1 **Abstract**

2   The isotopic compositions of iron in major mantle minerals may record chemical

3 exchange between deep-Earth reservoirs as a result of early differentiation and ongoing

4 plate tectonics processes. Bridgmanite (Bdg), the most abundant mineral in the Earth's

5 lower mantle, can incorporate not only Al but also Fe with different oxidation states

6 and spin states, which in turn can influence the distribution of Fe isotopes between Bdg

7 and ferropericlase (Fp) and between the lower mantle and the core. In this study, we

8 combined first-principles calculations with high-pressure nuclear resonant inelastic X-

9 ray scattering measurements to evaluate the effects of Fe site occupancy, valence, and

10 spin states at lower-mantle conditions on the reduced Fe partition function ratio (β-

11 factor) of Bdg. Our results show that the spin transition of octahedral-site (B-site) Fe^{3+}

12 in Bdg under mid-lower-mantle conditions generates a +0.09‰ increase in its β-factor,

13 which is the most significant effect compared to Fe site occupancy and valence. Fe^{2+}-

14 bearing Bdg varieties have smaller β-factor relative to Fe^{3+}-bearing varieties, especially

15 those containing B-site Fe^{3+}. Our models suggest that Fe isotopic fractionation between

16 Bdg and Fp is only significant in the lowermost mantle due to the occurrence of low-

17 spin Fe^{2+} in Fp. Assuming early segregation of an iron core from a deep magma ocean,

18 we find that neither core formation nor magma ocean crystallization would have

19 resulted in resolvable Fe isotope fractionation. In contrast, Fe isotopic fractionation

20 between low-spin Fe^{3+}-bearing Bdg/Fe^{2+}-bearing Fp and metallic iron at the core-

21 mantle boundary may have enriched the lowermost mantle in heavy Fe isotopes by up

22 to +0.20‰.

25

26 **1. Introduction**

27   Iron, the most abundant element in the Earth by weight, is the dominant component

28 of the core and the only major transition metal in the mantle. Signatures of planetary

29 accretion and differentiation may be recorded in the Fe isotopic compositions

30 ($\delta^i Fe=((^i Fe/^{54}Fe)_{sample}/(^i Fe/^{54}Fe)_{standard} - 1)*1000$ ‰, i=56 or 57) in the Earth's crust,

31 mantle, and core (Poitrasson et al., 2009; Polyakov, 2009; Poitrasson et al., 2013; Rubie

32   et al., 2015; Sossi et al., 2016; Elardo and Shahar, 2017; Teng et al., 2017). Terrestrial

33   mid-ocean ridge basalts (MORBs) exhibit strikingly high δ^{56}Fe of 0.105 ± 0.006‰

34   (Teng et al., 2013) relative to chondritic values, suggesting the enrichment of heavy Fe

35   isotopes in the Earth's upper mantle. Several hypotheses have been proposed to explain

36   the Fe isotope signatures in the mantle, including evaporation loss of light iron isotopes

37   during Earth's accretion (Poitrasson et al., 2004; Poitrasson, 2007), Fe isotopic

38   fractionation during core formation (Polyakov, 2009; Elardo and Shahar, 2017), and

39   mantle partial melting (Teng et al., 2008; Dauphas et al., 2014). Evaluation of the effects

40   of these processes on the Fe isotope composition requires Fe equilibrium isotopic

41   fractionation factors (Δ^{56}Fe) between major Fe-bearing mantle and core minerals/melts

42   under pressure-temperature (P-T) conditions relevant to the early and current Earth's

43   interior.

44   Bridgmanite (Bdg) and ferropericlase (Fp) are the most abundant Fe-bearing

45   minerals in the lower mantle. As such, the reduced Fe partition function ratios (β-factors)

46   for Bdg, Fp, and iron-light element alloys are key parameters for modelling Fe isotopic

47   fractionation between different minerals/melts in the lower mantle or between the

48   mantle and the core. Generally, β-factors are directly controlled by bond stiffnesses in

49   structures, which in turn depend on structural response to pressure, temperature, and

50   composition (Schauble, 2011; Huang et al., 2013; Huang et al., 2014; Wu et al., 2015a;

51   Shahar et al., 2016; Liu et al., 2017; Yang et al., 2019). In addition, Fe in both Bdg and

52   Fp have been found to undergo spin transitions under mid-lower-mantle conditions (e.g.,

53   Lin et al., 2013; Liu et al., 2018), which can significantly change their electronic

54   structures (Hsu et al., 2011), Fe bond stiffnesses (Polyakov, 2009; Rustad and Yin, 2009;

55   Lin et al., 2013), and hence presumably influence Fe isotope fractionation. A recent

56   work conducted by Yang et al. (2019) observed a significant increase in the β-factor of

57   Fp across its Fe^{2+} spin transition in the octahedral site at ~ 60 GPa and 300 K, whereas

58   the β-factor of Bdg remains unchanged with increasing pressure likely due to lattice

59   distortion. Additionally, the effects of light elements on the β-factor of metallic Fe alloy

60   at high P-T conditions will also affect our understanding of deep-Earth iron isotope

61   distribution (Chen et al., 2014; Shahar et al., 2016; Liu et al., 2017; Chen et al., 2018).

62   The pressure-dependence of the β-factor of Bdg can be very complex when

63   considering the two possible crystallographic sites can accommodate Fe with different

64   valences and spin states as well as other minor cations like Al. The individual

65   contribution of each lattice site to the mean force constant of the phase cannot be

66   uniquely determined in high-pressure nuclear resonant inelastic X-ray scattering

67   measurements (e.g., Yang et al. 2019) which yields only the total average inelastic

68   scattering behavior of the sample. The Bdg structure accommodates Fe in both the

69   larger pseudo-dodecahedral (8-fold) A-site and the smaller octahedral (6-fold) B-site

70   (Lin et al., 2013). While Fe^{2+} can only reside in the large A-site, Fe^{3+} can enter both

71   sites through different proposed substitution mechanisms such as $Mg^{2+}_A + Si^{4+}_B \rightarrow$

72    $Fe^{3+}_A + Fe^{3+}_B$ and $Mg^{2+}_A + Si^{4+}_B \rightarrow Fe^{3+}_A + Al^{3+}_B$ (Frost et al., 2004; Liu et al., 2015). Only

73   Fe^{3+} in the Bdg B-site is expected to undergo a high-spin (HS) to low-spin (LS)

74   transition at pressures corresponding to mid-mantle depths, while A-site Fe^{2+} and Fe^{3+}

75   experience lattice distortion but both valence states maintain HS state throughout the

76   lower mantle (Catalli et al., 2010; Hsu et al., 2011; Mao et al., 2015; Shukla and

77   Wentzcovitch, 2016; Fu et al., 2018b; Liu et al., 2018).

78   Many previous studies have argued that iron exists predominantly as Fe^{3+} in Bdg,

79   on the basis of increased stability of Fe^{3+} in Bdg structure at lower-mantle-relevant

80   oxygen fugacity conditions (Catalli et al., 2010; Frost et al., 2004; Frost and

81   McCammon, 2008; Li et al., 2006; Marquardt et al., 2009; McCammon, 1997).

82   Furthermore, a recent work (Armstrong et al., 2019) also found that Fe^{2+} in a deep

83   magma ocean would disproportionate to Fe^{3+} plus metallic iron at high pressures. As

84   such, consequent segregation of precipitated iron metal from the lower mantle into the

85   core could leave the Bdg enriched in Fe^{3+} after magma ocean crystallization. In addition,

86   experimental studies (Frost et al., 2004; Shim et al., 2017; Andrault et al., 2018) also

87   reporeted Fe^{3+}-rich Bdg in equilibrium with iron metal due to the disproportionation of

88   Fe^{2+}. Although recent experimental and theoretical studies have reported the β-factors

89   of several Bdg compositions (Shahar et al., 2016; Yang et al., 2019), none of the studies

90   have examined the effect of Fe^{3+} in the B-site, precluding the evaluation of the influence

91   of the B-site Fe^{3+} spin transition on the β-factors of Bdg. In addition to Fe^{3+}, Al^{3+} can

92   also enter A and B sites in Bdg through the coupled substitution mechanism $Mg^{2+}_A +$

93    $Si^{4+}_B = (Fe^{3+}, Al^{3+})_A + (Fe^{3+}, Al^{3+})_B$ (Frost et al., 2004; Liu et al., 2015; Shim et al.,

94   2017; Yang et al., 2019). As the radius of Al^{3+} is smaller than both A-site and B-site

95   Fe^{3+}, it prefers to substitute into the smaller B-site and the content of B-site Fe^{3+} is

96   influenced by the Fe^{3+}/Al ratio (Frost et al., 2004; Liu et al., 2015; Shim et al., 2017).

97   Thus, comparison of the β-factors between Al-bearing and Al-free Bdg is needed to

98   reveal the effect of Al on the β-factor of Bdg.

99   In this study, we determine the β-factors of $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Fe^{3+}_{0.5})O_3$ Bdg at

100   mantle-relevant pressures by both nuclear resonant inelastic X-ray scattering (NRIXS)

101   and the density functional theory (DFT) augmented by a Hubbard U correction method.

