1 **Abstract**

2 In daily life, two aspects of real-world object size perception—the *image size* of an object
3 and its *familiar size* in the real world are highly correlated. Thus, whether these two aspects of
4 object size differently affect goal-directed action (e.g., manual pointing), and how, has scarcely
5 been examined. Here participants reached to touch one of two simultaneously presented objects
6 based on either their image or familiar size, which could be *congruent* or *incongruent* (e.g., a
7 rubber duck presented as smaller and larger than a boat, respectively). We observed that when
8 pointing to target objects in the incongruent conditions, participants' movements were slower
9 and were more curved towards the incorrect object compared to the movements in the congruent
10 conditions. By comparing performance in the congruent and incongruent conditions, we
11 concluded that both image size and familiar size influenced action even when task-irrelevant,
12 indicating that both are processed automatically (Konkle & Oliva, 2012a). Image size, however,
13 showed influence earlier in the course of movements and more robustly overall than familiar
14 size. We additionally found that greater relative familiar size differences mitigated the impact of
15 image size processing, and increased the impact of familiar size processing on pointing
16 movements. Overall, our data suggest that image and familiar size perception interact both with
17 each other and with visually-guided action, but that the relative contributions of each are unequal
18 and vary based on task demands.

1 **Introduction**

2 In 2007 an art installation appeared floating in the harbor of Saint-Nazaire, a small town
3 in Western France. “Rubber Duck” by Florentijn Hofman quickly gained international attention
4 due to the unexpected scene created by a toy that typically measures 5.5 cm in height dwarfing
5 nearby boats at 32 m. The *familiar size* of a rubber duck, the size that we know it typically would
6 be based on past experience, and the *image size* of “Rubber Duck,” the size the piece appeared
7 visually to viewers, were dramatically in conflict.

8 In normal daily life, objects’ *familiar size* and *image size* are highly correlated. When
9 presented in the same context, real-world objects like rubber ducks which we know to be
10 relatively small in the real world typically appear smaller than objects like boats which we know
11 to be larger. Even when the sizes of objects on the retina vary, they are integrated with their
12 environment via size constancy mechanisms. Thus, taking size constancy into account, in the
13 real-world *image size* and *familiar size* are very rarely in conflict. Consequently, *image size* and
14 *familiar size* processing are highly confounded—when we see an object and its image size and
15 familiar size are congruent, how each of these two aspects of size affects our perception and
16 goal-directed action is difficult to disambiguate.

17 Attempts have recently been made to disentangle image size and familiar size perception.
18 Konkle & Oliva (2012a) implemented a Stroop-like paradigm, in which a pair of two objects
19 were presented at different image sizes on the screen. Participants were asked to indicate which
20 image size was bigger or smaller by key-press, while their familiar sizes were task-irrelevant.
21 This experiment demonstrated that incongruence between familiar size and image size (e.g., a
22 rubber duck presented with a larger image size than a boat) results in a “familiar size Stroop
23 effect,” captured by slower reaction times for image size judgments. This result suggests that

1 these two highly different aspects of real-world object size, *image* size and *familiar* size, are both
2 processed automatically, as in the classic Stroop Effect (Stroop, 1935).

3 However, despite disambiguating the two to some degree, Konkle & Oliva (2012a) only
4 examined the unidirectional influence of familiar size on image size, as opposed to the
5 bidirectional influence of each on the other. Furthermore, binary categories were used for large
6 and small image sizes, and large and small familiar sizes, though both exist on a continuum in
7 the real world. Therefore, the relative contributions of each type of object size on perception, and
8 other visual processes such as guiding goal-directed actions, bear further investigation.

9 Object size is a key component of *vision for action* in addition to *vision for perception*,
10 given that size constrains how we interact with the objects in our environment. For example, the
11 width of a target modulates the speed of goal-directed pointing movements to it (Fitts, 1954), and
12 grip aperture scales to the image sizes of objects (Jeannerod, 1984). Prior research has also
13 extensively explored how dissociating the veridical physical and perceived image sizes of objects
14 using contextual size illusions such as the Ebbinghaus, Ponzo, and Muller-Lyer illusions, affects
15 various goal-directed action such as manual pointing and grasping as well as eye movements
16 (e.g., Bernardis, Knox, Bruno, 2005; Binsted & Elliott, 1999; de Grave, Franz, & Gegenfurtner,
17 2006 Franz, 2001; Glover & Dixon, 2002; Milner & Goodale, 2008; Knol et al., 2017; Gamble &
18 Song, 2017).

19 However, less is known about how familiar size influences action. Image size is a low-
20 level visual feature—it is represented retinally and in V1, one of the earliest visual processing
21 regions (Murray, Boyaci, & Kersten, 2006). In contrast, familiar size is a high-level visual
22 feature requiring object identification and the recruitment of memory, and is represented in a
23 later visual processing region in the temporoparietal cortex (Konkle & Oliva, 2012b).

1 Though conflict between image and familiar size was demonstrated in the
2 aforementioned paper (Konkle & Oliva, 2012a) using a discrete behavioral response paradigm, it
3 is not known how action would respond to conflict between the two, again given that such
4 scenarios are highly uncommon in the real world. It has been shown that discrete behavioral
5 responses and action measures can produce different results for the same perceptual decision-
6 making task. For example, it is typically thought that strongly salient distractors capture more
7 attention and are more disruptive than weakly salient distractors (Theeuwes, 2010; Itti & Koch,
8 2001). Counterintuitively, Moher et al. (2015) found dissociable effects of salience on discrete
9 key-press and goal-directed action such as pointing. In a visually-guided pointing task, they
10 required participants to reach to a shape-defined target while trying to ignore salient distractors.
11 They observed that highly salient objects impacted hand movement trajectories *less* than less
12 salient objects did. Thus, a strongly salient distractor triggers suppression during goal-directed
13 action, resulting in enhanced efficiency and accuracy of target selection relative to when weakly
14 salient distractors are present. In contrast, in a task requiring key-press to select a target, they
15 found greater attentional interference from strongly salient distractors, reflected on slower
16 reaction time. This counterintuitive result suggests that sufficiently strong distractors may trigger
17 suppression, but only when a physical movement is required. These results also underscore the
18 value and necessity of combining visually-guided actions with traditional perceptual approaches
19 to fully understand how we resolve competing internal processes to achieve behavioral goals
20 (Moher, Anderson, & Song, 2015).

21 Furthermore, the continuous nature of manual pointing movements has provided new
22 insights into the temporal evolution of cognitive processes including language processing,
23 numerical cognition, attention allocation, social perception, and cognitive control (for review,

1 Song & Nakayama, 2009; Song, 2017; Erb, 2018; Dotan et al., 2019). Previous studies have
2 demonstrated that the evolution of reach trajectory curvature while selecting a target among
3 alternative choices can reveal various aspects of decision-making such as timing of information
4 process and the degree of competition (Erb, Moher, Sobel, & Song, 2016; McKinstry, Dale, &
5 Spivey, 2008; Song, 2017; Song & Nakayama, 2009; Moher & Song, 2019). For instance, Song
6 & Nakayama (2009) asked participants to determine whether a single Arabic numeral presented
7 in a central square was less than, greater than, or the same as the number five by reaching to one
8 of three corresponding squares on the screen. They observed that the greater the numeric
9 deviation between the target and the number five, the greater the deviation of the trajectory from
10 the standard trajectory. This provides direct evidence that the numeric magnitude of a target is
11 spatially encoded, and that the proximity and order of numbers are spatially represented along a
12 hypothesized mental number line. Such a methodology can therefore provide a tool to track how
13 competition between the processing of image and familiar sizes evolves and in turn resolves over
14 time.

15 Overall, gaps in the literature we seek to address in the present study are the potential
16 influence of familiar size (a higher-level visual feature) on action, how it compares to the
17 influence of image size (a lower-level visual feature) on action, and whether these interactions
18 change over time. In order to address these questions, we employed a similar paradigm to
19 Konkle & Oliva's aforementioned Stroop-like paradigm (Konkle & Oliva, 2012a), with the
20 addition of A) a familiar size judgment task in which image size was the conflicting task-
21 irrelevant feature, B) parametrically-varied familiar object sizes, and C) continuous action-based
22 responses as opposed to discrete behavioral responses. In Experiment 1, we tested the hypothesis
23 that the higher-level feature *familiar size* and the lower-level feature *image size* significantly

1 interfere with each other when the two are incongruent, while one type of size is task-irrelevant.
2 Furthermore, we sought to investigate the relative strength of interference between familiar and
3 image size processing by measuring temporal aspects (e.g., how fast movements are initiated)
4 and spatial aspects (e.g., how much reach trajectories are curved towards a wrong choice) of
5 goal-directed pointing movements. In Experiment 2, we evaluated the hypothesis that if familiar
6 size is treated as a spectrum, varying the magnitudes of relative familiar size differences between
7 pairs objects may lead to corresponding graded effects on action and on the interference between
8 image and familiar size.

9 Overall, we hypothesized bidirectional interference between image and familiar size, but
10 recognized that the influence of each might not be symmetrical. In other words, they might both
11 exert influence on visually-guided action, but not to the same degree or on the same timescale.
12 Specifically, in accord with classical models of object processing (Rosch et al., 1976; Collins &
13 Quillian, 1969; Jolicoeur, Gluck, & Kosslyn, 1984), if image size is a more intrinsic feature with
14 stronger, more fundamental neural correlates, it could cause more interference when it is task-
15 irrelevant and more strongly *resist* interference when it is task-relevant. In this case we would
16 expect to see image size exert a relatively strong influence in the familiar size task, and familiar
17 size exert a relatively weak influence in the image size task. Furthermore, if there is a temporal
18 component to the asymmetry, we would expect to see image size influence movements earlier in
19 the familiar size task, and familiar size influence movements later in the image size task.

20 On the other hand, if familiar size is represented more strongly, we would see familiar
21 size exert a relatively strong influence in the image size task, and image size exert a relatively
22 weak influence in the familiar size task. Similarly, we could expect to see familiar size influence

1 movements earlier in the image size task, and image size influence movements later in the
2 familiar size task.

3

4 **Experiment 1: Congruency between target image and familiar size in visually-guided**
5 **action**

6

7 **Methods**

8 *Participants*

9 Fourteen right-handed participants (8 women; mean age 25.7 years) with normal
10 color vision, and normal or corrected-to-normal visual acuity completed both tasks within
11 Experiment 1. Participants provided their informed consent and were compensated
12 monetarily (\$10 per hour) or with course credit for their participation. The experimental
13 protocol was approved by the Brown University Institutional Review Board in
14 accordance with the Code of Ethics of the World Medical Association (Declaration of
15 Helsinki) for experiments involving humans.

