ABSTRACT: Electrostatically defined quantum dots (QDs) in Bernal stacked bilayer graphene (BLG) are a promising quantum information platform because of their long spin decoherence times, high sample quality, and tunability. Importantly, the shape of QD states determines the electron energy spectrum, the interactions between electrons, and the coupling of electrons to their environment, all of which are relevant for quantum information processing. Despite its importance, the shape of BLG QD states remains experimentally unexamined. Here we report direct visualization of BLG QD states by using a scanning tunneling microscope. Strikingly, we find these states exhibit a robust broken rotational symmetry. By using a numerical tight-binding model, we determine that the observed broken rotational symmetry can be attributed to low energy anisotropic bands. We then compare confined holes and electrons and demonstrate the influence of BLG's nontrivial band topology. Our study distinguishes BLG QDs from prior QD platforms with trivial band topology.

KEYWORDS: *quantum dots, bilayer graphene, Berry curvature, quantum information, scanning tunneling microscopy*
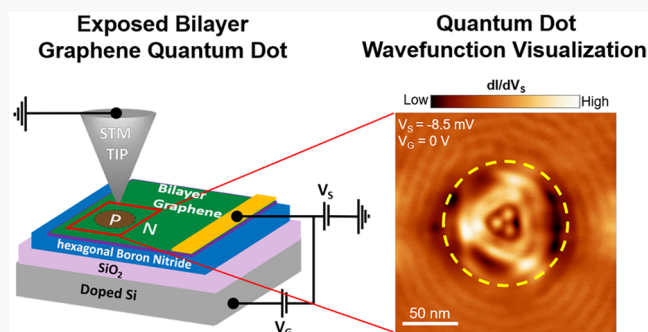

The visualization and manipulation of electronic states in quantum materials is of fundamental interest and has the potential for quantum information processing technologies.[1,2] Among the numerous quantum material platforms that are under consideration for these advanced technologies, Bernal stacked bilayer graphene (BLG) is highly attractive because it possesses an electric field tunable band gap.[3] This unique material property permits the realization of electrostatic quantum dots (QDs) with pristine boundaries and high flexibility to enable charge carrier confinement and QD state formation.[4,5] In addition, BLG QDs have long spin decoherence lifetimes,[6] controllable quantum degrees of freedom,[7,8] and nontrivial band topology.[9] These traits are all favorable for quantum information technology. Recent experimental progress with BLG QDs interfaced with sheets of hexagonal boron nitride (hBN) have demonstrated important advancements regarding quantum state control such as spin-valley resolved single electron charging[7,10] and magnetic field controlled valley splitting.[7,8] Of equal importance, is the understanding of the QD wave function shape, which determines the energy spectrum and allowable transitions between states. These energetics govern the preparation, manipulation, and readout of quantum information.[11] Theoretical predictions for BLG QD wave function shape are abundant;[12−16] however, the experimental validation of these predictions is lacking.

Here we use a scanning tunneling microscope (STM) tip to create an exposed circular p−n junction in a BLG/hBN heterostructure for imaging and manipulating new QD states. To create such nanostructures, we employed a tip voltage pulsing technique based on prior works with the formation of circular p−n junctions in graphene/hBN heterostructures[17,18] (see Supporting Information Section 1 for more information on tip pulsing technique). A schematized circular p−n junction and measurement setup is depicted in the left panel of Figure 1a. Our STM tip is grounded and a voltage bias (V_S) is applied to the sample. A gate voltage (V_G) is also applied to the underlying doped Si and is used to tune the BLG Fermi level.