102   The spin transition of the B-site Fe^{3+} in $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Fe^{3+}_{0.5})O_3$ Bdg at 43-50 GPa

103   has been inferred from X-ray diffraction, X-ray emission and electrical conductivity

104   measurements (Liu et al., 2018). This sample thus offers the possibility to

105   unambiguously determine the influence of the B-site Fe^{3+} spin transition on its β-factor.

106   In addition, the pressure- and temperature-dependent β-factors of Fe in four other

107   bridgmanite compositions were calculated by the DFT+U method, including Fe^{3+}- and

108   Al^{3+}-bearing Bdg, $(Mg_{0.9375}Fe^{3+}_{0.0625})(Si_{0.9375}Al_{0.0625})O_3$, $(Mg_{0.75}Fe^{3+}_{0.25})(Si_{0.75}Al_{0.25})O_3$,

109   and Fe^{2+}-bearing Bdg, $(Mg_{0.75}Fe^{2+}_{0.25})SiO_3$ and $(Mg_{0.5}Fe^{2+}_{0.5})SiO_3$. The calculated

110   results are used to constrain the effects of valence, spin states, and site occupancies of

111   Fe in Bdg on its β-factor at high pressure and temperature. To assess how Fe isotopes

112   distribute between Bdg and Fp in the lower mantle, our results are further used to model

113   the depth-dependence of $\Delta^{56}Fe_{Bdg-Fp}$ for various bulk mantle compositions. Finally, we

114   estimate the effect of Fe species in Bdg, Fp, and metallic iron-light element alloys on

115   the scale of Fe isotopic fractionation between the lower mantle and the core.

116

2. Materials and Methods

2.1. Bridgmanite sample synthesis and DAC preparation

119   ^{57}Fe-enriched $(Mg_{0.46}Fe^{3+}_{0.53})(Si_{0.49}Fe^{3+}_{0.51})O_3$ Bdg sample was synthesized as in

120   Liu et al. (2018). Briefly, fine-powdered 94.45% ^{57}Fe-enriched Fe_2O_3 (Cambridge

121   Isotope Laboratories) was homogeneously mixed with MgO and SiO_2 in 1:1:1 molar

122   ratios. $(Mg_{0.46}Fe^{3+}_{0.53})(Si_{0.49}Fe^{3+}_{0.51})O_3$ akimotoite was recovered from the multi-anvil

123   synthesis at 24 GPa and 1873 K for ~ 9 hours. The sample used in this study is from

124   the same multi-anvil press synthesis used in Liu et al. (2018) and (Dorfman et al. (2020).

125   Multiple experimental runs confirmed via refinement of X-ray diffraction data that this

126   akimotoite reproducibly and reversibly transforms to Bdg at ~24 GPa and 300 K

127   (Dorfman et al. 2018), therefore the NRIXS measurements collected at 32.5 GPa and

128   above are within the stability field of Bdg. Synchrotron Mössbauer spectroscopy (Liu

129   et al., 2018) and conventional Mössbauer spectroscopy (Dorfman et al., 2020) confirm

130   that all Fe in this sample is Fe^{3+}, which enters Bdg structure through coupled

131   substitution ($Mg^{2+}_A + Si^{4+}_B = Fe^{3+}_A + Fe^{3+}_B$).

132   A panoramic diamond anvil cell (DAC) equipped with a pair of 300-μm culet

133   diamonds was used for NRIXS measurements up to 60.9 GPa. NRIXS signals at higher

134   pressures were measured from a three-opening panoramic DAC equipped with a pair

135   of 150-μm culet diamonds and three APD detectors at Argonne National Laboratory. To

136   increase the signal-to-background ratio, the upstream diamond was partially perforated

137   to reduce scattering of the incoming X-ray beam. X-ray transparent, high-purity Be

138   gaskets 3 mm in diameter with cubic boron nitride (c-BN) inserts were used to support

139   sample chamber and provide windows for NRIXS signal collection. The c-BN insert

140   was preindented to ~30-μm thickness before a ~70-μm-diameter sample chamber was

141   drilled on its center. In the sample chamber, ~15×15×10 μm^3 sample was sandwiched

142   between two layers of ~5-μm-thick NaCl pressure medium. 5-μm ruby spheres next to

143   the samples were used as pressure gauge (Mao et al., 1986) below ~ 70 GPa. For higher

144   pressure experiments, pressures were determined from the edge of the diamond Raman

145   peak measured at the sample position (Akahama and Kawamura, 2010).

146

147   **2.2. NRIXS measurements and data analysis**

148   NRIXS measurements for ^{57}Fe-enriched $(Mg_{0.46}Fe^{3+}_{0.53})(Si_{0.49}Fe^{3+}_{0.51})O_3$ Bdg

149   sample (Fig. 1) at 32.5-60.9 GPa and 71.4-101.4 GPa were conducted at beamlines 16-

150   ID-D and 3-ID-B of the Advanced Photon Source, Argonne National Laboratory,

151   respectively. At both beamlines the incident X-ray beam was focused to ~10 μm in

152   diameter on the sample in a DAC. NRIXS spectra were collected by avalanche photo

153   diode (APD) detectors attached to DACs, respectively. Each NRIXS spectrum was

154   generated by scanning energy near the ^{57}Fe nuclear transition energy of 14.4125 keV

155   by tuning a high-resolution monochromator. The energy resolution was 1 meV with a

156 step size of 0.334 meV at beamline 3-IDB and 2 meV with a step size of 0.67 meV at

157 beamline 16-ID-D. Collection times were 3-5 s/step, for a total of ~1 hour per NRIXS

158 spectrum. At each pressure, 15-40 NRIXS spectra were collected and summed to make

159 sufficient signal-to-noise ratio (Fig. 1). The spectra at pressure below 60.9 GPa were

160 collected at 16 IDD while others were collected at 3-ID-B. The ranges of scanned

161 energy for each spectrum can be found in Fig. 1. These wide energy ranges are critical

162 for capturing the multi-phonon contributions to PDOS and reliable background removal

163 (Dauphas et al., 2018).

164   NRIXS data were processed using the software package *SciPhon* (Dauphas et al.,

165 2018). First the energy resolution function of the incident X-ray was used to

166 deconvolute the NRIXS spectrum and a linear background based on high-energy

167 (beyond ±100 meV) part of the spectrum was subtracted. The NRIXS spectrum was

168 then used to derive the phonon density of states (PDOS) of iron atoms in the lattice.

169 This derivation uses the harmonic approximation, which assumes the lattice potentials
170 are proportional to atomic displacement squared.

$(Mg_{0.46}Fe^{3+}_{0.53})(Si_{0.49}Fe^{3+}_{0.51})O_3$ Bridgmanite @ 300 K

171

172 **Figure 1.** NRIXS spectra of ^{57}Fe-enriched $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Fe^{3+}_{0.5})O_3$ bridgmanite sample at

173 300 K and high pressures. The peak at 0 meV corresponds to the recoilless elastic scattering,

174 while the other inelastic peaks origin from either phonon creation (E > 0) or annihilation (E <

175   0).

176

177   **2.3. First-principles calculations**

178   All calculations were performed using the Quantum Espresso package (Giannozzi

179   et al., 2009) based on density functional theory (DFT), plane wave, and pseudopotential.

180   The local density approximation (LDA) was adopted for the exchange correlation

181   function. The energy cutoff for plane waves was 70 Ry. The pseudopotentials for Mg,

182   Si, O, and Al were well described in our previous studies (Huang et al., 2013; Huang et

183   al., 2014; Wu et al., 2015a; Wang and Wu, 2018). The pseudopotential for Fe was

184   generated using the Vanderbilt method (Vanderbilt, 1990) with a valence configuration

185   of $3s^2 3p^6 3d^{6.5} 4s^1 4p^0$ and a cutoff radius of 1.8 Bohr. These pseudopotentials have been

186   successfully applied to predict the structures, vibrational properties, elasticity, and

187   equilibrium isotope fractionation of mantle silicate minerals including bridgmanite in

188   our previous studies (Núñez Valdez et al., 2012; Núñez-Valdez et al., 2013; Huang et

189   al., 2013; Huang et al., 2014; Feng et al., 2014; Wu et al., 2015b; Shukla et al., 2015;

190   Wang et al., 2017a; Wang et al., 2017b; Qian et al., 2018; Wang et al., 2019a). To

191   address the large on-site Coulomb interactions among the localized electrons (Fe 3d

192   electrons) (Anisimov et al., 1991), we introduced a Hubbard U correction to the LDA

193   (LDA+U) for all DFT calculations. U values for Fe^{2+} and Fe^{3+} on A- and/or B- sites in

194   bridgmanite are obtained from previous work (Hsu et al., 2010; Hsu et al., 2011), in

195   which values were non-empirically determined using linear response method

196   (Cococcioni and de Gironcoli, 2005). The U values for A-site Fe^{2+}, A-site HS Fe^{3+}, B-

197   site HS Fe^{3+}, B-site LS Fe^{3+} are 3.1 eV, 3.7 eV, 3.3 eV, and 4.9 eV, respectively. The

198   LDA+U method has been widely and successfully applied to predict the physical and

199   chemical properties of Fe-bearing Bdg and Fp (Hsu et al., 2011; Wu et al., 2013; Shukla

200   and   Wentzcovitch,   2016).   For $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Fe^{3+}_{0.5})O_3$

201    $(Mg_{0.9375}Fe^{3+}_{0.0625})(Si_{0.9375}Al_{0.0625})O_3$, and $(Mg_{0.75}Fe^{3+}_{0.25})(Si_{0.75}Al_{0.25})O_3$ Bdg, we

202   consider only configurations with the nearest neighbor $[Fe^{3+}]_{Mg}$-$[Fe^{3+}/Al^{3+}]_{Si}$ since they

203   are the lowest energy configurations (Hsu et al., 2011; Shukla and Wentzcovitch, 2016).