16

17 *Apparatus*

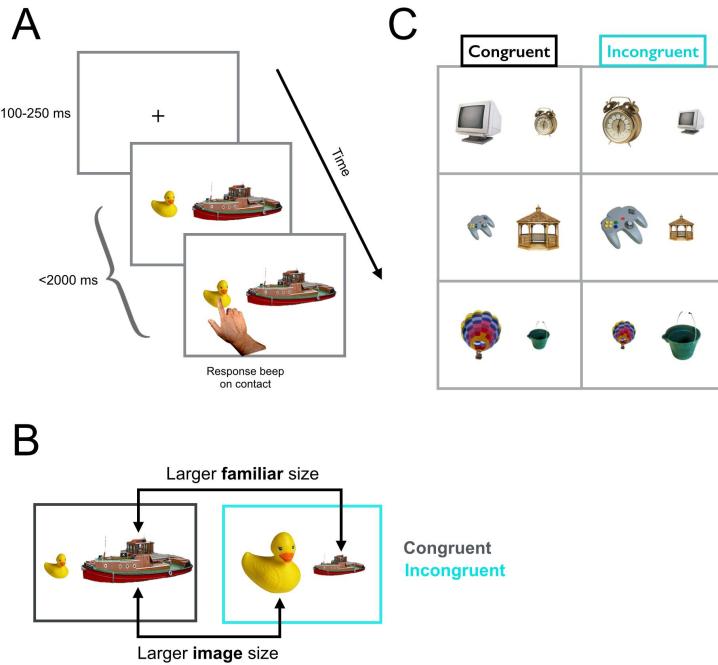

18 Stimuli were presented on an upright Plexiglas display facing the seated participant at a
19 distance of approximately 55 cm. A projector behind the display projected a screen measuring
20 44.1 × 33.0 cm (43.7° × 33.4° visual angle), which participants viewed binocularly. Stimulus
21 presentation was conducted using custom software designed with MATLAB (MathWorks,
22 Natick, MA) and Psychtoolbox (Brainard, 1997). Three-dimensional hand position was recorded
23 with an electromagnetic position and orientation recording system (Liberty; Polhemus,

1 Colchester, VT) at a rate of 160 Hz with a measuring error of 0.3 mm root mean square. A
2 motion-tracking marker was fastened to the tip of each participant's right index finger using a
3 Velcro strap. A foam starting block placed 27 cm in front of the participant, between the
4 participant and the display (28 cm from the display), served as the starting position on which the
5 index finger rested at the beginning of each trial.

6

7 *Stimuli*

8 Stimuli were adapted from Konkle & Oliva's "Object Size Stroop" database (Konkle &
9 Oliva, 2012a). All stimuli were presented on a white background. A black eye fixation cross,
10 measuring 7×7 mm (0.73° of visual angle) appeared at the center of the screen before each trial.
11 As shown in Figure 1A two real world objects were displayed, one to each side of fixation (14.2
12 cm or 14.7° measured from fixation to target center (35.5 cm diagonally from the foam starting
13 block). Sixteen unique object pairs were used each for the *image size task*, which required
14 participants to judge the sizes of the objects as they appeared on the screen, and for the *familiar*
15 *size task*, which required participants to judge the sizes of the objects in the real world. An
16 additional two unique object pairs were used for pre-experiment practice blocks. Thus, 34 total
17 object pairs were used, with each individual object being assigned to only one other object.
18 Example object pairs are shown in Figure 1B.

1

2 **Figure 1.** Task and Stimuli. **A.** While the index finger was positioned on the starting block, trials
 3 began with the eye-fixation cross for a variable period between 100 and 250 ms. Once stimuli
 4 were presented, participants had up to 2000 ms to complete the reach-to-touch hand movement
 5 indicating their choice. **B.** The objects' *image size* and *familiar size* could be presented as
 6 congruent (e.g. the left image where the rubber duck has a smaller image size than a boat) or
 7 incongruent (e.g. the right image where the rubber duck has a larger image size than a boat).
 8 Additionally, objects were counterbalanced such that the larger and smaller image size and
 9 familiar sizes were presented in both left and right positions. **C.** Examples of paired objects. The
 10 left column shows examples of *incongruent* conditions and the right-side *congruent* conditions.

11

12 In each trial one object had a larger relative familiar size and the other a smaller relative
 13 familiar size (see Figure 1C). Familiar sizes of objects ranged from 3 cm diagonally (a die) to

1 8776 cm diagonally (a cathedral), as reported by Konkle & Oliva (2012a). In parallel, each trial
2 had one object presented with a larger image size and one presented with a smaller image size.
3 Image sizes, as reported by Konkle and Oliva (2012a), were designed such that the objects with
4 “small” image sizes were bounded by a rectangle with a diagonal equal to 17.5% of our screen
5 height (5.8 cm or 6.0°) and objects with “large” image sizes were bounded by a rectangle with a
6 diagonal equal to 30% of our screen height (9.9 cm or 10.3°). This method was selected to
7 account for the variations in real-world objects’ aspect ratios (Konkle & Oliva, 2011, 2012a;
8 Kosslyn, 1978).

9 In congruent trials, the object with the larger *familiar* size was presented with a larger
10 *image* size and the object with the smaller *familiar* size was presented with a smaller *image* size.
11 For example, in a congruent trial a rubber duck would be presented as 5.8 cm diagonally and a
12 boat as 9.9 cm diagonally. In an incongruent trial, relative *familiar* and *image* sizes would be
13 incongruent, e.g. a rubber duck would be presented as larger on the screen (9.9 cm diagonally)
14 and a boat as smaller on the screen (5.8 cm diagonally).

15

16 *Procedure*

17 Two blocks of each task (image or familiar size judgment) were performed in an ABBA
18 order, with image and familiar size tasks assigned as A or B randomly. Task instructions
19 appeared at the beginning of each block (“Make your selections based on the sizes you know the
20 objects are in the real world” for the familiar size task, and “Make your selections based on the
21 sizes of the objects on the screen” for the image size task).

22 Each block was broken into two sequential sub-blocks, each of which contained trials
23 with the same task instructions (“Choose the object that is larger” or “Choose the object that is

1 smaller”). For example, in an *image size* task block, for the first sub-block participants would
2 select the object with the larger image size, and in the second sub-block, the object with the
3 smaller image size. The order of these sub-blocks was randomly determined (i.e. larger-smaller
4 or smaller-larger), and reversed in the second block of each task. In total each of the 32
5 experimental object pairs was repeated eight times for a total of 128 trials per experimental task.

6 At the beginning of each participant’s session, nine-point calibration was conducted for
7 the tracker. Participants also completed a practice block of 16 trials of the relevant size-judgment
8 task before the first experimental block of that task. In both the image size and familiar size
9 tasks, once participants rested their index finger on the starting position, each trial began with an
10 initial fixation-cross presented for a variable amount of time (100–250 ms). Participants were
11 asked to hold their eyes on the fixation cross though it was not monitored via eye tracker. This
12 was followed by the presentation of the object pair. Participants were instructed to make their
13 decisions as quickly and accurately as possible, by reaching out and touching the selected object
14 on the screen. In both tasks, the display was presented for a maximum of 2000 ms. Auditory
15 feedback was given when participants touched the display indicating either correct object
16 selection (single high beep) or incorrect object selection (single low beep), or if the time limit
17 had been exceeded (double low beep). An example trial of the task is diagrammed in Figure 1B.

18

19 *Data analysis*

20 Data analysis procedures were largely adapted from methods reported in our previous
21 work (Gamble & Song, 2017; Moher & Song, 2013, 2014).

22 Using custom MATLAB (MathWorks) software, we conducted off-line data analysis on
23 the pointing movement data. Movement velocity was calculated from the 3D position traces after

1 filtering with a low-pass filter (cutoff frequency of 10 Hz). An algorithm using velocity criteria
2 of 10 cm/s detected the beginning and end of pointing movements. The algorithm's identification
3 of these movements was visually inspected to verify its accuracy for every trial (Gamble & Song,
4 2017; Moher et al., 2015; Moher & Song, 2013, 2014); for trials in which the default threshold
5 clearly missed capturing part of the movement or included substantial post-selection movement,
6 thresholds were adjusted manually to more appropriate levels for that trial (~ 1% of all trials).

7 Pointing movements were classified as correct responses if they landed within a
8 standardized target boundary used for all targets (6 × 6 cm or 6.2° × 6.2° of visual angle). Thus,
9 *accuracy* was defined as the percentage of correct responses.

10 *Initiation latency* (IL) was defined as the time elapsed between stimulus onset and
11 pointing movement onset. *Movement time* (MT) was defined as the time elapsed between
12 movement onset and movement offset/target landing. *Maximum curvature* was calculated by
13 tracing the path of the hand, and calculating an ideal direct path between the movement's starting
14 and end points. The perpendicular deviation of the hand position from the ideal path was
15 calculated at every time point over the course of the movement. The maximum of these
16 perpendicular deviation lengths divided by the length of the ideal path results in a unitless ratio,
17 referred to as *maximum curvature*. Larger ratios thus represent a greater maximum deviation
18 from the ideal path, and greater overall curvature in the movement's trajectory. In order to
19 compare congruent and incongruent trials within subjects for each measure (IL, MT and
20 maximum curvature), and compare the *image* size and *familiar* size tasks directly, we performed
21 2x2 repeated measures ANOVAs with factors of congruency (congruent vs. incongruent) and
22 task (image size vs. familiar size judgments) for each measure. We also report partial eta
23 squared, with values of .2 indicating a small effect size, .5 indicating a medium effect size, and .8

1 indicating a large effect size (Cohen, 1973). Within each task (image size and familiar size) we
2 additionally performed paired t-tests comparing congruent and incongruent trials within subjects
3 for each measure (accuracy, IL, MT and maximum curvature).

4 In addition to these analyses, we also examined the evolution of the reach trajectories
5 over the course of the hand movements to the screen. In order to average and compare across
6 participants and across trials, which naturally vary in length, we normalized all hand movements.
7 First, movements to the left and right sides of the screen were collapsed. Additionally, we
8 normalized all movements for each participant to 101 evenly spaced data points based on the
9 linear distance of the hand from its starting point to the screen (the z-dimension, or “forward”
10 from the participant). Then, to directly compare performance between the congruent and
11 incongruent trials in each task, we focused on the lateralized horizontal movement on the x-
12 dimension (left-right direction), the dimension along which the two competing potential targets
13 differ. Specifically, at each of the 101 points, we calculated a difference between the averaged
14 trajectories on the x-dimension between the congruent and incongruent conditions ($x\text{-pos}_{\text{incongruent}}$
15 - $x\text{-pos}_{\text{congruent}}$). The resultant difference score was calculated as positive if there was a
16 measurable difference between the average position for the congruent and the incongruent
17 conditions, indicating attraction of the hand movement toward the incorrect response alternative
18 and significant interference from the task-irrelevant feature.

