shan and the northern margin of the Tibetan plateau (Figure 1). These structures have either reactivated or strongly modified the earlier tectonic configurations of the region (e.g., Yin & Nie, 1996). For example, Cenozoic structures that bound the southern margin of Tarim and North China cratons overprinted Mesozoic extensional basins (X. Chen et al., 2003; Vincent & Allen, 1999), an early Paleozoic arc-continent collision system (e.g., S. Song
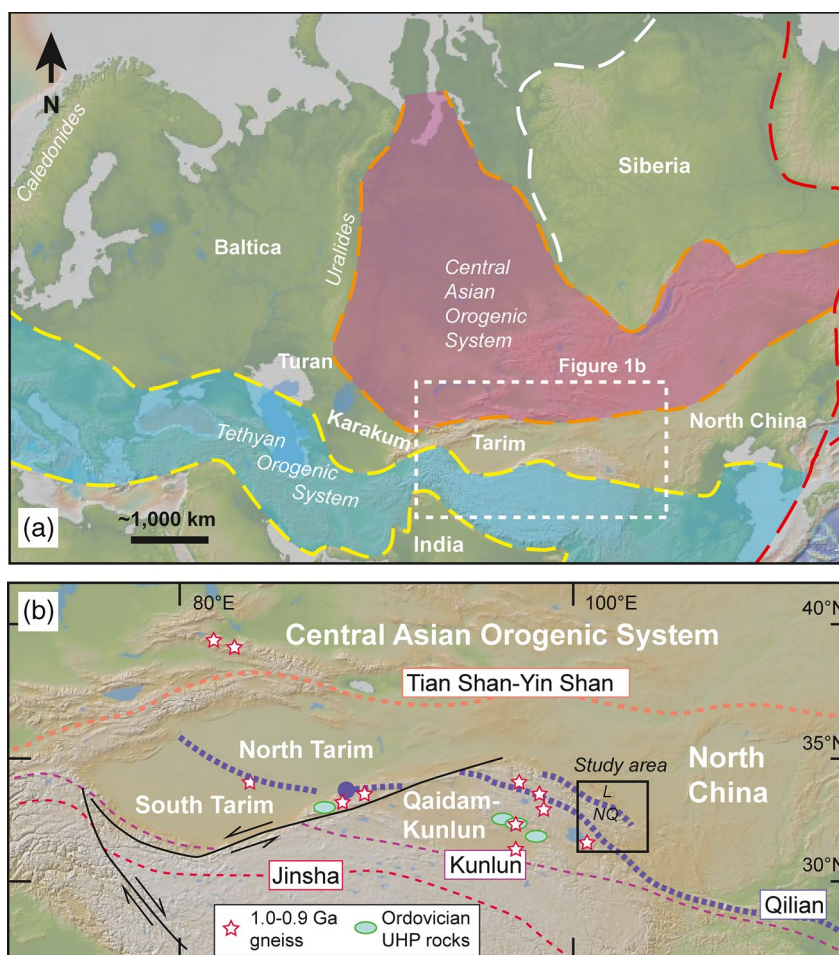

Figure 1. Overview of the Proterozoic-Paleozoic geology of northern Tibet and Central Asia. (a) Tectonic map of Eurasia showing cratons, orogenic systems, and the location of Figure 1b. (b) Configuration of the Jinsha, Kunlun, Qilian, and Tian Shan-Yin Shan suture zones, from north to south respectively, in northern Tibet and central Asia. Also shown are the locations of Neoproterozoic granitoid and gneiss rocks, and Ordovician UHP rocks (e.g., S. Song et al., 2014; C. Wu et al., 2016a). The study area of this work, Longshou Shan (*L*), and North Qilian Shan (*NQ*) are marked. Figures modified from Wu et al. (2016a).

et al., 2013; C. Wu et al., 2017; Xiao et al., 2009; Yin et al., 2007; A. V. Zuza et al., 2018), an enigmatic Neoproterozoic magmatic belt (e.g., Cowgill et al., 2003; G. E. Gehrels et al., 2003a, 2003b; Z. J. Guo et al., 2005; C. Wu et al., 2016a, 2017), and Archean-Proterozoic metamorphic basement rocks of North China craton and the Kunlun-Qaidam continent (Tseng et al., 2006; K. Tung et al., 2007; C. Wu et al., 2017).

Because of the complex geologic histories along the margins of Tarim and North China cratons and the nearby Kunlun-Qaidam continent, it remains unclear how the three ancient cratons, all having Neoproterozoic to Cambrian cover sequences, were related in the paleogeographic reconstructions prior to the appearance of the Paleo-Asian and Tethyan Ocean systems (Figure 2) (C. Wu et al., 2016a). This uncertainty is exemplified by the two competing models for the paleogeographic reconstruction of North China craton in the Cambrian. According to McKenzie et al. (2011) and updated publications (e.g., Y. Han et al., 2016; Myrow et al., 2015), the North China craton was positioned with its southern margin against Gondwana (i.e., contiguous Australia and India). In contrast, the predominant models for the tectonic evolution of the northern Tibetan plateau placed the current southern margin of North China craton against the Kunlun-Qaidam continent, which were separated by a Neoproterozoic-Cambrian ocean (i.e., the Qilian Ocean) that later closed in the Silurian (G. E. Gehrels et al., 2003a, 2003b; Sobel & Arnaud, 1999; S. Song et al., 2013; Yin & Nie, 1996).
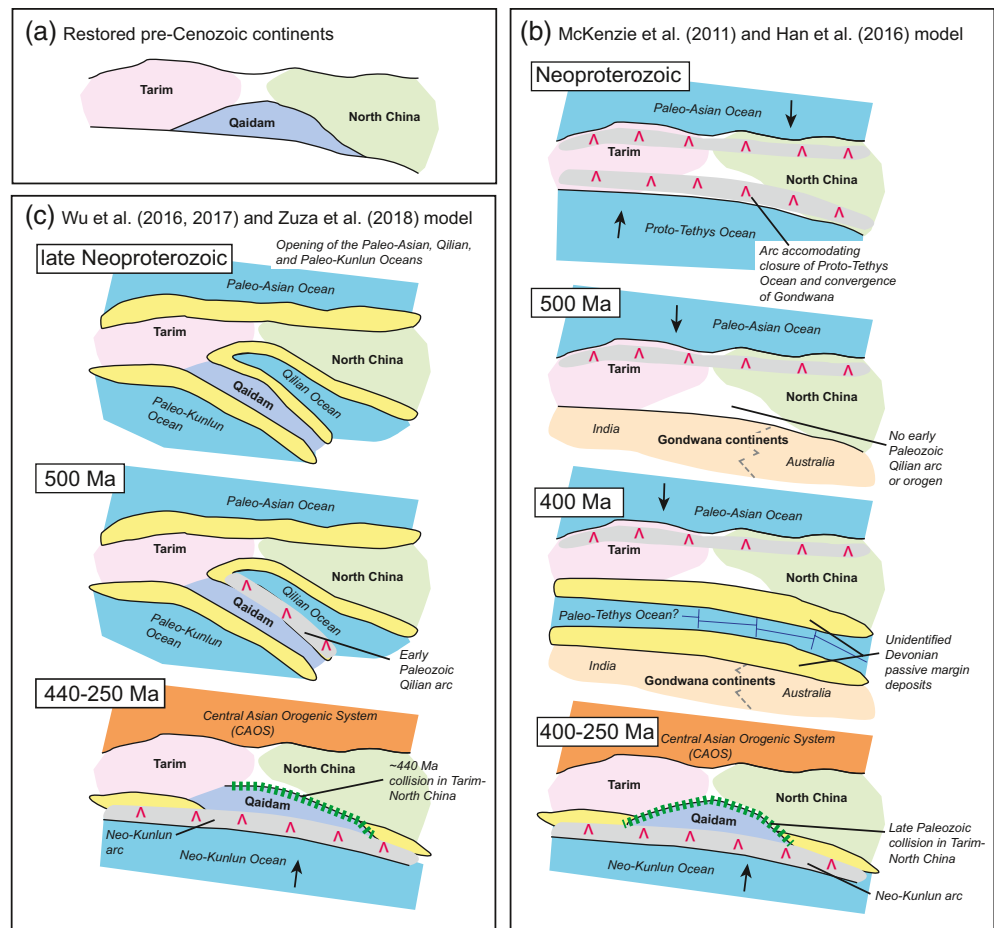

Figure 2. Major tectonic models for the Neoproterozoic-Paleozoic evolution of the Tarim-North China and Kunlun-Qaidam systems. (a) Schematic configuration of northern Tibet after restoring Cenozoic deformation in the Qilian Shan and Pamir thrust systems and left-slip faulting on the Altyn Tagh (e.g., Cowgill et al., 2003; Zuza et al., 2016). (b) Paleogeographic reconstruction of McKenzie et al. (2011) and Han et al. (2016) which positions Gondwana to the south of Tarim and North China in the Cambrian. Shortcomings of this model based on the observed regional geology include: (1) there is no space in the early Paleozoic for the Kunlun-Qaidam continent to collided against the southern margin of the Tarim and North China cratons. (2) Requires unidentified Devonian rifting to remove Gondwana and post-Devonian Qilian orogen, (3) suggests that the Paleo Asian ocean here was open north of North China prior to the Mesoproterozoic. What are our Neoproterozoic passive margin rocks representing? Note that there is no space in the early Paleozoic for the Kunlun-Qaidam continent to collide against the southern margin of the Tarim and North China cratons. This model also requires currently unidentified Devonian passive margins to develop as Gondwana rifts and separates from Tarim-North China. (c) Reconstruction envisioned by Wu et al. (2016a) and Zuza et al. (2017) where the Kunlun-Qaidam continent separates from the southern margin of North China in the Neoproterozoic as peninsular, still connected to Tarim. Counter-clockwise rotation of this continent in the Cambrian-Ordovician, accommodated by southward subduction along the northern margin of Kunlun-Qaidam, leads to the closure of the Qilian Ocean by ~445 Ma.

The Kunlun-Qaidam continent is truncated in the west by the Cenozoic Altyn Tagh fault that has accommodated >500-km left-slip motion (e.g., Cowgill et al., 2003; Peltzer & Tapponnier, 1988). The relationship implies that the microcontinent may have an extended portion to the west currently buried below the Taklimakan desert of Tarim (e.g., C. Wu, Yin et al., 2016; Wu, Zuza et al., 2017; Yin, Dang et al., 2007; Yin, Manning et al., 2007; Zuza et al., 2018). Except two reconnaissance studies (Z. J. Guo et al., 2005; A. Yin & Nie, 1996), the impact of the westward extent of the Kunlun-Qaidam continent west of the Altyn Tagh fault for reconstructions of the Tarim and North China cratons has yet been fully addressed. In this contribution, we explore this issue by examining the tectonostratigraphic relationship along the southern margin of North China craton and northern margin of the Kunlun-Qaidam continent in the Qilian Shan and

Longshou Shan regions (Figure 1). Our research involves geologic mapping, U-Pb magmatic-zircon and detrital-zircon geochronology, and whole-rock geochemistry. Due to the large extent of our study area, which has a north-south length of ∼350 km and east-west length of ∼250 km (Figure 1), we present site-specific geologic maps of critical areas, together with the details of our structural analysis and analytical results. Our findings contribute to a new understanding of the role of North China craton and Kunlun-Qaidam continent in the evolution of the Paleo-Asian oceans and their possible positions during supercontinent cycles in Earth's history.

2. Regional Geology

2.1. North China Craton

The North China craton is bounded to the southwest by the early Paleozoic Qilian and Qinling orogen, to the north by the late Paleozoic Central Asian Orogenic System (CAOS), and to the south by the Mesozoic Qinling-Dabie Shan orogen (Figure 1). The craton is composed of several Archean-Paleoproterozoic blocks (with predominately ca. 2.5 and 1.95–1.80 Ga ages), and the nature of these individual continents and how/ when they coalesced is a fiercely debated topic (e.g., Faure et al., 2007; Kröner et al., 2005; Kusky & Li, 2003; Kusky et al., 2016; L. L. Xiao et al., 2011; Polat et al., 2005; Trap et al., 2007; J. P. Wang et al., 2017, 2019; C. Wu et al., 2018; G. C. Zhao & Cawood, 2012; G. C. Zhao et al., 2001, 2005 and many others). The Mesoproterozoic–Neoproterozoic history of North China craton is best recorded through the deposition of the Changcheng Group (1.80–1.60 Ga), Jixian Group (1.60–1.40 Ga), a currently unnamed unit at 1.40–1.0 Ga, and Qingbaikou Group (1.0–0.80 Ga) in the northern part of North China craton (e.g., J. F. Sun et al., 2012; Y. Wan et al., 2011). Although absent across most of North China craton, Neoproterozoic (i.e., 850–550 Ma) strata occur sporadically along its southern (S. Xiao et al., 2014) and southeastern (Chang, 1980; C. L. Zhang et al., 2006) margins. Neoproterozoic intrusive rocks have been reported across the North China craton, which are correlative in age with rift-related rocks in southern Qaidam (e.g., Dan et al., 2014; X. H. Li et al., 2005; S. Liu et al., 2012; P. Peng et al., 2011; X. L. Wang et al., 2011, 2012; C. Wu, Yin et al., 2016; Wu, Zuza et al., 2017; H. F. Zhang et al., 2009). North China craton was surrounded to the north and south by open oceans (i.e., the Paleo-Asian and Paleo-Tethys Oceans, respectively) and corresponding passive margins. The passive-margin and cratonal sequences were strongly deformed along the cratonal margins during the closure of the ocean systems to the north and south from the late Paleozoic to the early Mesozoic (e.g., Dong et al., 2013; Eizenhöfer et al., 2014; Hacker, Ratschbacher, & Liou, 2004; Hacker, Wallis, et al., 2006; Ratschbacher et al., 2003; W. Xiao et al., 2003; W. J. Xiao, Windley, Huang, et al., 2009b; W. Xiao, Windley et al., 2009c; Yin & Nie, , 1996; Wu, Liu et al., 2016, Wu, Zuza et al., 2017; Zhang, 1997; Zhao & Coe, 1987; cf. Jian et al., 2016).

2.2. Tarim Craton

The Tarim craton consists of the North Tarim and South Tarim blocks that were joined in the Proterozoic (e.g., Ge et al., 2014; Z. J. Guo et al., 2005; C. Wang et al., 2015; Z. Q. Xu et al., 2013; H. Yang et al., 2018; F. Q. Zhang et al., 2019; A. V. Zuza & Yin, 2017). The geometry and age of this collision is debated due to the poor exposure of this orogen under the 10+ km thick Mesozoic-Cenozoic sediments of the Tarim Basin (e.g., X. Chen et al., 2003; Z. J. Guo et al., 2005). Our preferred model involves a Neoproterozoic collision between the continents, which links this event with the widespread ca. 1.0–0.9 Ga arc plutons that are observed from the Qilian Shan northwest to the Tian Shan and the Neoproterozoic Aksu suture in the northwest Tarim Basin (e.g., Z. J. Guo et al., 2005; C. Wu et al., 2016a, 2017; A. V. Zuza & Yin, 2017). Other authors have suggested that this collision occurred in the Paleoproterozoic time (e.g., H. Yang et al., 2018). Accordingly, South Tarim should correlate with the Kunlun-Qaidam continent and North Tarim would have connected with North China craton.

In general, the Archean basement of the Tarim craton consists of orthogneiss, tonalite-trondhjemite-granodiorite (TTG) gneiss, and amphibolite enclaves with predominately ages of ca. 2.8–2.55 Ga (e.g., Z. X. Li et al., 2015; Lu, 1992; Lu & Yuan, 2003; S. N. Lu et al., 2006; Mei et al., 1998), the oldest ages of ca. 3.6 Ga were found in the Altyn Tagh Range (e.g., S. Lu et al., 2008) and ca.3.7 Ga TTGs by Ge et al. (2018, 2020). Paleoproterozoic metapelites unconformably overlie Archean basement, and early Paleoproterozoic mag-

matism occurred throughout Tarim craton with the ages ranging from 2.45 Ga to 2.35 Ga (Lu, 2002; Lu & Yuan, 2003; Lu et al., 2006, 2008). The ca. 1.95 Ga magmatic and ca. 1.92–1.91 Ga metamorphic events are similar to that of the Khondalite orogen in North China craton (e.g., R. Ge et al., 2015; S. N. Lu et al., 2006, 2008; G. C. Zhao et al., 2005; Santosh et al., 2006, 2007; Zhao, 2009). In the late Paleoproterozoic, the occurrence of 1.85–1.77 Ga mafic dikes and rapakivi granites suggests that the Tarim craton may have undergone extension (Lu et al., 2006, 2008; W. Xiao et al., 2003). Island arcs accreted to South Tarim in the Mesoproterozoic were subsequently intruded by ca. 1.4 Ga A-type granites, whereas North Tarim have been an undisturbed passive margin throughout the Mesoproterozoic (e.g., K. Y. Guo et al., 2004; A. G. Wang et al., 2004; Ye et al., 2016).

