Abstract

Atmospheric rivers (ARs), narrow intense moisture transport, account for much of the poleward moisture transport in midlatitudes. While studies have characterized AR features and the associated hydrological impacts in a warming climate in observations and comprehensive climate models, the fundamental dynamics for changes in AR statistics (e.g., frequency, length, width) are not well understood. Here we investigate AR response to global warming with a combination of idealized and comprehensive climate models. To that end, we developed an idealized atmospheric GCM with Earth-like global circulation and hydrological cycle, in which water vapor and clouds are modeled as passive tracers with simple cloud microphysics and precipitation processes. Despite the simplicity of model physics, it reasonably reproduces observed dynamical structures for individual ARs, statistical characteristics of ARs, and spatial distributions of AR climatology. Under climate warming, the idealized model produces robust AR changes similar to CESM large ensemble simulations under RCP8.5, including AR size expansion, intensified landfall moisture transport, and an increased AR frequency, corroborating previously reported AR changes under global warming by climate models. In addition, the latitude of AR frequency maximum shifts poleward with climate warming. Further analysis suggests the thermodynamic effect (i.e., an increase in water vapor) dominates the AR statistics and frequency changes while both the dynamic and thermodynamic effects contribute to the AR poleward shift. These results demonstrate that AR changes in a warming climate can be understood as passive water vapor and cloud tracers regulated by large-scale atmospheric circulation, whereas convection and latent heat feedback are of secondary importance.

1. Introduction

Atmospheric rivers (ARs) are long, narrow corridors of synoptic horizontal water vapor transport in the midlatitude lower troposphere, accompanied with low-level jet streams ahead of the cold front of extratropical cyclones (e.g., Zhu and Newell 1998; Ralph et al. 2004; Neiman et al. 2008; Cordeira et al. 2013; Guan and Waliser 2015). These narrow corridors of concentrated moisture transport often originate from tropical oceans and carry large amounts of water vapor to the high latitudes, contributing 30-60% of the annual total precipitation to the west coasts of continents (e.g., Guan et al. 2010; Dettinger et al. 2011; Guan et al. 2012; Rutz and Steenburgh 2012; Viale et al. 2018). Too many, too strong, and/or long-lasting ARs, as well as a favorable antecedent soil moisture condition, bring extreme rainfall and floods to these regions (e.g., Dettinger 2006; Ralph et al. 2006; Stohl et al. 2008; Lavers et al. 2011; Neiman et al. 2011; Ralph et al. 2013; Konrad and Dettinger 2017; Paltan et al. 2017; Corringham et al. 2019; Ralph et al. 2019). ARs also breed snow accumulation and snowmelt events over both the Arctic and Antarctic (Gorodetskaya et al. 2014; Baggett et al. 2016; Hegyi and Taylor 2018; Mattingly et al. 2018; Wille et al. 2019), modulating the hydrological cycle in polar regions (Nash et al. 2018). An improved understanding of ARs in a warming climate is critical for predicting regional weather and hydrological extremes. In recent decades observations indicate that there are more landfalling ARs along with warming over the North Pacific (Gershunov et al. 2017). Under future warming, it is expected that ARs will become longer, wider and wetter (e.g., Espinoza et al. 2018). Both the intensity and the number of landfalling ARs and resultant heavy rainfall will increase in accordance with the projected warming (Lavers et al. 2015; Hagos et al. 2016; Curry et al. 2019; Gershunov et al. 2019; Huang et al. 2020; Ma et al. 2020b).

3

67   Given IVT consists of moisture and horizontal wind, the mechanisms for these AR changes

68   in a warming climate can be roughly divided into two interrelated aspects (see reviews by

69   Payne et al. 2020). The first mechanism is focused on the effects of robust thermodynamic

70   characteristics of greenhouse gas increases on moisture. The Clausius-Clapeyron (CC)

71   equation implies that the water-holding capability of the atmosphere increases with global

72   warming. This is supported by many model studies suggested that the future changes of ARs

73   are generally dominated by a uniform increase in atmospheric moisture and therefore the

74   enhanced IVT in a warming climate (e.g., Gao et al. 2015, 2016; Lavers et al. 2015; Payne

75   and Magnusdottir 2015; Warner et al. 2015). The other perspective is centered on the latitude

76   of ARs due to the circulation response to global warming, termed as dynamic change. A

77   poleward shift of ARs as the westerly jet shifts in a changing climate is found over North

78   Atlantic and South Hemisphere (e.g., Gao et al. 2016; Ma et al. 2020a) while a small but

79   robust reduction in IVT magnitude and an equatorward shift of ARs due to wind changes are

80   found over North Pacific (e.g., Payne and Magnusdottir 2015; Gao et al. 2015; Shields and

81   Kiehl 2016). In addition, ARs tend to occur with the extratropical cyclone development

82   (Eiras-Barca et al. 2018; Zhang et al. 2019), which may be impeded by the reduction in the

83   low-level baroclinic instability in a warmer climate, further increasing the complexity of AR

84   response to global warming. Thus, the large uncertainty in midlatitude circulation changes,

85   especially in comprehensive model simulation, can obfuscate a simple explanation of the AR

86   dynamical response to global warming.

87

88   Climate models to date represent observed statistics of ARs relatively well while large

89   regional biases still exist (e.g., Payne and Magnusdottir 2015; Guan and Waliser 2017 and

90   the review by Waliser and Cordeira 2020). While the earlier studies have characterized the

4

91   AR features and associated hydrological impacts in a warming climate using comprehensive

92   climate models, the fundamental dynamics (e.g., temperature gradient, baroclinic instability,

93   eddy momentum flux, and eddy heat flux) for changes in AR statistics (e.g., frequency, length,

94   width) are not well understood. Although simulating ARs as accurately as possible is vital to

95   pursue robust projections of AR changes, the large uncertainty and complexity in the

96   comprehensive climate model make it difficult to understand the fundamental dynamical

97   processes in the AR response to a warming climate.

98

99   In this study, we take a different approach and examine the AR change in a warming climate

100   using a combination of idealized and comprehensive climate models. Many idealized models

101   have no explicit hydrological cycle (e.g., the dry dynamical core in Held and Suarez 1994)

102   or unrealistic boundary conditions (e.g., the aquaplanet model in Neale and Hoskins 2000)

103   and thus cannot simulate realistic spatial distributions of ARs. We developed a new idealized

104   GCM with Earth-like global circulation with simple water vapor processes. Despite the

105   simplicity of model physics, the idealized model produces robust AR changes under climate

106   warming similar to a comprehensive model, improving our confidence in atmospheric

107   moisture transport and the fundamentals of AR dynamics in a warming climate.

108

109   The paper is organized as follows. Section 2 describes the model setup of this new idealized

110   model. The datasets used for model evaluation are also introduced in Section 2. Section 3

111   evaluates the performance of the idealized model in simulating the observed general

112   circulation and hydrological cycle. The modeled ARs in the control run are evaluated with

113   observations in Section 4. The circulation and AR responses to a warmer climate in the

114   idealized model and CESM LENS are presented in Section 5.

115

2. Model setup and datasets

2.1. Model setup

In this study, a simple GCM is constructed to simulate reasonably accurate ARs and their changes in a warming climate. Unlike the comprehensive GCMs designed to model every observed detail as much as possible, simple models are designed to capture the fundamental physical processes only, and thus are valuable for understanding nature and are suitable for our goal. To simulate the ARs in a GCM with relatively simple physics but with atmospheric circulations close to the real atmosphere, we set up a dry atmospheric dynamical core by introducing Newtonian relaxation of temperature towards an equilibrium temperature that helps reproduce the observed climatology, and water vapor and cloud are implemented into the dry dynamical core as passive tracers, as described below.

We begin with the GFDL dry dynamical core (Held and Suarez 1994), which relaxes the temperature to a three-dimensional radiative equilibrium temperature field T_{eq} by Newtonian relaxation to mimic diabatic heating in the form of $(\partial T/\partial t) = -(T - T_{eq})/\tau$, where T is temperature and τ is a prescribed relaxation time scale given in the appendix of Jucker et al. (2014). The T_{eq} fields are determined individually for each month of the year and then linearly interpolated to daily values. To create a more Earth-like atmospheric circulation in the model, we employ the zonal asymmetric relaxation temperature field T_{eq} generated based on the mean state of the observation following (Wu and Reichler 2018), which was achieved through the iterative procedure described in Chang (2006). We simply describe the algorithm in Appendix A. The effect of seasonal variations in the mean state is examined by individually calculating for each month. While only the mean climate is the target of the

6

139   iteration process, transient eddies are created internally by the baroclinically unstable

140   atmosphere. Eddy fluxes of momentum and energy highly resemble the observations with

141   some slight differences in magnitude (Chang 2006, Wu and Reichler 2018), likely due to the

142   close relationship between eddy statistics and mean climate. The actual Earth topography is

143   employed in the model to further generate realistic planetary waves. There is no explicit

144   boundary layer parameterization. The wind fields are damped by Rayleigh friction near the

145   surface. With the above setting, an Earth-like atmospheric general circulation, including the

146   stratospheric circulation and stationary planetary waves (Wu and Reichler 2018), is produced

147   in this idealized model.

148

149   Given that the object of this study is ARs, which involves hydrological processes including

150   moisture transport and precipitation as mentioned in the Introduction, a feasible technique to

151   model the hydrological cycle is required. We achieve this by adopting a simple cloud physics

152   in which the water vapor and cloud fraction are modeled as passive tracers, following Ming

153   and Held (2018, MH18 hereafter). Here we simply summarize this cloud physics and describe

154   a few technical differences of our work from MH18. In this simple cloud physics, there is no

155   convective parameterization. Water vapor and cloud fraction are modeled as passive tracers,

156   thus they do not affect the flow. There are three water tracers advected: specific humidity,

157   liquid, and ice condensates. Surface evaporation is mimicked by nudging RH at the bottom

158   layer to 100% with a time scale of 30min (as compared with RH below 850hPa is nudged in

159   MH18). As in the GFDL HiRAM (Zhao et al. 2009), the large-scale cloud scheme diagnoses

160   cloud fraction and condensation from grid-mean total water (water vapor and cloud

161   condensates) using an assumed subgrid-scale distribution, which takes the form of a beta

162   distribution with its width controlled by the grid-mean total water multiplied by a width

7

163   parameter, defined in Tompkins (2002). The beta distribution parameters are the same as

164   MH18. We adopt a single-moment cloud microphysics developed by Rotstayn (1997) and

165   Rotstayn et al. (2000), that has been successfully applied in GFDL AM2 and AM3. The main

166   pathways for transformation between cloud condensates, precipitation formation, and re-

167   evaporation of condensates, precipitation are involved. Same as MH18, this scheme assumes

168   condensation (re-evaporation) not to generate condensational heating (cooling) and thus does

169   not affect flow. No water vapor and cloud radiative effect is involved in this scheme either.