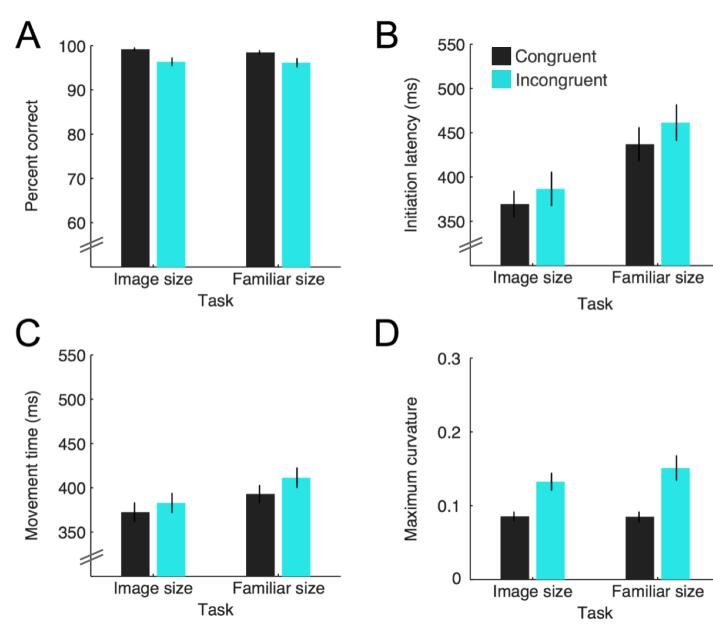

19 Comparing this difference score to zero reveals the points at which there was a
20 significant difference in position between congruent and incongruent trials. Significant
21 differences in position indicate interference from the task-irrelevant feature (e.g., in the *familiar*
22 *size* task, difference scores significantly above zero indicate significant interference from *image*
23 *size*).

1 These normalized positions were analyzed using a cluster-based permutation test. In
2 order to correct for the multiple comparisons arising from conducting 101 t-tests, we used the
3 Monte Carlo method to sample the datapoints in 500 iterations and find those points that were
4 more significant (at a 95% confidence level) than the calculated test statistic. This analysis was
5 performed using the Fieldtrip toolbox for Matlab (Oostenveld, Fries, Maris, & Schoffelen, 2011).
6 The key datapoint in this subset is the first datapoint that was significantly greater than zero,
7 indicating the point on average at which the trajectories of congruent and incongruent trials begin
8 to deviate.

9

10 Results

11 We excluded 5.34% ($\pm 1.09\%$ s.e.) of trials from data analysis for the image size task and
12 5.19% ($\pm 1.48\%$) for the familiar size task due to technical issues (e.g., expected occasional
13 sampling drop). Accuracy was 97.47% ($\pm 2.79\%$) for the image size task and 97.17% ($\pm 2.83\%$)
14 for the familiar size task. All subsequent analyses were restricted to correct trials.

15

1 **Figure 2.** Results for congruent versus incongruent trials in the image size and familiar size
2 tasks in Experiment 1. All error bars represent between-subjects standard error. **A.** Accuracy.
3 Accuracy was lower for the incongruent conditions than the congruent conditions in both tasks.
4 **B.** Initiation latency. IL was faster for congruent compared to incongruent trials in both tasks,
5 and faster overall for the image size task. **C.** Movement time. MT was faster for the congruent
6 conditions in both tasks, and faster overall for the image size task. **D.** Maximum curvature.
7 Movements were more curved in the incongruent trials for both tasks. Note, curvature values
8 represent a unitless ratio.

9

10 *Image size task*

11 As seen in Figure 2A, in the image size task (leftmost bars) participants performed more
12 accurately on congruent trials (black bars) compared to incongruent trials (cyan bars). This result
13 indicates that interference from familiar size was strong enough to lead to incorrect choices when
14 familiar size was in conflict with image size. This effect was supported by an overall main effect
15 of congruency $F(1,13) = 5.35, p = .038, \eta_p^2 = .292$, with no interaction between congruence and
16 task, $F(1,13) = .71, p = .794, \eta_p^2 = .005$. Further, a post-hoc t-test between congruent and
17 incongruent trials for the image size task similarly showed a significant effect, $t(13) = 2.83, p$
18 $= .014, d = .697$.

19 A congruency effect was also seen in initiation latency (Figure 2B) such that participants
20 were faster overall to initiate movements when image size and familiar size were congruent
21 compared when they were incongruent, $F(1,13) = 28.02, p < .001, \eta_p^2 = .683$ with no interaction
22 between congruence and task, $F(1,13) = .88, p = .365, \eta_p^2 = .063; t(13) = -2.84, p = .014, d =$
23 $-.199$. Similarly, congruency also affected online movement time (Figure 2C) such that

1 movements were executed more quickly overall when image size and familiar size were
2 congruent compared to incongruent, $F(1,13) = 41.14$, $p < .001$, $\eta_p^2 = .760$ with no interaction
3 between congruence and task, $F(1,13) = .519$, $p = .484$, $\eta_p^2 = .038$; $t(13) = -3.62$, $p < .001$, $d =$
4 -.259.

5 Finally, we examined maximum curvature (Figure 2D) over the course of the movement
6 as a measure of how much movements were pulled toward the incorrect object before ultimately
7 landing on the correct object. Figure 2D shows that the average maximum curvature of pointing
8 movements was greater when image size and familiar size were incongruent compared when
9 they were congruent, showing that familiar size interfered with the image size task (e.g., when
10 the task was to choose the larger object based on its image size, participants' hand movements
11 were drawn toward the object with the larger *familiar* size), $F(1,13) = 43.24$, $p < .001$, $\eta_p^2 = .760$
12 with no interaction between congruence and task, $F(1,13) = .79$, $p = .391$, $\eta_p^2 = .057$; $t(13) = -$
13 5.24 , $p < .001$, $d = -1.18$.

14 Overall, the results from the image size task indicate that the higher-level feature *familiar*
15 *size* significantly interferes with the lower-level *image size* when the two are incongruent, even
16 when familiar size is task-irrelevant. This is consistent with prior findings on the “familiar size
17 Stroop task” (Konkle & Oliva, 2012a).

18

19 *Familiar size task*

20 Figure 2A shows that, as in the image size task, participants were more accurate on
21 average for congruent compared to incongruent trials for the familiar size task (rightmost bars).
22 This demonstrates that image size interferes with familiar size even when it is task-irrelevant,
23 suggesting a bidirectional influence of both aspects of size on reaching. This effect was

1 supported by the aforementioned main effect of congruency overall, $F(1,13) = 5.35$, $p = .038$,
2 $\eta_p^2 = .292$, with no interaction between congruence and task, and a post-hoc t-test between
3 congruent and incongruent trials for the familiar size task, $t(13) = 2.43$, $p = .030$, $d = .802$.
4 Similarly, there was also an effect of congruency in IL (Figure 2B), $F(1,13) = 28.02$, $p < .001$,
5 $\eta_p^2 = .683$ with no interaction between congruence and task, $t(13) = -3.58$, $p = .003$, $d = -.328$
6 and MT (Figure 2C), $F(1,13) = 41.14$, $p < .001$, $\eta_p^2 = .760$ with no interaction between
7 congruence and task, $t(13) = -2.95$, $p = .011$, $d = -.461$ such that participants were slower when
8 image size and familiar size were incongruent. Finally maximum movement curvature (Figure
9 2D) was significantly greater when image size and familiar size were incongruent, as was also
10 the case in the image size task, $F(1,13) = 43.24$, $p < .001$, $\eta_p^2 = .760$ with no interaction between
11 congruence and task, $t(13) = -3.91$, $p = .002$, $d = -.876$.

12 Overall, these results suggest that there is significant interference from image size in the
13 familiar size task such that performance is impaired when image and familiar size are
14 incongruent, despite the fact that image size here is task-irrelevant.

15

16 *Comparing image and familiar size*

17 We additionally compared performance on the image and familiar size tasks in all the
18 aforementioned measures. We observed no difference between the tasks for accuracy, $F(1,13)$
19 $= .068$, $p = .799$, $\eta_p^2 = .005$, with no interaction between congruency and task $F(1,13) = .071$, p
20 $= .794$, $\eta_p^2 = .005$, or for maximum curvature, $F(1,13) = .636$, $p = .439$, $\eta_p^2 = .047$, with no
21 interaction between congruency and task $F(1,13) = .789$, $p = .391$, $\eta_p^2 = .057$. For initiation
22 latency we observed that participants were faster to initiate movements in the image size
23 judgment task compared to the familiar size judgment task, $F(1,13) = 69.22$, $p < .001$, $\eta_p^2 = .842$,

1 with no interaction between congruency and task $F(1,13) = .880$, $p = .365$, $\eta_p^2 = .063$. Similarly
2 online movement execution was faster, with faster MTs observed for the image size task, $F(1,13)$
3 = 11.96, $p = .004$, $\eta_p^2 = .479$, with no interaction between congruency and task $F(1,13) = .519$,
4 $p = .484$, $\eta_p^2 = .038$.