An early Neoproterozoic Tarim arc (ca. 970–890 Ga) created by a north-dipping subduction zone may have been developed prior to the collision between North Tarim and South Tarim along the inferred Aksu suture (e.g., Y. Chen et al., 2004; Cowgill et al., 2003; G. E. Gehrels et al., 2003a; Turner, 2010; Zheng et al., 2010; Zuza & Yin, 2017), and regional metamorphism occurred at ca. 830–790 Ma (e.g., Y. Chen et al., 2004; He et al., 2012; Ge et al., 2016). Tarim may have experienced rifting and the development of extensive passive margins in the middle and late Neoproterozoic, which was associated with the opening of the Tethys oceans (e.g., Turner, 2010; C. Wu, Yin et al., 2016; C. L. Zhang et al., 2016). The margins of the united Tarim craton were overlain by a succession of latest Neoproterozoic to Cambrian passive-margin strata (e.g., K. Y. Guo et al., 2004). Drill-hole and seismic reflection data suggest the existence of unconformities and an early Paleozoic thrust belt below Quaternary cover of the Tarim Basin (e.g., Carroll et al., 2001; Jia, 1997; Lin et al., 2012; P. Yang et al., 2020; Yin & Nie, 1996), which may correlate with the early Paleozoic Qilian orogen to the east (e.g., A. V. Zuza & Yin, 2017). Late Paleozoic-Mesozoic arc magmatism occurred along the southern margin of Tarim craton (Cowgill et al., 2003; W. J. Xiao et al., 2005), which represents the westward continuation of the Kunlun arc developed in the southeast of the Kunlun-Qaidam continent (e.g., Cowgill et al., 2003; Jiang et al., 1992; C. Wu, Yin et al., 2016; C. Wu, Zuza, Chen et al., 2019).

2.3. Kunlun-Qaidam Continent

The basement of the Kunlun-Qaidam continent consists of deformed Mesoproterozoic cover strata overlying Archean to Proterozoic crystalline basement rocks (G. E. Gehrels et al., 2003b; Pan et al., 2004; Qinghai BGMR, 1991; X. Yu et al., 2017). Precambrian basement in the Quanji massif consists of medium-to-high-grade metamorphic rocks overlain by Mesoproterozoic and Neoproterozoic strata (e.g., L. Chen et al., 2013; J. Gong et al., 2012; Lu, 2002; Qinghai BGMR, 1991; J. P. Sun et al., 2019; Y. Wan et al., 2006; Q. Wang et al., 2008, 2009; L. Zhang et al., 2014). The Kunlun-Qaidam continent underwent progressive subduction, arc magmatism, and orogeny throughout the Neoproterozoic, Paleozoic, and Mesozoic (e.g., X. H. Chen et al., 2012, 2014; Y. Dong et al., 2018; G. E. Gehrels et al., 2003a, 2003b; G. Gehrels, Kapp et al., 2011; S. Song et al., 2013, 2014; C. Wu et al., 2016a, 2019a, 2020; W. Xiao et al., 2009c; Yin, Dang, et al., 2007, 2008a; A. V. Zuza et al., 2018), which were associated with collision of the Proto-, Paleo-, and Neo-Kunlun arcs, respectively (e.g., C. Wu et al., 2016a, 2019a, 2020). The region has been reactivated by the Cenozoic North Qaidam and Qilian Shan thrust belts, and Kunlun and Haiyuan left-slip transpressional systems (e.g., Clark et al., 2010; A. R. Duvall et al., 2011, 2013; Yin, Manning et al., 2007, 2008a, 2008b; A. V. Zuza et al., 2016, 2018, 2019; C. Wu, Zuza, Chen et al., 2019; C. Wu, Zuza, Zhou et al., 2019; C. Wu, Liu, Fan et al. 2020).

2.4. Early Paleozoic Qilian Orogen

The early Paleozoic Qilian orogen is the most dominant feature of northern Tibet, and most of the rock exposures here are related to the orogen and proceeding arc system (Figure 3). This collisional orogen records the closure of the Qilian Ocean as the Kunlun-Qaidam continent collided against the North China craton (G. E. Gehrels et al., 2003a, 2003b; Sengör & Natal'in, 1996; Sobel & Arnaud, 1999; S. Song et al., 2013, 2014; C. Wu et al., 2017; Xiao et al., 2009a, 2009b; Yin & Harrison, 2000; Yin, Dang et al., 2007; Yin & Nie, 1996; Yin, Manning et al., 2007; A. V. Zuza et al., 2018). Northwest-trending discontinuous belts of Cambrian-Ordovician ophiolite-mélange material, Ordovician-Silurian arc rocks (e.g., plutons and volcanic rocks), and ultra-high-pressure rocks are distributed throughout the Qilian Shan and northern Qaidam Basin (Figure 3) (Menold et al., 2009, 2016; S. Song et al., 2013, 2014, 2019; Yin & Harrison, 2000; Yin, Dang et al., 2007; Yin
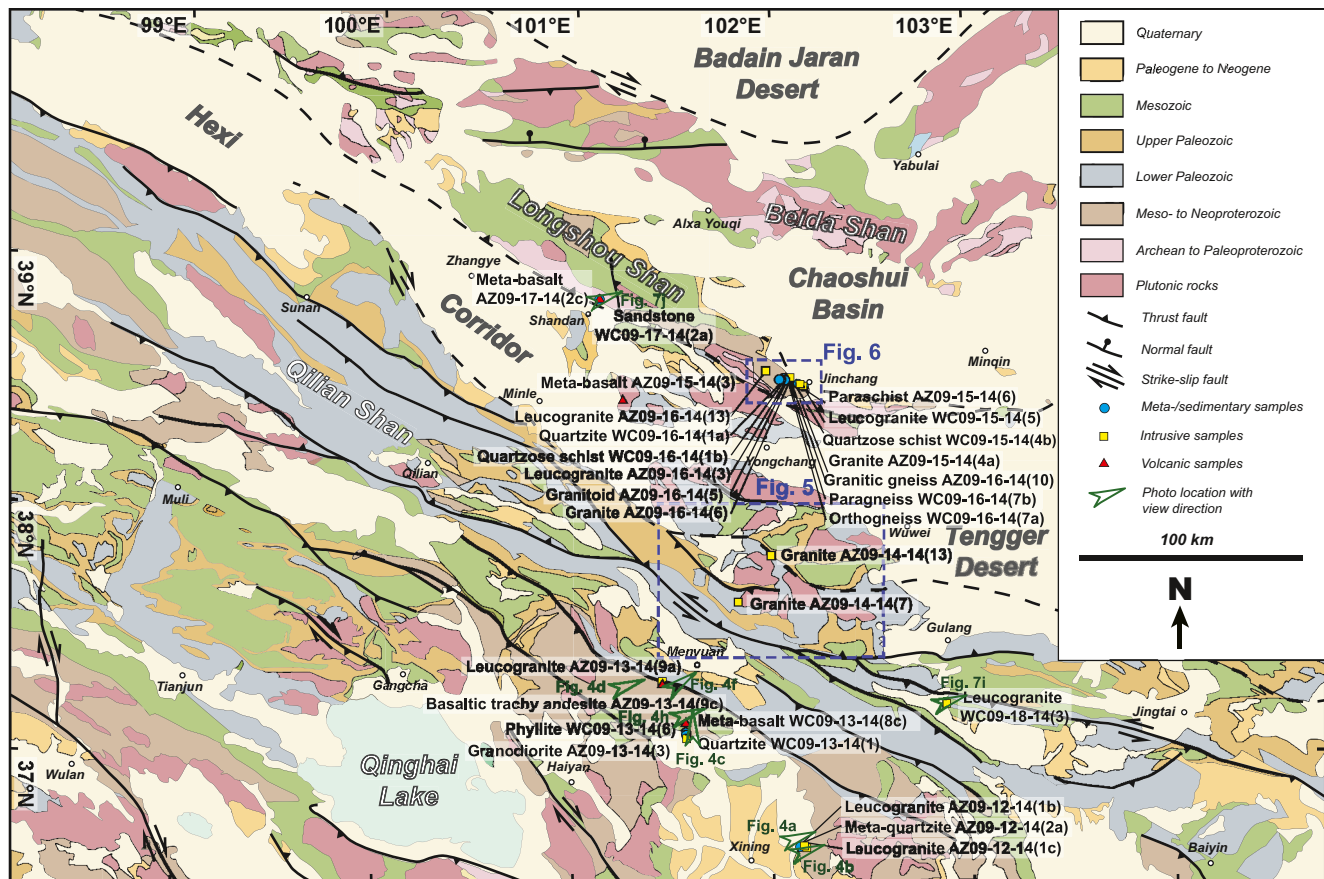

Figure 3. Simplified overview geologic map of the northeastern Tibetan Plateau and its northern foreland. Location shown in Figure 1b. The geology was compiled from Gansu Geological Bureau (1989), Qinghai BGMR (1991), Pan et al. (2004), Gong et al. (2013), and our own geologic mapping. Also shown are sample sites and the location of detailed geologic maps in Figures 4–6.

& Nie, 1996; Yin, Manning et al., 2007; S. Y. Yu et al., 2019; J. X. Zhang et al., 2005, 2008). Recent reviews of this orogen are provided in Song et al. (2013), Wu et al. (2017), and Zuza et al. (2018).

3. Field Mapping and Field Relationships

In this study, we examined several key areas across the Qilian Shan along the northeastern margin of the Tibetan plateau and the Longshou Shan in the foreland of the plateau along the southern margin of North China (e.g., the Hexi corridor) (Figure 1). Two of the field sites were relatively small (i.e., several important outcrops), and two involved larger regions (>500 km^2) where we synthesized existing geologic maps aided with our own mapping and more detailed field observations (Figure 4).

3.1. Datong Mountains North of Haidong

We examined the structural relationships and collected samples along a west-flowing Datong river drainage at ~36.63°N, ~102.15°E, just north of the town of Haidong (Figure 3). Here, relatively unmetamorphosed quartzite rocks are in fault contact with mylonitic schist/gneiss unit. Both units are assigned Proterozoic ages by Pan et al. (2004). The gneissic rocks are thrust over the quartzite unit along a 30° north-dipping fault (Figure 4a). The mylonitic gneiss, which includes lenses of schist, is intruded by leucogranite (Figure 4b).
3.2. Near Menyuan

We examined the structural relationships and collected samples along a southeast-flowing river drainage at ~37.1°N, ~101.5°E north of the city of Menyuan (Figure 3). Along this drainage, the Mesoproterozoic strata are composed of the meta-basalt, quartzite (Figure 4c), mylonitic paraschist with mullion structure (Figure 4d), phyllite, and mylonitic gneiss (Figure 4e), which are thrust over the Early Paleozoic slightly metamorphosed submarine sedimentary along a ~45° north-dipping Mesoproterozoic strata-parallel fault (Figures 3 and 4f). Metamorphic grade increases from south to north, and the mylonitic gneiss was intruded by an early Paleozoic-Neoproterozoic (dated in this study) granodiorite dike (Figure 4g). The unconformity between the quartzite and metasandstone is common at the northern margin of the Xining Basin (Pan et al., 2004) (Figure 4c). Here, coarse-grained marbles that have been assigned a Silurian age (Pan et al., 2004) are interbedded with slightly metamorphosed volcanic (intermediate to mafic) and volcaniclastic rocks, i.e., foliated trachy-andesite (Figure 4h), which were intruded by a small leucogranite dike.

3.3. Haiyuan Fault

At ~37.5°N, ~102°E, the Cenozoic left-slip Haiyuan fault makes a ~20-km right-step to produce a prominent restraining bend (Figures 3 and 4i–4j) (e.g., B. Li et al., 2019; Zuza et al., 2016). Shortening (left-slip oblique thrusting) across this restraining bends exposes early Paleozoic rocks (e.g., volcaniclastic rock, plutons, and conglomerates) related to the Qilian orogen, overlying conformable late Paleozoic-Mesozoic strata, and Cenozoic terrestrial deposits (Figure 5). Devonian-Carboniferous strata unconformably overlie a mingled package of Ordovician granites (U-Pb zircon age of ca. 462 Ma by Zuza et al., 2018), low-grade Ordovician metasedimentary rocks, and Silurian shales/mudstones (Figure 5). These rocks are variably thrust over Carboniferous-Cretaceous strata (Figure 5). Using apatite (U-Th)/He thermochronometry, Zuza et al. (2016) showed via that this restraining bend experienced rapid exhumation at ca. 15–8 Ma. Li et al. (2019) later found rapid exhumation across this bend at ca. 15 Ma via apatite fission track (AFT) dating, which they interpreted to represent the initiation of the left-slip Haiyuan fault. A cross section across this restraining bend requires a minimum of ~11 km northeast-southwest shortening, although this minimum estimate does not consider strike-slip offset (Figure 4i). Approximately 50 km to the east, Gaudemer et al. (1995) estimated a total of ~95 km left-lateral offset along the central Qilian Shan, which assuming a ca. 15 Ma initiation age equates to bulk left-lateral slip rates of ~6 mm/yr. To the southeast, a folded leucogranite dike was cut by a thrust, which intrudes into the Lower Paleozoic sandstone (Figure 4j). From this field locality, we conducted whole-rock geochemical analysis (results in Section 4.3), U-Pb zircon dating (presented in Zuza et al., 2018), and low-temperature thermochronology (e.g., B. Li et al., 2019; Zuza et al., 2016).
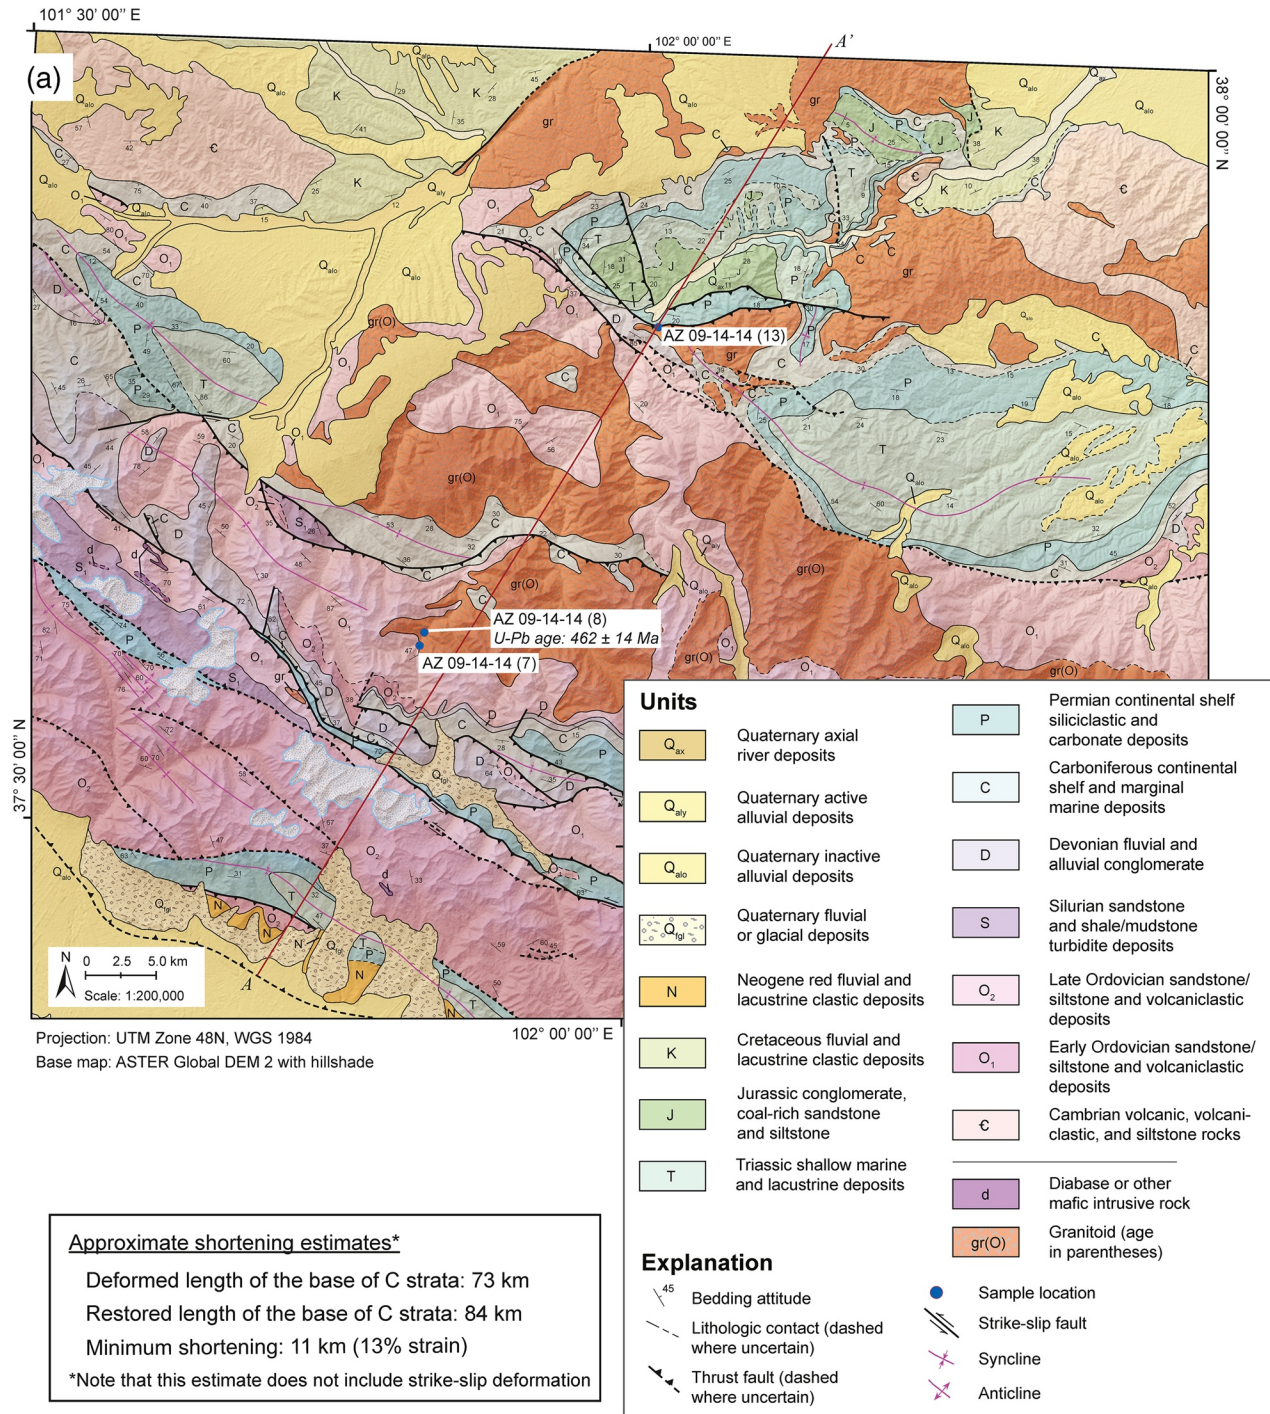

3.4. Longshou Shan

The northwest-trending ~30-km-wide Longshou Shan are a ~300-km-long range located in the Hexi Corridor, west of the city of Jinchang, that are separate from the higher elevation Tibetan Plateau to the south (Figure 1). The range primarily exposes Proterozoic strata and metamorphic rocks that are thought to represent the southern margin of the North China craton (e.g., Bai & Dai, 1996; J. H. Gong et al., 2013, 2016; Tang & Bai, 2000; J. X. Zhang et al., 2013) (Figure 6). The present-day range physiography and exposures are controlled by northwest-striking Cenozoic thrust faults. The northeastern range-bounding fault is active, and there is evidence for Cenozoic faulting throughout the Longshou Shan, including several east-striking left separation faults (Figure 6).