170   Thus, water vapor and cloud are completely passive.

171

172   Given the model is a spectral core, a finite-volume gridpoint advection scheme, applicable to

173   the gaussian grid, is used to advect the model's passive tracers. The horizontal tracer transport

174   is computed using the finite-volume formulation (Lin and Rood 1996). This formulation has

175   been examined by a study of tracer transport in baroclinic life cycle (Polvani and Esler 2007),

176   an investigation of subtropical water vapor source (Galewsky et al. 2005), and isentropic

177   mixing of tracers by large-scale atmospheric circulation (Chen and Plumb 2014). The reader

178   is referred to MH18 for a more detailed exposition for the tracer advection algorithm.

179

180   Our model has 40 levels in the vertical. A sponge layer is employed near the model cap. The

181   horizontal resolution is T42, with a resolution of about 2.8°×2.8°. We investigate the

182   sensitivity of parameters for the calculation of cloud fraction and condensation, such as the

183   width parameter for the tracer distribution that has been tested in MH18. The sensitivities in

184   the vertical structure simulation of water vapor are reasonable and consistent with that in

185   MH18 with a zonally symmetric circulation (figure not shown). More model evaluations for

186   the simulations of cloud fraction, cloud water, and cloud ice will be presented in Section 3.

8

187

188   2.2.   Datasets, method, and statistics

189 To evaluate the simulated circulation, hydrological cycle, and ARs, we compare the control

190 (Ctrl) run with ERA-Interim (ERAI) reanalysis (Dee et al. 2011). The variables from ERAI

191 have a horizontal resolution of 1.5°×1.5° and 37 levels in vertical. The daily data and the

192 long-term mean of 1979-2018 are used.

193

194 The outputs of 40 ensembles in the large ensemble simulation (LENS) based on CESM, a

195 comprehensive fully coupled climate model from NCAR, are employed (Kay et al. 2015).

196 Every member was under identical historical forcing before 2005 and RCP8.5 forcing after

197 that. We collect the daily data during 1979-2005 (27-year) in historical runs (Hist, hereafter)

198 and during 2074-2100 (27-year) in RCP8.5 runs (RCP8.5, hereafter). The projected AR

199 changes in CESM simulations are used to assess the AR response to climate warming in the

200 idealized model simulations.

201

202 The analysis in this study is based on the climatology of annual mean if no specific statement.

203 The pattern correlation coefficient (PCC) is employed to measure the pattern similarity

204 between the Ctrl run and observations. Vertical and latitudinal weights are considered, and

205 the global mean is removed before the calculation of PCC.

206

207 **3.   Atmospheric circulation and hydrological cycle**

208 It is important to verify that this simple model is able to achieve a realistic atmospheric

209 circulation and hydrological cycle. We first conduct a control simulation (Ctrl run) based on

210 the model setup described above. The Ctrl run is integrated for 36 model years and the outputs

9

211   from the last 30 years are analyzed.

212

213   Starting with the zonal mean circulation, Figure 1a presents the zonal mean zonal wind (color)

214   and temperature (contour) in the Ctrl run. As expected, the modeled temperature field highly

215   resembles the ERAI as shown in Figure 1b, including the spatial pattern and the magnitude,

216   since the T_{eq} used to drive this model is produced to reproduce observations by an iterative

217   approach as described in Section 2.1. Specifically, the pattern correlation coefficient (PCC)

218   between the Ctrl and the ERAI is effectively 1.0, indicating the model recovers the spatial

219   pattern of temperature through the iterative process. Correspondingly, the zonal mean zonal

220   wind is well reproduced in this idealized model. The correlation coefficient for the zonal

221   mean zonal wind reaches 0.97. The westerly jet positions and their non-symmetric pattern in

222   two hemispheres, even in the stratosphere, are very close to that in the ERAI. These well-

223   reproduced zonal mean zonal wind patterns are mainly determined by the well-simulated

224   temperature field, especially over the extratropics where the thermal wind balance is

225   dominant. Figure 1c and d compare the mean meridional circulation and relative humidity in

226   the simple model and ERAI. In the tropics, the lack of convective scheme in our model leads

227   to an underestimation of the tropical convection in the simulation (determined by the

228   prescribed T_{eq}), therefore a weaker Hadley Cell (tropical convection) is produced in

229   comparison with the observation. However, the spatial pattern of the Hadley cell is well

230   captured in the simple model (PCC=0.93). Therefore, the vertical structure of the relative

231   humidity, such as the dry subtropics and wet high latitudes, shares similarity with that in

232   observation (PCC=0.91). It should be noted that the simulated relative humidity is generally

233   higher than that in ERAI, since we simply nudge the relative humidity to 100% at the bottom

234   level of the idealized model which exaggerates the wetness over the land area. In addition,

10

235   due to the lack of convection scheme and thus the weak vertical motions in the deep tropics,

236   the model bias also lies in the vertical structure of RH (Fig.1cd). In the real atmosphere, the

237   large values of low-level humidity and associated CAPE will trigger convective instability,

238   which is generally treated by subgrid convective parameterizations in a comprehensive

239   climate model, including the release of CAPE and mixing with drier environmental air. This

240   setting prevents the excessive accumulation of moisture at the low level and the

241   disappearance of the RH vertical gradient in the mid-to-upper troposphere in the tropics

242   (Fig.1cd). Nevertheless, this simplification does not affect the simulation in the overall

243   picture of the zonal mean structure of relative humidity which is controlled by the moisture

244   transport associated with large-scale atmospheric circulation (Galewsky et al. 2005).

245

246   The moisture transport budget is $P - E = -\nabla \cdot Vq$ diagnosed in Figure 2 to assess the

247   simulation of the hydrological cycle in the idealized model. The modeled precipitation minus

248   evaporation (*P-E*) is balanced by the moisture transport $-\nabla \cdot Vq$. Compared to ERAI, while

249   the moisture transport over the tropics and the subtropics of the South Hemisphere in the

250   model is weaker due to the biases in the magnitude of the tropical convection, the water cycle

251   over extratropical regions where most ARs occur is very close to the reanalysis data. The

252   good simulation of the extratropical water vapor balance facilitates a reasonable simulation

253   of ARs in this model (will be discussed later).

254

255   Figure 3 depicts the simulated cloud fields (cloud fraction, cloud liquid, and cloud ice) in the

256   Ctrl run and ERAI reanalysis. The simulated clouds in the mid and low troposphere in the

257   tropics are unrealistic due to the lack of a convection scheme, as we mentioned earlier. Thus,

258   we consider the relevance of this model for the real atmosphere is confined to the extratropics.

11

259   Similar to MH18, the model is capable of qualitatively simulating some familiar aspects of

260   the highly inhomogeneous cloud distribution over the tropical upper troposphere and

261   extratropics compared with ERAI. Cloud fraction generally extends vertically through almost

262   the entire troposphere in the extratropics, especially over the storm tracks where ARs occur

263   frequently. The cloud fraction in the subtropical dry zones is also well reproduced in the

264   model. Similar to ERAI, the transition from cloud liquid to ice in the Ctrl run follows the

265   freezing line (Figure 3cdef).

266

267   **4.   Characteristics of Atmospheric Rivers**

268   According to the above evaluation, the simple model used here is capable of reasonably

269   modeling the realistic large-scale circulation and moisture transport, especially over the

270   extratropical regions. We next further verify that this model is able to simulate ARs,

271   including their fine-scale dynamical structure and climatological distribution. The AR

272   detection method in Guan and Waliser (2015) is employed in this study. This AR detection

273   algorithm is based on integrated water vapor transport (IVT) derived from specific humidity

274   and wind fields at the pressure levels between 1000 and 300hPa inclusive for the idealized

275   model and ERAI. For CESM LENS, IVT is calculated by vertically integrated specific

276   humidity and horizontal winds from near the surface to 200mb because data at 1000 and

277   100hPa is not archived. The 85th percentile of IVT strength or 100 kg m^{-1} s^{-1}, whichever is

278   greater, is chosen as the threshold for AR detection at each grid for each month. Since the

279   85th percentile IVT is used as a threshold most of the time, any bias in the IVT calculation

280   will be implicitly accounted for when detecting ARs. Therefore, this AR detection algorithm

281   is not sensitive to the ways how IVT is derived. Only objects with its meridional component

282   of mean IVT greater than 50 kg m^{-1} s^{-1} are considered, given the notion that ARs transport

12

283   water vapor from low to high latitudes. For the detected object to be considered as AR, there

284   should be less than half of the grid cells that have IVT deviating more than 45° from the

285   object's mean IVT direction. In addition, the direction of mean IVT deviates from the overall

286   orientation should be less than 45°. The overall orientation here is defined as the mean

287   azimuth of the arc connecting the two end grid cells of AR's axis with the maximum great

288   circle distance following Guan and Waliser (2015). In this algorithm, AR should be longer

289   than 2000 km and with a length to width ratio of at least 2:1.

290

291   Figure 4 gives the spatial structure of a specific AR in the model and in the ERAI,

292   respectively. We compose this figure following Ralph et al. (2017) and one can see that the

293   modeled AR captures the key AR characteristics, i.e., a narrow, elongated, synoptic-scale jet

294   of water vapor extending thousands of kilometers in length and an order of magnitude less in

295   width. As shown in the vertical cross-section of ERAI (Figure 4d), the low-level moisture

296   transport is concentrated in the bottom 3km of the atmosphere. While the low-level jet ahead

297   of the cold front carries the vast majority of the horizontal water vapor transport, the cold

298   upper-jet advects dry air aloft. Despite the coarse resolution and simple moist scheme, this

299   coherent spatial structure is well reproduced in the idealized model (Figure 4c), indicating a

300   major role of large-scale atmospheric circulation in the development of ARs through

301   isentropic mixing of air mass and moisture (Chen and Plumb 2014).