204   Crystal structures at variable pressures were optimized on a 6×6×4 k-point mesh, and

205   vibrational density of states (VDOS) were calculated using the finite displacement

206   method as implemented in the code PHONOPYT (Togo and Tanaka, 2015). At static

207   conditions, the B-site Fe^{3+} undergoes a HS-LS transition at ~52 GPa, consistent with

208   previous LDA+U calculations (Shukla and Wentzcovitch, 2016). This value is ~8 GPa

209   larger than the spin-transition pressure in $(Mg_{0.875}Fe^{3+}_{0.125})(Si_{0.875}Fe^{3+}_{0.125})O_3$ Bdg due

210   to the difference in Fe^{3+} content.

211   Reduced partition function ratios were computed from phonon frequencies

212   obtained from DFT calculations. The reduced partition function ratio β_A of the element

213   X in phase A, which represents the equilibrium isotope fractionation factor between the

214   phase A and an ideal gas of X atoms, can be expressed within the quasi-harmonic

215   approximation as:

$$\beta_A = \frac{Q_h}{Q_l} = \prod_i^{3N} \frac{u_{ih}}{u_{il}} \frac{e^{-\frac{1}{2}u_{ih}}}{1-e^{-u_{ih}}} \frac{1-e^{-u_{il}}}{e^{-\frac{1}{2}u_{il}}} \qquad (1)$$

217   where h and l refer to the heavy and light isotopes respectively; i is a running index for

218   the vibrational frequency, and N is the number of atoms in the unit cell. Q_h and Q_l

219   represent the vibrational partition function for the heavy and light isotopes, respectively.

220   Parameters u_{ih} and u_{il} are defined as:

$$u_{ih\ or\ il} = \hbar\omega_{ih\ or\ il}/k_B T \qquad (2)$$

222   Parameters $\hbar$ and k_B are the reduced Planck and Boltzmann constants, respectively;

223   T is temperature in Kelvin, and $\omega_{ih\ or\ il}$ is the vibrational frequency of the ith mode.

224   Notably, β in Eq. (1) is volume-dependent as phonon frequencies from the DFT+U

225   calculations are a function of volume. In order to express β as a function of pressure (P)

226   and temperature (T), we calculated the equation of state $V(P, T)$ from the Helmholtz

227   free energy, which can be written within the quasi-harmonic approximation as:

$$F(V,T) = U(V) + \frac{1}{2}\sum_{q,m}\hbar\omega_{q,m}(V) + k_B T \sum_{q,m} ln\left(1 - exp\left(-\frac{\hbar\omega_{q,m}(V)}{k_B T}\right)\right) \quad (3)$$

229   where q is a wave vector in the Brillouin zone and m is a running index of phonon mode.

230   The first, second, and third terms in Eq. (3) correspond to the static, zero-point, and

231   vibrational energy contributions, respectively. The calculated Helmholtz free energy

232   versus volume was fitted by the third-order Birch–Murnaghan finite strain equation of

233   state. Consequently, the pressure- and temperature-dependent β can be derived and the

234   equilibrium isotope fractionation factor between two Phases A and B can be obtained

235   in per mil (‰) as:

$$\Delta_{A-B} \approx 10^3 ln\alpha_{A-B} = 10^3 ln\beta_A - 10^3 ln\beta_B \qquad (4)$$

Figure 2. Representative partial phonon density of states (PDOS) of Fe^{3+} in $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Fe^{3+}_{0.5})O_3$ bridgmanite derived from both NRIXS measurements and DFT+U calculations. The open circles are the averaged PDOS of all Fe ions in the Bdg measured by NRIXS; (a): 32.5 GPa, (b): 101.4 GPa. The blue dotted, red dashed, and green dashed curves are the PDOS of A-site HS Fe^{3+}, B-site HS Fe^{3+} and B-site LS Fe^{3+} from DFT+U calculations, respectively. The black curves represent best-fit linear mixing model between DFT+U calculated PDOS of the A-site and B-site Fe^{3+}. The best-fit ratio of the weights is 50:50 for A-site and B-site HS Fe^{3+} PDOS in (a); the ratio changes to 70:30 for A-site HS and B-site LS Fe^{3+} PODS in (b).

3. Results

3.1 Partial phonon density of state of Fe in bridgmanite

For all pressures investigated, the calculated PDOS of Fe agree well with experimental PDOS (Fig. 2 and S1). Theoretical calculations provide the PDOS of the A-site and B-site Fe^{3+} individually, while the PDOS of Fe in $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Fe^{3+}_{0.5})O_3$ Bdg derived from NRIXS measurements is a sum of

255 contributions from both A-site and B-site Fe^{3+}. Comparisons between experimental

256 observations of the PDOS, predictions for individual sites, and best-fit weighted

257 average of calculated PDOS are shown for two representative pressures (Fig. 2). In

258 theory, the ratio of A-site and B-site Fe^{3+} contributions to the final PDOS is the

259 concentration ratio, 50:50. At ~30 GPa, the dominant peaks in the predicted PDOS of

260 the A-site and B-site HS Fe^{3+} are located at ~17-31 meV and 17-43 meV, respectively

261 (Fig. 2a). A 50-50 average of these calculated PDOS for A-site HS Fe^{3+} and B-site HS

262 Fe^{3+} by DFT+U matches well with the experimental PDOS (Fig. 2a). This is in good

263 agreement with the X-ray emission spectroscopy analysis that Bdg is 100% HS at this

264 pressure (Liu et al., 2018). At ~100 GPa, DFT+U calculations indicate that the transition

265 of B-site HS Fe^{3+} to LS state significantly change the PDOS: compared with the B-site

266 HS Fe^{3+}, the predicted PDOS of the B-site LS Fe^{3+} is narrower and the dominant peaks

267 are located at higher energies by ~11.7 meV (Fig. 2b). Accordingly, NRIXS

268 observations demonstrate a shift of the major peak to higher energy, from ~25 meV at

269 30 GPa to ~30 meV at 100 GPa, and an increase in intensity at ~45 meV due to this B-

270 site LS Fe^{3+} component. In order to match experimentally derived PDOS, the best

271 weights of the calculated PDOS of A-site HS Fe^{3+} and B-site LS Fe^{3+} are 70:30 (Fig.

272 2b). This difference in weight ratio implies that the inelastic component of B-site LS

273 Fe^{3+} from NRIXS measurements is significantly reduced across the spin transition. This

274 is also consistent with the pressure dependence of the Lamb-Mössbauer factor (f)

275 derived from NRIXS spectra (Fig. S2), which is directly controlled by the inelastic

276 component ($S_{inelastic}$) in the NRIXS spectra (Dauphas et al., 2018):

277 $$f_{LM} = 1 - \int_{E_{min}}^{E_{max}} S_{inelastic}(E)dE \quad (5)$$

278 Across the spin transition of B-site Fe^{3+} in $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Fe^{3+}_{0.5})O_3$ Bdg, the linear

279 slope of f_{LM} with respect to pressure increases from $6.7e^{-4}$ GPa^{-1} at 25-60 GPa to $1.6e^{-3}$

280 GPa^{-1} at ~60-70 GPa and changes to $3.7e^{-4}$ GPa^{-1} above ~70 GPa. Accounting for the

281 change in the inelastic scattering profile of LS Fe^{3+}, NRIXS experiments and DFT+U

282 calculation agree with complementary X-ray diffraction and X-ray emission

283 spectroscopy observations about the conditions of the spin transition in Bdg.