Our investigation was mainly focused around the easternmost Longshou Shan, near the city of Jinchang (Figures 3 and 6). The geologic map in Figure 6 was compiled from Pan et al. (2004), Tung et al. (2007),

Figure 4. Field photographs from the eastern Qilian Shan. (a) The gneissic rocks are thrust over the quartzite unit along a 30° north-dipping fault. (b) The leucogranite dike intrudes into the schist unit. (c) The syncline quartzite is in unconformable contact with the underlying meta-sandstone. (d) The A-type fold, i.e., mullion structure is developed in the mylonite. (e) Mylonitic gneiss shows the right shear stretching lineation. (f) Ordovician slightly metamorphosed sandstone thrust over the Mesoproterozoic schist. (g) Foliated granodiorite sample AZ 09-13-14 (3). (h) Proterozoic marble and foliated trachy-andesite unit, i.e., sample AZ 09-13-14 (9c). (i) a fault offset occurs within the Cenozoic coarse-grained sediments (j) Leucogranite dike intrudes into the Lower Paleozoic sandstone, which cut by a young thrust associated with the Haiyuan fault. The original filed pictures are shown in Figure S1.

Figure 6. Geologic map of the eastern Longshou Shan, near the Jinchuan intrusion in Jinchang (e.g., Lehmann et al., 2007). This map is based on our new observations, and previous mapping presented in Pan et al. (2004), Tung et al. (2007), and Gong et al. (2013, 2016). Samples from this study are shown, and the inset shows zircon ages of Gong et al. (2016).

Gong et al. (2013, 2016), and our new observations. Recent U-Pb zircon geochronology data from this study and Gong et al. (2016) are also included on this map (Figure 6). In the northeastern Longshou Shan, the most prominent rocks are part of the Paleoproterozoic Longshou Shan "Group" or "Complex" (J. Gong et al., 2016; J. H. Gong et al., 2013; Lehmann et al., 2007; K. Tung et al., 2007). These rocks consist of variably metamorphosed (amphibolite -grade) and folded marble, schist, amphibolite, quartzite and orthogneiss intruded by younger granitoids, leucogranites, and (ultra)mafic intrusions (Figures 7a–7d) (e.g., J. Gong et al., 2016; Lehmann et al., 2007). A key observation on a leucogranite intrusion help us better constrain the depositional age of the Longshou Shan Group in this study (Figures 7c and 7d).

Slightly metamorphosed Mesoproterozoic strata (i.e., siliciclastic and carbonate rocks) unconformably overlie the relatively higher-grade Longshou Shan Group rocks (Figure 6). These rocks are referred to as the Dunzigou Group (e.g., J. Gong et al., 2016), and in the eastern Longshou Shan they primarily consist of massive blue limestones with quartzite and minor paraschist (Figure 7e). Although these rocks are less deformed than the underlying Longshou Shan Group, they are locally isoclinally folded (bedding often transposed) and intruded by leucogranite sills and dikes (Figures 7f and 7g). The Neoproterozoic Hanmushan Group consists of siliciclastic, limestone, diamictite (interpreted as glacial deposits), phyllite, schist, and basalt (Figure 7h). The Cambrian Dahuangshan Group is mainly exposed at the central Longshou Shan near the city of Shandan, which is consist of the quartz sandstone, slate, and slightly metamorphic volcanic rocks intruded by younger granitoids (Figure 7i). The Upper Silurian-Devonian strata unconformity over the Lower Paleozoic strata (i.e., Cambrian), which is consistent with the field observations from C. L. Zhang et al. (2016).

Figure 5. Geologic map and cross section across the Cenozoic left-slip Haiyuan fault, where it makes a ~20 km right-step to produce a prominent restraining bend. See Figure 3 for location.
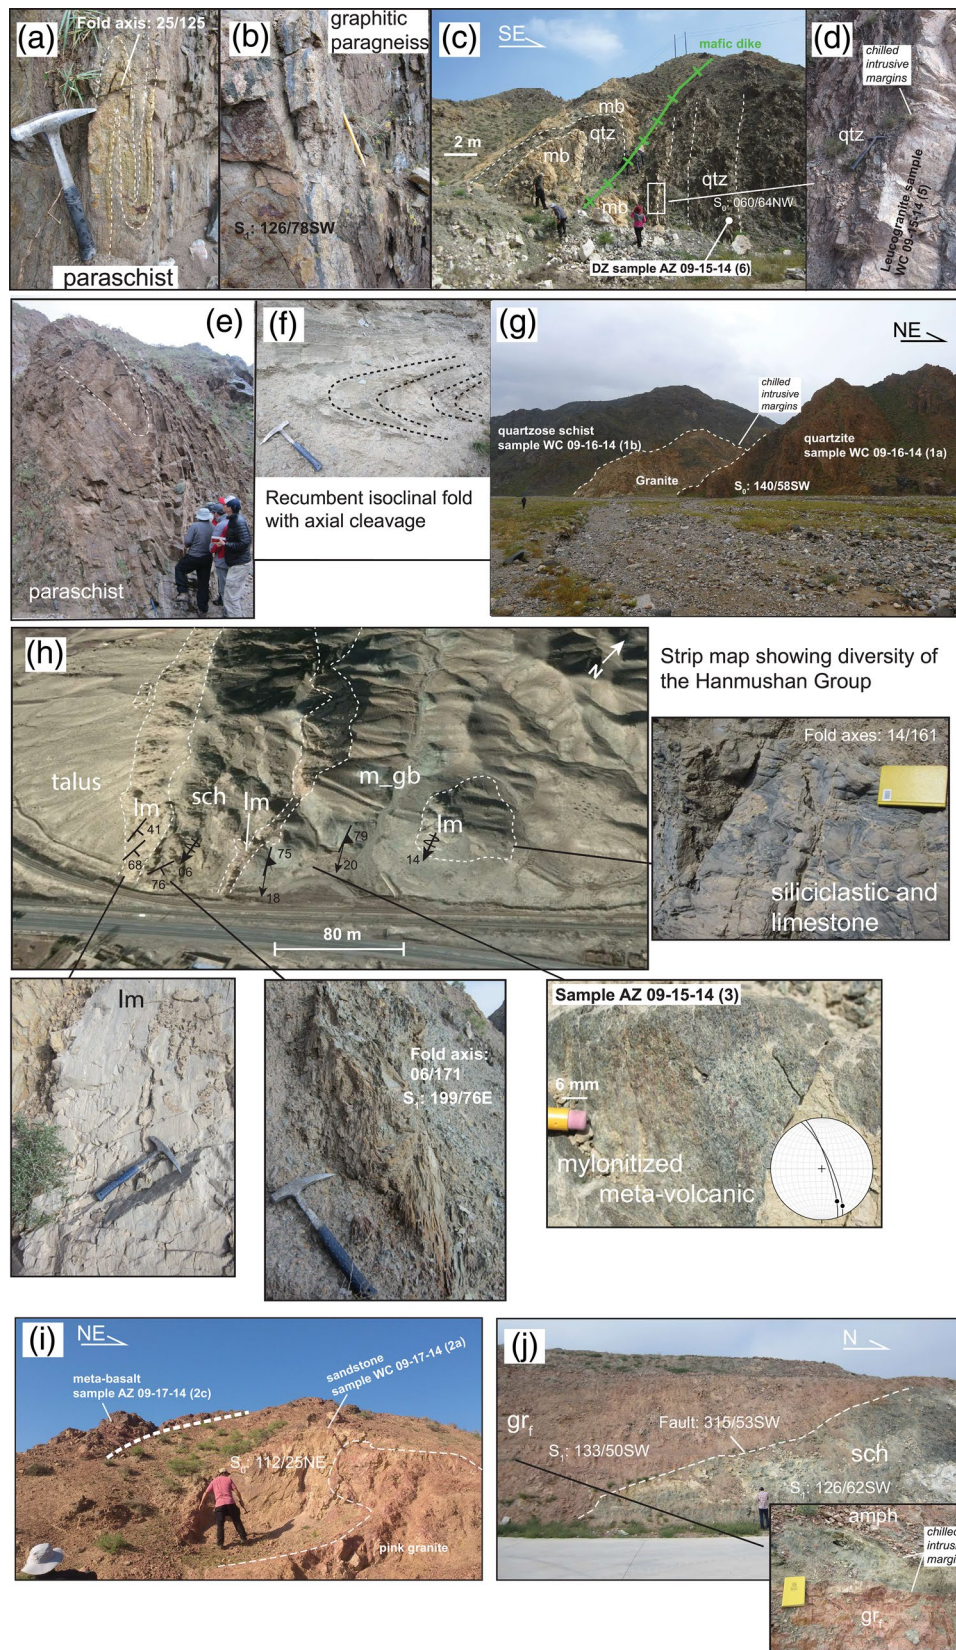

The easternmost segment of the Longshou Shan host the Neoproterozoic ultramafic Jinchuan intrusion (e.g., Lehmann et al., 2007; X. H. Li et al., 2004; X. Y. Song et al., 2006; M. Zhang et al., 2010), which is the third largest Ni-Cu deposit in the world. The intrusion has a U-Pb TIMS zircon age of 831 ± 0.6 Ma (M. Zhang et al., 2010), reported U-Pb SHRIMP zircon ages are ca. 827 Ma (X. H. Li et al., 2004, 2005), and inherited zircon ages are ca. 890 Ma and ca. 1840 Ma (X. H. Li et al., 2004). The intrusion has previously been related to Neoproterozoic continental rifting (Li & Ripley, 2011; Z. X. Li et al., 2005; Porter, 2016; Tang et al., 2014). We note that ca. 820 Ma extension related intrusions in the Longshou Shan may correlate with ca. 825 Ma A-type granitoids in the central Qilian Shan (C. Wu et al., 2017). We also observed the pink granite intrudes into the Longshou Shan Group schist and amphibolite unit near the Jinchuan Ni-Cu ore district (Figure 7j).

4. Geochronology and Geochemistry

4.1. Sample Descriptions

Samples for zircon geochronology and whole-rock geochemistry were collected during summer fieldwork in 2014, the detailed information is shown in the Table 1. North of Haidong, leucogranite (samples AZ 09-12-14 [1b] and AZ09-12-14 [1c]) (see location in Figure 3) crosscuts a Proterozoic mylonitic schist unit (Figure 4b). Field and map relationships suggest that this unit is thrust over an adjacent meta-quartzite assigned a Paleoproterozoic age (sample AZ 09-12-14 [2a]). Samples AZ 09-13-14 (1), AZ 09-13-14 (6), and WC 09-13-14 (8c) were collected from the quartzite, phyllite, and meta-basalt layers from Meso-to Neoproterozoic strata along the northern margin of the Xining Basin, which is the basement of the eastern Qilian Shan intruded by the Neoproterozoic granodiorite (sample AZ 09-13-14 [3]). West of the town of Menyuan, interbedded Silurian marble and meta-volcanic rocks are intruded by leucogranites. Samples AZ 09-13-14 (9a) and AZ 09-13-14 (9c) were collected from the leucogranite and meta-volcanic (basaltic trachy andesite) rocks, respectively. An early Paleozoic granite pluton yielding 462 ± 14 Ma reported by Zuza et al. (2018) was sampled from the central Haiyuan fault restraining bend (Figures 3 and 5) for geochemical analyses (samples AZ 09-14-14 [7] and AZ 09-14-14 [13]). Sample WC 09-18-14 (3) was collected from the leucogranite dike intruded into the Lower Paleozoic sandstone in the Central Haiyuan fault restraining bend (Figure 4j).

One early Paleozoic basaltic trachy andesite sample AZ 09-15-14 (3) was collected from the Hexi Corridor for geochemistry (Figure 7h). Metamorphic basement rocks in the eastern Longshou Shan near Jinchang were intruded by weakly foliated granitoids and leucogranites. We collected the two quartz schist samples WC 09-15-14 (4b) and WC 09-16-14 (1b), schist sample AZ 09-15-14 (6), quartzite sample WC 09-16-14 (1a), and orthogneiss sample WC 09-16-14 (7a) for the detrital zircon U-Pb analysis. Leucogranite samples WC 09-15-14 (5), AZ 09-16-14 (10), AZ 09-16-14 (13), WC 09-16-14 (7b), slightly foliated granitoid samples WC 09-15-14 (4a), granitoid samples AZ 09-16-14 (3), AZ 09-16-14 (5), and AZ 09-16-14 (6) were collected for the zircon U-Pb dating and/or geochemistry analysis. We collected one sample AZ 09-17-2014 (2c) from the meta-volcanic layer of the Lower Paleozoic strata (i.e., Cambrian) and one slightly metamorphic sandstone sample WC 09-17-14 (2a) from slightly deformed Devonian rocks (Figure 7j).

4.2. U-Pb Zircon Geochronology

Zircon grains for U-Pb dating were separated from 11 igneous rocks and 9 metasedimentary samples by traditional methods involving crushing, sieving, and magnetic and density separations, and mounted in epoxy with standard zircons (e.g., G. E. Gehrels et al., 2006, 2003a; Pullen et al., 2018). Individual zircon grains were picked under a binocular microscope. To identify the internal structure and texture of the zircon grains

Figure 7. (a-b) Filed photographs from the Longshou Shan Group, folded paraschist, foliated graphitic paragneiss. (c) Folded marble and quartzite unit is intruded by the mafic dike. (d) A leucogranite dike intrudes into the Longshou Shan Group quartzite. (e) Folded paraschist of the Dunzigou Group. (f) Isoclinal fold is developed within the Dunzigou Group meta-sandstone unit. (g) Granite sill intrudes into the Dunzigou quartzite and quartzschist units. (h) Strip map showing diversity of the Hanmushan Group. (i) Paleozoic sandstone intruded by a pink granite sill unconformity over the Cambrian meta-basalt unit in the central Longshou Shan. (j) Neoproterozoic pink granite intrudes into the amphibolite unit and thrust over the Longshou Shan Group schist unit. The original filed pictures are shown in Figure S2.