302

303   The AR climatology simulated in this idealized model is further assessed. Figure 5 presents

304   the climatologies of IVT and AR frequency. The strong moisture transport mainly occurs

305   over the tropical trade wind belts (i.e., ITCZ), monsoon regions and midlatitude oceanic

306   basins (Fig. 5b). Since there is no convective parameterization in the model, the ITCZ is

13

307   hardly simulated, while the water vapor transport over the Asian Monsoon region can be

308   reproduced mainly due to the topography effect. In contrast, the pattern of moisture transport

309   over the extratropics, especially over the midlatitude oceanic basins, where the storm tracks

310   and ARs are active, is well reproduced (PCC$_{extratropics}$=0.82), except that the values are lower

311   than the observation again due to the lack of convection scheme and thus no condensational

312   heating feedback in the model. In addition, the coarse resolution could contribute to this

313   underestimation as well. Given that ARs are defined with the threshold of 85th percentile

314   IVT, thus not sensitive to the climatological magnitude of IVT, the pattern of AR frequency

315   is well simulated in the model (PCC=0.95). In addition, the magnitude of the AR frequency

316   over the midlatitude ocean is in good agreement with that in the observation (8-14%).

317

318   Given the ARs are active at the midlatitudes as shown above, we calculate the zonally

319   integrated meridional IVT associated with AR transport and the AR zonal scale over 30°-

320   50°$N(S)$ following Guan and Waliser (2015). The results show that the ARs account for 81%

321   (82%) of the total meridional IVT and 9% (11%) of the zonal circumference over 30°-50° in

322   the Northern (Southern) Hemisphere in the Ctrl run. The AR fractional IVT is slightly lower

323   than that in the observations, 85% (89%) of total meridional IVT, which could be due to the

324   idealized setting of excessive surface moisture over the land where the AR activity is much

325   less. The AR fractional zonal-scale in the idealized model matches the observation, 8% (11%)

326   of the zonal circumference, indicating that the idealized model relatively well captures the

327   key characteristic of ARs found in early studies that estimated ARs, while covering ~10% of

328   the Earth's circumference at midlatitudes, accounts for the majority of the total poleward

329   water vapor transport at these latitudes (e.g., Zhu and Newell 1998; Newman et al. 2012;

330   Guan and Waliser 2015).

331

332 Figure 6 shows the probability density function (PDF) of AR basic characteristics in Ctrl run

333 and ERAI, including size (length and width), meridional range (lowest latitude and highest

334 latitudes), direction of mean IVT and coherence of IVT direction, mean magnitude of IVT,

335 landfall magnitude. Here, the coherence of the IVT direction of an AR event is measured by

336 the fraction of AR grid cells with IVT directed within 45° of the mean AR IVT (Guan and

337 Waliser 2015). For the AR size, the distribution of AR length is well reproduced in the

338 idealized simulation, while the AR width in Ctrl is about 200km wider than that in the

339 observation (Fig. 6ab). This biased PDF shift in the simulated AR width is likely due to the

340 coarser spatial grids in the idealized model compared to $1.5° \times 1.5°$ in ERAI, since the coarse

341 horizontal resolution of the model cannot capture the filamentation aspect of the ARs well

342 (Guan and Waliser 2015). The PDFs of the highest and lowest latitude of ARs in each

343 hemisphere, which measure the meridional range of AR activities, also match the

344 observations (Fig.6cd). The PDFs of the direction of mean IVT and its coherence in the Ctrl

345 run are well in agreement with the observation in both hemispheres (Fig. 6ef). For the

346 magnitude of landfall IVT and the mean magnitude of IVT, although bias is found in the

347 simulated PDFs, the basic shapes of the distribution are captured by the idealized model (Fig.

348 6gh). The too strong landfalling ARs in the idealized simulation is probably due to the setting

349 of humidity in the model, in which the relative humidity is simply nudged to 100% at the

350 lowest level without the moisture limitation over land. Overall, besides some biases in

351 quantitative values of width and magnitude, the general AR characteristics are well simulated

352 in the idealized model, further corroborating that the AR dynamics is dominated by large-

353 scale atmospheric circulation and associated moisture transport.

354

355 In summary, the simple model used in this study is capable of simulating not only the large-

356 scale circulation and hydrological cycle but also the 3-D spatial structure and statistical

357 characteristics of the ARs with some quantitative biases. These results demonstrate the basic

358 dynamics of ARs can be understood through the transport of passive water vapor and cloud

359 tracers, indicating the important role of large-scale circulation and advection in the simulation

360 of IVT and thus the AR activity.

361

362 **5.   AR response to global warming**

363 5.1.   Experimental design and the mean state response to climate warming

364 Since this idealized model is reliable for AR simulation as evaluated in the last section, we

365 next explore the response of ARs to a changing climate in this simple model. A series of

366 experiments with idealized warming (or cooling) forcing is conducted. The forcing employed

367 in this study is a uniform temperature perturbation in the troposphere and a schematic

368 diagram (Fig. 7a) shows the design for the vertical profile of the uniform, 4K for example,

369 tropospheric warming (Trop4K), which is comparable to a ~4.4K warming on average by the

370 end of 21 century in RCP8.5 scenario in CESM LENS simulations. Compared to the Ctrl

371 run, a 4K warming is prescribed in T_{eq} fields at each grid below the tropopause (red segment).

372 A linear transition zone is taken into account near the tropopause to mimic an uplifting

373 tropopause induced by tropospheric warming with no change to tropospheric lapse rate. For

374 each temperature profile for Trop4K forcing, the lapse rate in the transition zone is

375 determined by the averaged lapse rate in the three layers below the tropopause in the Ctrl run,

376 thus the thickness may vary from profile to profile. A similar approach was used in Lorenz

377 and DeWeaver (2007) for a raised tropopause. The dotted green line in Fig.7a denotes the

378 new tropopause for 4K warming. The actual temperature change for the 4K warming

16

379   experiment is shown in Figure 7b (color shading). More experiments demonstrate that the

380   results are not sensitive to the choice of the parameters to set up the transition zone (not

381   shown). Such a thermal forcing is designed to mimic the thermal effect of uniform SST

382   increase in aquaplanet simulations (e.g., Chen et al. 2013), with the effect of changes in lapse

383   rate excluded. Similarly, a series of experiments with a range of forcing, 2K tropospheric

384   warming, 2K and 4K tropospheric cooling, are conducted to explore the AR changes over a

385   range of climates. The transition zone for the tropospheric cooling forcing is determined

386   similarly as that in the warming forcing, except that the transition zone and the new

387   tropopause are below the tropopause in the Ctrl run. These perturbation experiments have

388   been run for 36 model years, respectively, and the last 30-year outputs are used for analysis,

389   same as the Ctrl run. The response is defined as the differences between the perturbation run

390   and the Ctrl run. The same IVT threshold, the 85th percentile of IVT in the reference state,

391   is used for AR detection in the perturbation scenarios.

392

393   We first show the responses of the zonal mean circulation to the tropospheric 4K warming

394   experiment (Trop4K) in Figure 8 (left column). The results are approximately opposite in

395   sign for the tropospheric 4K cooling experiments (Trop-4K) and thus are not shown here. To

396   further verify the model is able to simulate a reasonable response to tropospheric 4K warming,

397   we compared the responses in the idealized model to that in the comprehensive model

398   simulations, CESM LENS (right column of Fig. 8). The zonal mean results are also similar

399   to the atmospheric responses to 4K uniform SST increase in aquaplanet models (e.g., Chen

400   et al. 2013), which have an intermediate complexity in model physics between the idealized

401   model and CESM. The response in LENS/CESM is defined as the difference between the

402   climatologies of 2074-2100 in RCP8.5 and 1979-2005 in Hist. Compared to the tropospheric

403 4K warming in the idealized simulation, the global tropospheric temperature response is

404 about 4.4K in LENS/CESM. As a result of the uniform tropospheric 4K warming forcing, a

405 warmer troposphere can be seen in Fig. 8a. However, the pattern of temperature response is

406 not totally uniform, especially over extratropics, indicating the impact of the circulation

407 feedback. Although the projected deep tropical warming and polar amplification cannot be

408 fully represented, the uniform tropospheric warming still creates a temperature gradient

409 increasing at the upper troposphere over the subtropics to midlatitudes due to the slope in the

410 tropopause. Accordingly, consistent with the temperature changes and thermal wind balance,

411 the responses in the zonal mean zonal wind are characterized by a poleward shift in the

412 midlatitude westerly jet (more obvious in the South Hemisphere), with a large acceleration

413 near the subtropical tropopause (Fig. 8ac), resembling the zonal mean zonal wind responses

414 in the LENS/CESM (Fig. 8bd). The temperature gradient changes and jet shifts could

415 influence the Hadley Cell as well (see the review by Vallis et al. 2015). The response of the

416 mean meridional circulation to Trop4K warming shows a weaker Hadley cell, with a

417 poleward expansion in the Hadley cell and a poleward shift in the Ferrel cell (Fig. 8e) due to

418 the decrease of baroclinic instability and the eddy feedback, displaying the classic pattern of

419 the meridional circulation response to a warming climate, that has been found in the

420 comprehensive models (Fig. 8f) in many previous studies. This shift in atmospheric

421 circulation in response to uniform tropospheric warming in the presence of a sloping

422 tropopause is consistent with a recent study that quantifies a high sensitivity of the zonal jet

423 to changes to the upper-tropospheric temperature gradient (Chen et al. 2020).