To avoid the influence of adsorbates in our studies, we create circular p−n junctions in 200×200 nm^2 adsorbate free regions. The middle panel of Figure 1a shows the topography of one such region. The furthest right panel of Figure 1a shows an atomically resolved topography at the center of the region where a circular BLG p−n junction was created. Bright topographical features that form a triangular lattice are clearly
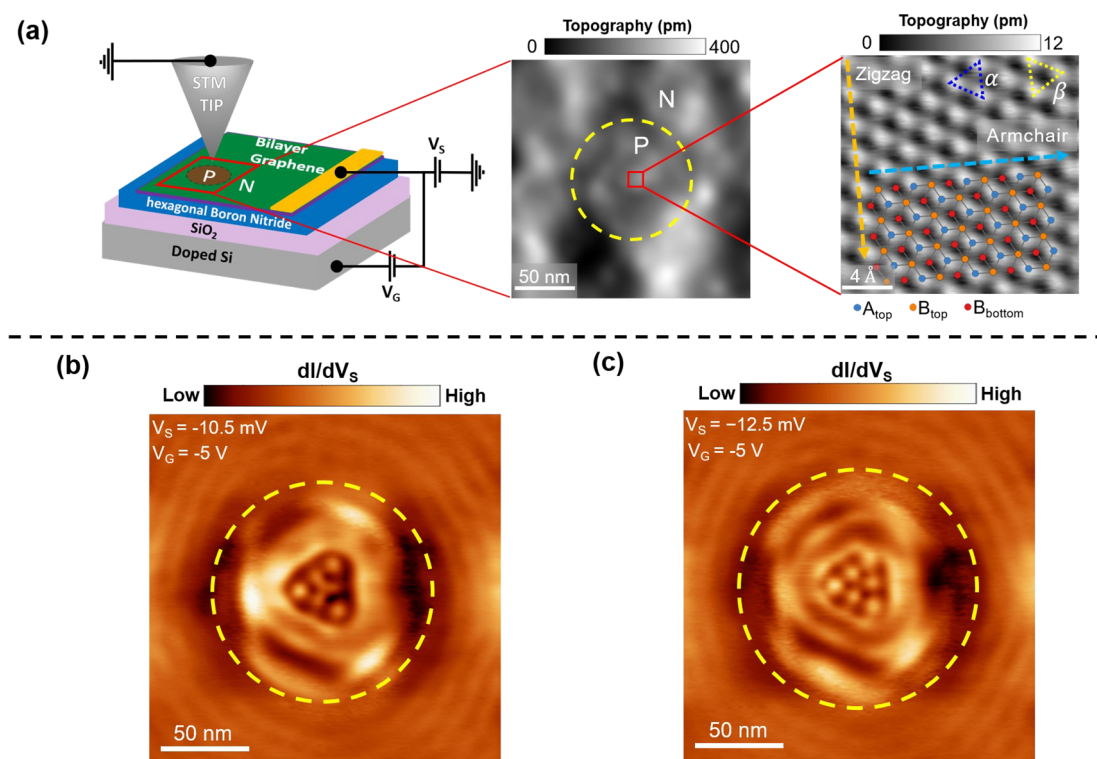

Figure 1. Scanning tunneling microscopy/spectroscopy (STM/STS) characterization of a circular bilayer graphene p−n junction. (a) Left panel: schematic of a STM tip probing a circular p−n junction in Bernal stacked bilayer graphene (BLG) that is supported by hexagonal boron nitride (hBN). The BLG/hBN heterostructure rests on a SiO$_2$/doped Si wafer.The STM tip is grounded, a sample bias V_S is applied between the BLG and ground, and a gate voltage V_G is applied between the doped Si and BLG. Middle panel: BLG topography after the creation of a circular p−n junction. Dashed yellow line denotes the p−n junction. The scanning parameters were $V_S = −8.5$ mV, $I = 0.3$ nA. Right panel: atomically resolved topography of BLG at the center of the p−n junction, the scanning parameters were $V_S = −100$ mV, $I = 2.5$ nA. BLG crystal structure is overlaid on the topography. The orange (blue) arrow indicates a BLG zigzag (armchair) direction(s). The blue and yellow triangles represent the two possible orientations for the BLG lattice by connecting the three closest bright atoms. (b, c) Constant sample bias dI/dV_S maps of circular BLG p−n junctions at $V_G = −5$ V (b, c). The yellow dashed line in (b) and (c) denotes the boundary between p and n doped regions. Scanning parameters for (b) and (c) are $V_{ac} = 2$ mV and $I = 0.3$ nA.

visible, as expected for BLG.[19,20] We overlay the atomic structure of BLG in this panel and use it to identify three of the four atoms within the BLG unit cell: A_{top}, B_{top}, and B_{bottom}. The fourth atom (A_{bottom}) on the bottom layer is obscured by B_{top}. In such a triangular lattice two orientations exist for the apparent triangles, we denote these orientations as α (dashed blue line that encloses B_{top}) and β (dashed yellow line that encloses B_{bottom}).