and to select potential positions for U-Pb analysis, cathodoluminescence (CL) images of zircons were taken on a JXA-880 electron microscope and an image analysis software was used under operating conditions of 20 kV and 20 nA, at the Institute of Mineral Resources, Chinese Academy of Geological Sciences, Beijing, China. Zircons of each sample were randomly selected, mounted in epoxy resin and polished, in order to conduct U-Pb laser ablation inductively coupled plasma mass spectrometer (LA-ICP-MS) dating. Most zircons were analyzed using an Agilent 7500a ICP-MS coupled with a New Wave Research UP193FX Excimer at the Key Laboratory of Continental Collision and Plateau Uplift, Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing. The LA-MC-ICP-MS analytical procedures employed for polished and depth-profile analyses are described in detail in G. Gehrels et al. (2011), and briefly summarized here. Common Pb corrections were made by using the measured ^{204}Pb and assuming an initial Pb composition from Stacey and Kramers (1975). The primary standard used was GJ1 (Jackson et al., 2004). The secondary standards were 91,500 (^{238}U/^{206}Pb age of 1,065 Ma; Wiedenbeck et al., 1995), and Plesovice (^{238}U/^{206}Pb age of 337 Ma; Sláma et al., 2008).
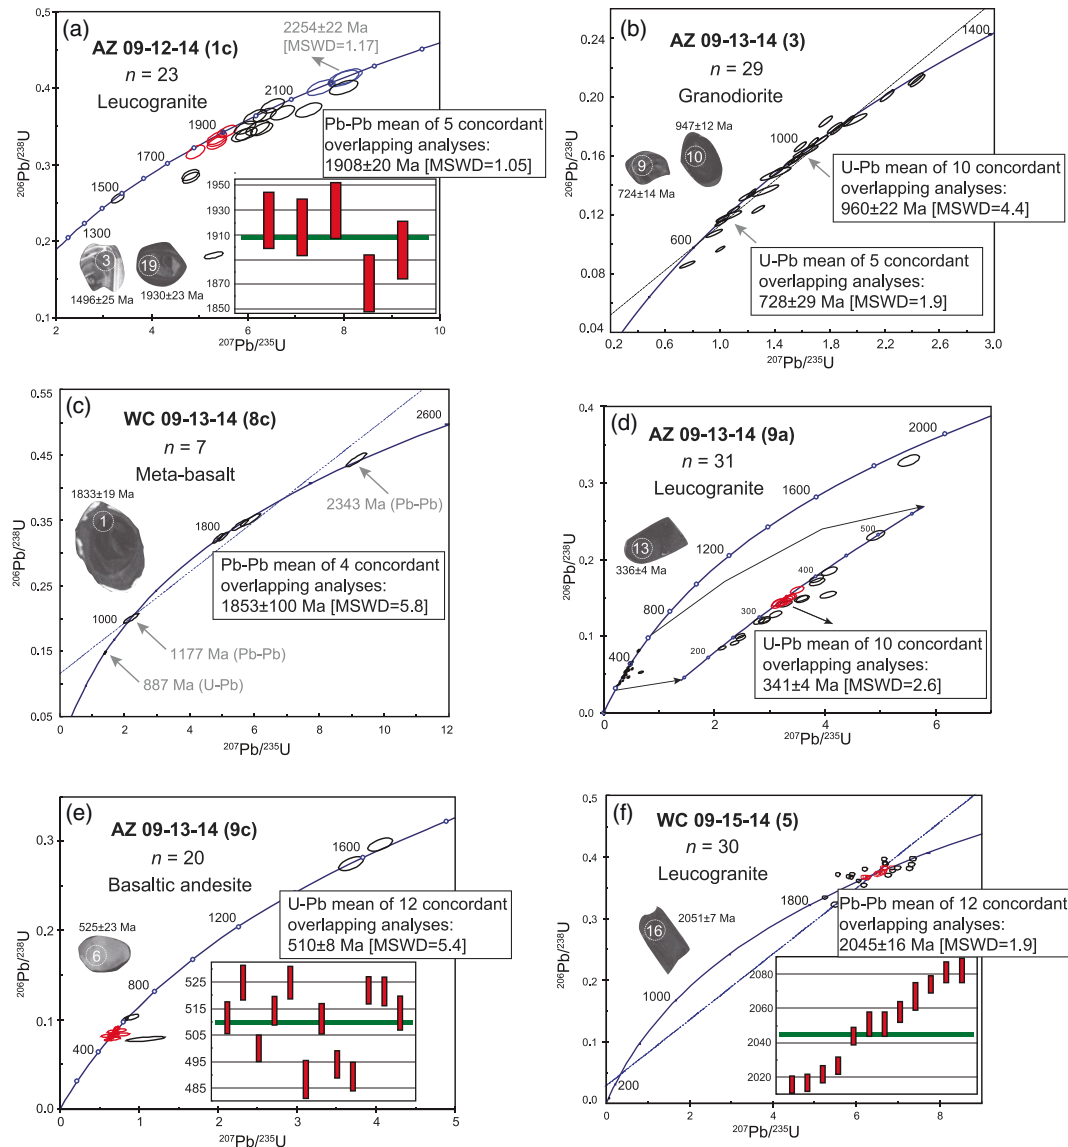

Figure 8. U-Pb concordia diagrams showing results of single shot zircon analyses and relative probability plots of zircon ages for each sample. Error ellipses are 2σ and red ellipses show individual analyses were included in the weighted mean age calculation.

The goal of our U-Pb zircon geochronology was to determine the crystallization age of the igneous samples and for the sedimentary samples, we examined the zircon-age spectrum to constrain the depositional age of the sample and constrain its provenance. The complete isotopic information for these analyses can be found in Table S1 and concise age results are presented in Table 1. The analytical data are presented in Figures 8 and 9.

For igneous samples, we aimed to analyze 20–35 zircon grains from each sample with the exception of samples AZ 09-16-14 (13) and WC 09-13-14 (8C). If multiple zircon-age populations existed, we interpreted the weighted mean age of the youngest population of concordant zircon ages to represent the crystallization age of the sample. We ascribe distinctly older zircon-age populations to inheritance and younger zircon ages to the results of Pb loss due to a younger metamorphic event. For zircon grains with Neoproterozoic-Paleozoic (or younger) ages, we use their $^{206}Pb/^{238}U$ ages, and for Mesoproterozoic and older zircon grains, we use their $^{206}Pb/^{207}Pb$ ages. For the detrital zircon samples, we considered analyses that were <30% discordant or <5% reversely discordant (e.g., G. Gehrels et al., 2011).
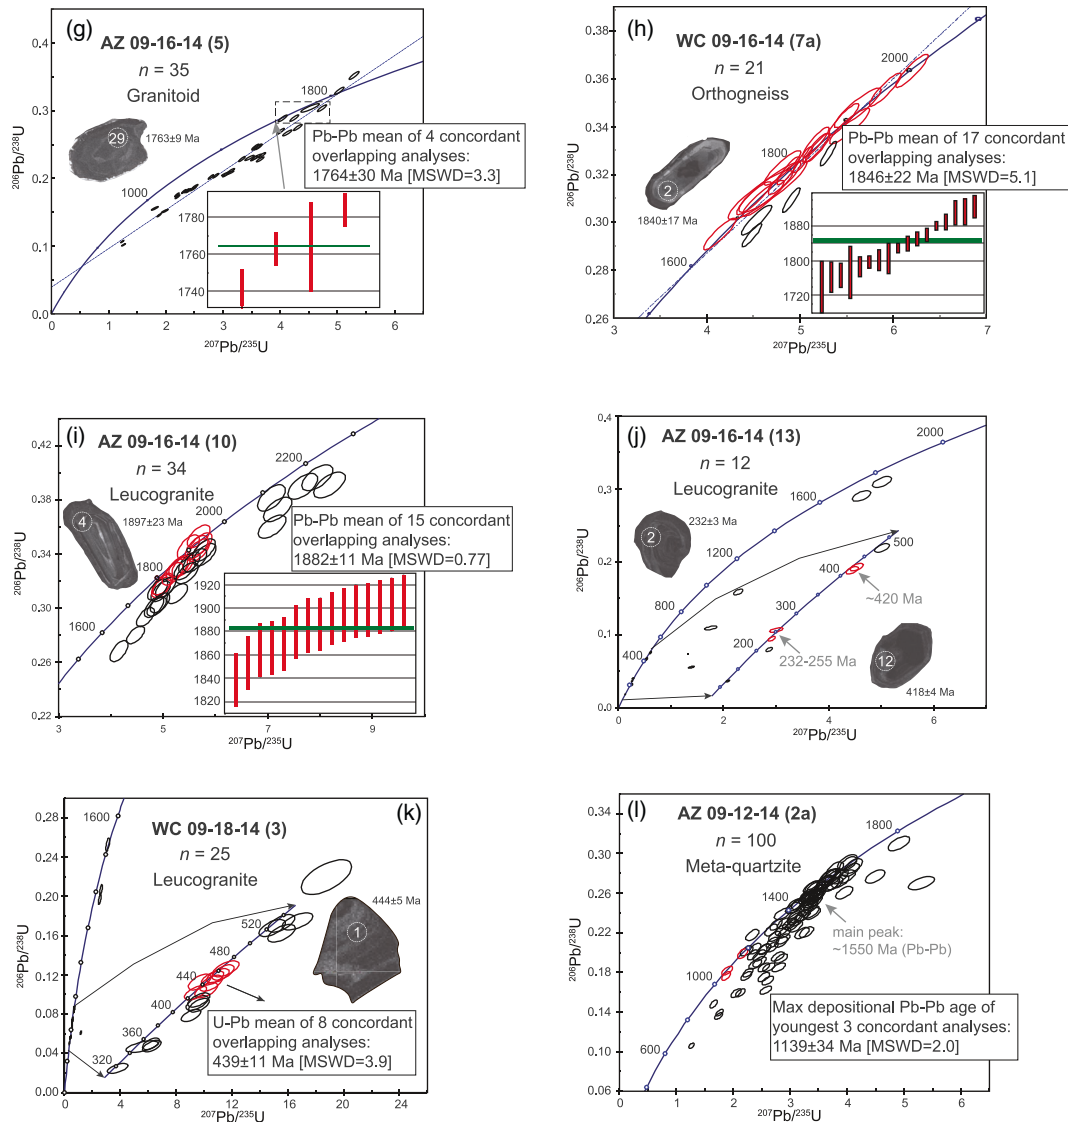

Figure 8. Continued

4.2.1. Leucogranite Sample AZ 09-12-14 (1c)

We analyzed 23 grains, of which 20 yield concordant ages ranging from 1.5 Ga to 2.3 Ga (Figure 8a). The youngest population of concordant analyses are clustered around ca. 1,900 Ma with a weighted mean age of 1,908 ± 20 Ma (MSWD = 1.05; *n* = 5) (Figure 8a; Table 1), and the youngest single concordant zircon yields an age of 1,496 ± 25 Ma (Table S1; Figure 8a). Because of the range of zircon ages in this leucogranite sample, we do not attempt to assign a crystallization age to this sample but note that it may record Paleo-to Mesoproterozoic crustal melting.

4.2.2. Granodiorite Sample AZ 09-13-14 (3)

We analyzed 29 zircon grains from this granodiorite sample, of which 24 yielded concordant ages ranging from 657 Ma to 1,290 Ma (Table S1; Figure 8b). The largest population of concordant analyses are clustered around ca. 950 Ma with a weighted mean age of 960 ± 22 Ma (MSWD = 4.4; *n* = 10) (Figure 8b; Table 1), and the youngest population of concordant zircon grains (*n* = 5) yields a weighted mean age of 728 ± 29 Ma (MSWD = 1.9) (Table S1; Figure 8b). We interpret the youngest population as the crystallization age of this granodiorite sample.
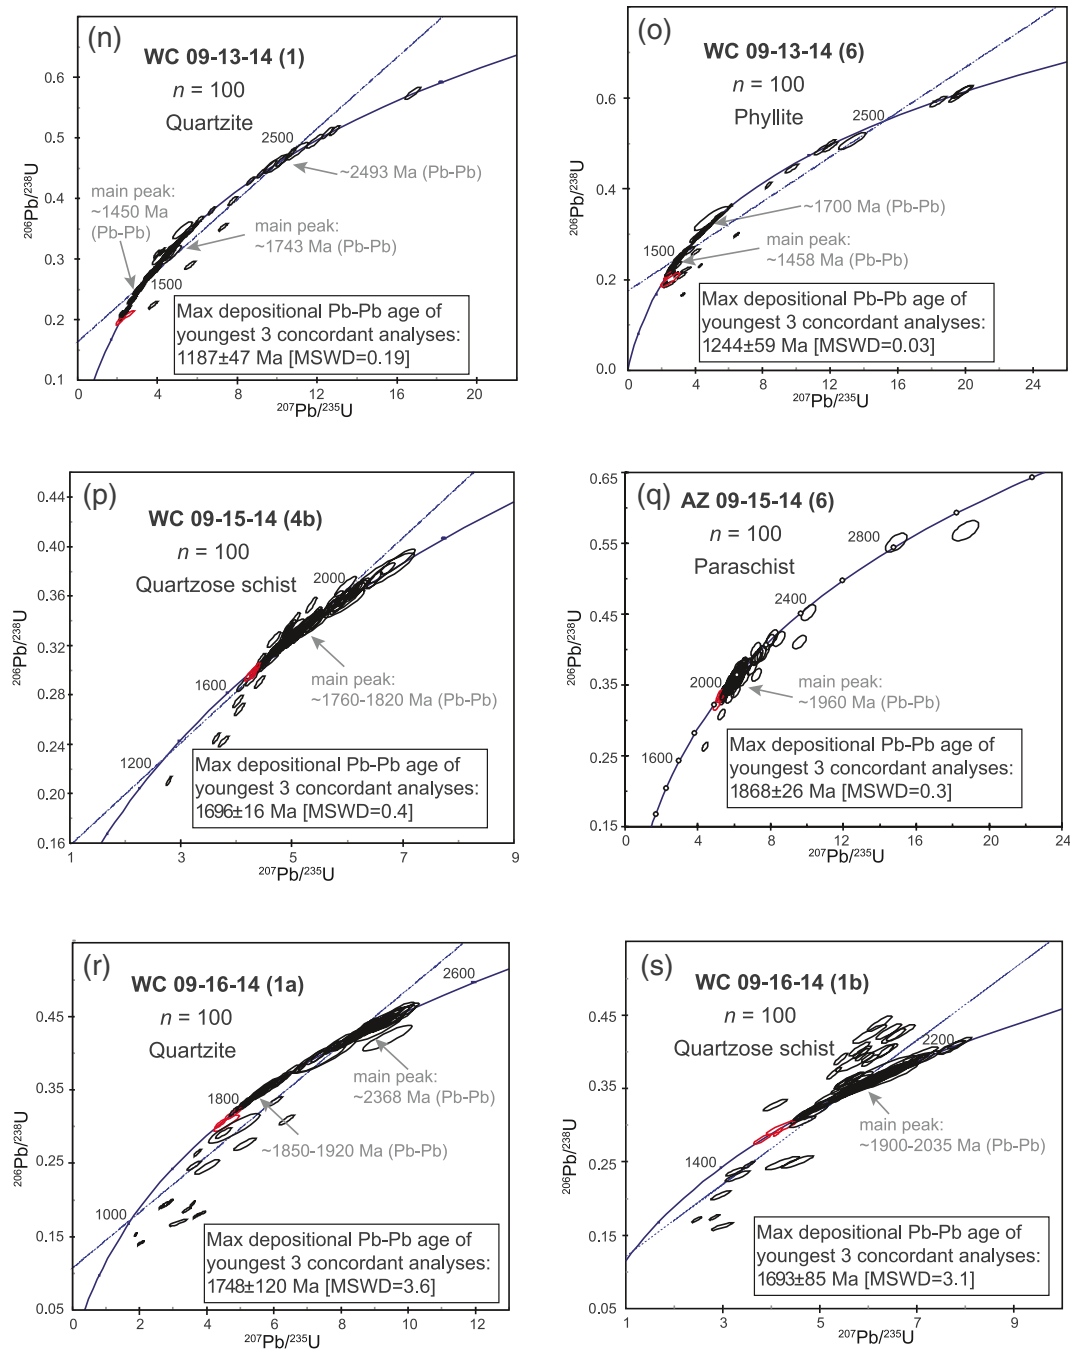

Figure 8. Continued

4.2.3. Meta-basalt Sample WC 09-13-14 (8c)

We analyzed 7 zircon grains and all yielded concordant ages ranging from 887 Ma to 2343 Ma (Table S1; Figure 8c). The largest population of concordant analyses are clustered around ca. 1,900 Ma with a weighted mean age of $1,853 \pm 100$ Ma (MSWD = 5.8; $n = 4$) (Figure 8c; Table 1), and the youngest single concordant zircon yields an age of 887 ± 12 Ma (Table S1; Figure 8c). In additional, there is a ~1,177 Ma age cluster, we also note the oldest single concordant zircon yields an age of $2,343 \pm 20$ Ma (Table S1; Figure 8c)
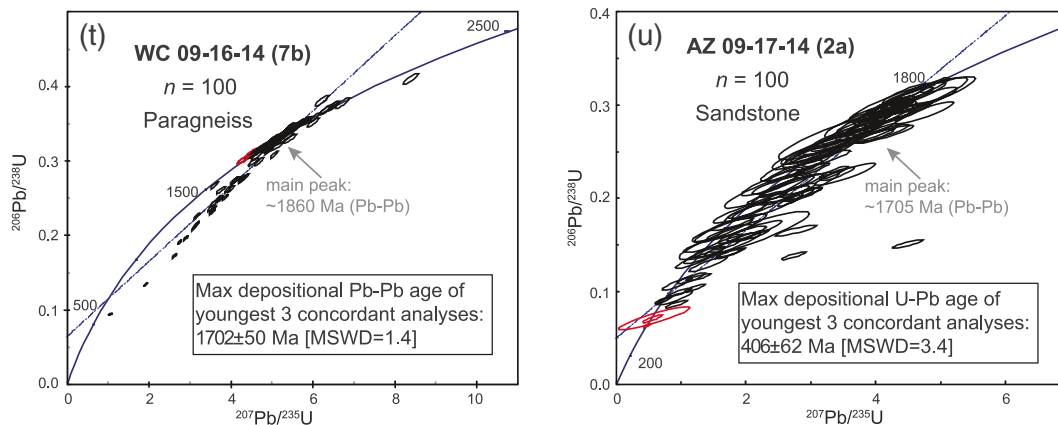

Figure 8. Continued

4.2.4. Leucogranite Sample AZ 09-13-14 (9a)

Thirty-one zircon grains were analyzed from this leucogranite sample, of which only 11 yielded concordant ages ranging from 225 Ma to 1,977 Ma (Table S1; Figure 8d). The weighted mean age of 6 concordant analyses is 341 ± 7 Ma (MSWD = 2.8) (Figure 8d; Table 1). However, minor populations of slightly discordant ca. 250 and ca. 300 Ma ^{206}Pb/^{238}U ages were also observed (Figure 8d).

4.2.5. Basaltic Trachy Andesite Sample AZ 09-13-14 (9c)

We analyzed 20 zircon grains and 14 yielded concordant ages ranging from 494 Ma to 1,608 Ma (Table S1; Figure 8e). The youngest population of concordant zircon grains ($n = 8$) yield a weighted mean age of 512 ± 10 Ma (MSWD = 4.2) (Figure 8e; Table 1), which we interpret as the crystallization age of this volcanic basaltic andesite. Two concordant zircon analyses yielded ca. 1.6 Ga ages, which may indicate that the Cambrian volcanic rocks passed through Mesoproterozoic crust prior to being erupted.