424

425 Changes in zonal mean circulation certainly lead to distinct changes in water vapor and

426 hydrological cycle. The responses of relative humidity are characterized by wetness in the

18

427   stratosphere and dryness in the tropospheric extratropics (Fig.8g). The former is likely the

428   result of increased water vapor entering the stratosphere in response to tropospheric warming

429   and the latter indicates a larger increase in the saturation vapor pressure than the vapor

430   pressure in a warming climate. These responses in relative humidity are generally in

431   agreement with that in the RCP8.5/LENS except the differences over the upper tropical

432   troposphere likely due to the lack of convective scheme (Fig. 8h). Previous studies (Wright

433   et al. 2010) suggested that the spatial distribution of zonal mean relative humidity responses

434   is largely dependent on circulation and transport changes, such as the poleward expansion of

435   the Hadley Cell, poleward shift of the extratropical jets, and increase in the height of the

436   tropopause as illustrated in previous sections. The tropospheric warming effects are also

437   reflected in changes of precipitation minus evaporation (*P-E*, Fig. 9), a measure of the global

438   water vapor budget. The responses roughly show a drying effect in the subtropical regions

439   where mean *P-E*<0 and a wetting effect in the extratropics and tropics where mean *P-E*>0

440   (Fig. 9), a well-known thermodynamic mechanism for the hydrological cycle response to

441   global warming (e.g., Chou and Neelin 2004; Held and Soden 2006). In addition, the

442   magnitude of *P-E* changes over the extratropics in the idealized simulation is close to that in

443   CESM LENS.

444

445   5.2.   Response of ARs in climate warming

446   As discussed above, the changes of atmospheric circulation and hydrological cycle in the

447   idealized model experiments resemble that in the comprehensive model simulations, paving

448   the way to explore the response of ARs under a warming climate with a combination of the

449   idealized and comprehensive model. Here we present the response of AR frequency in the

450   Trop4K run in Figure 10a. The AR frequency increases over the mid-high latitude regions in

19

451   response to the tropospheric 4K warming, especially over the poleward side of its

452   climatological maximum in the South Hemisphere in the Ctrl run. These more frequent AR

453   activities in a warmer climate are highly consistent with those in the RCP8.5/CESM

454   simulations (Fig. 10b) and many previous studies (see the review by Payne et al. 2020),

455   confirming that the idealized model design is capable of simulating the AR response to global

456   warming.

457

458   To explore the mechanisms of changes in ARs, we employ a simple scaling method

459   developed in Ma et al. (2020) to separate the AR response due to the moisture change with

460   climate warming (thermodynamic effect), i.e., Clausius-Clapeyron relation, and that due to

461   the dynamical effect (wind changes). Note that our method rescales daily IVT in a warming

462   climate by the change in climatological mean moisture, and then the same threshold can be

463   used to compare different scenarios. We create two hypothetical scenarios of daily IVT for

464   each perturbation run by a scaling method applying to specific humidity, given the moisture

465   changes are expected to scale in line with CC. In the first scenario for the ARs with dynamic

466   effect, the specific humidity at each time step, each pressure level, and each grid cell in the

467   perturbation run is scaled with a factor of q_c/q_p, where $q_c(q_p)$ is the climatological specific

468   humidity in the Ctrl (perturbation) run at the level and grid cell to which this factor applies.

469   By scaling the data this way, the AR response due to specific humidity changes is removed

470   in the hypothetical scenario. Then, the dynamic effect is isolated by contrasting this scaled

471   case against the Ctrl run. Similarly, for the second hypothetical scenario of thermodynamic

472   effect, the wind and specific humidity in Ctrl are used but the specific humidity in the Ctrl

473   run is scaled with a factor of q_p/q_c so as to remove the dynamic response. The thermodynamic

474   effect is the difference between the second hypothetical scenario and the Ctrl run. These two

475   components are linearly additive (see Fig.11e), indicating that the covariance of the two

476   components is negligible.

477

478   Additionally, we also analyze the sensitivity of the thermodynamic component to local

479   temperature   changes   (thermo_Local)   versus   global   temperature   changes

480   (thermo_GlobalMean). This separates the nonlinear moisture dependence on temperature.

481   That is, while the increase of saturation vapor pressure with temperature is commonly

482   referred to as 7% K^{-1} warming, this rate is larger at lower temperatures (e.g., polar regions).

483   Specifically, for the additional hypothetical scenario of thermo_GlobalMean, the wind and

484   specific humidity in the Ctrl run are used but the specific humidity in the Ctrl run is scaled

485   by a factor of $[q_p]/[q_c]$, where the [] denotes the global mean, and therefore the ARs with the

486   thermodynamic effect due to the global mean change are detected. The difference between

487   the thermodynamic effect and the Thermo_GlobalMean can be regarded as the

488   Thermo_Local effect.

489

490   The AR frequency increases are mainly attributed to the thermodynamic effect (Fig. 11a),

491   i.e., the moisture changes in line with CC, in which the thermo_GlobalMean dominates the

492   magnitude changes over the midlatitudes (Fig. 11c). In contrast, the thermo_Local and

493   dynamic effects contribute to the AR poleward shift (Fig.11bd). The thermo_Local is also

494   characterized by a dipole structure in the midlatitude oceans (Fig. 11d), which is likely the

495   imprint of the storm track shift in the tracer field of water vapor. We further quantify the

496   contribution of dynamic and thermo_Local effects in Fig. 11f by presenting the zonal mean

497   AR frequency. The dynamic effect leads to an AR decrease over the midlatitude and increase

498   over the high latitude, contributing to the poleward shift of ARs. The contribution of

21

499 thermo_Local to the AR increases in high latitudes is comparable to or even larger than the

500 dynamic effect. This thermo_Local effect on a global scale has not been studied yest while

501 most previous studies attribute the AR poleward shift only to the wind changes focusing on

502 region of interest. In addition, the dynamic effect also results in an AR increase over the

503 subtropics of the North Hemisphere, suggesting the topographic effect in the asymmetric

504 responses of two hemispheres.

505

506 Next, we check the responses in the basic characteristics of ARs in Figure 6. Robust

507 responses are found in length, width, coherence of direction, and landfall magnitude, as

508 illustrated in Fig. 12. In response to the uniform tropospheric 4K warming, the ARs become

509 longer and wider, denoting larger ARs are expected under global warming according to the

510 same detection threshold (Fig. 12ac). It is worthy to note that the coherence of IVT direction

511 decreases along with the size increasing (Fig. 12e), given the detected ARs are larger

512 according to the same threshold and thus presenting a less organized feature. The intensity

513 of landfalling ARs is enhanced in a warmer climate (Fig. 12g), consistent with previous

514 studies (e.g., Lavers et al. 2015; Hagos et al. 2016; Espinoza et al. 2018; Curry et al. 2019;

515 Gershunov et al. 2019; Huang et al. 2020). These results in the idealized model are in

516 agreement with the responses in the RCP8.5 scenario in CESM LENS simulations with a

517 ~4.4K warming on average (Fig.12, right column). The consistency in the responses of AR

518 characteristics between the idealized model and comprehensive model further indicates that,

519 although there are some biases in the simulation of AR characteristics (e.g., width in Fig6b),

520 the idealized model is able to simulate the AR changes in a warming climate. The simplicity

521 of model physics in the idealized model demonstrates that the projected AR changes under

522 global warming can be understood as passive water vapor and cloud tracers without explicit

22

523   consideration of convections and associated latent heating feedback, and thus are not

524   particularly sensitive to details of model physics. In other words, the dominant physical

525   mechanism for atmospheric rivers is the mixing of air mass and moisture along isentropic

526   surfaces associated with large-scale tropospheric weather systems (Chen and Plumb 2014),

527   which also play a major role in the humidity structure of the atmosphere (Galewsky et al.

528   2005; Wright et al. 2010).

529

530   One advantage of the idealized model over the comprehensive model is to test the sensitivity

531   of the response to climate forcing. Here we further investigate the AR changes among a range

532   of climates (-4K, -2K, 0, 2K, 4K temperature forcing; See Tab. 1). The zonal means of the

533   AR frequency in a series of experiments are shown in Figure 13a. The AR activities gradually

534   become more frequent along linearly with the tropospheric temperature changes, while a

535   clear poleward shift is found in the latitude of the AR frequency maximum, especially over

536   the South Hemisphere. The increase of AR frequency over the South Hemisphere along with

537   warming is larger than that in the North Hemisphere. This hemispheric asymmetry is

538   enhanced along with the forcing magnitude. The poleward shift of the ARs and its

539   hemispheric asymmetry in a warming climate is in agreement with that in the RCP8.5/CESM

540   simulations (Fig. 13b). Observations also witnessed a poleward shift in AR in recent decades,

541   with important implications for moisture transport into the Antarctic (Ma et al. 2020a).

542   Interestingly, the increase of AR frequency in the Trop4K run is 48.1%, while a 50% increase

543   is found in the RCP8.5/CESM simulation with a tropospheric 4.4K warming on average.

544   Thus, we conclude that the shift and intensification of AR frequency in response to global

545   warming in the idealized model experiments are comparable to those in the CESM simulation.

546

547   For the statistics of the basic characteristics of ARs, the PDFs present a monotonic change

548   among a range of climates (Fig. 14). The PDFs of AR size tend to shift to the longer and

549   wider sides in a warming world and to shift to the shorter and narrower sides in a cooling

550   world according to the same detection threshold (Fig. 14ab). Along with the AR size

551   expansion due to the monotonic temperature increases, the coherence of ARs is weakened

552   monotonically (Fig.14c). The PDF of the magnitude of landfalling IVT tends to shift to the

553   more intense side gradually along with temperature increases, indicating the amplified

554   influence on the coastal region following further warming in the future. The line chart in each

555   subplot of Fig. 14 explicitly shows the shifts of medians (gray line with colored stars) to their

556   reference state (the median in Ctrl or Hist). Similar to the response in AR frequency, the

557   change of the medians in simple model simulation Trop4K are quantitatively close to that in

558   CESM LENS RCP8.5 with a tropospheric 4.4K warming on average (compare the red star

559   and solid circle in each line chart in Fig. 14). The above results demonstrate that the responses

560   of ARs in a warming climate, albeit with some biases, can be understood as passive water

561   vapor and cloud tracers in a changing circulation. This simple physical setup helps to boost

562   our confidence in the model projections of ARs in a warmer climate. Further, the

563   contributions of dynamic and thermodynamic to the changes in AR characteristics are also

564   shown in the line chart in each subplot (green and orange lines, respectively). It is clear that

565   the thermodynamic response is dominant and the dynamic response can be ignored. These

566   analyses indicate that the AR structure changes (e.g., larger size) in a warmer climate are

567   mainly due to the higher moisture in a warmer climate that leads to more grids fulfilling the

568   same detection threshold, while the response in the wind field contributes little to the AR

569   structure changes. For the response of landfall IVT (Fig. 14d), the dynamic effect even

570   weakens the landfalling ARs, i.e., the weaker velocity of midlatitude storms in a warmer

24

571   climate (e.g., Caballero and Hanley 2012), while the moisture carried by landfalling ARs

572   predominantly increases in a warming climate, and thus their total effect enhances the

573   landfalling ARs.