284

285 **3.2 Force constant of Fe and β-factors of $^{56}Fe/^{54}Fe$ for bridgmanite**

286   From experimental and theoretical PDOS, the force constant of iron $<F>$ and the

287   β-factors of $^{56}Fe/^{54}Fe$ for $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Fe^{3+}_{0.5})O_3$ Bdg can be obtained within the

288   harmonic approximation by following Eq. (6) and Eq. (7) (Dauphas et al., 2012):

289
$$<F> = \frac{M}{\hbar^2} \int_0^{+\infty} E^2 g(E) dE \qquad (6)$$

290
$$10^3 ln\beta = 1000 \left(\frac{1}{M^{54Fe}} - \frac{1}{M^{56Fe}} \right) \frac{\hbar^2}{8k^2T^2} <F> \qquad (7)$$

291   Here $g(E)$ is PDOS, M is the mass of a ^{54}Fe or ^{56}Fe nucleus, k is Boltzmann's constant

292   and T is temperature in Kelvin. We find that $<F>$ obtained from calculated PDOS are

293   significantly larger than those calculated from experimental PDOS (Fig. 3), especially

294   at pressures > 60 GPa, although the calculated PDOS match well with experimental

295   PDOS (Fig. 2 and S1). To find out the factors that result in the $<F>$ differences, we

296   calculated the evolution of $<F>$ by changing the upper limit of energy (x) for the

297   integration by following Eq. (8):

298
$$<F> = \frac{M}{\hbar^2} \int_0^x E^2 g(E) dE, \ (x \text{ increases from 0 to } +\infty) \qquad (8)$$

299   As shown in Fig. 4, the integral values of $<F>$ from calculated PDOS agree well with

300   those from experimental PDOS until energy for the integration reaches a threshold,

301   above which the predicted $<F>$ still increases with x but the experimental one

302   maintains a constant value (Fig. 4). This is mainly because the experimental PDOS

303   intensity becomes indistinguishably close to zero due to the low signal noise ratio when

304   energy is larger than 85 meV at 32.5 GPa and 110 meV at 101.4 GPa, while the

305   predicted PDOS from DFT+U still have small non-zero values at these high-energy

306   parts (Fig. 2). Amplified by the integral $E^2 g(E)$, the small discrepancies in PDOS lead

307   to significant differences in the final $<F>$ by ~ 60 N/m at ~ 30 GPa and ~ 154 N/m at

308   100 GPa. Similarly, the predicted PDOS of A-site Fe^{3+} and Fe^{2+} in Bdg also agree well

309   with experimental measurements (Yang et al., 2019), but the $<F>$ from DFT+U are

310   larger than experimental values, especially at high pressures (Fig. S3 and S4). In

311   contrast, both of the calculated PDOS and $<F>$ of LS Fe in Fp agree well with

312   experimental results (Fig. S5). As a consequence, we use theoretical results of Bdg in

313   this study and experimental data of HS and LS Fp from Yang et al. (2019) for further

314   modelling and discussion.

315   Blanchard et al. (2015) found that compared to NRIXS, the DFT calculations

316   within GGA/GGA+U underestimate the <F> of iron in goethite. However, in their DFT

317   calculations, the cell parameters of goethite were fixed to their experimental values and

318   only atomic positions were relaxed. Because the GGA usually overestimates the volume,

319   this incorrect strategy would put artificial stress on the structure and the true pressure

320   from the GGA calculations should be higher than ambient pressure (Wang et al., 2017a;

321   Wang et al., 2019b). This indicates that the iron <F> in Blanchard et al. (2015) was

322   overestimated by their GGA/GGA+U calculations, and thus the <F> difference

323   between NRIXS and DFT was underestimated. The discrepancy between NRIXS and

324   GGA/GGA+U is mainly because the GGA underestimates the vibrational frequencies

325   (Schauble, 2011), shifting the PDOS to lower values.

326   The changes of PDOS by different cation sites and spin states of Fe^{3+} result in

327   variations in the corresponding <F> and β-factors. For instance, as the PDOS of B-site

328   HS Fe^{3+} concentrates at higher energy range compared with the corresponding A-site

329   HS Fe^{3+} (Fig. 2 and S1), <F> and β-factors are thus higher for HS Fe^{3+} in the B-site

330   than that in the A-site (Fig. 3 and Fig. 5). Notably, across the spin transition of the B-

331   site Fe^{3+} in $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Fe^{3+}_{0.5})O_3$ Bdg at ~ 60 GPa, the <F> and β-factors of B-

332   site Fe^{3+} increases by ~65%.
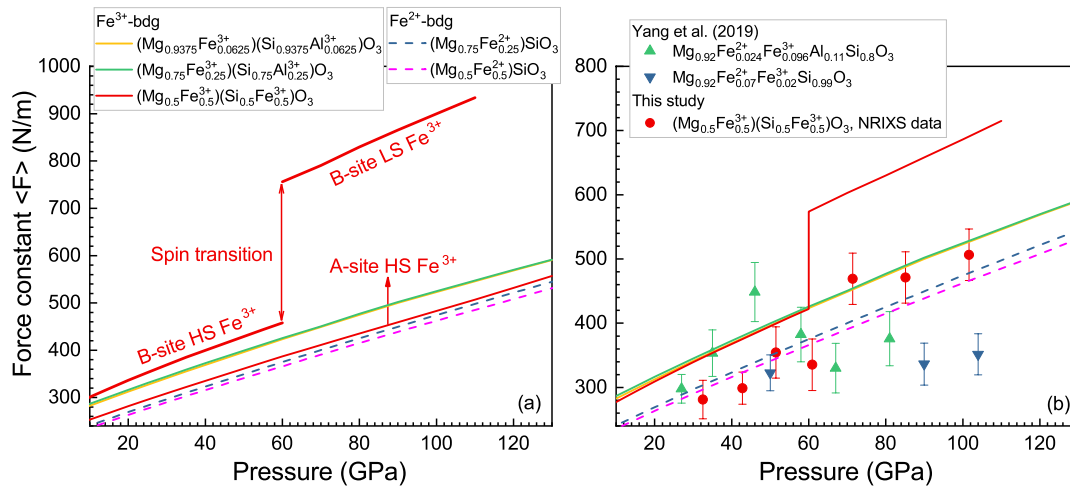

334   **Figure 3.** Force constant <F> of iron in Bdg from DFT+U calculations. **(a)** <F> of A-site Fe^{2+},

335   A-site Fe^{3+}, and B-site Fe^{3+} in Bdg. Compared with the <F> of A-site Fe^{2+}, those of both A-site

336   and B-site Fe^{3+} in Bdg are higher at the same pressure. Across the spin transition of the B-site

337   Fe^{3+} in $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Fe^{3+}_{0.5})O_3$ Bdg at ~ 60 GPa, the <F> of B-site Fe^{3+} increases by ~65%.

338   **(b)** comparisons of in <F> Bdg between theoretical and experimental results (Yang et al., 2019).

339 Although PDOS of Fe in Bdg from DFT+U agree well with experimental measurements (Fig.

340 2, Fig. S1, and Fig. S3-S4), the predicted $<F>$ are significantly larger than those from

341 experimental PDOS, especially at high pressures.

(Mg$_{0.5}$Fe$^{3+}_{0.5}$)(Si$_{0.5}$Fe$^{3+}_{0.5}$)O$_3$ Bridgmanite @ 300 K
Figure 4. Evolution of $<F>$ of Fe^{3+} in (Mg$_{0.5}$Fe$^{3+}_{0.5}$)(Si$_{0.5}$Fe$^{3+}_{0.5}$)O$_3$ Bdg with the upper limit of

344 energy (x) for the integration $< F >= \frac{M}{\hbar^2}\int_0^x E^2 g(E)dE$. The integral values of $<F>$ from

345 DFT+U calculations agree well with experimental results when x reaches a threshold, above

346 which the predicted $<F>$ still increases with x but the experimental one maintains a constant

347 value.

348

349   On the other hand, the β-factors can be also calculated from Eq. (1) within the

350 quasi-harmonic approximation (Urey equation). Following Bigeleisen and Mayer

351 (1947) and Kowalski et al. (2013), when the β-factor is expressed by the Taylor

352 expansions and the higher order terms are not taken into account, the Urey equation can

353 be then approximated by Eq. (7). The validity criteria restricts the usage of Eq. (6) to

354 frequencies $\nu [cm^{-1}] \leq 1.39T [K]$ (Bigeleisen and Mayer, 1947; Kowalski et al.,

355 2013). Here we calculated the β-factors of Bdg with different chemical compositions

356   from their full phonon vibrational spectra using Eq. (1). Our calculated results show

357   that the $10^3\ln\beta$ of Bdg decreases in the order of LS-$(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Fe^{3+}_{0.5})O_3$ > HS-

358      $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Fe^{3+}_{0.5})O_3$ > $(Mg_{0.9375}Fe^{3+}_{0.0625})(Si_{0.9375}Al^{3+}_{0.0625})O_3$ $\approx$

359      $(Mg_{0.75}Fe^{3+}_{0.25})(Si_{0.75}Al_{0.25})O_3$ > $(Mg_{0.75}Fe^{2+}_{0.25})SiO_3$ $\approx$ $(Mg_{0.5}Fe^{2+}_{0.5})SiO_3$ within

360   calculated pressure range. At 60 GPa and 1000 K, it varies from 1.58‰ for LS-

361      $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Fe^{3+}_{0.5})O_3$ to 0.98‰ for $(Mg_{0.5}Fe^{2+}_{0.5})SiO_3$ Bdg (Fig. 5a). Rustad and

362   Yin (2009) also calculated the β factor of Fe^{2+}-bearing Bdg using molecular clusters

363   and the $10^3\ln\beta$ of $^{56}Fe/^{54}Fe$ is ~1.44 ‰ at 120 GPa and 1000 K, similar to our predictions

364   (1.42 ‰). However, it should be noted that the modelling of crystals using molecular

365   clusters breaks the intrinsic periodic boundary of crystals.