4.2.6. Leucogranite Sample WC 09-15-14 (5)

Thirty zircon grains were analyzed from this leucogranite sample, of which 28 yielded concordant ages ranging from 1,856 Ma to 2,221 Ma (Table S1; Figure 8f). The weighted mean age of 12 concordant analyses is 2,045 ± 16 Ma (MSWD = 1.9) (Figure 8f; Table 1), which we interpret as the crystallization age of this leucogranite sample.

#### 4.2.7. Granitoid Sample AZ 09-16-14 (5)

Thirty-five zircon grains were analyzed from this granitoid sample, of which 8 yielded concordant ages ranging from 1,655 Ma to 1,848 Ma (Table S1; Figure 8g). The weighted mean age of 4 concordant analyses is 1,764 ± 30 Ma (MSWD = 3.3) (Figure 8g; Table 1), which we interpret as the crystallization age of this granitoid sample. A discordia line defined by the discordant grains projects toward ca. 1.8 Ga, which broadly supports the weighted mean age of ca. 1,764 Ga.

4.2.8. Orthogneiss Sample WC 09-16-14 (7a)

We analyzed 21 zircon grains from this orthogneiss sample, and all yielded concordant ages (Figure 8h). ^{207}Pb/^{206}Pb ages ranged from 1,657 Ma to 2,011 Ma (Table S1), and the weighted mean age of 17 concordant analyses is 1,846 ± 22 Ma (MSWD = 5.1) (Figure 8h), which we interpret as the crystallization age of this orthogneiss sample (Figure 8h).

4.2.9. Granitic Gneiss Sample AZ 09-16-14 (10)

We analyzed 34 zircon grains from this granitic gneiss sample, and all yielded concordant ages (Figure 8i). ^{207}Pb/^{206}Pb ages ranged from 1,838 Ma to 2,365 Ma (Table S1), and the weighted mean age of 15 concordant analyses is 1,882 ± 11 Ma (MSWD = 0.77) (Figure 8i), which we interpret as the crystallization age of this granit-
Figure 9. Mesoproterozoic-Neoproterozoic relative probability plot of detrital zircon data from around the northern Tibetan Plateau, detrital zircon samples from this study, Gehrels et al. (2003a), Zuza et al. (2018), Wu et al. (2017), Liu et al. (2018), Song et al. (2017), Gong et al. (2016), and Liu et al. (2020).

ic gneiss sample (Table 1). Note that six zircon grains had older $^{207}Pb/^{206}Pb$ ages of ca. 2.15–2.35 Ga (Table S1).

4.2.10. Leucogranite Sample AZ 09-16-14 (13)

We analyzed 12 zircon grains from this leucogranite sample, of which 10 yielded concordant ages ranging from 117 Ma to 1,912 Ma (Table S1; Figure 8j). Because of the range of zircon ages in this leucogranite sample, we do not attempt to assign a crystallization age to this sample but note that minor populations of slightly discordant 232–255 Ma and ca. 420 Ma $^{206}Pb/^{238}U$ ages (Figure 8j).

4.2.11. Leucogranite Sample WC 09-18-14 (3)

Twenty-five zircon grains were analyzed from this leucogranite sample, of which 22 yielded concordant ages ranging from 317 Ma to 1,479 Ma (Table S1; Figure 8k). The weighted mean age of 8 concordant analyses is 439 ± 11 Ma (MSWD = 3.9) (Figure 8k; Table 1), which we interpret as the crystallization age of this leucogranite sample. However, minor populations of slightly discordant ca. 317 and 350 Ma $^{206}Pb/^{238}U$ ages are also observed (Figure 8k).

4.2.12. Meta-quartzite Sample AZ 09-12-14 (2a)

We analyzed 100 grains and 14 grains yielded discordant ages (Figure 8l). Concordant ages ranged from 1,086 Ma to 1,924 Ma (Figure 9), and the weighted mean of the three youngest concordant zircon grains was 1,139 ± 34 Ma (mean square of weighted deviates, MSWD = 2.0) (Figure 8l; Table 1). We interpret this age to represent the maximum depositional age of this meta-quartzite sample. We also note the large population of 1.55 Ga zircon grains, and discordant zircons appear to define a discordia line that intercepts the concordia line at ca. 1.55 Ga (Figure 8l). This sample has a major zircon population of 1,400–1,700 Ma with prominent peak at 1,565 Ma (Figure 9).

4.2.13. Quartzite Sample WC 09-13-14 (1)

One hundred detrital zircon grains were analyzed from this sample (Figures 8n) and six grains yielded discordant ages (Figure 8n). Concordant ages ranged from 1,146 Ma to 2,925 Ma (Figure 9), and the weighted mean of the three youngest concordant zircon grains was 1,187 ± 47 Ma (mean square of weighted deviates, MSWD = 0.19) (Figure 8n; Table 1). We interpret this age to represent the maximum depositional age of this quartzite sample. This sample has two major zircon populations of 1,300–1,500 and 1,600–1,860 Ma, with two prominent peaks at ca. 1.45 and ca. 1.74 Ga, respectively (Figure 9). We noted a minor age population also occur at ca. 2.49-Ga (Figure 9).

4.2.14. Phyllite Sample WC 09-13-14 (6)

One hundred detrital zircon grains were analyzed from this sample (Figures 8o) and 11 grains yielded discordant ages (Figure 8o). Concordant ages ranged from 1,157 Ma to 3,083 Ma (Figure 9), and the weighted mean of the three youngest concordant zircon grains was 1,244 ± 59 Ma (mean square of weighted deviates, MSWD = 0.03) (Figure 8o; Table 1). We interpret this age to represent the maximum depositional age of this phyllite sample. This sample has two major zircon populations of 1,300–1,500 and 1,620–1,820 Ma, with two prominent peaks at ca. 1.46 and ca. 1.70 Ga, respectively (Figure 9). We noted a minor age population also occur at ca. 3.80-Ga (Figure 9).

4.2.15. Quartzose Schist Sample WC 09-15-14 (4b)

One hundred detrital zircon grains were analyzed from this sample (Figure 8p) and five grains yielded discordant ages (Figure 8p). Concordant ages ranged from 1,687 Ma to 2,085 Ma (Figure 9), and the weighted mean of the three youngest concordant zircon grains was 1,696 ± 16 Ma (mean square of weighted deviates, MSWD = 0.4) (Figure 8p; Table 1). We interpret this age to represent the maximum depositional age of this quartzose schist sample. This sample has a major zircon population of 1,700–2,000 Ma, with two prominent peaks at ca. 1.82 and ca. 1.91 Ga (Figure 9).

4.2.16. Schist Sample AZ 09-15-14 (6)

One hundred detrital zircon grains were analyzed from this sample (Figure 8q), and all analyses yielded concordant ages spanning from 1,860 Ma to 3,114 Ma (Table S1; Figure 9). The three youngest overlapping ages have a weighted mean age of 1,868 ± 26 Ma (MSWD = 0.3) (Figure 8q; Table 1), which represents the maximum depositional age of the meta-sedimentary rock. This sample has a major zircon population of 1.87–2.10 Ga with prominent peak at 1.96 Ga (Figure 9). The oldest two zircon grains have ages of 2,794 ± 21 and 3,114 ± 20 Ma.

4.2.17. Quartzite Sample WC 09-16-14 (1a)

One hundred detrital zircon grains were analyzed from this sample (Figure 8r) and 17 grains yielded discordant ages (Figure 8r). Concordant ages ranged from 1,665 Ma to 2,474 Ma (Figure 9), and the weighted mean of the three youngest concordant zircon grains was 1,748 ± 120 Ma (mean square of weighted deviates, MSWD = 3.6) (Figure 8r; Table 1). We interpret this age to represent the maximum depositional age of this quartzite sample. This sample has two major zircon populations of 1,830–2,080 and 2,200–2,390 Ma, with three prominent peaks at ca. 1.86, ca. 1.92, and ca. 2.33 Ga, respectively (Figure 9).

4.2.18. Quartzose Schist Sample WC 09-16-14 (1b)

One hundred detrital zircon grains were analyzed from this sample (Figure 8s) and 26 grains yielded discordant ages (Figure 8s). Concordant ages ranged from 1,611 Ma to 2,231 Ma (Figure 9), and the weighted mean of the three youngest concordant zircon grains was 1,693 ± 85 Ma (mean square of weighted deviates, MSWD = 3.1) (Figure 8s; Table 1). We interpret this age to represent the maximum depositional age of this quartzose schist sample. This sample has a major zircon population of 1,810–2,050 Ma, with two prominent peaks at ca. 1.87 and ca. 2.03 Ga (Figure 9). We note that a minor age population also occur at ca. 1.77-Ga (Figure 9).

4.2.19. Paragneiss Sample WC 09-16-14 (7b)

One hundred detrital zircon grains were analyzed from this sample (Figure 8t) and 26 grains yielded discordant ages (Figure 8t). Concordant ages ranged from 1,579 Ma to 2,328 Ma (Figure 9), and the weighted mean of the three youngest concordant zircon grains was 1,670 ± 100 Ma (mean square of weighted deviates, MSWD = 3.1) (Figure 8t; Table 1). We interpret this age to represent the maximum depositional age of this paragneiss sample. This sample has a major zircon population of 1,740–1,940 Ma, with two prominent peaks at ca. 1.86 Ga and ca. 1.90 Ga, respectively (Figure 9).

### 4.2.20. Sandstone Sample WC 09-17-14 (2a)

One hundred detrital zircon grains were analyzed from this sample (Figures 8u) and 25 grains yielded discordant ages (Figure 8u). Concordant ages ranged from 394 Ma to 1,831 Ma (Figure 9), and the weighted mean of the three youngest concordant zircon grains was 406 ± 62 Ma (mean square of weighted deviates, MSWD = 3.4) (Figure 8u; Table 1). We interpret this age to represent the maximum depositional age of this sandstone sample. This sample has a major zircon population of 1,500–1,830 Ma, with a prominent peak at ca. 1.70 Ga (Figure 9). We noted two minor age populations also occur at ca. 900 and ca. 500 Ma, respectively (Figure 9).

4.3. Whole-Rock Geochemistry

Granitoid and volcanic rock samples were analyzed for major and trace elements at the Chinese Academy of Geologic Sciences in Beijing, China. Major elements were analyzed using an X-ray fluorescence spectrom-
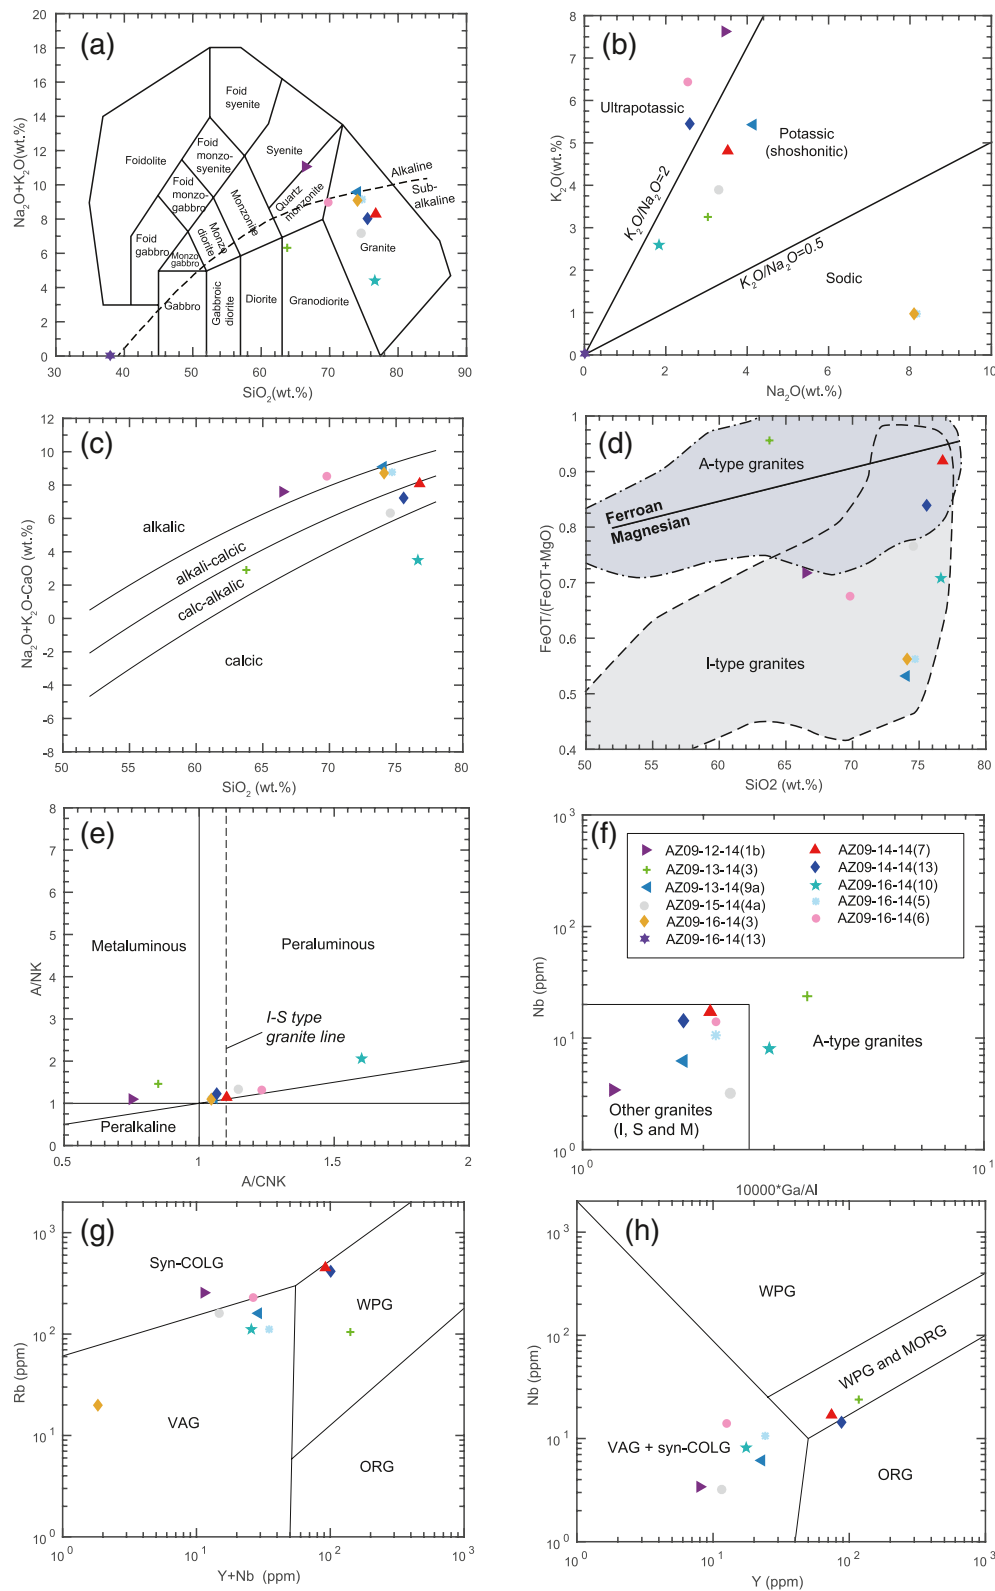

Figure 11. (a) Primitive mantle-normalized trace element variation diagram for the analyzed granitoids (Sun & McDonough, 1989). (b) Chondrite-normalized rare earth element diagram for the analyzed granitoids (Boynton, 1984).

eter using the methods of Norrish and Chappel (1977); analysis precision is estimated to be ~0.5% for SiO_2 and 3%–7% for other oxides. Trace elements were measured on an inductively coupled plasma-mass spectrometry (ICP-MS) following procedures outlined in Dulski (1994); uncertainties were estimated to be better than 5%. Complete detailed methods can be found in the supporting information. All geochemical data is presented in Table S2, and is plotted in Figures 10–12. We use discrimination diagrams to evaluate the tectonic setting our own igneous samples (e.g., Eby, 1990, 1992; Pearce, 1996; Pearce et al., 1984; S. P. Turner et al., 1992; Whalen et al., 1987), but note that these classifications schemes can be problematic (Snow, 2006). Thus, the tectonic interpretations based on our geochemistry results are tentative, and we further consider the samples' ages and geologic setting when incorporating this data into our final tectonic model.

We analyzed a total of 15 samples for their geochemistry, including 11 plutonic and meta-plutonic samples and 4 volcanic and meta-volcanic samples. All plutonic samples have relatively high silica concentrations (SiO_2 > ~65 wt%) and are classified on a $Na_2O + K_2O$ versus SiO_2 total alkali-silica (TAS) plot as quartz monzonite, granodiorite, and granite (Figure 10a) (Middlemost, 1994), and generally belong to the subalkaline series in the total alkalis versus silica (TAS) diagram (Figure 10a) with the exception of sample AZ09-12-14 (1b). Most samples span the potassium and ultrapotassic series, with the exception of sodic samples AZ 09-16-14 (3) and AZ 09-16-14 (5) (Figure 10b) (Le Maitre et al., 1989; Rickwood, 1989), whereas all the samples fall in calc-alkalic to alkalic series in the alkali-lime index plot (Figure 10c) with the exception of sample AZ09-16-2014 (10). The rocks show variable, but generally high, $Mg^\#$ values (28.9–62.3) (Figure 10d; Table S2), with an exception of sample AZ09-13-14 (3) showing a ferran-rich character ($Mg^\#$ value of 9.8) (Figure 10d; Table S2). Almost all samples are peraluminous with A/CNK values varying from 1.4 to 1.7, whereas samples AZ 09-12-14 (1b) and AZ 09-13-14 (3) are metaluminous with A/CNK values varying from 1.0 to 1.3 (Figure 10e; Table S2).