574

575   **6.   Conclusions**

576   In this study, we have presented the statistics of atmospheric river response to global warming

577   in idealized and comprehensive climate models. In particular, we developed a new idealized

578   GCM with Earth-like global circulation and hydrological cycle to simulate the spatial

579   distribution of the ARs and their response to a warming climate. In this idealized model, the

580   mean temperature resembles the observations through relaxation to prescribed equilibrium

581   temperature with an iterative method (Chang 2006; Wu and Reichler 2018), and water vapor

582   and clouds are modeled as passive tracers with cloud microphysics and precipitation

583   processes but without cloud radiative effects or latent heat release (MH18). Despite the

584   simplicity of model physics, this idealized GCM produces qualitatively similar global

585   moisture transport, *P-E*, and cloud distributions as compared with observations; especially

586   over the extratropics, the model produces remarkable simulations in the dynamical structure

587   of individual ARs, the basic statistical characteristics of ARs and the realistic spatial

588   distributions of AR climatology. This idealized model under uniform tropospheric warming

589   projects robust AR changes in response to global warming similar to the CESM LENS

590   simulations under RCP8.5, including the AR size expansion according to the same detection

591   threshold, intensified landfall moisture transport magnitude, and an increase in AR frequency,

592   which is mainly attributed to the higher moisture with warmer climate (i.e., thermodynamic

593   effect), further improving our confidence in previously reported AR changes under global

594   warming (e.g., Lavers et al. 2015; Payne and Magnusdottir 2015; Warner et al. 2015; Gao et

595   al. 2016; Hagos et al. 2016; Gershunov et al. 2017; Espinoza et al. 2018; Curry et al. 2019).

596   In addition, the AR frequency shifts poleward with uniform tropospheric warming. We

597   further suggest that this poleward shift is attributed not only to the dynamic effect but also to

598   the thermodynamic effect due to the nonlinear moisture dependence on temperature, with a

599   larger increase in saturation vapor pressure with warming at lower temperatures (e.g., polar

600   regions). The contribution of the local nonlinear effect to the poleward shift in ARs has not

601   been studied yet. This poleward shift is more notable in the South Hemisphere, where

602   observations saw a poleward shift in AR in recent decades, with important implications for

603   the moisture transport into the Antarctic (Ma et al. 2020a).

604

605   These results demonstrate, despite their fine-scale structures, the basic dynamics of ARs in a

606   warming climate can be understood as passive water vapor and cloud tracers without explicit

607   consideration of convections and associated latent heat feedback. In other words, the

608   dominant physical mechanism for atmospheric rivers is the mixing of air mass and moisture

609   along isentropic surfaces associated with large-scale tropospheric weather systems (Chen and

610   Plumb 2014), which also play a major role in the humidity structure of the atmosphere

611   (Galewsky et al. 2005; Wright et al. 2010). This may be a little counterintuitive as latent heat

612   release is often considered as a major source of energy that reinforces the synoptic storm

613   associated with an AR. This may be explained by a recent study on midlatitude extreme

614   precipitation, in which the latent heat feedback is largely canceled by the increased

615   stratification in a warming climate (Li and O'Gorman 2020).

616

617   Although the idealized model simulates the ARs and their responses in changing climate well,

618   care must be taken in generalizing this simple model to some studies of ARs in the real

26

619   climate. For example, given some tropical factors, such as Madden-Julian Oscillation (MJO)

620   and El Nino-Southern Oscillation (ENSO), could influence extratropical ARs through

621   atmospheric teleconnections (Guan et al. 2012; Guan and Waliser 2015; Mundhenk et al.

622   2016), the biased simulation over the tropics in the idealized model may limit its capability

623   to model the variability of ARs. In addition, the modeled landfalling ARs are too strong as

624   compared to observations, because of the excessive moisture over the land simulated by the

625   model in which the relative humidity is simply nudged to 100% at the lowest model level. A

626   more realistic evaporation scheme with realistic land-sea contrast is warranted to describe

627   better the landfalling ARs and their impact on the coastal regions.

628

629   Finally, this idealized model provides a new tool for understanding Earth-like global

630   circulation and hydrological cycle on regional scales. Our study has demonstrated that the

631   idealized model can capture many features of atmospheric general circulation, midlatitude

632   storms, and moisture transport in a warming climate. Many idealized models have no explicit

633   hydrological cycle (e.g., Held and Suarez 1994) or unrealistic boundary conditions (e.g.,

634   Neale and Hoskins 2000) and thus cannot simulate realistic spatial distributions of ARs. The

635   new idealized model developed in this study overcomes these limitations and reproduces

636   individual ARs and their climatology well, and thus helps improve our confidence in regional

637   atmospheric moisture transport and AR dynamics in a warming climate.

638

639   **Appendix A:**

640   The model is supposed to reproduce a temperature field similar to a given reference

641   temperature climatology T_R. Here, T_R is the mean state of the MERRA2 in 1980-2015 (Wu

642   and Reichler 2018). For an iteration step (i), a model run forced with a $T_{eq}(i)$ produces a time-

27

643   mean output temperature field $\bar{T}(i)$. Then we calculate the difference between $\bar{T}(i)$ and T_R and

644   define $T_{eq}(i+1)$ as

645   $$T_{eq}(i+1) = T_{eq}(i) - \alpha(\bar{T}(i) - T_R) \qquad (1)$$

646   to yield $\bar{T}(i+1)$ closer to T_R. $\alpha = 2/3$ is used here following Chang (2006) to avoid

647   overshooting the optimal T_{eq}. Equation (1) is then iterated until $T_{eq}(n)$ that yields a $\bar{T}(n)$

648   sufficiently close to T_R is generated.

Figure list
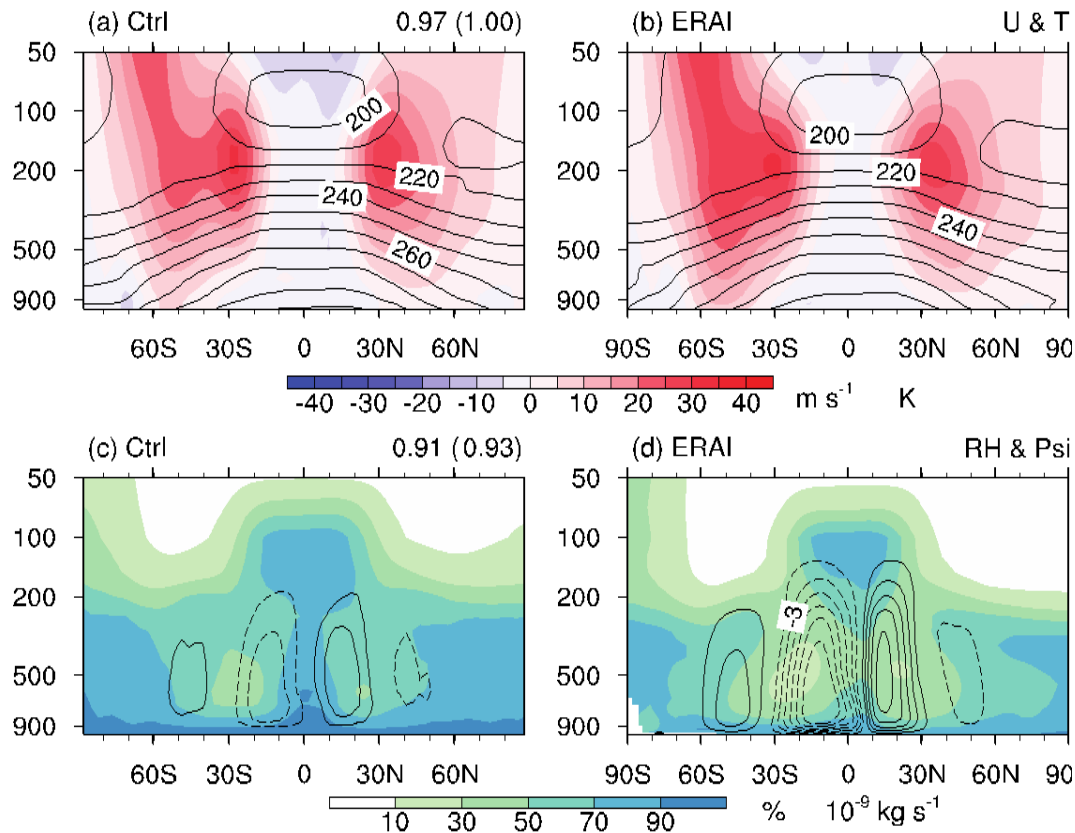

Fig.1 Zonal mean zonal wind, temperature， relative humidity and mean meridional circulation in the idealized model and observations. (a-b) Zonal mean zonal wind (color shading, m s^{-1}) and temperature (contour, K) in Ctrl run and ERAI. (c-d) Zonal mean relative humidity (Units: %) and meridional stream function (interval is 1.5×10^{-9} kg s^{-1}) simulated in Ctrl run and ERA. The value 0.97(~1.0) at the upper right of (a) is the pattern correlation coefficients between Ctrl and ERAI for zonal mean zonal wind (zonal mean temperature). The value 0.91(0.93) in (c) is that for RH (meridional stream function) between Ctrl and ERAI.

912
913

914   Fig.2 Hydrological cycle in the idealized model and observations. Zonal mean *P-E*

915   (precipitation minus evaporation; solid line; mm day^{-1}) and horizontal convergence of

916   moisture transport (dotted line; mm day^{-1}) in Ctrl run (red lines) and ERAI (gray lines) are

917   shown.

