## Abstract

Serializability is a well-understood concurrency control mech-sistency, Weak Isolation anism that eases reasoning about highly-concurrent database

ACM Reference Format: programs. Unfortunately, enforcing serializability has a high performance cost, especially on geographically distributed under serializability, with the expectation that transactions would only be so marked when necessary to avoid serious 25, 2021, Virtual, Canada ACM, New York, NY, USA, 16 pages. concurrency bugs. However, this is a significant burden to https://doi.org/10.1145/3453483.3454028 impose on developers, requiring them to (a) reason about subtle concurrent interactions among potentially interfering transactions, (b) determine when such interactions would 1 violate desired invariants, and (c) then identify the minimum number of transactions whose executions should be serial-tous: bank accounts, shopping carts, inventories, and social ized to prevent these violations. To mitigate this burden, this paper presents a sound and fully automated schema refactinformation. For performance and fault tolerance reasons, toring procedure that transforms a program's data layout s rather than its concurrency control logic s to eliminate statically identified concurrency bugs, allowing more transactions to be safely executed under weaker and more perfor-grams which interact with such databases is notoriously mant database guarantees. Experimental results over a range difficult, because the programmer has to consider an expoof realistic database benchmarks indicate that our approach nential space of possible interleavings of database operations is highly effective in eliminating concurrency bugswith safe refactored programs showing an average of 120% higheone approach to simplifying this task is to assume that sets throughput and 45% lower latency compared to a serialized of operations, or transactions, executed by the program are baseline.

#### Introduction

Programs that concurrently access shared data are ubiquimedia applications all rely on a shared database to store the underlying databases that manage state in these applications are often replicated and distributed across multiple. geographically distant locations 4, 36, 48, 51. Writing proin order to ensure that a client program behaves correctly. serializable [0], i.e. that the state of the database is always consistent with some sequential ordering of those transactions. One way to achieve this is to rely on the underlying database system to seamlessly enforce this property. Unfortunately, such a strategy typically comes at a considerable performance costThis cost is particularly significant for distributed databases, where the system must rely on expensive coordination mechanisms between different replicas. in effect limiting when a transaction can see the effects of another in a way that is consistent with a serializable execution [5]. This cost is so high that developers default to weaker consistency guarantees, using careful design and testing to ensure correctness, only relying on the underlying system to enforce serializable transactions when serious bugs are discovered [27, 37, 45, 50].

Uncovering such bugs is a delicate and highly error-prone task even in centralized environments: in one recent study, Warszawski and Bail[\$6] examined 12 popular E-Commerce applications used by over two million well-known websites and discovered 22 security vulnerabilities and invariant violations that were directly attributable to non-serializable transactions. To help developers identify such bugs, the community has developed multiple program analyses that report potential serializability anomalies 2, 13, 27, 31, 39. Automatically repairing these anomalies, however, has remained a challenging open problem: in many cases full application safety is only achievable by relying on the system to enforce strong consistency of all operations. Such an approach results in developers either having to sacrifice performance for the sake of correctness, or conceding to operate within a potentially restricted ecosystem with specialized services and APIs 4] architectured with strong consistency in mind.

In this paper, we propose a novel language-centric approach to resolving concurrency bugs that arise in these distributed environments. Our solution is to alter the schema, that data. Our key insight is that it is possible to modify shared state to remove opportunities for transactions to witness changes that are inconsistent with serializable execu-work and conclusions are given in Section 8 and Section 9. tions. We, therefore, investigate automated schema transformations that change how client programs access data to ensure the absence of concurrency bugs, in contrast to using To illustrate our approach, consider an online course mantions can concurrently access the database.

For example, to prevent transactions from observing nonatomic updates to different rows in different tables, we can fuse the offending fields into a single row in a single table tency guarantee. Similarly, consecutive reads and writes on aSTUDENable maintains a reference to a student's email row can be refactored into !functionalž inserts into a new table, which removes the race condition between concurrently (and altering how transactions access data accordingly), with registration status is stored in fieldt\_reg . Each entry in out altering a transaction's atomicity and isolation levels, we can make clients of distributed databases safer without of a course and the number of enrolled students. sacrificing performance. In our experimental evaluation, we were able to fix on average 74% of all identified serializabil- transactions. TransactionetSt, given a student's id, first reity anomalies with only a minimal impact (less than 3% on average) on performance in an environment that provides only weak eventually consistent guarantees4. For the remaining 26% of anomalies that were not eliminated by our refactoring approach, simply marking the offending transactions as serializable yields a provably safe program that STUDENand an update to the MAIltable (J2). Finally, transnonetheless improves the throughput (resp. latency) of its