All plutonic rocks plot in the I- and S-type granite fields, associated with arc magmatism and/or crustal anataxis, in the (10,000×Ga/Al)-Nb discrimination diagram, with the exception of samples AZ 09-13-14 (3) and AZ 09-16-14 (10) (Eby, 1990, 1992; Pearce, 1996; Pearce et al., 1984; S. P. Turner et al., 1992; Whalen

(b) AFM diagram for the volcanic samples; A = $K_2O + Na_2O$; F = $Fe_2O_3 + FeO$; M = MgO. Curve for calc-alkaline and thoeliitic division is from Kuno (1968). (c) Chondrite-normalized rare earth element (REE) diagram for the volcanic samples (Boynton, 1984). (d) Primitive mantle-normalized spider diagram for the volcanic samples (Sun & McDonough, 1989).

et al., 1987) (Figure 10f). These two samples plot in the A-type granite field (Figure 10f), which is generally associated with extension regardless of the origin of the magma source (e.g., Eby, 1990, 1992; S. P. Turner et al., 1992; Whalen et al., 1987). Samples AZ 09-14-14 (7) and AZ 09-14-14 (13) straddle the A-type

and I-type boundaries (Figures 10d and 10f). Additional discrimination diagrams (Pearce, 1996; Pearce et al., 1984) allow for further classification of the analyzed plutonic rocks (Figures 10g and 10h). Most samples plot in the syn-collisional and volcanic arc fields, samples AZ 09-14-14 (7) and AZ 09-14-14 (13) straddle the syn-collisional and within-plate boundaries, and sample AZ 09-13-14 (3) (i.e., the A-type granodiorite) plots entirely within the within-plate granite fields (Figures 10g and 10h). Of note, leucogranite sample AZ 09-12-14 (1b) is the only sample that distinctly plots in the syn-collisional field on the Rb versus Y + Nb discrimination diagram (Figure 10g).

In a multielement diagram normalized to primitive-mantle compositions (Sun & McDonough, 1989), all samples show strong negative Nb anomalies, positive Pb anomalies, and negative Ti anomalies (Figure 11a). The samples generally show enrichment in large ion lithophile elements (LILEs) and depletion in high field strength elements (HFSEs) (Figure 11a). The rare earth element (REE) abundances normalized by chondrite values (Sun & McDonough, 1989) reveal that all samples are generally enriched in light rare-earth element (LREE) and flat heavy rare-earth element (HREE) profiles without distinct Ce anomalies (Figure 11b). Most samples display a prominent negative Eu anomaly, with the exception of samples AZ 09-13-14 (3) and AZ 09-12-14 (1b) (Figure 11b). This anomaly is commonly associated with removal of plagioclase from felsic melts during crystal fractionation (e.g., Rollinson, 2014).

Four volcanic samples with SiO_2, MgO, and Al_2O_3 contents of 42.5–50.3 wt%, 5.2–6.6 wt%, and 12.1–14.8 wt%, respectively, can be classified as basaltic trachy-andesite (AZ 09-13-14 [9c]), basalt (AZ 09-17-14 [2c]), and tephrite basanites (AZ 09-15-14 [3] and WC 09-13-2014 [8c]) on a $Na_2O + K_2O$ versus SiO_2 TAS plot (Figure 12a) (Le Maitre et al., 1989). All four samples follow a calc-alkaline trend (Figure 12b) (Arculus, 2003; Irvine & Baragar, 1971; Kuno, 1968; Le Maitre et al., 1989). The more mafic samples (i.e., AZ 09-15-14 [3], WC 09-13-2014 [8c], and AZ 09-17-14 [2c]) have relatively high total REE concentrations, especially are enriched in light rare earth elements (LREE), similar with OIB type (Figure 12c). The intermediate sample AZ 09-13-14 (9c) has a relatively flat REE chondrite-normalized profile (Figure 12c), whereas the E-MORB rock display slight to significant LREE depletion, similar with N-MORB (Figure 12c). All these samples show very slight to no Eu negative anomalies (δEu = 0.27–0.37; Figures 12c and 12d, and Table S2). On a Primitive Mantle-normalized diagram, these more mafic three samples generally display enrichment in LILE and Pb, and show no Nb and Ta anomalies (Figure 12d). Similarly, the intermediate sample AZ 09-13-14 (9c) also shows LILE enrichment and Pb, but relatively enriched in U and slightly negative Nb and Ta anomalies (Figure 12d). The more mafic samples are plotted into the field of OIA, whereas the intermediate sample AZ 09-13-14 (9c) is plotted into the field of IAT in the TiO_2-MnO*10-P_2O_5*10 diagram (Figure 12e). All these samples follow an "Ocean Island" trend with an exception of the intermediate sample AZ 09-13-14 (9c) placing between the "Ocean Island" and "Ocean Ridge & Floor" fields in the FeO^T-MgO-Al_2O_3 diagram (Figure 12f).

5. Discussion

5.1. Construction of a Tectonostratigraphic Framework

Our geochronological studies, together with the field observations, focused on the U-Pb zircon ages of the Paleoproterozoic-Paleozoic metamorphic sedimentary and volcanic rocks, key leucogranites and intrusions, and the structural contacts among these units between the North China and Kunlun-Qaidam continents. New geochemistry analyses helped better constrain the tectonic setting and arc-continent evolution of this region. Below we describe the important structural, geochemical, and geochronological observations and their correlation with existing knowledge in the literature allow us to construct a tectonostratigraphic section that constrains the evolution of the southwestern margin of North China craton and northern margin of Kunlun-Qaidam continent (Figure 13a).

5.1.1. Proterozoic Rocks

We observed at least two distinct units of Proterozoic strata across the regional study area. The youngest single concordant zircon from leucogranite sample AZ 09-12-14 (1c) yielded an age of 1,496 ± 25 Ma (Figure 8a), which provides a minimum age for the Proterozoic gneissic rocks that the leucogranite cuts. We note that this single zircon age is not robust, and alternatively the 1.8–1.9 Ga (i.e., concordant age of
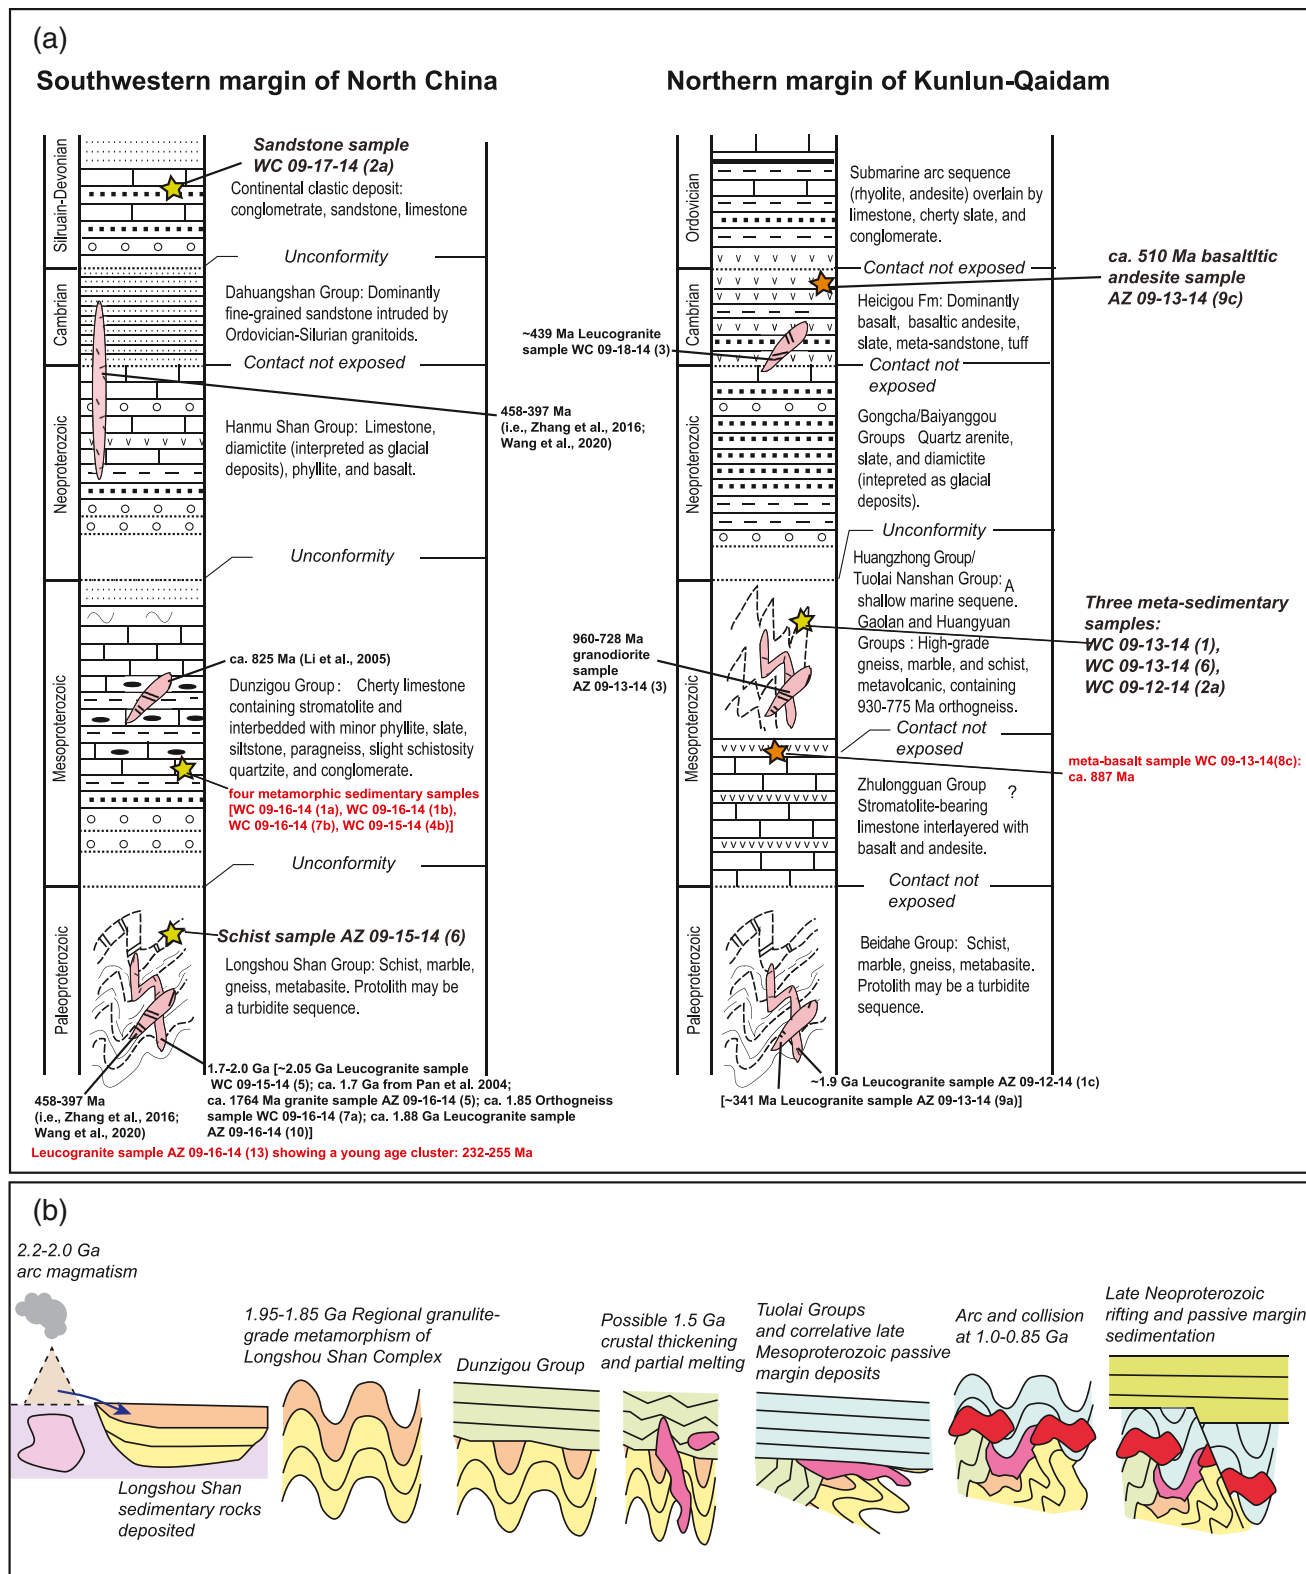

Figure 13. (a) Tectono-stratigraphic sections of the Longshou Shan and the eastern Qilian Shan, key references used for constructing these sections include: Pan et al. (2004), Li et al. (2005), Qinghai BGMR (1991), Gong et al. (2016), and Zhang et al. (2016); (b) schematic representation of the key tectonic relationships of samples and strata from the eastern Qilian Shan and Longshou Shan from the Mesoproterozoic to the Neoproterozoic.

1,908 ± 20 Ma; Figure 8a) zircon-age population from the leucogranite provides a more conservative minimum age for the Proterozoic gneiss. Geochemistry data suggests that the leucogranite is syn-collisional, and it probably was generated during orogen-related crustal melting (e.g., Noble & Searle, 1995) in the Mesoproterozoic (i.e., ca. 1.5 Ga). The Proterozoic gneiss is juxtaposed via a thrust contact over a meta-quartzite unit that yields detrital zircon ages spanning the Proterozoic (i.e., sample AZ 09-12-14 [2a]) (Figure 8l). The youngest three zircon ages suggest that the maximum depositional age of this quartzite was ca. 1.14 Ga (Figure 8l). We note that the detrital zircon age spectrum from this sample is very similar to other Mesoproterozoic rocks in the central Qilian Shan (e.g., G. E. Gehrels et al., 2003a; C. Wu et al., 2017; Zuza et al., 2018) (Figure 9). All four samples contain a youngest zircon population of ca. 1.15–1.25 Ga, distinct 1.4–1.5 Ga ages, and Paleoproterozoic to Archean zircons (except for Gehrels et al., 2003a sample GA206, which only had a total of 22 zircon analyses) (Figure 9). In addition, the Mesoproterozoic samples from Gehrels et al. (2003a), Wu et al. (2017), and Zuza et al. (2018) were all intruded by 900–950 Ma granitoids (Figure 9), which constrains their depositional ages between ca. 0.95 Ga and ca. 1.15 Ga. We assume that sample AZ 09-12-14 (2a) from this study was deposited in a similar timeframe, although we do not directly observe the cross-cutting ca. 0.95 Ga intrusions in this study of the eastern Qilian Shan.

The Proterozoic gneiss was thrust over the younger Mesoproterozoic quartzite (Figure 4a). The age of this thrusting is unconstrained, but the complete lack of a topographic expression of this fault suggests it probably occurred prior to the Cenozoic. Future thermochronology and cooling-history analysis of the thrust fault's hanging wall may better constrain the age of thrusting, but for now, we posit that thrusting may have occurred either in the early Paleozoic during the Qilian orogeny or during the early Neoproterozoic related to the enigmatic 0.9–1.0 Ga magmatic event (e.g., C. Wu et al., 2016a, 2017; Zuza & Yin, 2017).

About 80 km to the northwest, the same meta-quartzite unit (e.g., Pan et al., 2004, Figure 3) is intruded by foliated ca. 728 Ma granodiorite (sample AZ 09-13-14 [3]) (Figure 8b) that has an A-type within-plate geochemical signature (Figure 10), which probably indicates that the intrusion was generated in an extensional setting (Eby, 1990, 1992; S. P. Turner et al., 1992; Whalen et al., 1987). Wu et al. (2017) reported ca. 820 Ma extension-related A-type granitoids in the Qilian Shan that preceded continental rifting the opening of the Neoproterozoic-early Paleozoic Qilian orogen. The igneous rock is strongly foliated and folded with the quartzite rock (sample WC 09-13-14 [1]) that it intrudes, and older inherited zircons record Qilian enigmatic ca. 960 Ma tectonic event (e.g., G. E. Gehrels et al., 2003a; C. Wu et al., 2016a, 2017; Zuza & Yin, 2017) (Figure 8b). Thus, we suggest that the granodiorite intruded the quartzite, after ca. 1.19 Ga (i.e., the maximum depositional age) (Figure 8n), during an episode of regional extension, and was later deformed with the quartzite during contractional deformation, possibly related to the early Paleozoic Qilian orogen. Another phyllite sample WC 09-13-14 (6) was also collected from the Mesoproterozoic strata, together with the quartzite sample WC 09-13-14 (1) and above meta-quartzite sample AZ 09-12-14 (2a), show the similar age populations to other Mesoproterozoic rocks in the Qilian Shan as discussed above (e.g., G. E. Gehrels et al., 2003a; C. Wu et al., 2017; Zuza et al., 2018).

The youngest single concordant zircon from OIB-like type meta-basalt sample WC 09-13-14 (8c) yielded an age of ca. 887 Ma (Figures 8c and 12). The basalt was interbedded with Meso-to Neoproterozoic marble layers, and we therefore interpret that this rock unit was part of a Neoproterozoic rift and drift basin developed in the eastern Qilian Shan. Alternatively, if the meta-basalt is ca. 1.2 Ga, using the next youngest population of grains (Figure 8c), this unit could be interpreted as Mesoproterozoic in age.