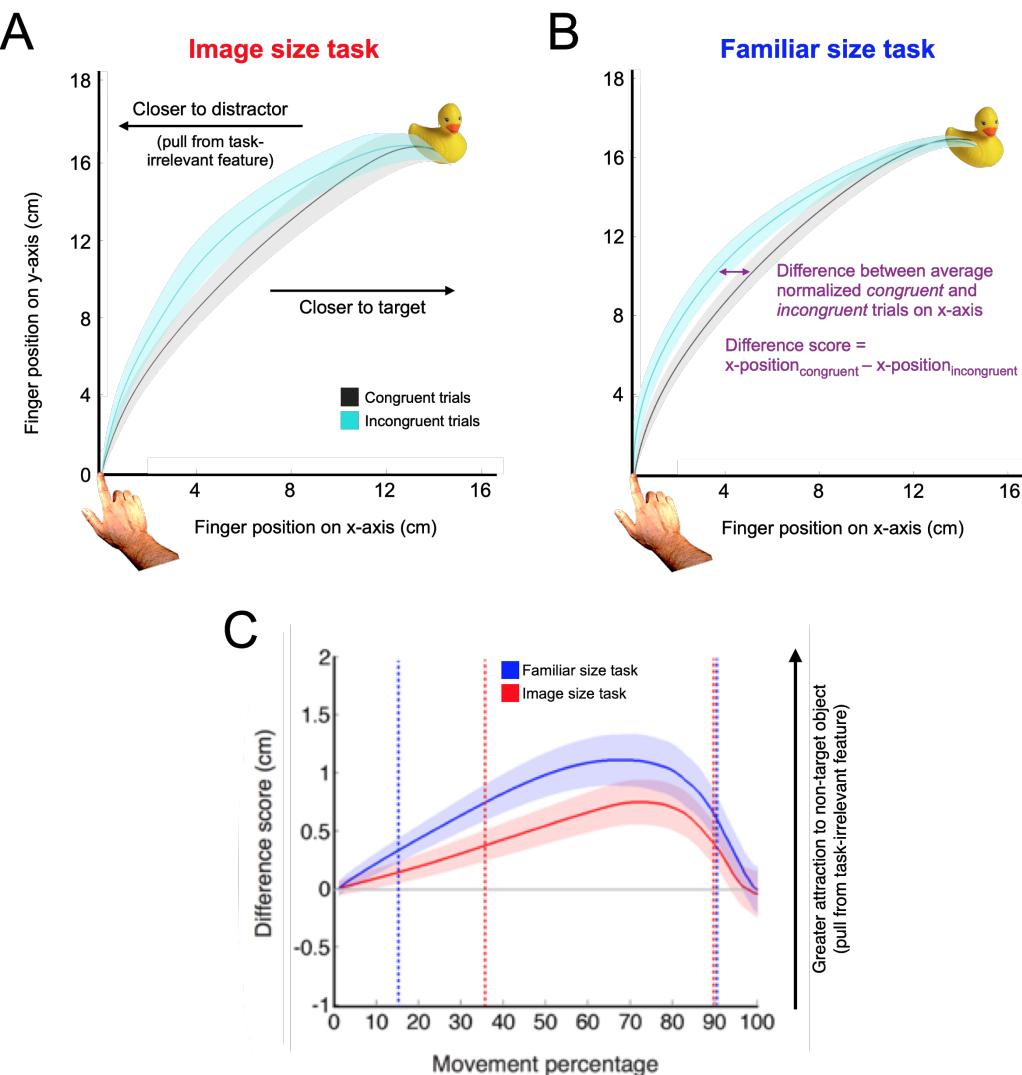

5 Overall then, participants took longer to plan and execute their movements in the familiar
6 size task compared to the image size task. This result, perhaps, is related to the fact that familiar
7 size is characterized as *high level* and image size is characterized as *low level* meaning that
8 evaluating familiar size requires more cognitive processing than evaluating image size. For
9 instance, according to classical models of object processing, once the visual system extracts
10 feature information such as image size, curvature, and depth, basic-level object recognition
11 precedes accessing knowledge about that object such as its familiar size (Rosch et al., 1976;
12 Collins & Quillian, 1969; Jolicoeur, Gluck, & Kosslyn, 1984). This effect though was not seen in
13 accuracy or maximum curvature, suggesting that the key difference between the two tasks is
14 temporal in nature.

15

16 *Time course of movement modulation in the image and familiar size tasks*

17 Our analysis of hand movement trajectory revealed key differences in maximum
18 curvature between congruent and incongruent trials, in both the image and familiar size tasks
19 (Figure 2D). In addition to the spatial measure of *maximum curvature*, which refers to a discrete
20 point in a hand movement, we can additionally examine the impact of incongruency over the
21 course of our continuous movement data. Comparing hand positions over the course of the
22 movement for congruent and incongruent trials in the image and familiar size tasks provides
23 insight into *when* image and familiar size interact in addition to previous measures of *how much*

1 they interact. As mentioned previously, movements were normalized to space with respect to
 2 reach distance from the starting point to the target (see, *Reach trajectory normalization* in
 3 *Methods* for details). Space-based normalization has the advantage of minimizing a potential
 4 confound from MT differences across trials. Thus, in evaluating the evolution of conflict
 5 between image and familiar size, we discuss the percentage into the course of the movement at
 6 which differences occur (Gallivan & Chapman, 2014).

7
 8 **Figure 3.** Average normalized trajectory of hand movements in congruent (black line) and
 9 incongruent (cyan line) trials over the course of accurate reach-to-touch movements across all

1 participants. **A.** Image size task trials, where familiar size is the task-irrelevant interfering
2 feature. **B.** Familiar size task trials, where image size is the task-irrelevant interfering feature.
3 Movements to the left and right targets are collapsed across the midline, such that positions
4 farther to the right are closer to the target, and farther to the left are closer to the midline and the
5 incorrect object. Ribbons represent 95% confidence intervals. Hand and target are not to scale.
6 **C.** Difference scores between congruent and incongruent trials representing the magnitude of
7 interference by incongruency, in the image and familiar size tasks. Greater positive values
8 represent greater attraction to the alternative (incorrect) object in incongruent trials, i.e., the
9 strength of interference from the task-irrelevant feature. Scores in the familiar size task (where
10 interference is from image size) rise significantly above zero earlier and peak earlier than the
11 scores for the image size task (where interference is from familiar size). The ribbons represent
12 95% confidence intervals.

13 Figure 3 shows average normalized hand movements in real space for the image size task
14 where familiar size is the interfering feature (Figure 3A), and the familiar size task where image
15 size is the interfering feature (Figure 3B). For both tasks, trials where image and familiar size
16 were congruent are shown in black, and trials where image and familiar size were incongruent
17 are shown in cyan. Though trials were counterbalanced such that reaches were performed with
18 equal frequency to the left and right sides of the screen, here we have collapsed all trials along
19 the midline such that greater values on the x-axis represent hand positions closer to the correct
20 target object and smaller values on the x-axis represent hand positions closer both to the starting
21 position and to the incorrect non-target object. In both tasks, we observed that the movements
22 were relatively direct to the target in the congruent trials (black lines). In contrast, movements
23 were more pulled by the task-irrelevant feature and therefore curved toward the distractor object

1 in the incongruent trials (cyan lines), leading to significant deviations between movement paths
2 for congruent and incongruent trials in both tasks.

3 In order to analyze the deviation between congruent and incongruent trials over time, and
4 particularly to compare the deviations in the image size with the deviations in the familiar size
5 tasks over time, we calculated a difference score between normalized congruent and incongruent
6 trials along the x-dimension in each task, as shown in Figure 3C. Our goal in calculating a
7 difference score was to isolate and quantify the interference from the task-irrelevant feature.
8 Given that the correct target (defined by the task-relevant feature) and the incorrect distractor
9 object (defined by the task-irrelevant feature) were separated in space on the screen only in the x-
10 dimension, we analyzed this dimension exclusively to most precisely examine this interference.

11 Here the difference between incongruent and congruent trials is depicted in red for the
12 image size task and in blue for the familiar size task. In the familiar size task (blue solid line),
13 where image size is the competing feature, difference scores are significantly greater than zero
14 between 15% - 91% (two vertical blue dotted lines) of the movement, indicating that the average
15 paths of the congruent and incongruent trials were significantly different in this span. In contrast,
16 in the image size task (red solid line), where familiar size is the competing feature, the congruent
17 and incongruent trajectories deviated later than in the familiar size task, approximately between
18 36% - 90% into the movement (two vertical red dotted lines). Thus, congruency becomes a
19 factor in the familiar size task after a smaller portion of the movement; or said another way,
20 image size influences movements at an earlier proportion than familiar size does (Bennett, 2007).
21 There is no significant difference in the points at which the difference scores return to zero,
22 indicating that congruent and incongruent trials converge at similar points of the movement for
23 the image and familiar size tasks.

1 Taken together, these results suggest that the image sizes of objects impact movement to
2 a greater degree than familiar size does, as demonstrated by a greater effect of incongruity in
3 the familiar size compared to the image size task. Not only is the magnitude greater, but the
4 impact of image size is observed earlier in the course of the decision-making process than
5 familiar size is. This suggests that image size may be processed more robustly overall than
6 familiar size, though once again both are automatic and robust enough to interfere with the other.

7

8 **Summary**

9 The goal of Experiment 1 was to examine if, and how, the processing of *image size* and
10 *familiar size* influences goal-directed pointing movements when one type of object size is task-
11 irrelevant. Overall, we demonstrated that both the image and familiar sizes of real-world objects
12 play a role in planning and generating goal-directed action. Specifically, when we manipulated
13 the congruency of targets' image and familiar sizes, each of these two aspects of object
14 perception interfered with the other. This suggests that both image size and familiar real-world
15 size are aspects of object perception and identification that occur automatically, even when task-
16 irrelevant, and furthermore are not independent from action. Despite the bidirectional
17 interference, however, image size may be more robustly processed and represented, and interfere
18 with familiar size judgments more than familiar size interferes with it (e.g., Figure 3C). This
19 observation was investigated in more detail in Experiment 2, along with questions regarding
20 absolute and relative familiar size differences and their relationship with action.

21

22

23

1 **Experiment 2: Effects of familiar size difference magnitude on action**

2 In Experiment 1, like in much of the existing literature, we categorized the familiar size
3 of the two objects presented concurrently by which of the two was “larger” and which was
4 “smaller,” while largely ignoring the magnitude of this relative size difference. (Chao & Martin,
5 2000; Downing, Chan, Peelen, Dodds, & Kanwisher, 2006; Kanwisher, 2001; Macuga &
6 Papailiou, 2012; Wang & MacKenzie, 1999). Thus, it is still unknown whether it only matters
7 that one object’s familiar size is larger than the other, or whether *how much* larger it is has an
8 impact as well. For example, does comparing two objects where one is only slightly larger than
9 the other (e.g., a peanut and a paperclip) have the same effect as comparing two objects that are
10 vastly different sizes (e.g., a bathtub and a paperclip)? In Experiment 2, to examine whether
11 differing degrees of real-world size differences impact goal-directed pointing, we expanded our
12 set of real-world objects to include a wider range of familiar sizes, and systematically
13 manipulated the magnitude of the difference in familiar sizes between the paired targets. We
14 expected that if familiar size is treated as a graded spectrum, varying the magnitudes of familiar
15 size differences may lead to corresponding graded effects on action, and on the interference
16 between image and familiar size.

17

18 **Methods**

19 *Participants*

20 Twelve new right-handed participants (10 female, mean age 21.6) who did not participate
21 in Experiment 1, with normal color vision and normal or corrected-to-normal visual
22 acuity completed both visually guided pointing tasks: familiar size judgment and image
23 size judgment. Of these, eleven (10 female, mean age 21.7) additionally performed a

1 familiar size rating task to validate our relative familiar size category manipulation.
2 Participants provided their informed consent and were compensated monetarily (\$10 per
3 hour) or with course credit for their participation. The experimental protocol was
4 approved by the Brown University Institutional Review Board in accordance with the
5 Code of Ethics of the World Medical Association (Declaration of Helsinki) for
6 experiments involving humans.