By performing constant sample bias dI/dV_S maps, we image the electronic states inside and outside of our circular BLG p−n junctions. In Figure 1b,c we show maps taken at two different energies $V_S = −10.5$ mV and $V_S = −12.5$ mV, but at the same $V_G = −5$ V. A dashed yellow line provides a guide to the eye for the p−n junction. The electronic states outside of the p−n junction exhibit an approximate circular symmetry consistent with the p−n junction shape itself. In contrast, the states within the p−n junction display a rich nodal pattern that breaks rotational symmetry. For example, in Figure 1b there is a "Y" shaped feature that can be seen at the center of the p−n junction with three antinodes that surround it. The pattern in Figure 1c, on the other hand, contains three distinct antinodes at the center of the junction. Despite the diverse nature of the patterns in each map, a clear C_3 symmetry is shared between both of them. Closer inspection of these electronic states also reveals that they are aligned with the orientation of the α triangle of the BLG lattice (see Supporting Information

Section 4 for additional data on C_3 symmetry and BLG lattice alignment reproducibility).

To attain a more comprehensive understanding of the spatial distribution for the electronic states within our BLG p−n junctions, we acquired dI/dV_S spectra along zigzag and armchair directions across the center of the p−n junction from Figure 1b,c. The results of these measurements are shown in Figure 2a,b. The color scale corresponds to dI/dV_S amplitude and is plotted as a function of V_S and the distance across the circular p−n junction. These measurements were taken at $V_G = −5$ V. A distinct nodal level structure with high dI/dV_S amplitude is visible and is surrounded by a dark envelope (low dI/dV_S amplitude) in each of the two plots. Moreover, for the dI/dV_S spectra taken along the armchair direction (Figure 2a), the nodal distribution exhibits an asymmetric dI/dV_S intensity with respect to the center of the p−n junction. On the other hand, along the zigzag direction (Figure 2b), the nodal distribution of the same p−n junction exhibits a clear mirror symmetry with respect to the center of the junction. The well-defined difference seen between the armchair and zigzag directions indicates that the broken rotational symmetry observed in Figure 1b,c persists for a wide energy range.

Insight into the origin of our observations can be gained by considering the behavior of BLG charges corralled within a circular electrostatic potential well that is defined by a circular
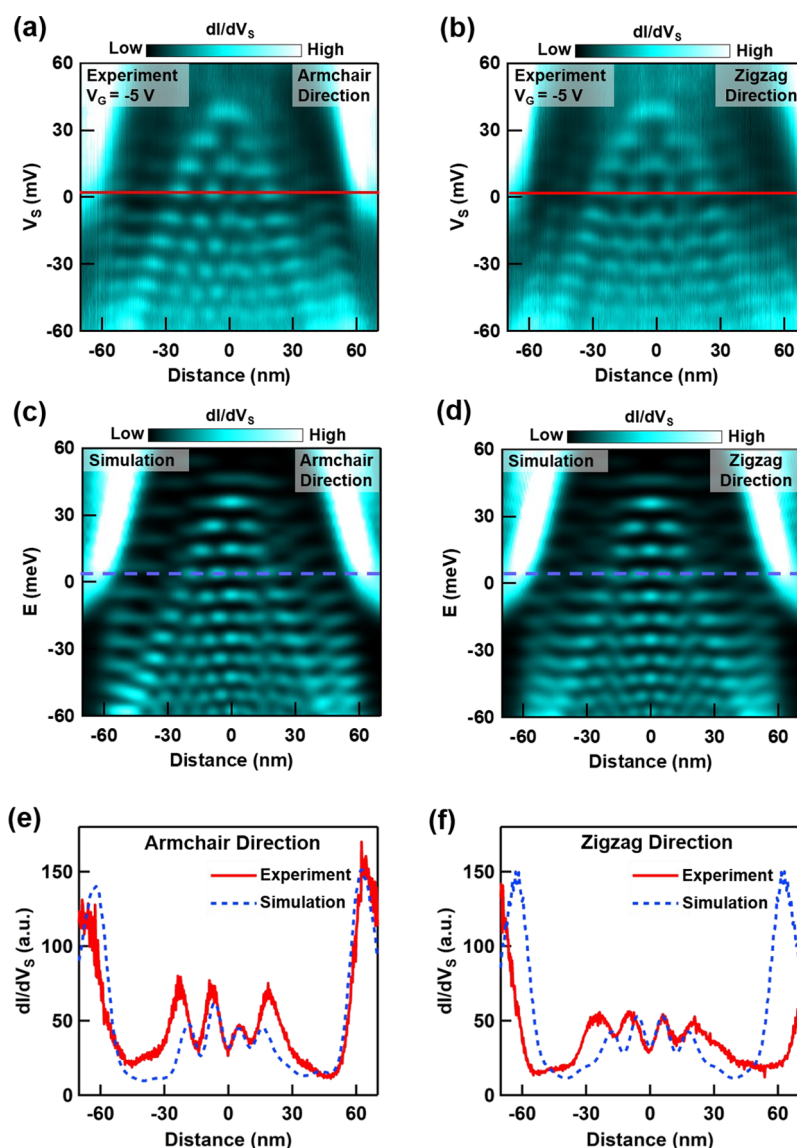