366

367

368   **Figure 5.** Comparisons between the $^{56}Fe/^{54}Fe$ β-factors and the Fe-O bond length of bdg at 30-

369   100 GPa and 1000 K for different compositions in DFT+U calculations. (**a**) Compared with the

370   β-factors of Fe^{2+} in the A-site of Bdg, those of both A-site and B-site Fe^{3+} in Bdg are higher at

371   the same P-T condition. Across the spin transition of the B-site Fe^{3+} in

372      $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Fe^{3+}_{0.5})O_3$ Bdg at ~ 60 GPa, the $^{56}Fe/^{54}Fe$ β-factor of B-site Fe^{3+} at 1000 K

373   increases by 0.835‰. (**b**) The average Fe-O bond lengths in Bdg with different compositions

374   at static conditions. Across the spin transition of B-site Fe^{3+} in $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Fe^{3+}_{0.5})O_3$ Bdg

375   at ~ 60 GPa, the lengths of A-site and B-site Fe^{3+} decrease by 0.014 Å and 0. 0.072 Å,

376   respectively. In contrast, the concentration effect on both A-site Fe^{2+}-O and A-site Fe^{3+}-O bond

377   lengths in Bdg is negligible.

378

4. Discussion

4.1 Effects of site occupancy, spin transition, chemical composition, and valence state on β-factors of Bdg

The pressure dependences of β-factors of Bdg are controlled by multiple factors as shown in Fig. 2a. Here we show the β-factors anchored at 1000 K as a representative temperature to address these effects since the factors are almost linearly proportional to $1/T^2$ at different pressures (Fig. S6). In $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Fe^{3+}_{0.5})O_3$ Bdg, compared to the A-site HS Fe^{3+}, B-site HS Fe^{3+} has a higher β-factor and the difference between two sites is ~0.17‰ at 40 GPa and 1000 K (Fig. 5a). This is also consistent with the much shorter bond lengths, and correspondingly higher bond strength, of Fe^{3+}-O in the 6-coordinated B-site relative to the 8-coordinated A-site (Fig. 5b). B-site Fe^{3+} in Bdg is expected to undergo a HS to LS transition at middle-mantle depths (Catalli et al., 2010; Hsu et al., 2011; Mao et al., 2015; Shukla and Wentzcovitch, 2016; Fu et al., 2018b; Liu et al., 2018). The spin transition of the B-site Fe^{3+} in $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Fe^{3+}_{0.5})O_3$ Bdg occurs at ~ 50 GPa (Liu et al., 2018), which leads to shortening of the average B-site Fe^{3+}-O bonds by 0.072 Å, equal to 3.8% relative change (Fig. 5b). Such a change in the average Fe-O bond induces an increase of 0.83‰ in the β-factor of B-site Fe^{3+} at 1000 K and 0.21‰ at 2000 K (Fig. S6). However, the spin transition of the B-site Fe^{3+} does not significantly change the A-site Fe^{3+}-O bonds and the β-factor of A-site Fe^{3+}. Thus, the contrast between the β-factors of B-site and A-site Fe^{3+} is also strongly enhanced by the Fe spin transition in the B-site from 0.19‰ to 1.01‰ at 1000 K and 60 GPa (Fig. 5a).

The presence of Al in Bdg will weaken the effect of B-site Fe^{3+} spin transition on its β-factor by preventing Fe^{3+} from occupying the B-site. Depending on the bulk Al/Fe^{3+} molar ratio, Al^{3+} can either occupy the B-site only with Fe^{3+} filling in the A-site or it occupies both the B-site and the available A-site left by A-site Fe^{3+} (Lin et al., 2013; Liu et al., 2015). For Al/Fe^{3+} molar ratio equal to 1, all Fe^{3+} would occupy the A-site and all Al stays in the B-site. Here we calculated the β-factors of three Fe^{3+}- and Al-bearing Bdg with different $FeAlO_3$ concentration at 1000 K to illustrate the compositional dependence of both Fe^{3+}-O bond length and the β-factor of $^{56}Fe/^{54}Fe$ (Fig. 5a). Our results show that the incorporation of 6.25-50 mol% $FeAlO_3$ into Bdg only

410 changes the A-site Fe^{3+}-O bond length by 0-0.007 Å under lower-mantle pressures (Fig.

411 5b). As the Fe-O bond length controls the magnitude of the corresponding β-factor (Fig.

412 S7), the effect of $FeAlO_3$ concentration on the β-factors of the A-site Fe^{3+} is

413 insignificant. For example, the largest difference in the β-factor of Al^{3+}- and Fe^{3+}-

414 bearing Bdg $(Mg_{0.9375}Fe^{3+}_{0.0625})(Si_{0.9375}Al^{3+}_{0.0625})O_3$, $(Mg_{0.75}Fe^{3+}_{0.25})(Si_{0.75}Al_{0.25})O_3$,

415 and $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Al^{3+}_{0.5})O_3$ is smaller than 0.06‰ at 1000 K and all pressures (Fig.

416 5a). In contrast, the β-factor of A-site Fe^{3+} in $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Al^{3+}_{0.5})O_3$ Bdg is ~ 0.14‰

417 larger than that of A-site Fe^{3+} in $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Fe^{3+}_{0.5})O_3$ Bdg, consistent with

418 relatively shorter Fe^{3+}-O bonds in the A site of $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Al^{3+}_{0.5})O_3$ Bdg (Fig.

419 5b). This reveals that the speciation of B-site ion (Fe^{3+} or Al^{3+}) also has a mild effect on

420 the A-site Fe^{3+}-O bond strength and its β-factor. However, such an effect of Al on A-

421 site Fe^{3+} β-factor is much weaker than the influence of spin transition and can be further

422 diminished by mantle high temperatures, which results in only 0-0.01‰ difference in

423 β-factor along the normal lower-mantle geotherm (Fig. 6). As long as some Fe^{3+}

424 occupies the Bdg B-site, the change in β-factor due to the spin transition is independent

425 of the identity of other ions on A- and B-site. Therefore, although Al^{3+} incorporation

426 itself does not change the Bdg structure enough to impact isotopic fractionation, it

427 prevents Fe^{3+} from occupying the B-site and thus reduces the significant impact of B-

428 site Fe^{3+} spin transition on the β-factor of Bdg.

429   In addition to Fe^{3+}, the A site in Bdg is also large enough to accommodate Fe^{2+},

430 which maintains a HS state in Bdg throughout the lower mantle. The Fe^{2+}-bearing Bdg

431 compositions in our DFT+U calculations, $(Mg_{0.5}Fe^{2+}_{0.5})SiO_3$ and $(Mg_{0.75}Fe^{2+}_{0.25})SiO_3$,

432 have the smallest β-factors that are also insensitive to the Fe^{2+} content (Fig. 5a). This

433 difference in β-factor between A-site Fe^{3+} and Fe^{2+} ranges from 0.04‰ to 0.15‰ at

434 1000 K (Fig. 5a) but will be diminished along an expected geotherm of the lower mantle

435 (Fig. 6). In particular, the β-factor increases with pressure along the adiabat, because

436 the increase due to compression outweighs the decrease from the $1/T^2$ dependence. The

437 enrichment of light Fe isotopes in Fe^{2+}-bearing Bdg relative to other Fe^{3+}-bearing

438 species is mainly caused by the longer Fe^{2+}-O bond lengths than those Fe^{3+}-O bonds

439 (Fig. 5b and S7). Moreover, the valence state also partially contributes to the smaller β-

440 factors of Fe^{2+}-bearing Bdg as revealed by the longer Fe-O bond length of HS A-site

441   Fe^{2+} than that of HS A-site Fe^{3+} (Fig. S7). In summary, the pressure- and temperature

442   dependent β-factor of $^{56}Fe/^{54}Fe$ for Bdg is controlled by the Fe^{3+}/Fe^{2+}, Al/Fe^{3+}, and spin

443   transition if there is some Fe^{3+} accommodated in B site.
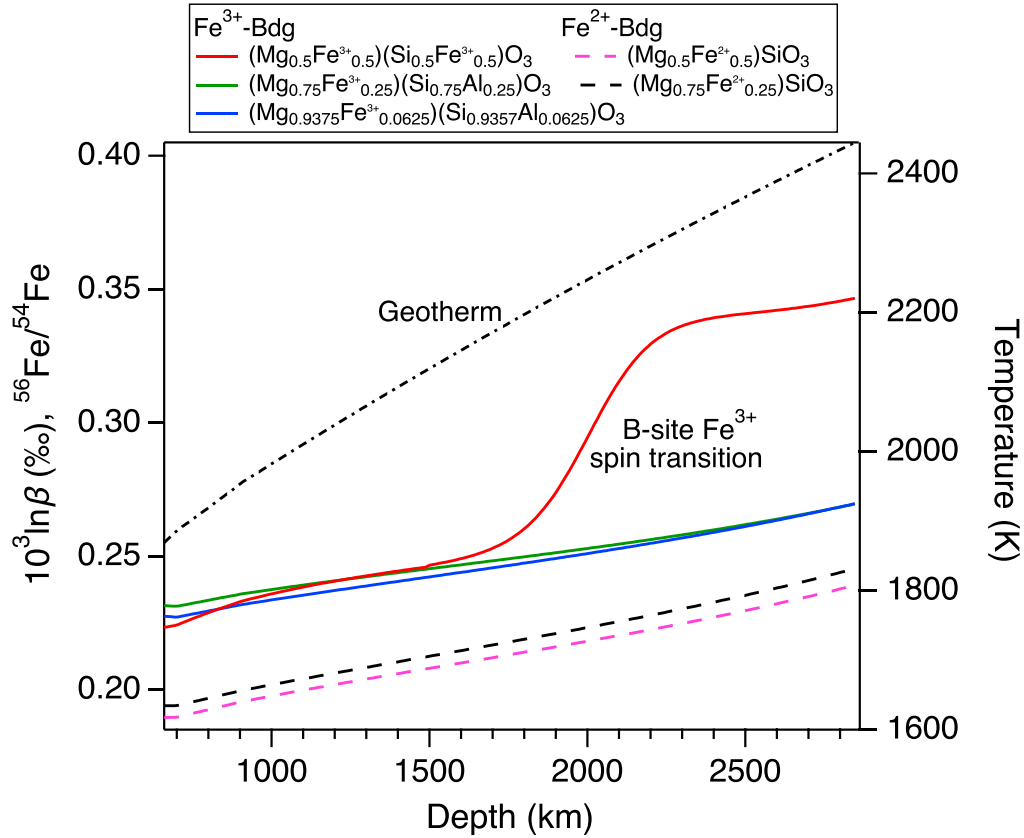