7 *Apparatus*

8 The same apparatus was used as in Exp. 1.

9 *Stimuli*

10 Experiment 2 stimuli were similar to those used in Experiment 1. We created image pairs
11 from individual objects in the Konkle et al. “Object Size Range” database (Konkle & Oliva,
12 2011). Images in this database are divided into eight groups based on their familiar real-world
13 sizes. These groups were independently defined and validated by participants (Konkle & Oliva,
14 2011). Using these eight familiar size groups, we defined four categories of paired images
15 ranging from small familiar size differences to large familiar size differences. Objects in
16 Category 1 were selected from within the same familiar size group (e.g. a peanut and a paperclip
17 [both group 1], or a space shuttle and an airplane [both group 8]), Category 2 were two groups
18 apart (e.g. a wineglass [group 3] and a teabag [group 1]), Category 3 were four groups apart (e.g.
19 a cooler [group 5] and a die [group 1]), and Category 4 were six groups apart (e.g. a car [group
20 7] and a key [group 1]). All eight groups defined by familiar size by Konkle et al. (2011) were
21 represented in all of our four categories defined by relative familiar size difference between
22 pairs. Thus, in this four category by eight group manipulation there was a total of 32 image pairs.

1 Examples of pairs from each category, in their congruent and incongruent configurations, are
2 shown in Figure 4A. All image pairs can be seen in Figure 4B.

7 **Figure 4.** Representative examples of familiar size categories. **A.** Representative examples of
8 each of the four relative familiar size categories for object pairs, in both congruent and
9 incongruent conformations. Categories 1-4 have progressively greater differences in familiar size
10 magnitude. **B.** Every image pair used in its congruent conformation, arranged by category and
11 group.

12

1 *Procedure*

2 The Exp. 2 procedure was the same as in Exp. 1. Our four relative familiar size category
3 manipulation based on the established image dataset was validated by participants' ratings of
4 how different the familiar sizes of the objects in each pair were on a 0-10 scale representing no
5 difference to extreme size differences. All image pairs from the pointing tasks were presented
6 with a rating bar at the bottom of the screen representing a continuum from 0 to 10. Participants
7 were instructed to use the mouse to click anywhere within the bar rating how large the relative
8 familiar size difference was for the object pair shown (e.g., "How different are the sizes of a
9 rubber duck and a boat in the real world?"). As in Experiment 1, object pairs were presented with
10 relative image size and familiar size either congruent or incongruent. This task took place after
11 both the image and familiar size judgment tasks in order not to bias performance.

12

13 *Data analysis*

14 All data analysis was identical to Experiment 1, with the following exceptions. The
15 measure *rating* was defined as the average value given to each object pair when participants
16 were instructed to rate the pairs based on their relative *familiar size* differences. To analyze the
17 effects of task and congruency in movement accuracy, initiation latency, movement time, and
18 maximum curvature, and to compare between the two tasks as in Exp. 1, we performed a series
19 of 2x4x2 ANOVAs with factors of congruency (congruent or incongruent), category (1-4), and
20 task (image size vs. familiar size judgment).

21

22 **Results**

23 In total, 10.75% ($\pm 1.02\%$, s.e) of trials were excluded from data analysis from the image

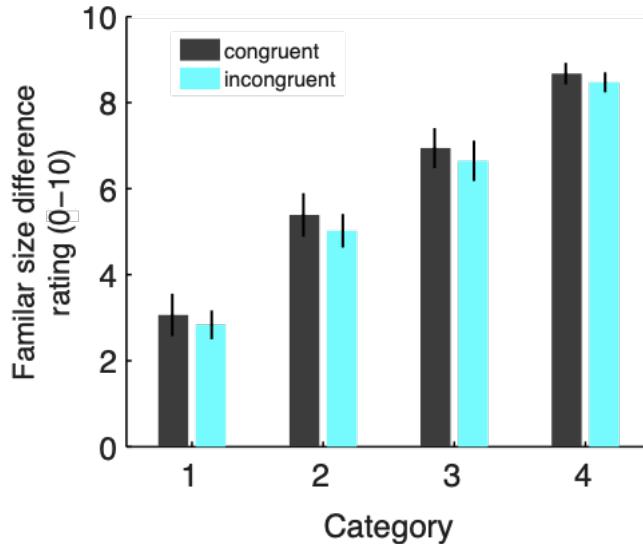

1 size task and 10.93% ($\pm 1.27\%$) from the familiar size task due to technical issues (e.g. sampling
2 drop). Accuracy was 89.25 % ($\pm 1.02\%$) for the image size task and 88.09 ($\pm 1.27\%$) for the
3 familiar size task. All data analyses were restricted to correct trials.

4

5 *Ratings*

6 To validate the four categories that we designed based on relative familiar size difference
7 magnitude, we asked participants to rate this difference for each pair of objects. Additionally, we
8 presented each pair in both its congruent and incongruent conditions, in order to evaluate the
9 effect of congruency on subjective ratings of familiar size difference.

10 Figure 5 shows the average ratings assigned by participants to the image pairs in each of
11 the four relative familiar size difference categories (1-4), when the relative familiar and image
12 sizes were congruent (black) and incongruent (cyan). Participant ratings validate our
13 manipulation of creating image pairs that fit these four categories—Figure 6 shows a clear trend
14 of average rating increasing in a stepwise manner across categories 1-4 (small to large familiar
15 size difference). This was supported by a 2x4 repeated measures ANOVA with factors of
16 congruency (congruent vs. incongruent) and category (1-4), which revealed a main effect of
17 category, $F(3,30) = 55.80, p < .001, \eta_p^2 = .848$.

1

2 **Figure 5.** Average ratings of relative familiar size differences for image pairs in each relative
3 image size category, when paired objects' image and familiar sizes are congruent and
4 incongruent. Ratings supported our category definitions, with higher ratings given to categories
5 designed to show larger familiar size differences. There was no significant difference in rating
6 based on congruency. All error bars represent between-subjects standard error.

7

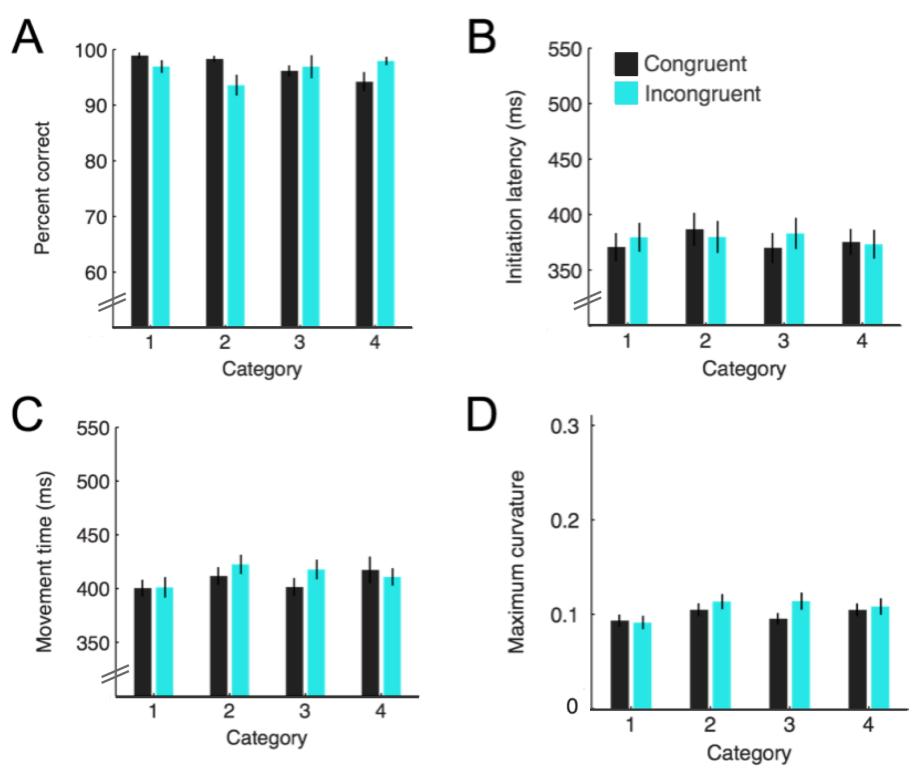

8 Figure 5 appears to show a trend such that ratings of the familiar size differences were
9 higher on average in the congruent compared to incongruent condition. Such an effect would
10 suggest that participants attended to the objects' image sizes despite task-irrelevance, and that
11 congruent *image size* differences magnified the perceived difference in familiar size. However,
12 there was no significant effect of congruency, $F(1,10) = .874$, $p = .372$, $\eta_p^2 = .080$, and no
13 interaction between congruency and category, $F(3,30) = .705$, $p = .557$, $\eta_p^2 = .066$. This could be
14 due to the absence of a meaningful effect, or insufficient power. This latter possibility may
15 reflect the relative weakness of a perceptual button-press task compared to the more robust
16 action measures employed in the main task (which show consistent effects of congruency) in
17 accord with past research (Finkeiner et al., 2008).

1 *Image size task*

2 Accuracy. As shown in Figures 6A, there were no clear trends in accuracy across
3 conditions in the image size task. There was no main effect of congruency (*congruent* vs.
4 *incongruent*), $F(1,11) = .223, p = .648, \eta_p^2 = .024$, or category (1-4), $F(3,33) = 1.42, p = .259, \eta_p^2 = .136$. There was however a significant interaction between the two such that the strength of
5 the congruency effect was different in different categories, $F(3,33) = 6.62, p = .002, \eta_p^2 = .424$.
6 This difference does not appear to follow a systematic trend across categories as familiar size
7 difference magnitude varies, and thus it is impossible to make any claims about a meaningful
8 effect of category on congruency or vice versa.

9

10

11

12 **Figure 6.** Results for congruent versus incongruent trials across relative familiar size conditions
13 in the image size task of Experiment 2. All error bars represent between-subjects standard error.

1 **A.** Accuracy. Accuracy was consistent across all conditions. **B.** Initiation latency. IL was
2 consistent across all conditions. **C.** Movement time. MT was slower overall for categories with
3 larger familiar size differences. **D.** Curvature. Movements were more curved in the incongruent
4 trials overall, and for categories with lower relative familiar size differences.

5

6 Initiation latency. In order to examine how congruency and the relative differences
7 between real-world objects' familiar sizes affected movement preparation we again analyzed
8 initiation latency (IL). Figure 6B shows that for the image size task, unlike in Exp. 1, IL was
9 consistent across conditions. There was no significant difference based on congruency, $F(1,11) =$
10 $1.27, p = .282, \eta_p^2 = .096$, based on category, $F(3,33) = 2.37, p = .087, \eta_p^2 = .165$, and no
11 interaction between the two, $F(3,33) = 2.34, p < .085, \eta_p^2 = .166$.

12 Movement time. Again, to examine how congruency and familiar size difference affected
13 the online control of pointing we analyzed movement time (MT). Figure 6C shows a marginal
14 effect of congruency on MT in the image size task, $F(1,12) = 4.02, p = .068, \eta_p^2 = .251$.
15 Additionally we observed that with larger familiar size differences, MTs were slower overall,
16 $F(3,33) = 10.10, p < .001, \eta_p^2 = .457$. As in the accuracy data, there was an interaction between
17 congruency and category, $F(3,33) = 5.36, p = .004, \eta_p^2 = .309$. Again though, this effect does not
18 appear to vary systematically with category; Figure 6C shows that categories 2 and 3 display
19 greater differences between congruent and incongruent trials than 1 and 4, so we can draw no
20 conclusions about the interaction in terms of MT.