918

919
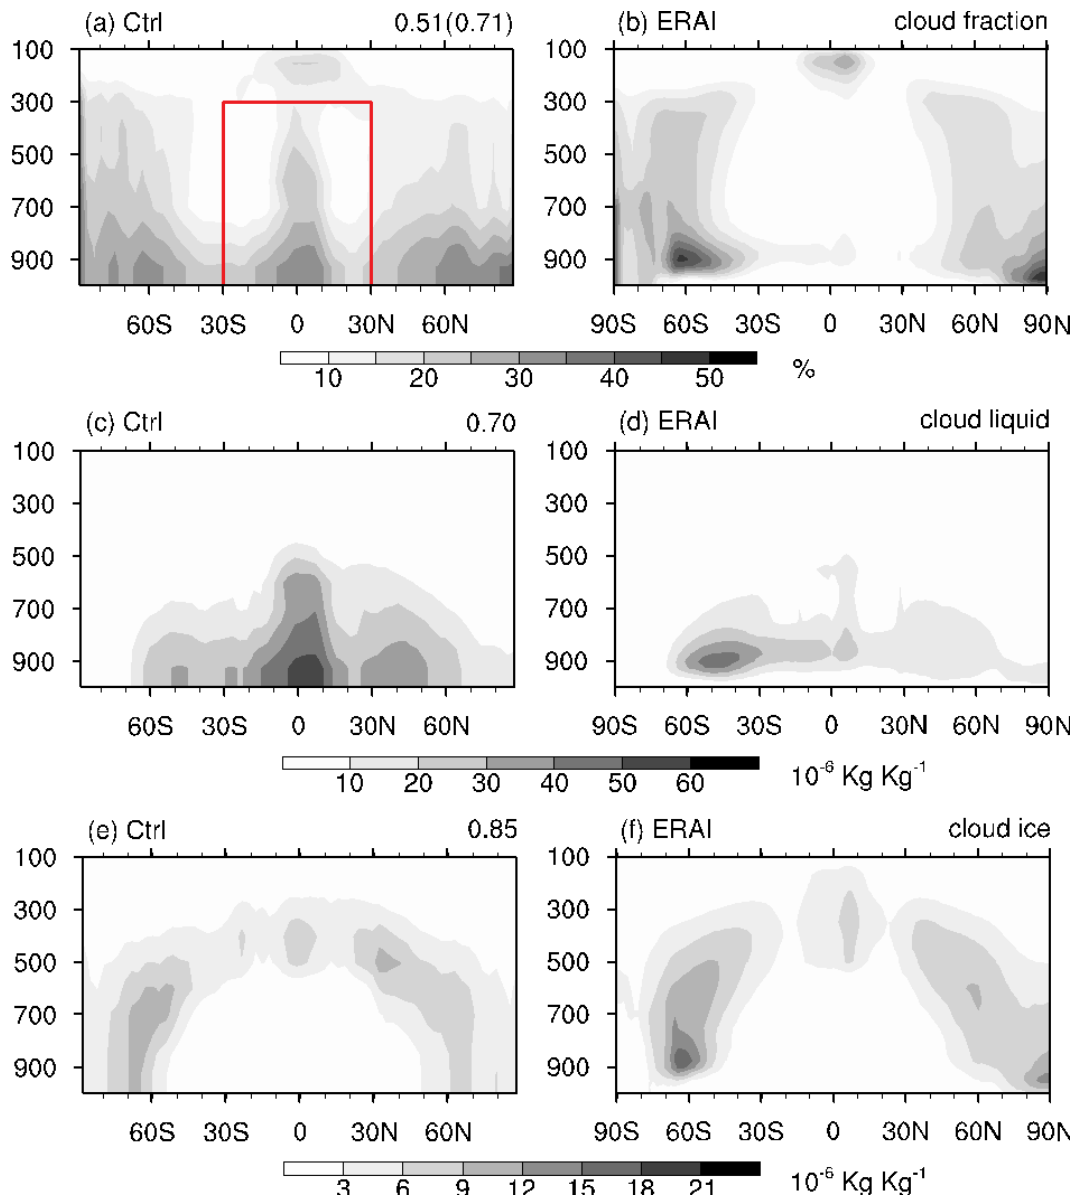

Fig.3 Clouds in the idealized model and observations. (a-b) Cloud fraction (%), (c-d) cloud liquid (10^{-6} kg kg^{-1}), (e-f) cloud ice (10^{-6} kg kg^{-1}) simulated in control run and that in ERAI. Weighted centered pattern correlation coefficients between the Ctrl and ERAI are shown at the upright of (a, c, d) for corresponding variables. The red box in (a) marks the tropical middle-low level clouds produced in this idealized model due to the lack of convection parameterization. The correlation coefficient in the brackets in (a) shows the pattern correlation with the exclusion of the red box region.

929   Fig.4 An AR case simulated in Ctrl run and a case in observation (ERAI), respectively. (a-b)

930   Integrated water vapor transport (IVT; kg m^{-1} s^{-1}) vectors (gray arrows; not shown if the

931   magnitude is smaller than 100 kg m^{-1} s^{-1}) and its magnitude (color shading), and integrated

932   water vapor (IWV; red contours; cm) in Ctrl (a) and ERAI (b). The position of the cross-

933   sections shown in (c-d) is denoted by the dotted line A-A' in (a) and B-B' in (b), respectively.

934   (c-d) Vertical cross-section perspective, including the core of the water vapor transport in the

935   atmospheric river (color shading), water vapor mixing ratio (red dotted lines; g kg^{-1}) and

936   cross-section isotachs (blue contours; m s^{-1}) in Ctrl (c) and ERAI (d). The tropopause is

937   denoted by the black dashed line in (c-d).

938

939
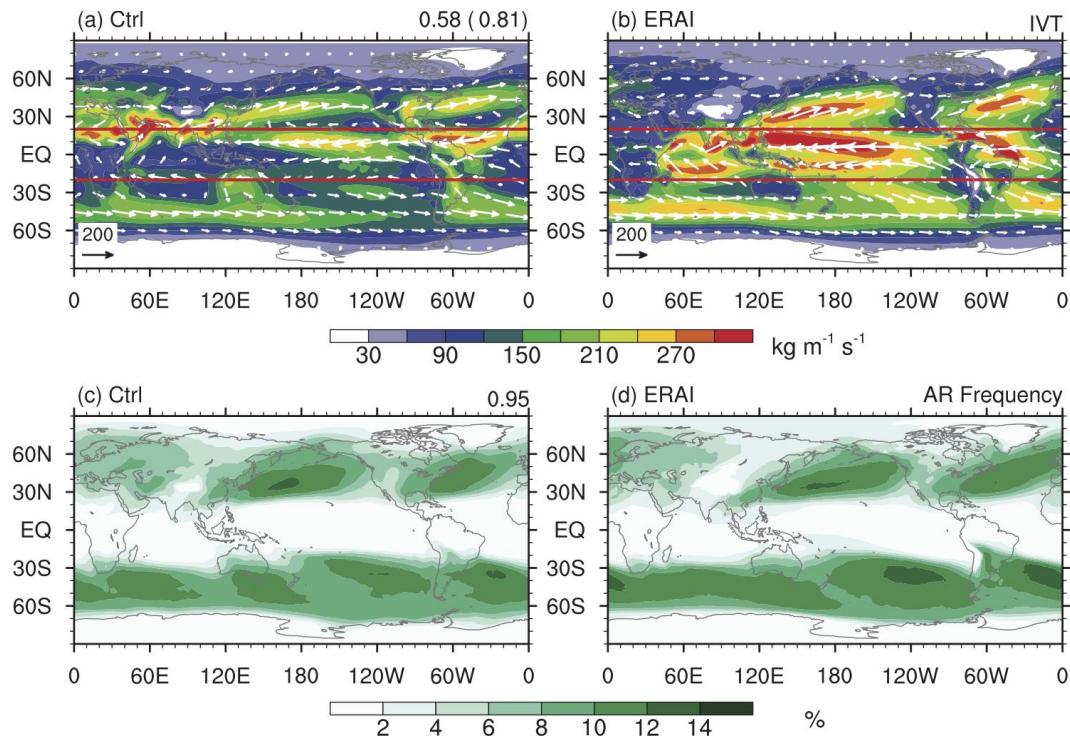

Fig.5 Mean integrated water vapor transport (IVT; kg m^{-1} s^{-1}) vector (white arrows) in Ctrl

run (a) and ERAI (b). (c-d) same as (a-b) but for atmospheric river (AR) frequency (%).

Weighted centered pattern correlation coefficients between the Ctrl and ERAI are shown at

the upright of (a, c) for corresponding variables. The correlation coefficient in the brackets

in (a) shows the pattern correlation excluding the tropical region (20°S-20°N; denoted by the

red lines).

946

947
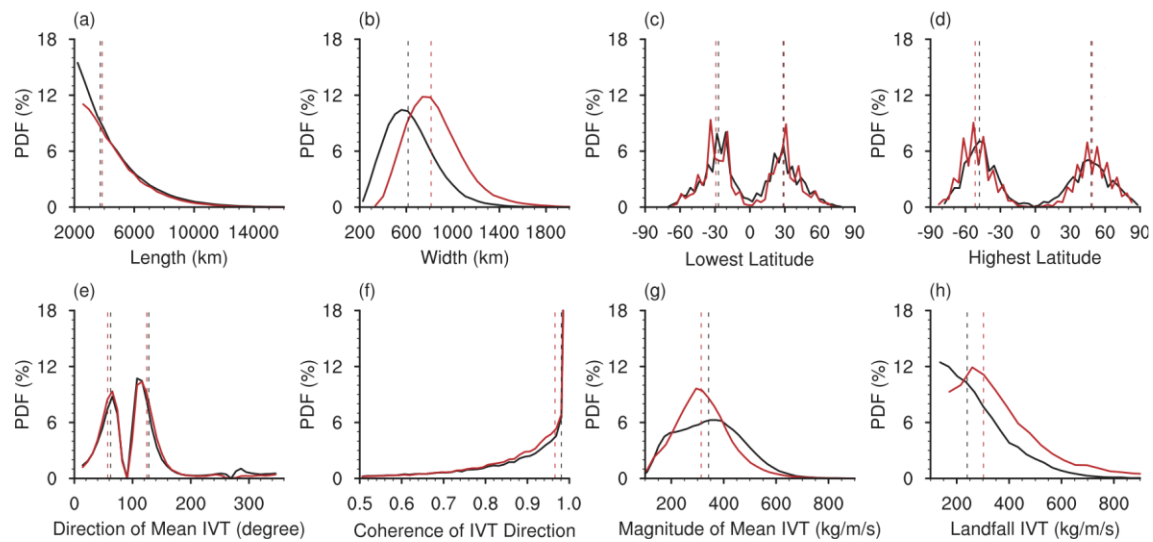

948 Fig. 6 PDFs of the basic characteristics of ARs in Ctrl run (red) and ERAI (black). (a) Length

949 of ARs. (b) Width of ARs. (c) Latitude of equatorward tip. (d) Latitude of poleward tip. (e)

950 Direction of mean IVT. (f) Coherence of IVT direction. (g) Magnitude of mean IVT. (h)

951 Magnitude of landfall IVT. The dashed vertical lines in each panel denote the median (in

952 case of one red line and one black line) or the median in each hemisphere (in case of two red

953 lines and two black lines) in Ctrl and ERAI, respectively.