444

Figure 6. $^{56}Fe/^{54}Fe$ β-factors of various Bdg compositions computed by DFT+U along an adiabat representative of the average lower mantle. As the B-site Fe^{3+} undergoes high-spin to low-spin transition, the $^{56}Fe/^{54}Fe$ β-factor of $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Fe^{3+}_{0.5})O_3$ Bdg increases by ~0.09‰ across the spin transition of the B-site Fe^{3+}. The expected geotherm (dot dash line) was taken from Brown and McQueen (1986).

451

4.2 Fe isotopic fractionation in the deep mantle

4.2.1 Inter-mineral iron isotope fractionation

454   The $^{56}Fe/^{54}Fe$ β-factor of Bdg and Fp as a function of depth in likely bulk mantle

455   compositions can be used to estimate fractionation of Fe isotopes in the deep Earth. The

456   depth-dependence of Fe isotopic fractionation between Bdg and Fp in the lower mantle

457   is modelled based on the following equations:

$$\Delta^{56}Fe_{Bdg-Fp} = \delta^{56}Fe_{Bdg} - \delta^{56}Fe_{Fp} \qquad (9)$$

$$\delta^{56}Fe_{LM} = n_{Bdg} \times \delta^{56}Fe_{Bdg} + n_{Fp} \times \delta^{56}Fe_{Fp} \qquad (10)$$

where $\delta^{56}Fe_{Bdg}$, $\delta^{56}Fe_{Fp}$, and $\delta^{56}Fe_{LM}$ are the Fe isotopic compositions of Bdg, Fp, and the bulk lower mantle, respectively. $\delta^{56}Fe_{LM}$ is set to 0 as the representative chondritic value (Craddock and Dauphas, 2011). n_{Bdg} and n_{Fp} are the Fe fractions in Bdg and Fp (Table S1), respectively, based on a pyrolitic lower mantle composition (Irifune et al., 2010). The pressure effect, including the pressure-induced spin transition, is taken into account on the evaluation of β-factors of Bdg and Fp.

Previous studies (Wang et al., 2015; Zhang et al., 2016; Wu, 2016) suggested that the lower mantle may be represented by a pyrolitic composition with ~ 8 wt% FeO and a Al/Fe ratio ~0.8 (McDonough and Sun, 1995). The lower-mantle $Fe^{3+}/\Sigma Fe$ ratio range was thought to be higher than 0.5 (Frost and McCammon, 2008), and the $Fe^{3+}/\Sigma Fe$ ratio of Bdg could be 0.5-1 for most part of the lower mantle (Wang et al., 2015). Because the site occupancy of Fe^{3+} is controlled by Al^{3+}/Fe^{3+} ratios (Frost et al., 2004; Lin et al., 2013; Liu et al., 2015; Liu et al., 2018), we consider three different endmembers for Bdg compositions: (1) Fe^{3+}- and Al^{3+}-free, Fe^{2+}-bearing; (2) Fe^{3+}- and Al^{3+}-bearing (3) Fe^{3+}-bearing but Al^{3+}-free (Fig. 7). These three endmembers demonstrate the range of possible compositional effects on Fe isotopic compositions of Bdg and Fp in the lower mantle:

1) For a simplified Fe^{3+}- and Al^{3+}-free, Fe^{2+}-bearing system, the major factor that impacts Fe-O bonds and Fe isotopic fractionation is the spin transition of Fe^{2+} in Fp at mid-lower-mantle depths. In this system, there is no significant iron fractionation between Bdg and Fp ($\Delta^{56}Fe_{Bdg-Fp}$ = 0-0.02‰) below 60 GPa. The spin transition occurs only in Fp at ~60-120 GPa, and increases the β-factor of Fp. This effect significantly decreases $\Delta^{56}Fe_{Bdg-Fp}$ from 0‰ at ~ 60 GPa to -0.17‰ at ~ 120 GPa (Fig. 7a). As a result, Fp would be enriched in ^{56}Fe with $\delta^{56}Fe_{Fp}$ up to 0-0.08‰ below mid-lower mantle and $\delta^{56}Fe_{Bdg}$ would be as low as -0.07‰ (Fig. 7b).

2) For a more realistic Fe^{3+}- and Al^{3+}-bearing system with the Fe^{3+}/Al ratio of < 1, our computational results suggest that the presence of Fe^{3+} in the Bdg A-site increases the β-factor of Bdg by 0.03-0.04‰ along an expected geotherm (Fig.

489   6). No significant difference across the spin transition of B-site Fe^{3+} in Bdg is

490   expected in this composition relative to the Fe^{3+}- and Al^{3+}-free, but Fe^{2+}-bearing

491   system. Therefore, $\Delta^{56}Fe_{Bdg-Fp}$ of the Fe^{3+}- and Al^{3+}-bearing system is ~0.03-

492   0.04‰ higher than that of the simplified Fe^{3+}- and Al^{3+}-free, Fe^{2+}-bearing

493   system (Fig. 7a). In this case, $\Delta^{56}Fe_{Bdg-Fp}$ decreases from +0.05‰ in the upper

494   part of the lower mantle to -0.15‰ in the deeper part (Fig. 7b). This results in

495   $\delta^{56}Fe_{Bdg}$ of +0.02‰ in the uppermost lower mantle but the number decreases to

496   ~ -0.07‰ in the lowermost lower mantle (Fig. 7b).

497   3) In a Fe^{3+}- bearing but Al^{3+}-free system, the spin transitions of both Fe^{2+} in Fp

498   and B-site Fe^{3+} in Bdg are expected to occur at the middle mantle depths and

499   extend to the deeper part (Fig. 7a). Consequently, $\Delta^{56}Fe_{Bdg-Fp}$ in Fe^{3+}- bearing

500   and Al^{3+}-free system is significantly higher than the other two systems beneath

501   the middle mantle depths (Fig. 7a). The spin transition in B-site Fe^{3+} of Bdg

502   results in $\delta^{56}Fe_{Bdg}$ as high as +0.04‰ in the middle mantle depth, which

503   decreases to -0.03‰ in the lowermost lower mantle (Fig. 4b).

504   In a pyrolitic lower mantle, Fe^{3+} is generally not expected to occupy the B-site of

505   Bdg as the Al/Fe^{3+} ratios of synthesized Bdg samples from pyrolitic starting materials

506   are consistently higher than 1 (summarized in Shim et al., 2017). Harzburgite has a

507   similar iron content but less Al_2O_3 content (~0.6%) compared to pyrolite (Irifune and

508   Ringwood, 1987) and its $Fe^{3+}/\Sigma Fe$ ratio is usually < 5% (Canil and O'Nell, 1996;

509   Woodland et al., 2006). As such, the Fe^{3+}/Al ratio in harzburgite is typically < 0.5 and

510   no Fe^{3+} would occupy the B-site of Bdg when Bdg crystallizes from a harzburgitic

511   composition. Therefore, the $\Delta^{56}Fe_{Bdg-Fp}$ in a pyrolitic or harzburgitic composition is

512   similar to the results in scenarios (1) and (2). On the other hand, Fe^{3+}-rich materials

513   (such as banded iron formation and goethite) could be carried to the lower mantle by

514   subducted slabs, resulting in local chemical heterogeneous regions enriched in Fe^{3+}.