21 Maximum Curvature. In the image size task, maximum curvature results are consistent
22 with those seen in movement time, and replicate the congruency effect seen in maximum
23 curvature in Exp. 1 (Figure 2D, left). Maximum curvature was greater overall in the incongruent

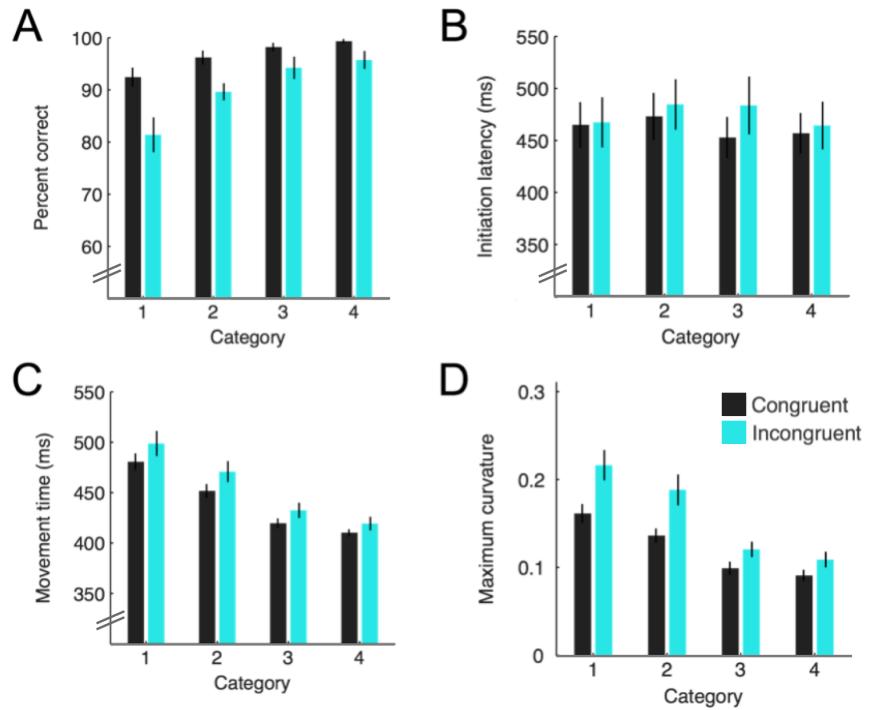

1 conditions, $F(1,11) = 6.72, p = .024, \eta_p^2 = .359$, suggesting interference from familiar size when
2 the two were incongruent (Figure 6D). Maximum curvature was also larger when familiar size
3 differences were larger, $F(3,33) = 7.68, p < .001, \eta_p^2 = .390$. There was additionally an
4 interaction between congruency and category, $F(3,33) = 2.99, p = .044, \eta_p^2 = .199$, indicating
5 that congruency doesn't have the same impact across categories where familiar size differences
6 vary.

7

8 *Familiar size task*

9 Accuracy. In the familiar size task, we see several effects in accuracy not seen in the
10 image size task. As seen in Figure 7A, there was a significant effect of congruency such that
11 accuracy was lower when image and familiar size were incongruent, $F(1,11) = 11.37, p = .008,$
12 $\eta_p^2 = .558$. There was additionally an effect of category such that accuracy was lower for the
13 conditions with smaller familiar size differences, $F(3,33) = 32.48, p < .001, \eta_p^2 = .783$. This
14 suggests that judgments of relative familiar size were more difficult when paired objects were
15 closer in their familiar size. Here familiar size was the task-relevant feature while it was task-
16 irrelevant in the image size task. Thus, it is not surprising to see an effect of category here but
17 not in the image size task (Figure 6A). In Figure 7A there appears to be a trend such that the
18 congruency had a smaller effect in larger categories, suggesting that larger familiar size
19 differences were processed more robustly and more successfully resisted interference from
20 image size, however this interaction was only marginally significant, $F(3,33) = 2.61, p = .072, \eta_p$
21 $^2 = .225$.

22

1

2 **Figure 7.** Results for congruent versus incongruent trials across relative familiar size conditions
3 in the familiar size task of Experiment 2. All error bars represent between-subjects standard
4 error. **A.** Accuracy. Accuracy was higher for congruent compared to incongruent conditions, and
5 for larger relative familiar size category. **B.** Initiation latency. IL was faster for congruent trials.
6 **C.** Movement time. MT was faster for congruent trials, and for larger relative familiar size
7 difference categories. **D.** Curvature. Movements were more curved in the incongruent trials
8 overall, and for categories with lower relative familiar size differences.

9

10 Initiation latency. Figure 7B shows that, unlike in the image size task, ILs were
11 marginally slower for incongruent compared to congruent trials, $F(1,11) = 4.53, p = .055, \eta_p^2$
12 $= .274$. Additionally, there was a significant effect of category, $F(3,33) = 5.35, p = .004, \eta_p^2$
13 $= .308$, and interaction between congruency and category, $F(3,33) = 3.48, p = .026, \eta_p^2 = .225$.

1 In the image size task, familiar size was the task-irrelevant interfering factor, whereas

2 here in the familiar size task, image size is the interfering factor. Overall, familiar size failed to

3 exert any influence on IL in the image size task (Figure 7B), but image size significantly

4 interfered with the speed of movement initiation for the familiar size task (Figure 7B).

5 Additionally, unlike the image size task, differences in familiar size impacted IL, as might be

6 expected given that image size here was the task-relevant feature. However, these differences

7 between category do not appear to follow any systematic trend, but rather be driven primarily by

8 Category 3. Thus, no strong claims can be made based on this effect.

9

10 Movement time. Figure 7C shows that in the familiar size task, movements were faster

11 overall when image and familiar size were congruent, $F(1,11) = 12.74, p = .004, \eta_p^2 = .515$.

12 Additionally, MTs were significantly faster when familiar size differences were larger (category

13 1-4), $F(3,33) = 78.06, p < .001, \eta_p^2 = .867$. There was no interaction between these factors,

14 $F(3,33) = .216, p = .885, \eta_p^2 = .018$. As with IL, it is not surprising that category, which is based

15 on relative familiar size difference, would modulate the familiar size task more than the image

16 size task. That said, a clear asymmetry exists between image size's influence on familiar size,

17 and familiar size's influence on image size, as seen in the difference between congruency effects

18 in Figure 6C and 7C.

19

20 Maximum Curvature. As in the image size task, maximum curvature was again greater

21 overall in the incongruent compared to congruent conditions, $F(1,11) = 18.47, p < .001, \eta_p^2$

22 $= .606$, (Figure 7D). Here though, there was less maximum curvature overall when familiar size

23 differences were smaller compared to larger (categories 1-4), $F(3,33) = 68.95, p < .001, \eta_p^2$

1 = .852. Again, familiar size here is the task-relevant factor while it is the interfering factor in the
2 image size task, leading to opposite effects of increasing familiar size difference in the two tasks.
3 What is consistent across both is that with larger familiar size differences, there is a larger effect
4 of familiar size.

5 Similarly, there was an interaction between these two factors such that as relative familiar
6 size difference (category) increased, the incongruity effect decreased, $F(3,33) = 40.96, p$
7 $< .001, \eta_p^2 = .773$. Again, this reflects a decreasing degree of interference from image size as
8 relative familiar size differences increase, and is expectedly the reverse of the effect seen in
9 image size.

10

11 *Comparisons between image and familiar size tasks*

12 In addition to the above within-task measures, we again compared the image and familiar
13 size tasks to each other. We found greater accuracy, $F(1,11) = 6.48, p = .031, \eta_p^2 = .419$, faster
14 initiation latency, $F(1,11) = 40.06, p < .001, \eta_p^2 = .770$, faster movement time $F(1,11) = 46.41, p$
15 $< .001, \eta_p^2 = .795$, and smaller maximum curvature, $F(1,11) = 107.25, p < .001, \eta_p^2 = .899$ in
16 the image than the familiar size task. Taken together, this suggests that the familiar size task may
17 have been more difficult than the image size task, consistent with participants' subjective
18 reports.

19 There were additionally task by congruency interactions in accuracy, $F(1,11) = 7.20, p$
20 $= .025, \eta_p^2 = .444$, movement time, $F(1,11) = 84.62, p < .001, \eta_p^2 = .876$, maximum curvature,
21 $F(1,11) = 10.81, p = .006, \eta_p^2 = .474$, and a marginally significant effect in initiation latency,
22 $F(1,11) = 4.37, p = .059, \eta_p^2 = .267$. Together, these all point to image size interfering in the
23 familiar size task more than familiar size did in the image size task.

1 We also observed interactions between category (i.e. the degree of familiar size
2 difference between paired objects) and task for both movement time and maximum curvature,
3 such that categories with larger familiar size differences led to shorter movement times, $F(3,33)$
4 = 84.32, $p < .001$, $\eta_p^2 = .89$, and less curvature, $F(3,33) = 85.12$, $p < .001$, $\eta_p^2 = .89$, in the
5 familiar size compared to the image size task. This effect is not surprising given that familiar size
6 was task-relevant in the familiar size task, and task-irrelevant in the image size task.

7 Finally, for maximum curvature, there was a three-way interaction between task,
8 congruency, and category, $F(3,33) = 11.21$, $p = .007$, $\eta_p^2 = .51$. Such an interaction is expected
9 given both the individual main effects seen in the previous analysis, and the way our categories
10 are defined based on magnitude of familiar size difference. In the image size task (Figure 6D),
11 larger familiar size differences (category) led to more curved trajectories $F(3,33) = 7.68$, p
12 $< .001$, $\eta_p^2 = .390$. However this effect seems to be driven entirely by the incongruent
13 conditions—maximum curvature increases across the incongruent conditions based on category,
14 while the congruent trials are stable across category, consistent with a category by congruency
15 interaction, $F(3,33) = 2.99$, $p = .044$, $\eta_p^2 = .199$. This suggests that increasing the familiar size
16 difference increases the interference of familiar size in performing the image size task. However,
17 when familiar size and image size are congruent familiar size difference plays no role, or a
18 negligible role compared to the perception of image size.