This paper makes the following contributions:

- 1. We observe that serializability violations in database programs can be eliminated by changing the schema of the underlying database and the client programs in order to eliminate problematic accesses to shared database state.
- 2. Using this observation, we develop an automated refactoring algorithm that iteratively repairs statically identified serializability anomalies in distributed database clients. We show this algorithm both preserves the semantics of the original program and eliminates many identified serializability anomalies.
- 3. We develop a tool, Atropos <sup>1</sup>, implementing these ideas, and demonstrate its ability to reduce the number of serializability anomalies in a corpus of standard benchmarks with minimal performance impact over the original program, but with substantially stronger safety guarantees.

The remainder of the paper is structured as follow ₹he next section presents an overview of our approach. Section 3 defines our programming model and formalizes the notion or data layout, of the data maintained by the database, rather of concurrency bugs. Section 4 provides a formal treatment than the consistency levels of the transactions that access of our schema refactoring strategy. Sections 5 and 6 describe our repair algorithm and its implementation, respectively. Section 7 describes our experimentelvaluation. Related

agement program that uses a database to manage a list of course offerings and registered students. Figure 1 presents a simplified code snippet implementing such a program. The database consists of three tables, maintaining information whose updates are guaranteed to be atomic under any consistent of the consistence of the entry in schemæMAIL(via secondary kest\_em\_id) and a reference to a course entry in tab@OURS@a secondary running instances of the program. wish to register for \$5, and an update to that course's availability (U4) indicating that it is available now that a student has registered for it.

The desired semantics of this program is these transactions guarantees that a transaction never observes intermediate 13 39 56. Given potential serializability violations, the stanupdates of another transaction. Isolation guarantees that a transaction never observes changes to the database by other committed transactions once it begins executing. Taken together, these properties ensure that all executions of this program are serializable, yielding behavior that corresponds to some sequential interleaving of these transaction instances, rency and availability in order to recover the pleasant safety

While serializability is highly desirable, it requires using costly centralized locks [45] or complex version management systems [0], which severely reduce the system's available concurrencyespecially in distributed environments where database state may be replicated or partitioned to improve availability. In such environments, enforcing serializability typically either requires coordination among all replicas whenever shared data is accessed or updated, ensuring replicas always witness the same consistent order picked for repairing a serializability anomaly are the transof operations [6]. As a result, in most modern database sys- actions from the computationabomponent:by injecting tems, transactions can be executed under weaker isolation additional concurrency control through the use of locks or levels, e.g. permitting them to observe updates of other com-isolation-strengthening annotations, developers can control mitted transactions during their execution 34, 38, 43, 48. Unfortunately, these weaker guarantees can result in serial-of performance and availability. izability anomalies, or behaviors that would not occur in a current executions of this program's transaction instances of potentially conflicting accesses to shared staffer exthat exhibit non-serializable behaviors.

Lastly, the execution on the right shows two instances of egSt that attempt to increment the number of students in a course. This undesirable behavior. known as a lost update, leaves the database in a state inconsistent with any sequential execution of the two transaction instances. All of these anomalies can arise if the strong atomicity and isolation guarantees afforded by serializability are weakened.

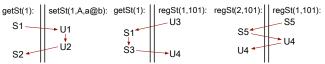

Figure 2. Serializability Anomalies

Several recent proposals attempt to identify such undesirable behaviors in programs using a variety of static or dynamic program analysis and monitoring techniquéន្ស [ dard solution is to strengthen the atomicity and isolation requirements on the offending transactions to eliminate the undesirable behaviour, at the cost of increased synchroniza-

Atropos. Are developers obligated to sacrifice concurproperties afforded by serializability? Surprisingly, we are able to answer this question in the negative see why, observe that a database program consists of two main components - a set of computations that includes transactions, SQL operations (e.g., selects and updates), locks, isolationlevel annotations, etc.; and a memory abstraction expressed as a relational schema that defines the layout of tables and the relationship between them. The traditional candidates the degree of concurrency permitted, albeit at the expense

This paper investigates the under-explored alternative of serial execution. particular row. Alternatively, it is possible to decompose data-successfulOn one hand, the set of potential solutions is effectively acts as a functional update to a table. To be sure, and error-prone [55]. these transformations affect read and write performance to notably impose no additional synchronization costs. In scal- and program refactorings, and returns a new version with this is a highly favorable trade-off since the cost of global concurrency control or coordination is often problematic in these settingsan observation that is borne our in our experimental results.