954

955
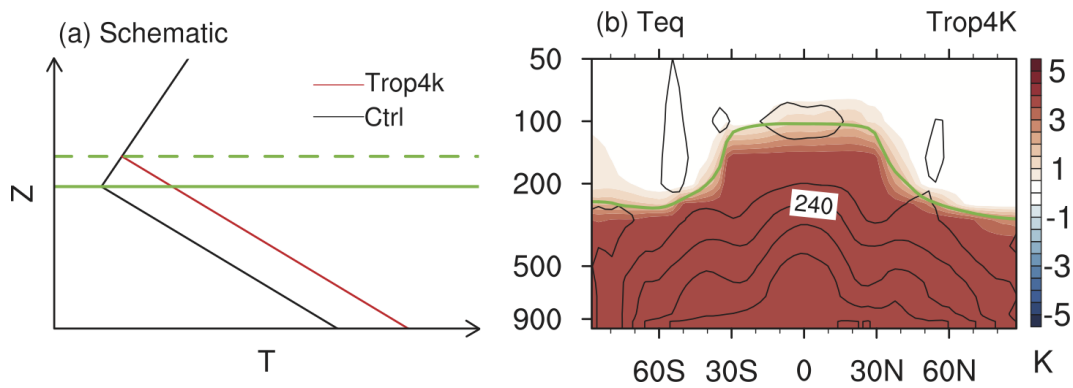

956 Fig.7 Design of uniform tropospheric warming forcing. (a) Schematic diagram for the

957 changes to the vertical profile of tropospheric temperature due to global warming. Black line

958 is an idealized profile of temperature in the troposphere and lower stratosphere. Red line

959 denotes a uniform warming in the troposphere. Solid and dashed green lines in (a) denote the

960 tropopause and its elevation due to the tropospheric warming forcing. (b) Equilibrium

961 temperature (T_{eq}, units: K) in Ctrl (contour) and the 4K uniform tropospheric warming in T_{eq}

962 for the Trop4K run (color shading). Green line shows the position of the tropopause in Ctrl.

963 The forcings for Trop2K, Torp-2K and Trop-4K experiments were implemented in the model

964 in a similar way.

965

42

966
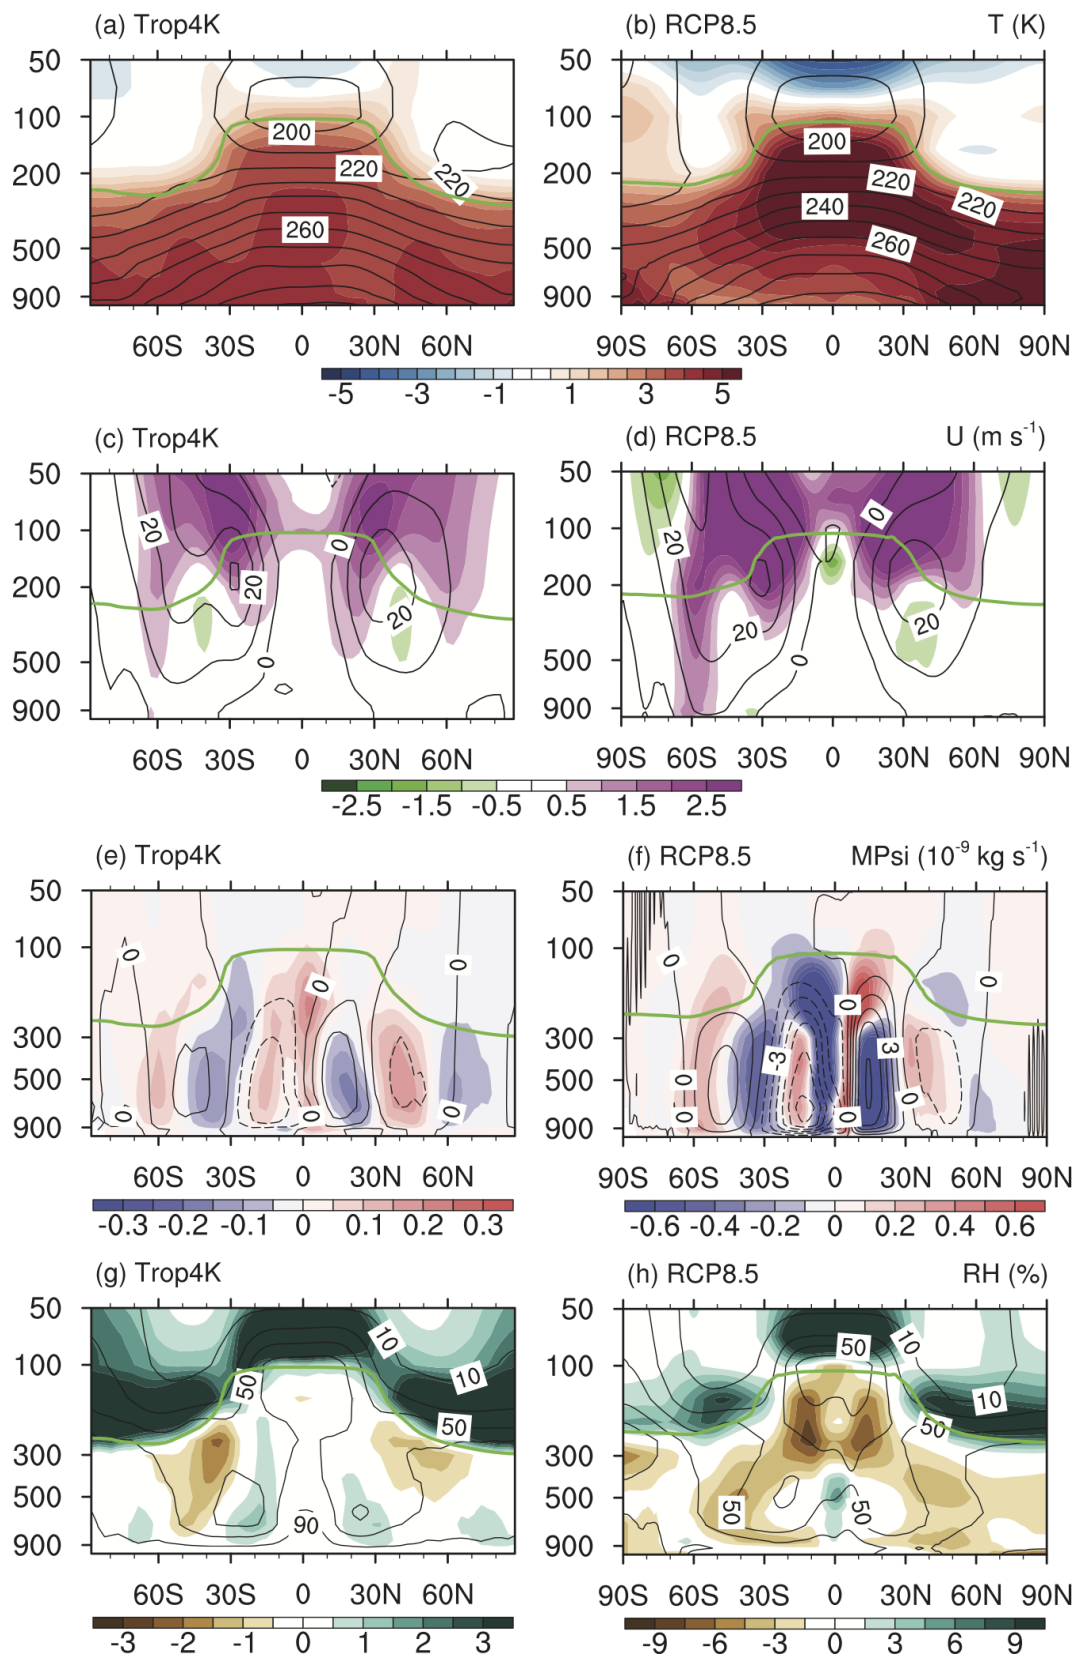

Fig. 8 Response of zonal mean temperature, zonal wind, meridional stream function and

968   relative humidity in the Trop4K run (left column) and RCP8.5 in CESM LENS (right

969   column). The contours denote the corresponding variables in Ctrl run (left column) and

970   historical simulations in CESM LENS (right column). Green lines denote the tropopause in

971   their reference states, respectively.

972

973

974   Fig. 9 Responses of *P-E* in the Trop4K run (red line) and CESM LENS RCP8.5 (gray line).

975
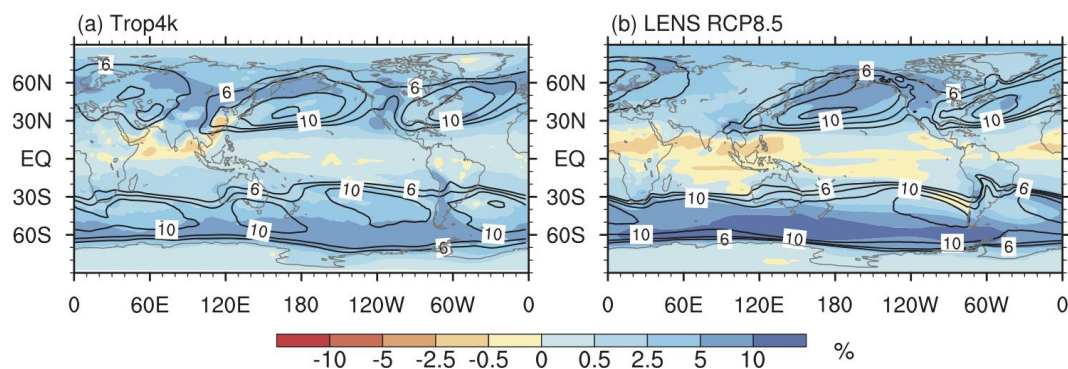

977 Fig.10 Frequency changes of Atmospheric Rivers in response to global warming. (a) AR

978 frequency (%) in Ctrl (contour) and its response (Trop4k-Ctrl) in Trop4K run (color shading).

979 (b) AR frequency in historical runs of CESM LENS during 1979-2005 (contour) and its

980 response in RCP8.5 runs during 2074-2100 (color shading).

981

982

Fig.11 Decomposition of the response in AR frequency in Trop4K simulation. (a) Thermodynamic effect. (b) Dynamic effect. (c) Thermodynamic effect due to global mean warming. (d) Thermodynamic response due to local effect. (e) Full response and the sum of the thermodynamic and dynamic effects in zonal mean AR frequency. (f) Thermo_Local and dynamic effects in zonal mean AR frequency.