515   Under such a scenario, Bdg may have much lower Al content and higher Fe^{3+} content,

516   and therefore more Fe^{3+} could occupy both the A-site and B-site by the coupled

517   substitution mechanism (Frost et al., 2004; Liu et al., 2015; Shim et al., 2017; Liu et al.,

518   2018). Compared with Fe^{3+}- and Al^{3+}-bearing Bdg forming in a pyrolitic composition,

519   the spin transition of the B-site Fe^{3+} in Bdg would increase $\Delta^{56}Fe_{Bdg-Fp}$ by as much as

520   0.08‰ (Fig. 7b), which slightly exceeds the highest precision measurements of δ^{56}Fe

521   (~ 0.03‰, Sossi et al., 2015). Overall, Fe isotopic fractionation between Bdg and Fp is

522   insignificant in most parts of the lower mantle, except the lowermost parts (Fig. 7). In

523   the upper and middle part of the lower mantle, the stronger Fe-O bond strength in Fe^{3+}-

524   enriched Bdg would only enrich Bdg in ^{56}Fe with δ^{56}Fe$_{Bdg}$ as high as +0.02‰, with

525   correspondingly indistinguishable Δ^{56}Fe$_{Bdg-Fp}$ in these depths based on the highest

526   precision of MC-ICP-MS measurements (~ 0.03‰, Sossi et al., 2015). In the lowermost

527   lower mantle, the spin transition of Fe^{2+} in Fp would lead to the enrichment of heavy

528   Fe in Fp with Δ^{56}Fe$_{Bdg-Fp}$ as low as -0.15‰ in a pyrolitic composition. For the Fe^{3+}-rich

529   but Al-poor system, the spin transition of B-site Fe^{3+} in Al-poor Bdg would diminish

530   Δ^{56}Fe$_{Bdg-Fp}$, making the Fe isotopic compositions of the coexisting oxidized Bdg and Fp

531   indistinguishable (Fig. 7b). Therefore, the magnitude of Δ^{56}Fe$_{Bdg-Fp}$ in a pyrolitic

532   composition would probably exceed the technical resolution for Fe isotope

533   measurements in the lowermost lower mantle, whereas no significant Δ^{56}Fe$_{Bdg-Fp}$ would
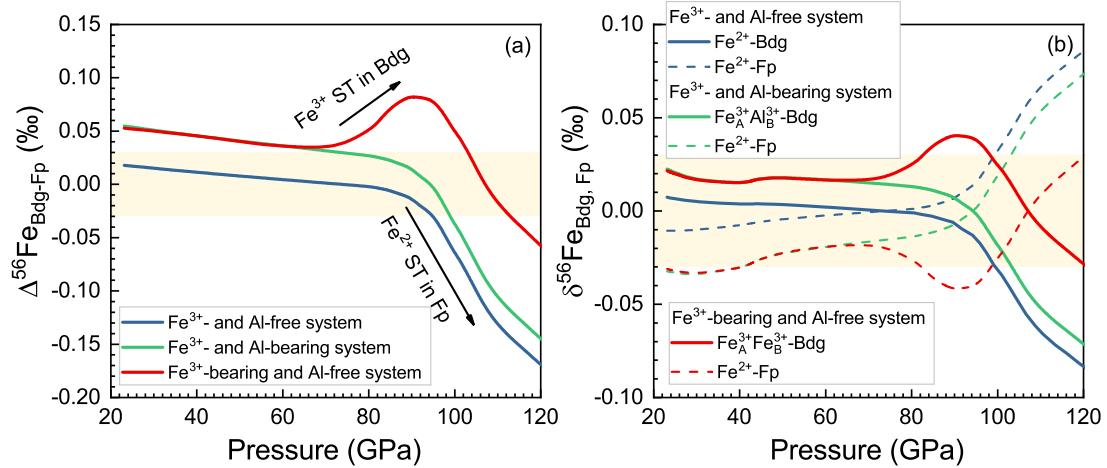

534   be found in the Fe^{3+}-rich but Al-poor system.

535

537   **Figure 7.** Equilibrium ^{56}Fe/^{54}Fe isotopic fractionation between coexisting Bdg and Fp (a) and

538   the corresponding Fe isotopic compositions of these two phases (b) along an expected geotherm

539   (Brown and McQueen, 1986). Solid and dash lines in (b) represent Fe isotopic compositions of

540   Bdg and Fp, respectively. Three compositional assemblages are considered: Fe^{3+}-bearing but

541   Al-free system (red curves); Fe^{3+}- but Al-bearing system (green curves) and Fe^{3+}- and Al-free

542   system (blue curves). The light yellow areas represent the best resolution of MC-ICP-MS

543   measurements (~ 0.03‰, Sossi et al., 2015). The spin transition (ST) of Fe^{2+} in Fp would occur

544 at the middle depth of the lower mantle, where only the B-site Fe^{3+} in Bdg would undergo a HS

545 to LS transition at ~60 GPa.

546

4.2.2 Iron isotope fractionation during magma ocean crystallization

548 In addition to the possible Fe isotope fractionation between solid phases, how Fe

549 isotopes would be fractionated between silicate melts and minerals during magma

550 ocean crystallization (Boukaré et al., 2015) is also important for understanding the

551 variability in iron isotopic composition in deep mantle (Yang et al., 2019). Based on the

552 *<F>* of solid phases and basaltic glass, Yang et al. (2019) investigated the evolution of

553 Fe isotopic fractionation during terrestrial magma ocean crystallization and found no

554 significant Fe fractionation between minerals and silicate melts. Here, following the

555 model proposed in Yang et al. (2019), we also revaluated the Fe isotope fractionation

556 between Bdg+Fp and silicate melts during magma ocean crystallization using the *<F>*

557 of Bdg from DFT+U calculations in this study. The <F> of solid phase was calculated

558 from the <F> of Fp and Bdg using $<F>_{sum}=n_{Fp}*<F>_{Fp}+n_{Bdg}*<F>_{Bdg}$, where n_{Fp} and n_{Bdg}

559 are the fractions of iron in Fp and Bdg in the solid phase, respectively, and $n_{Fp}+n_{Bdg}=1$.

560 The *<F>* of basaltic glass extrapolated to 130 GPa was used as an analogue to basaltic

561 melts (Liu et al., 2017). The chemical compositions of solid aggregates and the residual

562 melt were calculated after each 1 wt% increment of crystallization and can be found in

563 Yang et al. (2019). Fractional crystallization and a mass-balance relationship were used

564 in the model. For the ith separation of solids, the isotopic composition of solids

565 equilibrated with the residual melt can be calculated by $\delta^{56}Fe_{solids-i+1}=\delta^{56}Fe_{melts-}$

566 $_i+\Delta^{56}Fe_{solids-melts}$. Based on the isotopic mass balance, we have:

567 $\delta^{56}Fe_{melts-i+1}=[\delta^{56}Fe_{melts-i}-(\delta^{56}Fe_{melts-i}+\Delta^{56}Fe_{solids-melts})*n_{solid}]/(1-n_{solids})$ (11)

568 $\delta^{56}Fe_{solids-i+1}=-\delta^{56}Fe_{melts-i+1}*n_{melts}/(1-n_{melts})$ (12)

569 where n_{solids} is the fraction of iron taken up by solids at each step and n_{melts} is the fraction

570 of total iron in the remaining melt. We note that the chemical composition of residual

571 melt would be dominated by FeO (Fe/(Fe+Mg) > 60%) when the fraction of melt is

572 lower than 10% with temperature decreasing to 4200 K (Figure 7 in Boukaré et al.,

573 2015). At this stage, the *<F>* of basaltic glass may not be used as an analogue to silicate

574 melts due to the large difference in chemical compositions, and we stopped the

575   simulations.

576   Our results show that silicate melts are isotopically lighter than Bdg+Fp but the

577    $\Delta^{56}Fe_{solids-melts}$ are smaller than +0.03‰ for Fe^{2+}-bearing and Fe^{3+}-free systems and

578   Fe^{3+}- and Al^{3+}-bearing system. As Fe^{3+} is generally not expected to occupy the Bdg B-

579   site in a pyrolitic lower mantle with the Al/Fe^{3+} ratios of higher than 1, it can be

580   concluded that no significant Fe isotope fractionation between Bdg+Fp and silicate melt

581   has been produced during the crystallization process. For the Fe^{3+}-bearing but Al-poor

582   system, $\Delta^{56}Fe_{solids-melts}$ could be up +0.06‰, if we also used the $<F>$ of basaltic melts

583   as an analogue to Fe^{3+}-rich melts. However, Fe^{3+}-rich melts should be expected to be

584   enriched in heavy Fe isotopes relative to the Fe^{2+}-rich one (Dauphas et al., 2014),

585   because the $<F>$ of Fe^{3+}-bearing silicate glass is ~150 N/m larger than that of Fe^{2+}-

586   bearing silicate glass (Dauphas et al., 2014). As a result, the $<F>$ of Fe^{3+}-rich melts

587   were underestimated in this case and the $\Delta^{56}Fe_{solids-melts}$ (up +0.06‰) could have been

588   overestimated by 0.025‰, if the $<F>$ difference between Fe^{3+}-rich and Fe^{2+}-rich melts

589   at 130 GPa is modeled by the value for silicate glasses at ambient pressure (Dauphas et

590   al., 2014). Although the $<F>$ of Fe^{3+}-rich melts at 130 GPa are still unknown, the

591   crystallization process of Fe^{3+}-rich melts in some local regions also cannot produce

592   resolvable Fe isotope fractionation between solids and melts. Therefore, we suggest that

593   crystallization of the magma ocean is unlikely to have resulted in significant iron

594   isotopic fractionation in deep mantle.