Proterozoic strata in the Longshou Shan have been divided into the Paleoproterozoic Longshou Shan Group (or Complex), the Mesoproterozoic Dunzigou Group, and the Neoproterozoic Hanmushan Group (J. Gong et al., 2016; J. H. Gong et al., 2013). We analyzed detrital zircons from one Longshou Shan Group quartzite sample: AZ 09-15-14 (6) (Figure 9). Here we discuss these ages with additional ages from adjacent samples presented by Gong et al. (2016) (inset of Figure 9). Most samples have dominant age peaks ca. 1.9 and 2.1 Ga peaks and various minor older Paleoproterozoic zircon grains. Gong et al. (2016) inferred that the ca. 1.85 Ga zircon grains were metamorphic zircons, and our new age data support this inference; older >1.95 Ga zircon ages generally have Th/U ratios >0.15 whereas most of the younger <1.95 Ga grains have lower <0.15 Th/U ratios (Table S2). The shallow marine sediments of the Longshou Shan Group were suggested to have

been deposited between ca. 2.0–1.95 Ga (e.g., J. Gong et al., 2016; Pan et al., 2004; Xu et al., 2014; this study). However, our field observation shows that Paleoproterozoic (i.e., ca. 2.05 Ga) leucogranite dike intrudes into the Longshou Shan Group quartzite unit (Figure 7d), so we further constrain that the deposition age of the Longshou Shan Group should older than ca. 2.05 Ga. In additional, a 2.2–2.0 Ga magmatic arc may have developed in the Longshou Shan area (e.g., Fan et al., 2010; Dan, Li, Guo, Liu, & Wang, 2012; C. Y. Dong et al., 2007; J. Gong et al., 2016; Li et al., 2004; H. C. Wang et al., 1999; C. Wu et al., 2018; ca. 2.05 Ga leucogranite sample WC 09-15-14 [5] in this study), and Lu-Hf isotopes showed reworking of older crust, i.e., ca. 2.45–2.65 Ga basement of the North China (J. Gong et al., 2016; C. Wu et al., 2018). The entire Longshou Shan Group/complex was metamorphosed ca. 1.92–1.85 Ga (i.e., ca. 1.88 Ga A-type leucogranite sample AZ 09-16-14 [10] and ca. 1.85 Ga orthogneiss sample WC 09-16-14 [7a]), which is consistent with the reported tectonothermal events in the northern margin of the North China Craton (i.e., S. X. Han et al., 2020; Kusky & Li, 2003; Kusky et al., 2007, 2016; Wan, Windley, Xiao, Feng, & Zhang, 2015; C. Wu et al., 2018). Meso- to Neoproterozoic continental and/or passive margin deposits were deposited on top following orogeny, such as the Bayan Obo Group in the northern North China and Tuolai Group in the Qilian Shan (e.g., C. Wu et al., 2017, 2018; Zhou et al., 2018; A. V. Zuza et al., 2018).

The overlying Mesoproterozoic Dunzigou Group has been interpreted to be composed of unmetamorphosed sedimentary strata including conglomerate, limestone, and sandstone. However, our field observations suggest that these rocks have been transformed to phyllite, paraschist, quartzite, and bedding is often transposed by penetrative cleavage (Figure 7f). The strata are intruded by leucogranite and folded together. The nearby ca. 825 Ma Jinchuan intrusion, and related dikes, do not show signs of such foliation development and deformation (Figure 7j). Thus, our observations suggest that the Dunzigou Group was deformed between the Mesoproterozoic and ca. 825 Ma, possibly during the 1.0–0.9 Ga inferred orogen. We analyzed detrital zircons from four Dunzigou Group samples: quartzose schist sample WC 09-15-14 (4b), quartzite sample WC 09-16-14 (1a), quartzose schist sample WC 09-16-14 (1b), and paragneiss sample WC 09-16-14 (7b). These samples yielded dominant age peaks of ca. 1.85, 1.9, and 2.1 Ga and various minor younger Late Paleoproterozoic zircon grains (i.e., ca. 1.76–1.82 Ga). The younger zircon age population are widely distributed in North China, which are interpreted as being generated in an extensional setting (e.g., S. X. Han et al., 2020; P. Peng et al., 2008; granitoid sample AZ 09-16-14 [5] in this study) (Figure 10). The OIB-like mafic sample AZ 09-15-14 (3) was interbedded within the Neoproterozoic Hanmushan Group limestone layer, which probably indicates that Neoproterozoic rift-basin development in eastern Longshou Shan. The detrital zircon age populations of a meta-sandstone sample from the Hanmushan Group (Song et al., 2017; Figure 10) are similar to Qilian Shan Neoproterozoic sample GA209 from G. E. Gehrels et al. (2003a) (Figure 10).

5.1.2. Paleozoic Rocks

Near Menyuan city, lower Paleozoic slightly metamorphosed interbedded marbles and ca. 512 Ma meta-basaltic trachy-andesite (i.e., sample AZ 09-13-14 [9c]; Figure 8d) are crosscut by a leucogranite (i.e., sample AZ 09-13-14 [9a]). The volcanic rocks were mostly likely derived as part of the Cambrian Qilian arc. Interpretation of the crosscutting leucogranite is less straightforward due to its spread of Paleozoic zircon ages (Figure 8c). The youngest population of truly concordant analyses yields a weighted mean age of ca. 341 Ma, which implies that this leucogranite may have been generated from crustal melts in the latest Devonian-Carboniferous during the Qilian orogen (Figure 8c) (e.g., S. Song et al., 2013, 2014; C. Wu et al., 2017). This age may be too young for the Qilian orogen because by Carboniferous shallow marine sediments overly much of northern Tibet, suggesting that orogeny was complete by this time (A. V. Zuza et al., 2018). Alternatively, the younger, slightly discordant analyses from this sample are Permian in age, which would suggest that this leucogranite was generated during the Permian closure of the Paleo-Asian Ocean to the north (W. Xiao et al., 2003). Either way, a phase of Paleozoic anatexis appeared to have occurred in response to Paleozoic orogeny, generating leucogranite with complex zircon populations in the eastern Qilian Shan.

Early Paleozoic granites from the Haiyuan-fault restraining bend yield a U-Pb zircon age of ca. 460 Ma (sample AZ 09-14-14 [8]) (Zuza et al., 2018), together with a ca. 439 Ma leucogranite to the east (sample WC 09-18-14 [3]), which both intruded the Lower Paleozoic forearc strata (Figures 4 and 6). Our geochemistry characteristics from arc magmatism samples AZ 09-14-14 (7) and AZ 09-14-14 (13) supports the interpreta-

tion of northward slab rollback at the south-dipping Qilian arc subduction zone (Zuza et al., 2018). Paleozoic molasse deposition in Longshou Shan mainly occurs near Shandan city (Figure 4), our sandstone sample WC 09-17-14 (2a) has dominant age peaks ca. 1.7, 0.9 and 0.5 Ga peaks and the maximum depositional age of ca. 406 Ma. The two younger age populations are widely distributed in Qilian Shan and Longshou Shan, whereas the older age peak is widely distributed in North China-Tarim and Longshou Shan. We further suggest that the linkage again between the Qilian Shan and North China-Tarim corresponds to this time period.

5.2. Proterozoic Tectonic Configuration

Here, we first discuss a possible Proterozoic linkage between the North Tarim and North China continents. Permo-Triassic closure of the Paleo-Asian Ocean against their northern margins is broadly similar along strike (e.g., Windley et al., 1990; W. Xiao et al., 2003; Zuza & Yin, 2017), thus supporting their connection by the late Paleozoic. The early Paleozoic Qilian orogen affected both the southern margin of North China (e.g., S. Song et al., 2013; A. V. Zuza et al., 2018) and northern Tarim Basin, as evidenced by observations of an Ordovician-Silurian fold-thrust belt in the subsurface (e.g., Jia, 1997; Carroll et al., 2001; Yin & Nie, 1996) and early Paleozoic thermal pulses (e.g., P. Yang et al., 2020). Therefore, North China and North Tarim were contiguous at the start of the Paleozoic. Expanding on these lines of evidence, we suggest that Tarim and North China were linked in the Proterozoic time, and the belt of 1.0–0.9 Ga plutonic rocks stretching from the Tian Shan, through Tarim, to the Kunlun-Qaidam continent (Figure 1b) supports this was a continuous margin for Neoproterozoic subduction and arc magmatism. Without evidence for a Paleozoic-Mesozoic arc-subduction system between North China and Tarim and a reasonable explanation to resolve the aforementioned lines of evidence, we argue that models of their separation in the Phanerozoic are unjustified.

The detrital zircon spectra of samples from Tarim, Kunlun-Qaidam, and North China can be used to test a possible Proterozoic linkage between these continents. Mesoproterozoic quartzite and schist samples from these locations are remarkably similar (Figure 9; G. E. Gehrels et al., 2003a; J. Gong et al., 2016; S. Lu et al., 2008; Y. L. Li, Xiao et al., 2020; C. F. Liu et al., 2018; Peng et al., 2019; D. F. Song et al., 2017; K. Tung et al., 2007, 2012, 2013; Y. Wan et al., 2006; C. Wu et al., 2017; Yu et al., 2013; A. V. Zuza et al., 2018; this study): (1) Paleoproterozoic-Archean zircons (except for G. E. Gehrels et al., 2003a sample GA206), (2) dominant ca. 1.4–1.5 Ga zircon grains, (3) youngest zircon age populations of ca. 1.15–1.25 Ga, and (4) intrusions by 0.90–0.95 Ga granitoids. These resemblances highlight that the regionally widespread strata are of comparable ages (i.e., late Mesoproterozoic to early Neoproterozoic) and received sediments from broadly similar sources. Although the exact shape of the detrital zircon spectrum (i.e., the proportion of particular age populations) from each sample varies (Figure 9), these minor variations may be caused by variations in the individual drainage systems (e.g., Teng et al., 2020; C. L. Zhang et al., 2016, 2019). We acknowledge that detrital zircon correlations offer nonunique solutions, as many of these age signatures are important globally. However, these observations make our proposed North Tarim and North China correlation from the Archean to early Neoproterozoic permissible. The Kunlun-Qaidam microcontinent may have been partially or completely rifted away from combined North China-Tarim as a result of the opening of the Qilian ocean in the late Neoproterozoic (i.e., Yin & Harrison, 2000; C. Wu et al., 2016a, 2017; A. V. Zuza et al., 2018).

The early Paleozoic suture zone classically separates the Kunlun-Qaidam continent from the North China craton (e.g., Song et al., 2005; X. -Y. Song et al., 2006; S. Song et al. 2013; Yang et al., 2001; A. V. Zuza et al., 2018). The existence of this suture zone, and a contemporaneous-to-slightly-older arc system, is clear evidence that Kunlun-Qaidam continent collided with North China craton. This separation allows for ambiguity for the pre-suturing connection between Kunlun-Qaidam continent and North China craton, but also highlights how such a suture-arc belt is both (1) required to join continental fragments and (2) observable in the geologic record (see related discussion in A. V. Zuza & Yin, 2017). Therefore, the lack of identified suture-arc rocks separating northern Tarim and North China cratons makes their separation from the middle Proterozoic to present highly unlikely. In addition to the geologic similarities between the continents, their geologic history, and the sediments deposited over them, the lack of intervening suture complexes is a strong argument for their contiguous nature.

We note here that many of our samples from the southwestern margin of North China craton and northern margin of Kunlun-Qaidam continent contain detrital or inherited Paleoproterozoic and Archean zircon grains (Figures 7 and 9) (J. Gong et al., 2016; D. F. Song et al., 2017; C. Wu et al., 2017; A. V. Zuza et al., 2018; this study). For igneous samples, this suggests that the zircon-host plutons intruded through Archean-Paleoproterozoic crust, and for detrital metasedimentary samples, this suggests that there was Archean basement in the source region or sedimentary rocks with recycled Archean zircons. Although no Archean basement has been confirmed for the Qilian Shan and Longshou Shan, the detrital or inherited information improve the possibility for the Archean source basement. Four phases of Paleoproterozoic tectono-magmatic activity occurred in the Longshou Shan as observed via our geochronology and geochemistry analysis. This sequence of events is similar to what has been documented along the northern margin of the North China craton, including ca. 2.0 Ga arc, 1.88 and 1.85 Ga metamorphic, and 1.76 Ga extension events (e.g., J. Gong et al., 2016; S. X. Han et al., 2020; Kusky et al., 2016; C. Wu et al., 2018). The rock assemblages and age populations of the Mesoproterozoic Dunzigou Group in Longshou Shan and Qilian correlative strata are similar to coeval units in the northern margin of the North China craton (e.g., C. Wu et al., 2017; A. V. Zuza et al., 2018; Zhou et al., 2018; this study). The 1.0–0.9 Ga granitoid belt that is exposed throughout Qaidam, the Qilian Shan, and Tarim, also has sparse exposures in northern North China craton (Cowgill et al., 2003; G. E. Gehrels et al., 2003b; P. Peng et al., 2008; S. Song et al., 2013; K. Tung et al., 2007; C. Wu et al., 2016a, 2017, A. V. Zuza et al., 2018; this study). Leucogranites and metamorphic zircons have been reported with ages of ca. 0.9–0.85 Ga in the Tarim continent and Qilian Shan (G. E. Gehrels et al., 2003b; Kröner et al., 2013; H. Wang et al., 2014; C. Wu et al., 2017; Zhu et al., 2011; A. V. Zuza et al., 2018).

We document a ca. 887 Ma OIB-like basalt unit (sample WC 09-13-14 [8c]) in the eastern Qilian Shan. The ca. 825 Ma Jinchuan ultramafic intrusion (Li et al., 2005) and the Neoproterozoic Hanmushan Group passive margin deposition may have been associated with the opening of the Paleo-Asian Ocean, and A-type ca. 820 Ma granitoids in the Qilian Shan have been related to postorogenic extension (C. Wu et al., 2017; A. V. Zuza et al., 2018). Our ca. 728 Ma granodiorite in the eastern Qilian Shan may similarly been associated with the opening of the Qilian Ocean.