To illustrate the intuition behind our approach, consider the database program depicted in Figure This program behaves like our previous example, despite featuring very order to put it into a form amenable for our analysis. Next, a different database schemas and transactions. The first of the refactoring engine applies a variety of transformations in an two tables maintained by the program, UDE Niemoves the references to other tables from the original UDENtable, instead maintaining independent fields for the student's email address and their course availability. These changes make theom which it was extracted. original course and email tables obsolete, so they have been removed. In addition, the number of students in each course

is now stored in a dedicated tab@OURSE\_CO\_ST\_CN.T\_LO Each time the enrollment of a course changes, a new record is inserted into this table to record the change. Subsequent queries can retrieve all corresponding records in the table and aggregate them in the program itself to determine the number of students in a course.

The transactions in the refactored program are also modified to reflect the changes in the data model. The transaction getSt now simply selects a single record from the student table to retrieve all the requested information for a student. We adopt a commonly-used modelfor database applica-The transactionsetSt similarly updates a single record. Note tions [41, 42, 44], in which programs consist of a statically Similarly, regSt updates the student'sst\_co\_id field and inserts a new record into the scher@OURSE CO ST CNT LO@Lefined in terms of a set of database scher@Lasand a set

Using the functionuid() ensures that a new record is inserted every time the transaction is callethese updates remove potential serializability anomalies by replacing the disjoint updates to fields in different tables from the original with a simple atomic row insertion. Notably, the refactored program can be shown to be a meaningful refinement of the original program, despite eliminating problematic serializability errors found in it. Program refinement ensures that the refactored program maintains all information maintained by the original program without exhibiting any new behaviour.

The program shown in Figure 3 is the result of several database schema refactoring§,[21, 24], incremental changes to a database program's data model along with corresponding semantic-preserving modifications to its logic. Manually searching for such a refactored program is unlikely to be

base state to minimize the number of distinct updates to a large [3], rendering any manual exploration infeasible. On field, for example by logging state changes via table inserts, the other hand, the process of rewriting an application for a rather than recording such changes via updates. The former (even incrementally) refactored schema is extremely tedious

We have implemented a tool named Atropos that, given a database tables and change the memory footprint, but they database program, explores the space of its possible schema able settings such as replicated distributed environments, possibly many fewer concurrency bugs. The refactored program described above, for example, is automatically generated by Atropos from the original shown in Figure 1. Figure 4 presents the Atropos pipeline. A static analysis engine is used to identify potential serializability anomalies in a given program. The program is then pre-processed to extract the components which are involved in at least one anomaly, in attempt to eliminate the bugs identified by our static analysis. Finally, the program is analyzed to eliminate dead code, and the refactored version is then reintegrated into the program

#### 3.1 Data Store Semantics

Database states are modeled as a triple(str , vis , cnt), where str is a set of database events that captures the history of all reads and writes performed by a program operating over the database, ands is a partial order on those events. The execution countemt, is an integer that represents a global timestamp that is incremented every time over a program containing a set of transaction B<sub>xn</sub>. At

a database command is executed; it is used to resolve conflicts among concurrent operations performed on the same elements, which can be used to define a linearization or arbitration order on updates[5]. Given a database state)( and a primary key  $\in R_{id}$ , it is possible to reconstruct each field f of a record, which we denote a $\Sigma(r)$ .

Retrieving a record from a table generates a set of read eventsrd $(\tau, r)$ , which witness that the field of the record with the primary key  $r \in R_{id}$  was accessed when the value of the execution counter was Similarly, a write event,  $wr(\tau, r, \hbar)$ , records that the field of record was assigned the value n at timestamp  $\tau$ . The timestamp (resprecord) associated with an event is denoted by  $\eta_{\tau}$  (resp.  $\eta_{r}$ ).