Figure 2. Spatially resolved energy levels inside a BLG quantum dot (QD) along zigzag and armchair directions. (a, b) Measured dI/dV_S spectra along BLG's armchair (a) and zigzag (b) directions at $V_G = -5$ V. The "0" on the horizontal axis in (a) and (b) denotes the center of the QD. The set point used in (a) and (b) was $I = 1$ nA, $V_S = -60$ mV, with a 2 mV ac modulation. (c, d) Simulated dI/dV_S spectra along the BLG armchair and zigzag direction, respectively. The "0" on the horizontal axis in (c) and (d) denotes the center of the QD in the TB model. A constant 60 meV gap (top layer was set at a higher energy than the bottom layer, $U = +60$ meV) and $\gamma_3 = -0.38$ eV were included in the model. (e) Comparison between experimental and simulated constant energy dI/dV_S profile along the BLG armchair direction. The experimental dI/dV_S profile was acquired from (a) at $V_S = 2$ mV, indicated by the red solid line. The simulated dI/dV_S profile was acquired from (c) at $E = 4$ meV, indicated by the blue dashed line. (f) Comparison between experiment and simulated constant energy dI/dV_S profile along zigzag direction. Theses profiles were acquired at the same energies as in (e).

p−n junction. This setup has extensive previous theoretical inquiry, yet as we will show, our experimental findings cannot be explained by these prior works. The touching BLG bands at the p−n junction are opened by the presence of a finite perpendicular electric field,[21,22] thus yielding charge carrier confinement and formation of QD states within the interior region of the circular p−n junction.[4,5,12,23] The dark envelope in Figure 2a,b indicates a reduction of electronic states at the p−n junction, hence revealing the presence of an electric field induced gap. Consequently, the nodal pattern enclosed by this electric field induced gap corresponds to the QD states in our experiment. The energetic and spatial distribution of these states are reminiscent of charges confined within a harmonic potential. For example, we find that the energy spacing of QD

states that reside in the center is roughly uniform and approximately 24 meV. For BLG QDs, most theoretical investigations predicted circularly symmetric states[12−16] akin to QD states seen in monolayer graphene.[17,24] Notably, the C_3 symmetry that is clearly present in our QD states breaks rotational symmetry and is thus inconsistent with these prior predictions.

Interestingly, the electronic states within our QD exhibits the same symmetry as anisotropic low energy BLG bands that arise from the incorporation of a skewed interlayer hopping term γ_3.[25] This connection suggests an explanation for our findings and is also supported by a recent BLG QD theory that considered γ_3 hopping.[26] To verify this possibility, we proceeded by using numerical tight-binding (TB) calculations
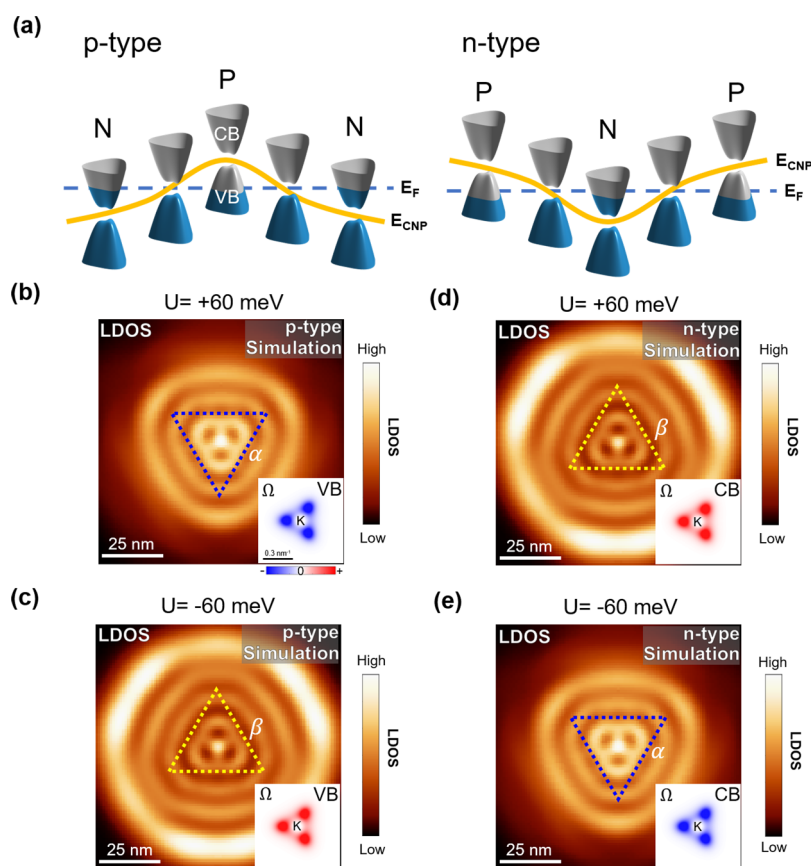