19 In the familiar size task, there was an overall decrease in maximum curvature as the
20 familiar size difference (category) increased (Figure 7D), $F(3,33) = 68.95$, $p < .001$, $\eta_p^2 = .852$.
21 This is the reverse of the effect seen in the image size task because here participants' decisions
22 were made based on *familiar size* as opposed to *image size*, while category was defined by
23 relative familiar size difference in both cases. Thus, the lower maximum curvature for the greater

1 familiar size differences may reflect lower task difficulty. Similarly, the interaction effect
2 suggests that the effect of congruency is different across categories. Specifically, the congruency
3 effect is greater in the smaller familiar size difference categories, showing that image size
4 interferes with participants' ability to judge familiar size more when the familiar size difference
5 is smaller (i.e., the familiar sizes of the paired objects are closer). This decrease in the effect of
6 congruency across category was supported by a post-hoc linear trend analysis in which we found
7 that difference scores ($\text{curvature}_{\text{incongruent}} - \text{curvature}_{\text{congruent}}$) significantly decreased across
8 category, as familiar size difference increased, $r = -.32, p = .028$.

9 Taken together with converging evidence that image size is processed more robustly than
10 familiar size, this suggests that image size is the greater influence on trajectory overall, but that
11 familiar size exerts a larger influence the larger the magnitude of familiar size differences. This
12 increased modulation of movement by familiar size leads both to greater interference from
13 familiar size in the image size task, and greater resistance against interference from image size in
14 the familiar size task.

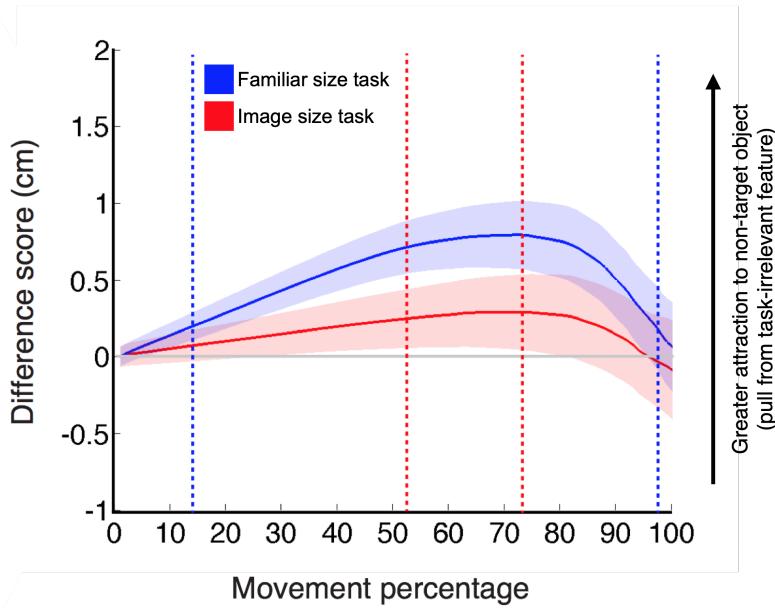

15

16 *Time course of movement modulation in the image and familiar size tasks*

17 As in Experiment 1, we again calculated difference scores from the normalized congruent
18 and incongruent trials in each task to examine the influence of image and familiar size over time
19 (Figure 8). Specifically, we were interested in the effect of varying the magnitude of the familiar
20 size difference between paired images on the time course of both image size's and familiar size's
21 impact on movement.

22 We first performed the same time course analysis as in Exp. 1 by comparing the
23 difference scores between congruent and incongruent trials for the image size task (solid red line)

1 and familiar size task (solid blue line). Figure 8 shows that the difference scores were
 2 significantly above zero 53% - 71% into the movement for the image size task (vertical red
 3 dotted lines) and 14% - 97% into the movement for the familiar size task (vertical blue dotted
 4 lines). This replicates our Exp. 1 findings that image size “came online” and influenced
 5 movements earlier in the course of movements than familiar size did.

6
 7 **Figure 8.** Difference scores between congruent and incongruent trials representing the
 8 magnitude of interference by incongruity, in the image and familiar size tasks. Scores in the
 9 familiar size task (blue), where image size is the interferer rise significantly above zero earlier
 10 than the scores for the image size task (red), where familiar size is the interferer. The ribbons
 11 represent 95% confidence intervals.

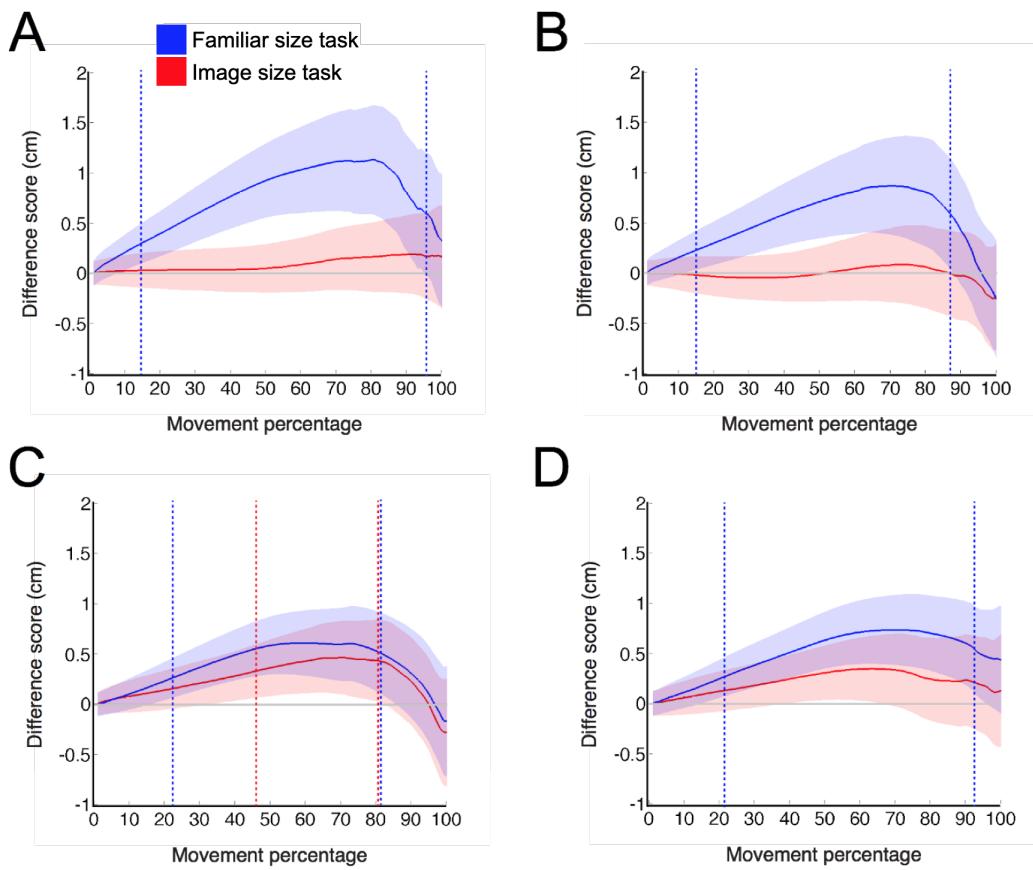

12

13 It is worth noting that the precise timing and the magnitude of interference in Exp. 2 did
 14 not completely replicate the results in Exp. 1. In the image size task specifically, familiar size
 15 interfered later and less robustly in Exp. 2 than in Exp. 1. This could reflect the fact that the

1 range of familiar sizes was much larger in Exp. 2 compared to Exp. 1, and thus there was a wider
2 range of interference effects and more noise overall.

3 We additionally compared the influences of image and familiar size on the movements
4 between categories. Figure 9 shows the time course of difference scores for each category, with
5 the image size task presented in red and the familiar size task in blue: Figures 9A-D represent
6 data from Category 1 to Category 4, which contained the smallest to the largest familiar size
7 difference magnitudes, respectively.

8

9

10 **Figure 9.** Time course of different scores across categories in Experiment 2. Red and blue lines
11 represent mean difference scores in the image size task and familiar size task, respectively. The

1 ribbons represent 95% confidence intervals. **A.** Category 1. **B.** Category 2. **C.** Category 3. **D.**
2 Category 4.

3 For the image size task (red), where familiar size was the interfering factor, there was an
4 overall main effect of congruency. However, only Category 3 independently displays a
5 difference scores significantly above zero, 46% - 82% into the movements. Thus, familiar size
6 interference in the known size task cannot be compared between all familiar size categories.

7 In the familiar size task (blue) where image size was the interfering factor, difference
8 scores were significantly greater than zero for all categories, 15% - 96% into the movement for
9 category 1, 16% - 88% for category 2, 23% - 81% for category 3, and 22% - 93% for category 4.
10 Thus, there was no overall effect of category in terms of where in the movement interference
11 from image size came online, indicating that the magnitude of the familiar size difference did not
12 significantly impact how congruence effects unfolded.

13 Overall then, we replicate the time course effect seen in Exp. 1 (Figure 3C), with image
14 size influencing trajectory earlier in the course of the movement than familiar size. However,
15 when we separate out the categories defined by familiar size difference, we see no differences in
16 the timing of a congruency effect in the familiar size task, and no reliable congruency effect in
17 the image size task. Thus, the magnitude of relative familiar size difference (i.e. category)
18 modulated movements in both the image and familiar size tasks in terms of *trajectory* (i.e.
19 maximum curvature), but not in terms of *timing*. This suggests that differences in the familiar
20 sizes of objects lead to corresponding differences in the degree of interference between image
21 and familiar size, but not *when* the interference occurs. This result might also suggest that the
22 conflict resolution process in our paradigm is sensitive during movements, and may even be
23 dynamically tailored to this period.

1 **Summary**

2 The goal of Experiment 2 was to examine whether differing degrees of real-world size
3 difference impact goal-directed pointing to differing degrees, and to do this we expanded our set
4 of real-world objects to include a wider range of familiar sizes and systematically manipulated
5 the magnitude of the difference in familiar sizes between paired targets. Here, we again
6 demonstrated bidirectional interference between the perception of *image size* and *familiar size*
7 when the two are presented in an incongruent manner, though here we also found evidence of
8 image size exerting greater influence on familiar size than vice versa. Furthermore, we observed
9 several trends associated with greater magnitudes of familiar size difference between paired
10 objects. Namely, in the familiar size judgment task, the larger the familiar size difference, the
11 lower the maximum curvature of goal-directed pointing movements overall. This is consistent
12 with greater differences in familiar size making familiar size judgments easier.

13 Additionally, the incongruence effect in the familiar size task diminished with increasing
14 familiar size difference magnitude. This indicates that image size did interfere with familiar size
15 judgment across categories, but did so less when the relative familiar size difference was greater.
16 Similarly, in the image size judgment task, the interference from familiar size increased with
17 increasing familiar size difference across the four categories. Overall our result is consistent with
18 image size perception being the more automatic of the two, and exerting greater influence on the
19 decision making process and on hand movements. However, the greater the difference between
20 the familiar real-world sizes of the objects, the greater the effect that familiar size has, and the
21 more it mitigates/interferes with image size's influence.