Our semantics enforces record-level atomicity guarantees: transactions never witness intermediate (non-committed) updates to a record in a table by another concurrently exof transactions  $\overline{\mathcal{I}}$ ). A database schema consists of a schema ecuting one. Thusall updates to fields in a record from a database command happen atomically. This form of atomicity is offered by most commercial database systems, and is database state [9, 20, 35, 57]. In this paper, we consider to denote the set of all possible primary key values for the behaviors induced when the database guarantees only a very ing to every primary key. Every schema includes a special actions to see an arbitrary subset of committed updates by other transactions. Thus, a transaction which accesses multiple records in a table is not obligated to witness all updates performed by another transaction on these records.

To capture these behaviors use a visibility relation between eventsyis, that relates two events when one witsequence of parameters, a body, and a return expression. The esses the other in its local view of the database at the time of

ConstructView) str 
$$\subseteq$$
 str  $\forall_{\eta' \in \text{str}} \forall_{\eta \in \text{str}} (\eta_r = \eta_r' \land \eta_\tau = \eta_\tau') \Rightarrow (\eta \in \text{str}')$   $\forall_{\eta' \in \text{str}} \forall_{\eta \in \text{str}} (\eta_r = \eta_r' \land \eta_\tau = \eta_\tau') \Rightarrow (\eta \in \text{str}')$   $\forall_{\eta' \in \text{str}} \forall_{\eta \in \text{str}} (\eta_r = \eta_r' \land \eta_\tau = \eta_\tau') \Rightarrow (\eta \in \text{str}')$   $\forall_{\eta' \in \text{str}} (\eta_r = \eta_r' \land \eta_\tau = \eta_\tau') \Rightarrow (\eta \in \text{str}')$   $\forall_{\eta' \in \text{str}} (\eta_r = \eta_r' \land \eta_\tau = \eta_\tau') \Rightarrow (\eta \in \text{str}')$ 

The above definition ensures that an event can only be present in a local views,tr ', if all other events on the same record with the same counter value are also present in str (ensuring record-level atomicity). Additionally, the visibility relation permitted on the local view, vis, must be consistent with the global visibility relation, vis.

Figure 6 presents the operational semantics of our language, which is defined by a small-step reduction relation,  $\Rightarrow \subseteq \Sigma \times \Gamma \times \Sigma \times \Gamma$ , between tuples of data-store states  $(\Sigma)$  and a set of currently executing transaction instances  $(\Gamma \subseteq c \times e \times (\text{Var} \rightarrow \overline{R_{\text{id}} \times F}))$ . A transaction instance is a tuple consisting of the unexecuted portion of the transaction body (i.e., its continuation), the transaction's return expression, and a local store holding the results of previously processed guery commandshe rules are parameterized

Figure 6. Operational semantics of weakly-isolated database programs.

every step, a new transaction instance can be added to the view. All updates are performed atomically, as the set of corset of currently running transactions via (txn-invoke). Alprocessed via (txn-step). Finally, if the body of a transaction has been completely processed rettsurn expression is evaluated via (txn-ret); the resulting instance simply records the binding between the transaction instance and its return value  $f_n$ ).

The semantics of commands are defined using a local reduction relation (+) on database states, local states, and by our data store programming model using execution histocommands. The semantics for control commands are straight ries; finite traces of the form  $\Sigma_1$ ,  $\Gamma \Rightarrow \Sigma_2$ ,  $\Sigma \Rightarrow \cdots \Rightarrow \Sigma_k$ ,  $\Gamma \Rightarrow \Sigma_k$ forward outside of the (iter) rule, which uses an auxiliary function concat(n,  $\delta$  to sequence copies of the command c. Expression evaluation is defined using the big-step rela-actions have finished, i.e., the fin $\overline{\mathbf{B}}$ lin the trace is of the tion  $\Downarrow \subseteq (Var \rightarrow \overline{R_{id} \times F}) \times e \times Val$  which, given a store holding the results of previous query commands, determines the final value of the expression. The full definition ofcan be found in the supplementary material.