Figure 3. Simualted BLG QD LDOS tracks the Berry curvature sign switch. (a) Band diagrams for BLG QD with p-type (left panel) and n-type (right panel) central doping. The orange and blue curves indicate the BLG charge neutrality point (E_{CNP}) and Fermi level (E_F), respectively. BLG QDs with p-type and n-type central doping confine holes and electrons, respectively. (b)−(e) Simulated LDOS maps for a QD with p-type and n-type central doping. The potential well and the gap size is the same in (b, c), but the interlayer potential difference polarity (U) is +60 meV for (b) and (d) and −60 meV for (c) and (e). The blue triangle in (b) and (e) and yellow triangle in (c) and (d) represents the orientation of the α and β triangles of the BLG lattice in the TB model, respectively. Insets in (b, c) and (d, e) show the calculated Berry curvature (Ω) of the valence band (VB) and the conduction band (CB) near the K valley with U = +60 meV and U = −60 meV, respectively.

of a BLG QD that incorporates γ_3 hopping and a band gap. The potential well and the size of the band gap used in this calculation were extracted from the experiment (see Supporting Information Section 5 for details on the numerical calculation and model[27]). On the basis of this calculation, we simulated dI/dV_S spectra along BLG zigzag and armchair crystallographic directions that cross the center of the potential well. These simulations are shown in Figure 2c for the armchair direction and Figure 2d for the zigzag direction. Remarkably, the nodal distribution and dark envelope in the simulated dI/dV_S spectra closely resemble the measured spectra. For instance, the mirror symmetry about the center of the QD is clearly evident (absent) for the zigzag (armchair) direction(s). This symmetric (asymmetric) distribution of QD states along the zigzag (armchair) direction(s) can be attributed to the preservation (breaking) of mirror symmetry for BLG QDs along the zigzag (armchair) direction(s). The agreement between simulation and experiment is more apparent by comparing constant energy dI/dV_S profiles, as shown in Figure 2e,f. A strong agreement is also seen between experimental dI/dV_S maps and simulated constant energy local density of states (LDOS) maps (see Supplementary Section 6 for comparison). Crucially, we found that this agreement breaks down if either γ_3 or a band gap is excluded in the

numerical TB calculation (see Supporting Information Section 7 for comparison).

The observed strong influence of gapped and anisotropic bands for BLG QD states has intriguing implications for accessing the nontrivial band topology of BLG. This is because such bands lead to a finite Berry curvature that is also anisotropic.[28] To explore this possible attribute of our QD system, we use simulations based on numerical TB calculations to study QDs with p-type and n-type central doping and with different interlayer potential difference polarities ($U > 0$ and $U < 0$). As shown in Figure 3a, the different types of QDs with gapped and anisotropic bands enable trapping of low energy holes (upper panel) and low energy electrons (lower panel). Simulated LDOS maps for analogous QDs with the same potential well curvature and gap size but with different polarity for the interlayer potential difference are shown in Figure 3b−e. First, we focus on QDs with p-type central doping (Figure 3b,c). We find that the orientation of the LDOS distribution for these QDs exhibits a 180° rotation between U = +60 meV and U = −60 meV. In addition, for U = +60 meV, the LDOS pattern is aligned with the α triangle of the BLG lattice, while for U = −60 meV the LDOS pattern is aligned with the β triangle of the BLG lattice. A similar rotation and LDOS pattern alignment with respect to the BLG lattice can also be seen for QDs with n-type central doping (Figure 3d,e).
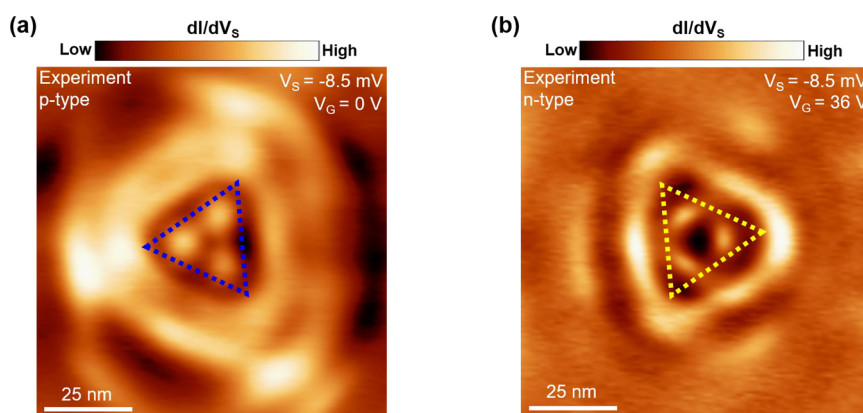