988

989
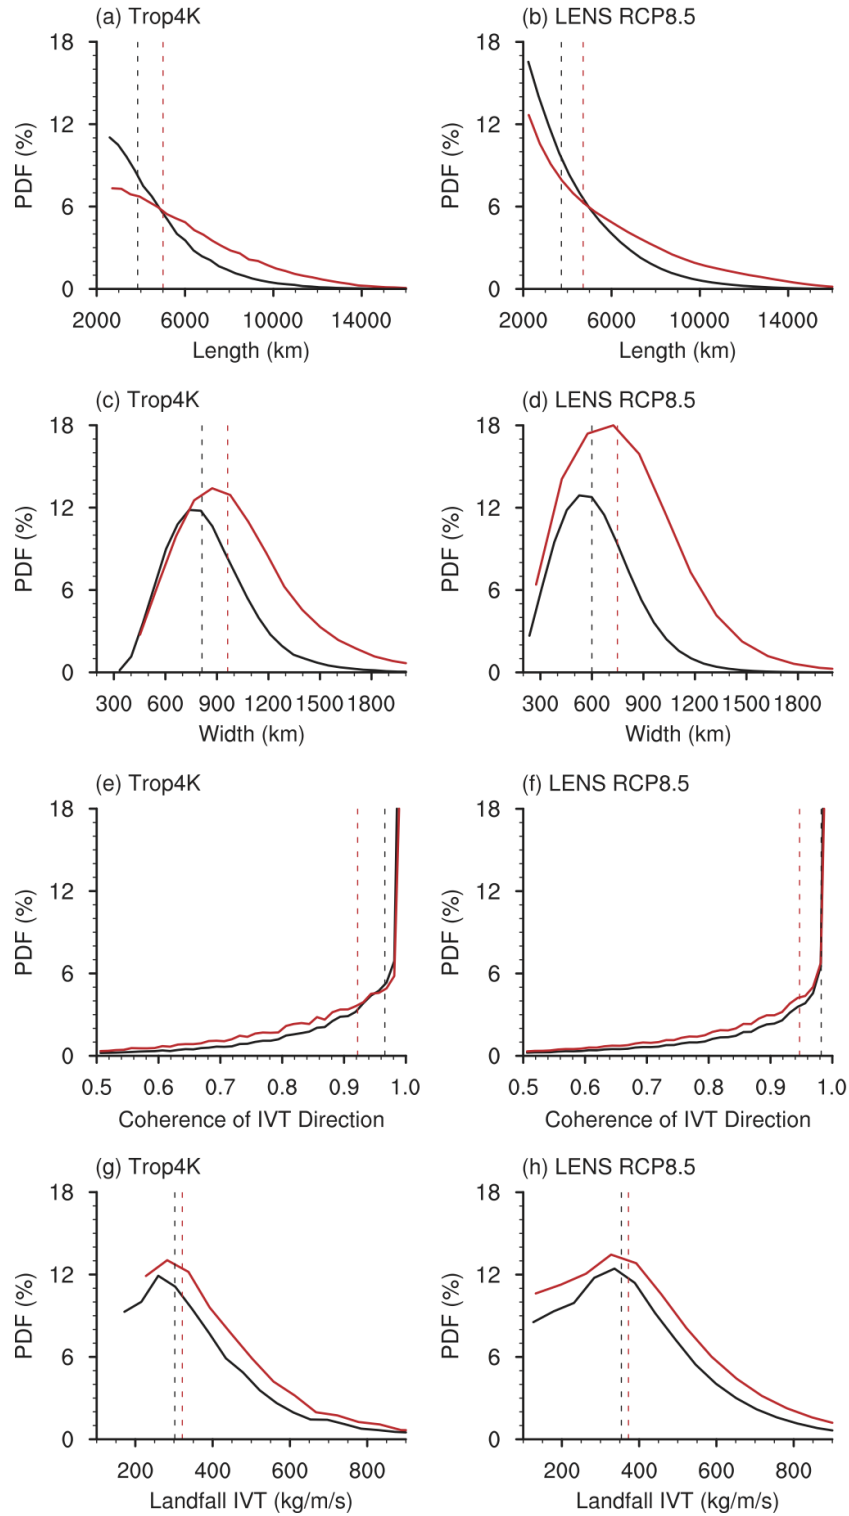

Fig. 12 Responses in the PDFs of AR characteristics to global warming in idealized model

experiments (left) and CESM LENS outputs (right). (a-b) Length of ARs. (c-d) Width of ARs.

(e-f) Coherence of IVT direction of ARs. (g-h) Magnitude of IVT at the landfalling point.

48

993   Black indicates the reference state (Ctrl or Hist) and red indicates the warmer climate

994   (Trop4K or RCP8.5). The two dashed vertical lines in each panel denote the median.
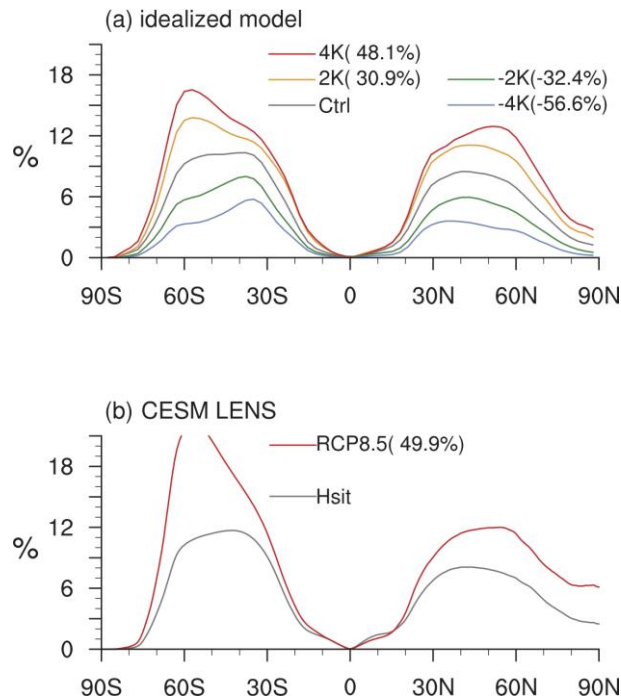

995

(a) idealized model

(b) CESM LENS

996

997   Fig.13 (a) Zonal mean of AR frequency (%) among a range of climates in idealized

998   simulations. The AR frequency changes relative to the Ctrl run are shown in legend (the

999   percentages, calculated as changes divided by reference state). (b) Same as (a) but for that in

1000   CESM LENS. For the tropospheric temperature response in CESM LENS, there is about

1001   4.4K warming in 2074-2100 in RCP8.5 runs compared to 1979-2005 in historical runs.
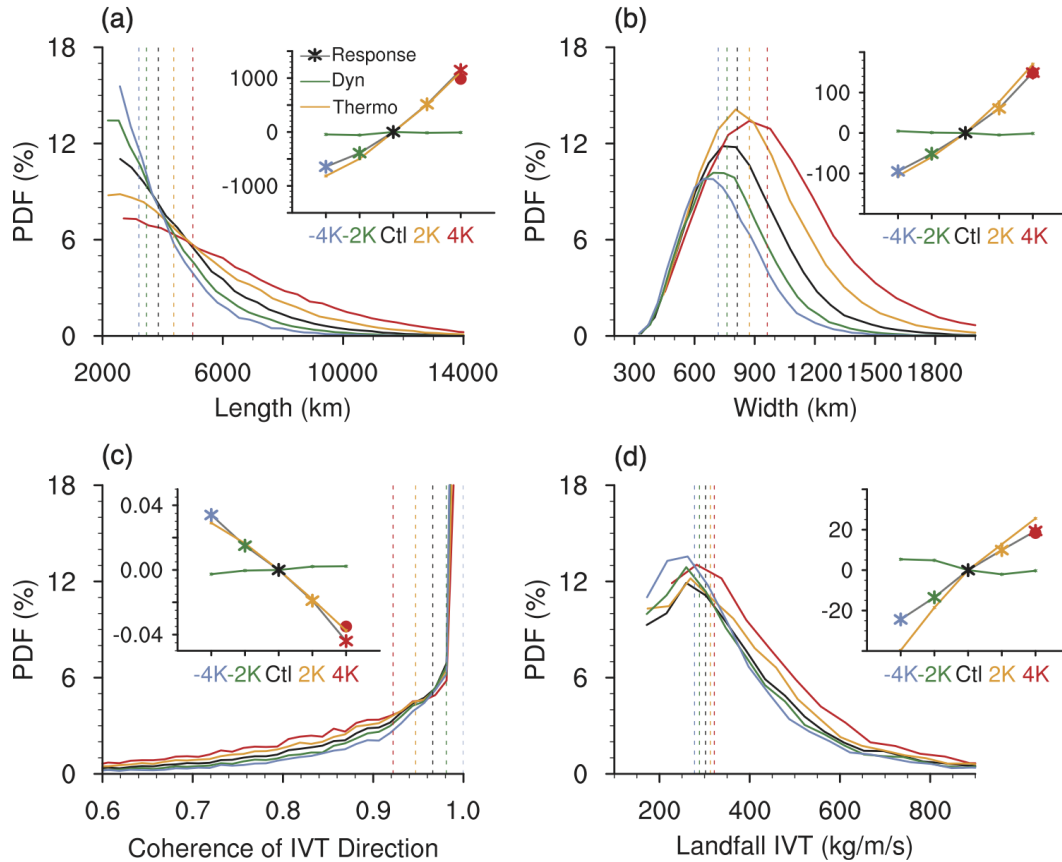

1002

Fig.14 Same as Fig.11 but for that in Trop-4K (blue), Trop-2K (green), Ctrl (black), Trop2K (orange) and Trop4K (red) experiments. The line with colored stars in the line charts in every panel shows the median changes in sensitivity experiments, respectively. The green line and orange line in the line charts in each panel show the median changes in dynamic response and thermodynamic response, respectively. The median changes for each variable are defined as the differences between the medians in the 5 experiments and the Ctrl. The median changes with a 4.4K warming in RCP8.5 compared to HIST in CESM LENS are marked as red solid circles in the line charts.

51

1013 Table 1 Model experiments conducted in this study

	Exp name	Description
1	Trop4K	Forced by an additional uniform 4K warming in the troposphere
2	Trop2K	Same as Trop4K but with a 2K forcing
3	Ctrl	Control run
4	Trop-2K	Same as Trop4K but with a -2K forcing
5	Trop-4K	Same as Trop4K but with a -4K forcing