5.3. Early Paleozoic Geology in the Qilian Shan and Longshou Shan

The Qilian arc was active on the northern margin of the Kunlun-Qaidam continent during most of the Ordovician (D. Fu et al., 2019; C. L. Fu et al., 2018; C. Wu, Yin et al., 2016; C. Wu, Liu et al., 2016; C. Wu et al., 2017; Yan et al., 2019; A. V. Zuza et al., 2018). The nature of this subduction system and arc, including subduction polarity (i.e., north or south dipping), has been debated (e.g., D. Fu et al., 2019; S. Song et al., 2013; Xiao, Windley, Yuan et al., 2009; Xiao, Windley, Huang et al., 2009; Xiao, Windley, Yong et al., 2009; Yan et al., 2019; Yin, Dang et al., 2007; Yin, Manning et al., 2007; Zuza et al., 2018). Partly based on the prevalence of Ordovician arc granites throughout Qaidam, and the general lack of these plutons in the North China craton, Zuza et al. (2018) and Wen et al. (2017) recently presented tectonic models that involve a south-dipping Qilian arc, expanding upon previous suggestions by Sobel and Arnaud (1999) and G. E. Gehrels et al. (2003a, 2003b). In this study, we document an arc-related Cambrian basaltic trachy andesite (i.e., sample AZ 09-13-14 [9c]) near Menyuan that was subsequently intruded by ca. 341 Ma leucogranite (i.e., sample AZ 09-13-14 [9a]) (Figure 4). The location of these samples south of the Qilian suture trace(s) supports that the Cambrian Qilian arc developed within the Kunlun-Qaidam continent. The range of zircon ages in the leucogranites intrusion (Figure 8c) indicates that crustal melting, possibly due to crustal thickening during orogeny or underthrusting of hydrated sediments (e.g., Harrison & Weilicki, 2016), occurred in the Silurian to early Carboniferous. This timing generally corresponds to the protracted deformation during the Qilian orogen, although it is somewhat younger than the main phase of Silurian-Devonian orogeny (e.g., S. Song et al., 2013; Zuza et al., 2018). An alternative interpretation for this sample is that the rare younger zircons better reflect the age of this leucogranite sample, possible as Permo-Triassic crustal melting during closure of the Paleo-Asian Ocean (e.g., W. Xiao et al., 2003). The newly dated ca. 460 Ma arc granites and ca. 439 Ma leucogranite from the east Qilian Shan might have been associated with the subduction of Qilian oceanic crust and initial collision between the Tarim-North China and Kunlun-Qaidam continents, respectively (e.g., C. Wu et al., 2017; A. V. Zuza et al., 2018).
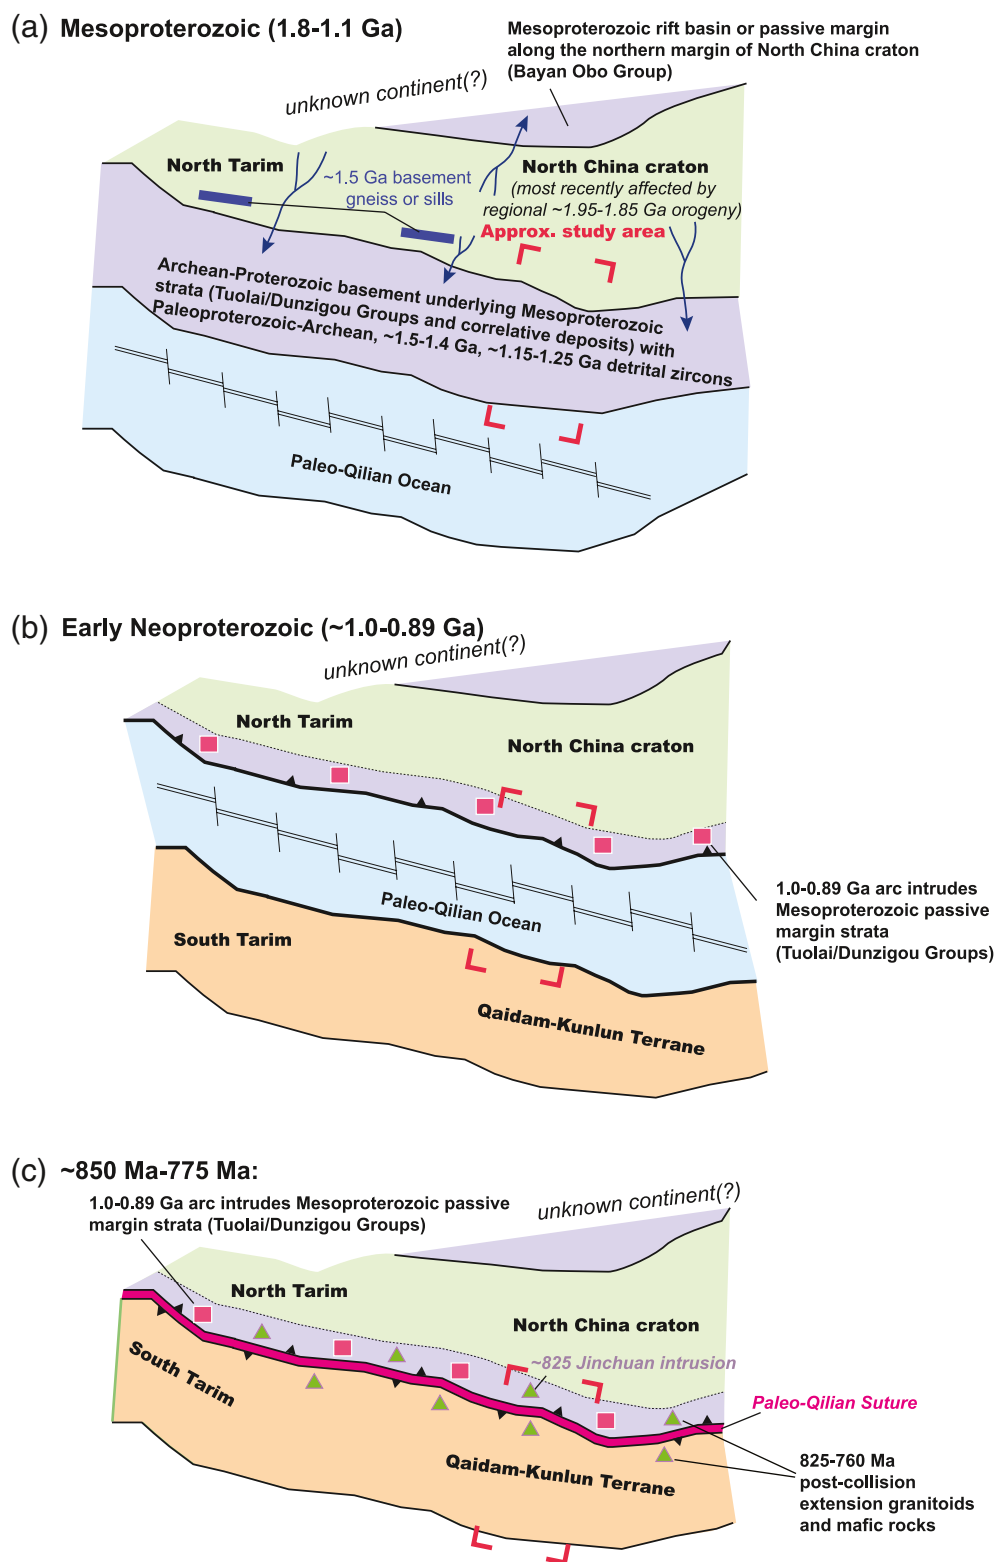

Figure 14. Models for the tectonic evolution of northern Tibet and the Tarim-North China from the Mesoproterozoic through the Silurian, see the text for the details. Note that the scale is relative and changes, adapted from C. Wu et al. (2017).
Figure 14. Continued

The lower Paleozoic Dahuangshan Group passive continent margin deposition occurred near Yongchang city, which was unconformity covered by the Devonian molasse sedimentary (e.g., C. L. Zhang et al., 2016). Early Paleozoic igneous rocks in the southern Longshou Shan consist of Silurian-Devonian granitoids (i.e., ca. 440–400 Ma), with some designated A-type granitoids (e.g., Z. Z. Wang et al., 2020). With respect to the early Paleozoic Qilian orogen, these intrusions are syn-to postcollisional (e.g., S. Song et al., 2013; A. V. Zuza et al., 2018) and may reflect crustal melting and/or postcollision extensional magmatism. The detrital zircon age populations from our Devonian sandstone sample in Longshou Shan (i.e., sample WC 09-17-14 [2a]) constrains that the provenance is similar to Qilian Shan, this suggests that the collision between North China and Kunlun-Qaidam continents was completed in this period (e.g., B. Li et al., 2020a).

5.4. Paleoproterozoic-Early Paleozoic Tectonic Evolution of Northern Tibet

Based on the field observations and analytical data presented in this study, we propose the following tectonic model for the Paleoproterozoic to early Paleozoic geologic history of northern Tibet, including the regions around the Qilian Shan, Longshou Shan, and North China (Figures 13b and 14). In the Paleoproterozoic, the protolith sediments of the Longshou Shan Complex were sourced predominantly from the

North China craton and deposited along its southwestern margin (Figure 13b). These rocks experienced amphibolite-grade metamorphism during a regional 1.95–1.85 Ga orogenic event that affected much of the North China and Tarim cratons (Figure 13b), with 1.9 Ga and 1.85 Ga metamorphic zircons observed in the Qilian Shan-Qaidam continent. The 1.78–1.75 Ga intraplate extensional tectonic setting is generally considered in much of the North China craton, including Longshou Shan and Kunlun-Qaidam continents (e.g., S. X. Han et al., 2020; Kusky & Li, 2003; S. N. Lu et al., 2006; P. Peng et al., 2008; X. Yu et al., 2017; this study) (Figure 13b). Mesoproterozoic passive continent margin strata deposited along the northern margin of the North China, Longshou Shan, and Qilian Shan (Figures 13b and 14a), which shows the similar detrital zircon age populations, i.e., Tuolai Group in Qilian Shan, Dunzigou Group in Longshou Shan, and Bayan Obo in the northern North China craton (J. Gong et al., 2016; G. E. Gehrels et al., 2003a; C. F. Liu et al., 2018; C. Wu et al., 2017; J. X. Zhang et al., 2013; Zhou et al., 2018; A. V. Zuza et al., 2018) (Figure 14a). These ages are observed in the detrital zircon spectra of Mesoproterozoic strata, and some rocks of these ages are observed, such as sills in North Tarim as part of a poorly exposed large igneous province (LIP) (C. Z. Wu et al., 2014). However, the exact source for the large population of 1.5 Ga zircons remains unclear.

A 1.0–0.9 Ga arc intruded the Mesoproterozoic passive margin deposits widespread in the Qilian Shan and Tarim, potentially during north-dipping subduction, and eventual closure, of the Paleo-Qilian Ocean (e.g., G. E. Gehrels et al., 2003b, 2011; C. F. Liu et al., 2019; C. Wu et al., 2016a, 2017; A. V. Zuza et al., 2018) (Figures 13 and 14b). The configuration and kinematics of this ocean-closure event are poorly resolved. This configuration would involve contiguous South Tarim-Qaidam colliding against North Tarim-North China. A possible ca. 887 Ma rift-basin was developed in the eastern Qilian Shan as evidenced by contemporaneous OIB-like basalt. The opening of the Qilian Ocean was preceded by bimodal volcanism (ca. 830–600 Ma) observed throughout Qaidam, Qilian, and Tarim-North China and the deposition of Neoproterozoic passive margin deposits observed in the northern Qilian Shan (Tseng et al., 2006, 2007; X. Xu et al., 2015; C. Wu et al., 2017; A. V. Zuza et al., 2018) (Figures 13b and 14c). The ca. 825 Ma Jinchuan ultramafic intrusion (X. H. Li et al., 2005) and deposition of Neoproterozoic Hanmushan Group passive-margin strata in Longshou Shan may have been associated with the opening of the Qilian ocean to the south (e.g., C. Wu et al., 2016a; Zuza et al., 2018), and also possible Paleo-Asian Ocean to the north of the North China craton (Figures 13b and 14d).

A Cambrian-middle Ordovician Qilian arc sequence developed along the northern margin of the Qaidam, which suggests a south-dipping subduction of the Qilian oceanic crust (C. F. Liu et al., 2019; C. Wu et al., 2016a, 2017; A. V. Zuza et al., 2018) (Figure 14e). Silurian-Devonian plutonic intrusions along the southern margin of the Longshou Shan may be syn- to postcollisional after the closure of the Qilian Ocean occurred at ca. 445–440 Ma (e.g., C. F. Liu et al., 2019; Zuza et al., 2018) (Figure 14e). Alternatively, early Paleozoic plutons in the Longshou Shan may be evidence for bivergent subduction of the Qilian Ocean (e.g., X. H. Chen et al., 2019; B. Li et al., 2020a). The subsequent Silurian-early Devonian postcollision granitoids, Silurian flysch and Devonian molasse deposits occurred at the Longshou Shan and northern Qilian Shan (D. Fu et al., 2019; Z. Z. Wang et al., 2020; C. Wu, Yin, et al., 2016, 2017; C. L. Zhang et al., 2016; A. V. Zuza et al., 2018).

5.5. Implications for Proterozoic-Phanerozoic Paleogeographic Reconstructions of Eurasia

Herein, we have provided new geologic observations for evaluating the tectonic history of the Qilian Shan, Longshou Shan, and northwest North China regions of Eurasia. These data refine our knowledge of the tectonic evolution of the region, but also provides key constraints for important intercontinent relationships. First, as discussed above, we argue that available geologic evidence suggests that Tarim and North China cratons were contiguous since the Proterozoic, and the lack of appropriate Phanerozoic suture-arc structures separating these continents confirms this assertion. Accordingly, this continental strip separated the Paleo-Asian and Tethyan oceanic realms in the Neoproterozoic and Paleozoic, following global Neoproterozoic rifting. This rifting tectonically calved microcontents from Tarim-North China into the Paleo-Asian Ocean domain (e.g., Levashova et al., 2010, 2011) (Figure 14). The late Paleozoic counter-clockwise wrapping of this continent around continental arc fragments within the Paleo-Asian Ocean ultimately led to its closure as part of the last stages of the Central Asian Orogenic System (e.g., A. V. Zuza & Yin, 2017).

Second, our traverse and published literature are at odds with North China and Tarim being located along the northern margin of Gondwana. The potential Cambrian connection between North China and India was established on the basis of trilobite fossils and detrital zircon comparisons (McKenzie et al., 2011), which has been perpetuated in the literature (e.g., Y. Han et al., 2016; Myrow et al., 2015). However, these reconstructions do not allow for an ocean to exist south of North China and provide no space for the Qilian arc-orogen to exist along this margin (e.g., Figure 2). Our observations of the early Paleozoic Qilian orogen transitioning northward to the North China craton requires abandonment or reevaluation of North China-Gondwana reconstructions. Furthermore, recent reconstructions based on new paleomagnetic poles have placed the Tarim craton along the western margin of Laurentia in the Neoproterozoic (Wen et al., 2017, 2018). Based on our interpretations of a contiguous North Tarim-North China (A. V. Zuza & Yin, 2017; this study), one can extrapolate that North China may have also been adjacent to Laurentia in the Rodinian supercontinent (e.g., A. V. Zuza & Yin, 2013, 2017), which would provide a relatively long continental strip to be the conjugate of western Laurentia's classic linear rift margin (see discussion of Eyster et al., 2020). Our new detrital zircon analyses from Mesoproterozoic strata yielded zircon spectra similar to Mesoproterozoic rocks in western North American, including 1.5–1.6 Ga ages that are observed in Belt-Purcell Supergroup strata are otherwise rare in North American zircons (e.g., Link et al., 2007; Ross et al., 1992; Ross & Villeneuve, 2003). Further testing of this hypothesis is not within the scope of this study. The ca. 1.5 Ga basement gneiss or sills probably originated from North Tarim or western North China (e.g., Demoux et al., 2009; C. Z. Wu et al., 2014; C. Wu et al., 2017). Alternatively, we acknowledge that 1.5–1.6 Ga rocks and detrital zircon ages are reported in the Australia and South China cratons (e.g., Giles et al., 2004; Zhao & Cawood, 2012).

Last, the complex polyphase arc-collisional history in this region probably focused Cenozoic shortening and strike-slip faulting related to the India-Asia collision. This region occupies the northernmost margin of the Tibetan Plateau, and available thermochronology constraints suggest that exhumation and deformation here started shortly after initial India-Asia collision (i.e., Eocene; e.g., An et al., 2020; Dupont-Nivet et al., 2004; B. Li et al., 2020b; Qi et al., 2016). This relationship strongly suggests that orogeny since the Proterozoic weakened the crust and mantle lithosphere here to be reactivated in the Himalayan-Tibetan orogen (e.g., Bian et al., 2020; L. Chen et al., 2017), thus establishing the northern limit of the Tibetan Plateau.

5.6. Implications for Paleoproterozoic Supercontinent Reconstruction

Supercontinent configurations and paleogeography are partly based on spatial and temporal correlations of important geologic features, such as crystalline basement, arc magmatic events, and tectono-metamorphism. Two stages of Paleoproterozoic orogeny-related leucogranites were developed in the Longshou Shan region, i.e., ca. 1.88 Ga and ca. 2.05 Ga. A ca. 1.9–1.88 Ga mélange was reported along the northern margin of the North China craton, which was considered that the North China craton was beginning to the context of the Columbia supercontinent from ca. 1.9 Ga (e.g., Kusky et al., 2016; Rogers & Santosh, 2002; C. Wu et al., 2018; G. C. Zhao et al., 2002). The northern North China orogenic event between the North China craton and possible Siberia craton indicates the existence of ca. 2.0 Ga arc, which is supported by scattered 2.0–2.1 Ga magmatic ages in the northern North China craton (e.g., Fan et al., 2010; J. Gong et al., 2016; Kröner et al., 2005; C. Wu et al., 2018; R. F. Zhao et al., 2011, 2008). Our observed ca. 1.88 Ga leucogranite could be interpreted as part of the northern North China orogeny.

Orogeny at 2.0–2.05 Ga is relative rare on Earth and therefore may be a useful for reconstructing continental connections in the Paleoproterozoic. The Limpopo orogenic belt in southern Africa consists mostly of supracrustal assemblages intruded by ca. 3.2 Ga and 2.7–2.6 Ga felsic plutons modified by ductile folding, granulite-amphibolite facies metamorphism, and anatexis at 2.7–2.6 Ga and ca. 2.0 Ga (e.g., Brandt et al., 2018; Kramers & Mouri, 2011; Kröner et al., 2018; Yin et al., 2020), which were folded by north-south compression at ca. 1.97–1.88 Ga (Yin et al., 2020). In addition, ca. 2.05 Ga leucogranite was reported in the Limpopo belt (Zeh et al., 2010). Although the Archean basement is not reported in the Longshou Shan area, the Lu-Hf isotopes of amphibolite-grade folded Longshou Shan Group showed reworking of ca. 2.45–2.65 Ga basement of the North China craton (e.g., J. Gong et al., 2016). Undeformed ca. 1.88 Ga mafic dike intrusions are developed within the folded Paleoproterozoic strata in the South Africa and North China cratons (e.g., Hanson et al., 2004; C. Wu et al., 2018; Yin et al., 2020), which is also consistent with field observations

in Longshou Shan (Figure 7c). Although the age of the mafic dike in Longshou Shan is not constrained, the undeformed ca. 1.88 Ga leucogranite dike is exposed in the same outcrop (Figure 7d). We propose a possible connection between the Limpopo belt in South Africa and Longshou Shan along southwestern margin of the North China craton at ca. 2.05 Ga. In this regard, future detailed tectonic geology studies of the both South Africa and North China cratons should provide further tests of our proposed hypothesis.

6. Conclusions

In this study, we present detailed field, geochronological, and geochemical observations from several key locations in the Qilian Shan, Hexi Corridor, and Longshou Shan areas to decipher complex relationships between the Tarim, North China, and Kunlun-Qaidam continents. This region has been deformed during at least five phases of orogeny since the Proterozoic, including (1) regional granulite-facies metamorphism in the Paleoproterozoic, (2) an enigmatic Neoproterozoic arc-collision, (3) the early Paleozoic Qilian arc development and its amalgamation with the Kunlun-Qaidam continent and the North China, (4) Permian-Triassic magmatism and deformation related to the closure of the Paleo-Asian Ocean to the north, and (5) the most recent Cenozoic contractional deformation related to the India-Asia convergence. Furthermore, our updated geochronology and structural synthesis allows for us to consider a possible connection between the North China and southern Africa at ca. 2.05 Ga.

Data Availability Statement

All data supporting the interpretations and conclusions of this study can be found in the manuscript text, figures, and the supporting information file. Presented geochemistry data used in this study are available in the Interdisciplinary Earth Data Alliance (IEDA) (at https://doi.org/10.26022/IEDA/111780), and the U-Pb zircon geochronology data are available in the Interdisciplinary Earth Data Alliance (IEDA) (at https://doi.org/10.26022/IEDA/111781). There are no restrictions to the data usage.