Figure 4. dI/dV_S maps reveal Berry curvature manipualtion within BLG QDs. (a) Measured constant energy dI/dV_S maps for a BLG QD with p-type central doping with scanning parameters I = 0.3 nA and V_{ac} = 2 mV. (b) Measured constant energy dI/dV_S maps for a BLG QD with n-type central doping with scanning parameters I = 0.1 nA and V_{ac} = 3 mV. The blue triangle in (a) and yellow triangle in (b) represent the orientations of α and β triangles of the BLG lattice, respectively.

The rotation in the simulated LDOS patterns indicates that a property of BLG has been modified between the different interlayer potential difference polarity configurations. The band structure of BLG does not depend on the interlayer potential difference polarity (see Supporting Information Section 9 for TB calculation of BLG band structure[25]). In contrast, the Berry curvature, which is related to the BLG band topology, does depend on the sign of the interlayer potential difference.[28−30] For example, for confined holes, the Berry curvature of BLG's valence band in the K valley is negative for U = +60 meV (see inset of Figure 3b). The Berry curvature of the same band is positive for U = −60 meV (see inset of Figure 3c). A similar Berry curvature sign flip can be seen for QDs with n-type central doping as well (insets of Figure 3d,e). Here we focus on one valley because the Berry curvature sign flip also occurs in the other valley when the interlayer potential polarity changes. Additionally, because time reversal symmetry is preserved in our BLG QDs, we expect that the two valleys remain degenerate and have the same LDOS distribution. The LDOS distribution can also be explained by considering that the Berry curvature sign and Fermi surface orientation are reversed in the two valleys (see Supporting Information Section 10 for further discussion). Thus, the simulated LDOS patterns in Figure 3b−e suggest that imaging the states within BLG QDs can reveal Berry curvature manipulation.

To experimentally verify this intriguing possibility, we created a circular p−n junction in the same region as the previous junctions but with different central doping types. We used this approach because in our experiment we were unable to modify the polarity of the interlayer potential difference (see Supporting Information Section 11 for additional details on interlayer potential difference[22]). Nonetheless, our simulations in Figure 3b,d reveal a 180° rotation between trapped holes and electrons. In addition, the LDOS pattern for trapped holes (electrons) is aligned with the α (β) triangle of the BLG lattice. These predictions from the simulations are consistent with the Berry curvature sign flip for the corresponding bands shown in the insets of Figure 3b,d.[28−30] Notably, panels a and b of Figure 4 show the measured dI/dV_S maps for QDs with p-type and n-type central doping, respectively. In exact agreement with the simulations, the orientations of the dI/dV_S patterns differ by a 180° rotation and they align with the α triangle of the BLG lattice for trapped holes and with the β triangle of the BLG lattice for trapped electrons.

In conclusion, we have spatially mapped BLG QD wave functions and demonstrated manipulation of their Berry curvature. We found that consideration of gapped and anisotropic low energy bands is crucial for understanding the behavior of electrostatically corralled BLG charges. Additionally, we revealed manifestations of the nontrivial BLG band topology by imaging the quantum interference in our BLG QDs. This finding could inspire future works using quantum interference to study the properties of materials that have finite Berry curvature such as semiconducting transition metal dichalcogenides[31] (e.g., MoS_2), topological insulators[32] (e.g., WTe_2), and Weyl semimetals[33−35] (e.g., TaAs). The technical advancements presented here can also be used to study more sophisticated platforms for quantum information technology such as BLG double and multiple QDs. The tunable couplings in these systems make them promising for the realization of quantum bits based on spin and valley degrees of freedom.[36,37]