22

23

1 **General Discussion**

2 Our perception of real-world objects involves conceptualization of how large or small
3 they are in the real world—we expect a rubber duck to be physically smaller than a boat (though
4 artists have taught us that this doesn't have to be the case) (Konkle & Oliva, 2011, 2012a,
5 2012b). In the current study we presented participants with pairs of real-world objects, and
6 manipulated their relative *image* and *familiar* sizes. By using a visually-guided pointing
7 paradigm and decision-making task based on either image size or familiar size, we were able to
8 assess the relationship between these two aspects of object perception and their impacts on
9 visually-guided action. Overall, we observed that the conflict between image and familiar sizes is
10 resolved over the course of the movement and results in curved trajectories, suggesting early
11 processing of each feature, and a later conflict resolution between the two.

12

13 *Mechanisms of image and familiar size perception*

14 Object perception relies on a hierarchy of perceptual processes representing increasingly
15 complex object features (Riesenhuber & Poggio, 1999). Image size is a low-level feature, and is
16 represented essentially by the size of the stimulus on the retina—far earlier in the visual
17 processing pathway than anything related to object identity. However, recent studies have
18 demonstrated that familiar size can be represented and processed earlier than classical models of
19 object processing assume (Rosch et al., 1976; Collins & Quillian, 1969; Jolicoeur, Gluck, &
20 Kosslyn, 1984).

21 For instance, as early in the image processing pathway as V1, representations have been
22 shown to reflect viewers' subjective perception of objects' sizes as opposed to their veridical
23 image size. Sperandio, Chouinard, and Goodale (2012) found that, despite constant retinal image

1 size, V1 activity reflected perceived object size in a size constancy task that manipulated target
2 viewing distance, suggesting that image size perception is influenced by other aspects of
3 perception even at this early stage in processing.

4 Furthermore, the familiar sizes of real-world objects have been shown to have neural
5 representations independent of image size. Konkle and Oliva (2012b) showed that familiar object
6 size is represented in the occipitotemporal cortex (OT) much like object categories, with larger
7 objects represented in medial OT and smaller objects in lateral OT. Thus, our observation that
8 both image size and familiar size are processed automatically is consistent with known
9 mechanisms underlying object perception. In addition, recent studies have shown that processing
10 mid-level perceptual features can be sufficient to distinguish objects of different familiar sizes
11 without real-world context (Long et al., 2016; Long et al., 2018).

12 Here, we report evidence of bidirectional interference that suggests interactions between
13 image and familiar size mechanisms. Image size was consistently the more dominant of the
14 two—it was processed earlier and more robustly, and participants anecdotally reported finding it
15 more salient than familiar size. That said, we demonstrated in Experiment 2 that the robustness
16 of familiar size’s influence on movements, and we infer therefore its representation strength,
17 increased with increasing familiar size magnitude, and that this robustness mitigated image sizes’
18 effects when the two were in conflict. Essentially the more robust process—image size
19 judgment—became *less* robust and more susceptible to influence from the task-irrelevant feature
20 familiar size when the familiar size difference was greater in magnitude.

21 Similarly we observed that, in the familiar size task, task-irrelevant image size processing
22 interfered *less* the greater the magnitude of the familiar size difference. Thus, in both tasks
23 greater familiar size differences more strongly counteracted the influence of image size. This is

1 possibly due to increased salience of familiar size as a feature when the familiar sizes of the two
2 paired real-world objects was more discrepant. Furthermore, the parametric nature of our
3 manipulation in Experiment 2 and the resulting graded effects of familiar size suggest that
4 familiar size may be represented in a continuous manner as opposed to the binary “large object”
5 and “small object” areas found by Konkle & Oliva (2012a).

6 Overall, we present converging evidence that image size is processed earlier and more
7 robustly than familiar size, but that increasing familiar size differences somewhat mitigate this
8 effect, indicating dynamic interactions between image and familiar size perception, and action.

9

10 *Processing conflict in the familiar size Stroop task*

11 The “familiar size Stroop” task used here was inspired by the classic Stroop task in which
12 identifying the color a word is printed in is impaired when the word is the name of an
13 incongruent color (Konkle & Oliva, 2012a; Stroop, 1935). In order to accurately perform the
14 Stroop task participants must suppress the automatic response produced by a *direct processing*
15 *pathway* in order to respond to the relevant feature for their current goal, processed by an
16 *indirect processing pathway* (Botvinick et al., 2001; Ridderinkhof, van der Molen, & Bashore,
17 1995; Shenhav, Botvinick, & Cohen, 2013; Van der Stigchel, van Koningsbruggen, Nijboer,
18 List, & Rafal, 2012).

19 The prioritization of task-relevant over task-irrelevant features is a key aspect of
20 cognitive control, and the Stroop task has been investigated extensively within the cognitive
21 control literature (Memelink & Hommel, 2013). Resolving conflict in the Stroop task is thought
22 to comprise three processes: monitoring conflict between the direct pathway and indirect
23 pathway, adjusting the response threshold by inhibiting motor output, and recruiting top-down

1 processes in order to resolve conflict between the two pathways (Botvinick et al., 2001; Erb et
2 al., 2016; Shenhav et al., 2013). Erb et al. (2016) investigated these individual processes in a
3 classic Stroop task using a visually-guided pointing paradigm, and showed that they manifested
4 in different aspects of visually-guided action. Specifically, movement initiation latency was
5 shown to reflect the response threshold adjustment process while maximum curvature reflected
6 the final conflict resolution between the direct and indirect pathways.

7 By using a similar visually-guided pointing paradigm and the familiar size Stroop task we
8 are able to speculate about the processing of image size and familiar size, and the conflict
9 between the two. When objects' image and familiar sizes were in conflict participants were
10 slower to initiate movements, and their movements were more curved toward the incorrect
11 response. We propose that the former effect results from motor output being suppressed to allow
12 for more processing time, an early conflict resolution process. The latter effect suggests that
13 representations of both alternatives persist even after movements are initiated (Erb et al., 2016).
14 Thus, conflict resolution processes begin early, but conflict is not resolved until later. This also
15 demonstrates that both image size and familiar size, as well as their conflict, influence both
16 movement preparation and movement execution, with a larger effect from image size.

17 Again though, despite the fact that image size influenced familiar size more than familiar
18 size did image size, we did observe bidirectional interference. While the classical Stroop effect is
19 largely reported in terms of the unidirectional influence of reading a word on reporting a color, a
20 "reverse Stroop effect" has also been observed in which participants' ability to read a color name
21 is impaired by incongruent text color (MacLeod, 1991). However, the effect of the written word
22 on printed color identification is more pronounced than the impact of ink color on reading the

1 written word. Thus, interference in the classical Stroop effect is bidirectional but asymmetrical,
2 like our reported effects in the familiar size Stroop.

3 Based on these results, processing image size in the familiar size Stroop task parallels
4 reading the word in the classical Stroop task, and familiar size processing parallels reporting the
5 text color. From this we speculate that the perception of an object's *image size* is a direct
6 pathway process and the perception of *familiar size*, an indirect pathway process, again
7 consistent with participants' subjective reports of their relative ease.

8 These observations have important implications for target selection, action control, and
9 perception/action integration more broadly. There are a number of reasons image size processing
10 could be a direct pathway process in this action-based Stroop paradigm. First, image size is
11 arguably more relevant for the guidance of action than familiar size is—we can process the size
12 of an object in front of us and interact with it even if it is not an object we are familiar with, and
13 when familiar objects' image and familiar sizes are incongruent their current image size is far
14 more important for action than their typical familiar size.

15 In the classic Stroop task the direct pathway process is reading a word while the indirect
16 process is naming the color of the ink, again somewhat counterintuitive given that reading is a
17 higher order process than color perception. However, reading proceeds more automatically due
18 to the relative frequency of performing this learned behavior. Similarly, attending to image size
19 in isolation may be performed more frequently in daily life than processing familiar size in
20 isolation. These two explanations are not mutually exclusive. It is likely that the automaticity of
21 image size processing and its influence on action is the result of its frequency and utility in daily
22 life.

1 That said, our results show that familiar size is processed automatically as well. This
2 learned behavior is more relevant to visual perception than it is to visually guided action in a
3 classical perception/action dissociation framework. However, as we have shown, perception and
4 action are not truly distinct and perception does influence action. Thus, if image size influences
5 action more readily and familiar size influences perception more readily, this doesn't mean that
6 familiar size doesn't influence action, just that the influence emerges later as in other
7 perception/action integration processes.

8 It is additionally worth noting that just as the Stroop effect can be replicated with features
9 other than color names, and can inform our understanding of *direct* and *indirect* processing
10 pathways, we believe that the action-based Stroop effect seen here is not limited to incongruency
11 between image and familiar size. While object size has a significant impact on reach-to-point as
12 well as other types of hand movements, the conflict revealed in these experiments is as much
13 about cognitive control and conflict-resolution as about visual perception and action control.
14 Thus, we hypothesize that these results would be replicated with other forms of perceptual
15 incongruency or conflict tasks, and the same asymmetry observed as long as one feature
16 represents a *direct* and the other an *indirect* pathway.

17

18 **Conclusion**

19 By examining the modulation of goal-directed hand movements by the image sizes and
20 familiar sizes of real-world objects, the present study can contribute to a more complete picture
21 of how objects are perceived and identified, how hand movements are guided, and how these
22 processes interact. Comparing the impact of image size and familiar size, image size appears to
23 exert more impact, and be processed faster than familiar size is. That said, the more complex and

1 difficult perceptual process of judging the familiar sizes of objects, requiring higher level
2 perceptual identification and the recruitment of prior experiences and memory, also occurs
3 automatically and robustly enough to interfere with judgments of image size. Critically, both
4 image and familiar size are processed even when task-irrelevant.

5 The strength of this bidirectional influence of image size on familiar size judgment, and
6 familiar size on image size judgment is not absolute, however. Experiment 2 demonstrated that
7 when the familiar size difference between paired objects was larger, the effects of familiar size
8 on action became more robust. This had two effects. First, choosing the larger or smaller object
9 based on its familiar size in the real world became easier the larger the difference between the
10 two, despite the fact that a difference was always readily apparent. Secondly, and more
11 importantly, familiar size interfered with the effects of image size—image size judgments in the
12 image size task, and image size *interference* in the incongruent trials of the familiar size task—
13 more strongly with greater relative familiar size differences, suggesting greater salience and
14 representation robustness.

15 Overall, the present study provides evidence that even high-level aspects of visual
16 perception—the identification of real-world objects and the integration of prior knowledge
17 regarding their sizes in the real world—interact with visually-guided action automatically and
18 systematically. This points to a far more integrated view of perception and action than classically
19 hypothesized. However, the current study alone is insufficient to explain these interactions on a
20 mechanistic level. Further investigations are needed to identify the mechanisms responsible for
21 the perception of object size (image size, familiar size, and other aspects), decision-making,
22 visually-guided action, and their relationships.