595

Figure 8. Equilibrium Fe isotope fractionation between solids and melts during magma ocean crystallization at 130 GPa. The modelling details were described in details in Yang et al. (2019). Similarly, the initial δ^{56}Fe of magma ocean is set as 0‰ and the solid crystallization sequence was obtained from Boukaré et al. (2015). Red and blue lines represent δ^{56}Fe of solids (Bdg+Fp) and melts, respectively. Solid, short dash, and dash lines refer to Fe^{2+}-bearing and Fe^{3+}-free, Fe^{3+}- and Al^{3+}-bearing, and Fe^{3+}-bearing and Al^{3+}-free systems, respectively. The <F> of solids and melts at 130 GPa are used for modelling. Data sources: Bdg, DFT+U calculations in this study; Fp, extrapolated to 130 GPa, Yang et al. (2019); melts, imitated by basaltic glass, extrapolated to 130 GPa (Liu et al., 2017). The case for a pyrolitic composition, in which both Fe^{2+} and Fe^{3+} could be present but Fe^{3+} is not expected to occupy the Bdg B-site, can be represented by shade areas enclosed by solid and short dash lines.

4.3 Fe isotope fractionation between core and mantle

Mid-ocean ridge basalts (MORB) in the Earth were found to be enriched in heavy Fe isotopes (^{56}Fe/^{54}Fe) by ~+0.1‰ relative to the chondrites (Teng et al., 2013), while basalts from Mars and Vesta have Fe isotope compositions similar to the chondrites

613 (Sossi et al., 2016; Elardo and Shahar, 2017). The elevated $^{56}Fe/^{54}Fe$ ratio in MORB

614 was thought to be caused by mantle partial melting (Teng et al., 2008; Dauphas et al.,

615 2014), but this process can only induce an iron isotopic shift of +0.023‰ (Dauphas et

616 al., 2014). Some other interpretations, including loss of light Fe isotopes during

617 vaporization and condensation (Poitrasson et al., 2004; Poitrasson, 2007), core

618 formation (Polyakov, 2009; Elardo and Shahar, 2017), have been proposed to enrich

619 Earth's mantle in heavy Fe isotopes. Some studies suggested that the Fe isotope

620 composition of mantle peridotites is close to that of chondrites (Poitrasson, 2007;

621 Craddock et al., 2013), while it has been argued that mantle peridotites may be slightly

622 heavier (~+0.05 ‰) than chondrites (Poitrasson et al., 2013; Sossi et al., 2016). It is not

623 well-known whether the Fe isotope composition of the primitive mantle has been

624 modified by core formation.

625   In order to check the effect of core formation on the Fe isotope composition of

626 bulk silicate Earth, previous studies have widely investigated the $<F>$ of metallic alloys

627 (Chen et al., 2014; Shahar et al., 2016; Liu et al., 2017; Chen et al., 2018) and basaltic

628 glass (Liu et al., 2017), which were used as analogues to metallic and silicate melts,

629 respectively. In addition, Fe^{2+}-bearing Bdg was also used as the analogue to silicate

630 melt (Shahar et al., 2016). Here we also assume that the $<F>$ of silicate melts could be

631 represented by those of Bdg, as we find that Fe^{2+}-bearing and Fe^{3+}-free Bdg has similar

632 $<F>$ to the Fe^{2+}-bearing basaltic glass at 40-60 GPa (Fig. 9). Our results show that Bdg

633 has relatively larger $<F>$ than metallic alloys and the $<F>$ difference between Bdg and

634 metallic alloys depends on their chemical compositions (Fig. 9). Using the high-

635 temperature approximation, we conclude that the equilibrium Fe isotope fractionation

636 between silicate and metallic melts is ~0-0.04‰ under core-formation conditions for

637 the Earth (~40-60 GPa and 3500 K) (Li and Agee, 1996; Siebert et al., 2012; Fischer et

638 al., 2015). This implies that core formation can only shift the Fe isotope composition

639 of Earth's mantle by 0-0.04‰, which is not sufficient to account for the enrichment of

640 heavy Fe isotopes in MORB with the consideration of partial melting.

641   In contrast, heavy Fe isotopes might be enriched in the lowermost lower mantle

642 with respect to the adjacent liquid outer core, as low-spin Fe species likely to be present

643 in phases at the base of the mantle are expected to have high β-factors and

644 corresponding force constants $<F>$ (Fig. 9). At P-T conditions near the CMB, Fe^{2+} is

645 expected to adopt LS state in both solid and liquid FeO-MgO system (Mao et al., 2011;

646 Fu et al., 2018a; Yang et al., 2019); while Fe^{3+} in the octahedral site of both Bdg and

647 Ppv is expected to adopt LS state (Catalli et al., 2010; Yu et al., 2012; Liu et al., 2018).

648 At a representative P-T condition near the CMB (130 GPa and 3000 K), the calculated

649 $\Delta^{56}Fe_{Bdg\text{-}core}$ from the corresponding $<F>$ with LS Fe^{3+} in the B-site of Bdg could range

650 from +0.09‰ to +0.12‰ for various outer core compositions, such as Si, S and C (Fig.

651 9), if there is a chemical exchange and equilibration of solid mantle with outer

652 core. $(Fe^{2+}, Mg)SiO_3$–Ppv was found to be enriched in heavy iron isotopes relative to

653 metallic iron with $\Delta^{56}Fe_{Ppv\text{-}core}$ of ~0.1‰ at the CMB (Polyakov, 2009), and Fe^{3+}-

654 bearing Ppv should be more enriched in heavy iron isotopes. Meanwhile, $\Delta^{56}Fe_{Fp\text{-}core}$

655 ranges from +0.17‰ to +0.20‰ for CMB regions with high concentrations of LS FeO,

656 such as some ultra-low velocity zones (Wicks et al., 2010; Fu et al., 2018a). These

657 fractionation factors suggest that Fe isotopes might be redistributed during the mantle-

658 core interaction and some local regions above the CMB could be enriched in heavy Fe

659 isotopes. However, whether such a Fe isotopic signature could be produced and

660 preserved or not also depends on the interaction pattern and the geodynamic mantle
661 convention (Lesher et al., 2020).

662

Figure 9. Comparison of force constants $<F>$ of Bdg computed in this work with previous studies of Fp and Fe/Fe alloys. At a given *P-T* condition, Fe equilibrium isotopic fractionation factor can be obtained by following $\Delta^{56}Fe_{A-B}=2940$ $(<F>_A-<F>_B)/T^2$. Experimental data sources: Bdg, this study; $(Mg_{0.75}Fe_{0.25})O$ Fp, Yang et al. (2019); Basaltic glass $(Na_{0.036}Ca_{0.220}Mg_{0.493}Fe_{0.115}Al_{0.307}Ti_{0.012}K_{0.002}Si_{0.834}O_3)$, Fe, $Fe_{86.8}Ni_{8.6}Si_{4.6}$, $Fe_{85}Si_{15}$, Fe_3S: Liu et al. (2017); Fe_7C_3: Chen et al. (2014); Fe_3C: Chen et al. (2018); FeHx: Shahar et al. (2016).

5. Conclusion

We have investigated the effects of site occupancies, chemical composition, spin transition, and valence state on the reduced Fe partition function ratio (β-factor) of $(Mg, Fe^{2+}, Fe^{3+}, Al^{3+})(Fe^{3+}, Al^{3+}, Si)O_3$ Bdg under lower-mantle pressure-temperature conditions by performing first-principles calculations and synergistic nuclear resonant inelastic X-ray scattering measurements. The computational partial phonon density of states of Fe^{3+} in $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Fe^{3+}_{0.5})O_3$ bridgmanite agree well with experimental measurements at high pressures. Our results reveal that Fe^{2+}-bearing Bdg has the smallest β-factor relative to other Fe^{3+}-bearing species. Site occupancies for Fe^{3+} can

680 have a significant effect on the β-factor of Bdg. Compared to the A-site HS Fe^{3+}, the B-

681 site HS Fe^{3+} has a higher β-factor by $\sim$0.17‰ at 40 GPa and 1000 K. The spin transition

682 of B-site Fe^{3+} in Bdg influences its β-factor more significantly than variations in valence

683 state and chemical composition, with an increase of $\sim$ +0.83‰ across the spin transition

684 at 1000 K. This change would be diminished to +0.09‰ along an expected geotherm

685 of the lower mantle. The variation of β-factors is mainly controlled by the Fe-O bond

686 lengths, and the shorter bond lengths correspond to higher bond strength and β-factors.

687 In addition, although the incorporation of Al^{3+} into the Bdg B-site results in a mild effect

688 on the β-factor of A-site Fe^{3+} when compared to $(Mg_{0.5}Fe^{3+}_{0.5})(Si_{0.5}Fe^{3+}_{0.5})O_3$ Bdg, the

689 presence of Al in Earth's lower mantle would decrease the impact of B-site Fe^{3+} spin

690 transition on the β-factor of Bdg by preventing Fe^{3+} from occupying the B-site.

691 Combined with previous data, our models demonstrate that Fe isotopic fractionation

692 between Fp and Bdg in most parts of the lower mantle would not be significant, except

693 the lowermost parts. The crystallization of the magma ocean is also unlikely to have

694 resulted in significant iron isotopic fractionation in any deep-mantle reservoir. In

695 contrast, under the conditions of the core-mantle boundary, low-spin Fe-bearing mantle

696 minerals could concentrate heavy Fe isotopes by up to +0.20‰ through core-mantle

697 interaction.