The semantics of database commands, given by the (select) and (update) rules, expose the interplay between global and local views of the database. Both rules construct a local view of the database  $\Sigma$  $\Sigma$ ) that is used to select or update the contents of records Neither rule imposes any restrictions on  $\Sigma'$  other than the consistency constraints defined by (ConstructView). The key component of each rule is how it defines the set of new events that are added to the database. In the select rule1 captures the retrievals that occur on database-wide scans to identify records satisfying the action (identified by the relation) to be visible to another SELECTommand's where clause. In an ab<u>use of notation, weif any of them are; in particular, any recorded event of a</u> write  $\Delta$ ,  $\phi(f:n)$   $\psi(n)$  as shorthand for  $\Delta$ ,  $\phi(f:n)$   $\psi(n)$ €2 constructs the appropriate read events of these retrieved events to precede all of be 's. records. The (update) rule similarly defines  $\varepsilon$ , the set of write events on the appropriate fields of the records that satisfy the where clause of the DATE ommand under an arbitrary (but consistent) local view () of the global store  $(\Sigma)$ . Both rules increment the local timestamp, and establish new global visibility constraints reflecting the dependencies introduced by the database command, i.e., all the generated

responding write events all have the same timestamp value. ternatively, a currently running transaction instance can be however, other transactions are not obligated to see all the effects of an update since their local view may only capture a subset of these events.

#### 3.2 Anomalous Data Access Pairs

We reason about concurrency bugs on transactions induced that capture interleaved execution of concurrently executing transactions A complete history is one in which all transform:  $\{t_1 : \text{skip}; m_1, \Delta_i\} \cup ... \cup \{t_k : \text{skip}; m_k, \Delta_i\}$ . As a shorthand, we refer to the final state in a histogras  $h_{\text{fin}}$ . A serial execution history satisfies two important properties:

Strong Atomicity: 
$$(\forall \eta, \dot{\eta}, \eta_{cnt} < \eta_{cnt} \Rightarrow vis(\eta, \dot{\eta})) \land \forall \eta, \dot{\eta}, \ddot{\eta} \cdot st(\eta, \dot{\eta}) \land (vis(\eta, \ddot{\eta}) \Rightarrow vis(\eta, \ddot{\eta}))$$
  
Strong Isolation:  $\forall \eta, \dot{\eta}, \ddot{\eta} \cdot st(\eta, \dot{\eta}) \land vis(\eta^{"}, \dot{\eta}) \Rightarrow vis(\eta^{"}, \dot{\eta})$ 

The strong atomicity property prevents non-atomic interleavings of concurrently executing transactionshe first constraint linearizes events, relating timestamp ordering of events to visibility. The second generalizes this notion to multiple events, obligating all effects from the same transtransaction $T_1$  that precedes an event  $T_2$  requires all of  $T_1$  s

The strong isolation property prevents a transaction from observing the commits of other transactions once it begins execution. It does so through visibility constraints on a transactionT that require any event generated by any other transaction that is visible to an even't generated by to be visible to any event that precedes it in T's execution.

A serializability anomaly is an execution history with a read and write events depending upon the events in the local final state that violates at least one of the above constraints. These sorts of anomalies capture when the events of a trans- COURSEO action instance are either not made visible to other events in totality (in the case of a violation of strong atomicity) or which themselves witness different events (in the case of a violation of strong isolation). Both kinds of anomalies can be eliminated by identifying commands which generate sets of problematic events and altering them to ensure atomic execution. Two events are executed atomically if they witness the same set of events and they are both made visible to other events simultaneously, iatomic( $\eta$ ,  $\eta$ ) =  $\forall \eta^{"}$ . (vis( $\eta$ ,  $\eta^{"}$ )  $\Rightarrow$  vis( $\eta^{'}$ ,  $\eta^{"}$ )) $\wedge$ (vis( $\eta^{"}$ ,  $\eta$ )  $\Rightarrow$  vis( $\eta^{"}$ ,  $\eta^{"}$ )).

Given a programP, we define a database access pair ( as a quadruple  $(c_1, f_1, g_1, f_2)$  where  $c_1$  and  $c_2$  are database commands from a transaction in P, and  $f_1$  (resp.  $f_2$ ) is a subset of the fields that are accessed by (resp. $c_2$ ). An access pair is anomalous if there is at least one execution i the execution history of P that results in an event generated by  $c_1$  accessing a fiel  $f_1 \in f_1$  which induces a serializability anomaly with another event generated byaccessing field  $f_2 \in f_2$ . An example of an anomalous access pair for the program from in Section 2,(is1, {st\_name}, 2, {em\_addr}) and  $(U1, \{st name\}, U2, \{em addr\})$ ; this pair contributes to

pair strategy that given a program and a set of anomalous access pairs produces a semantically equivalent program with fewer anomalous access pairs. In particular, we repair programs by refactoring their database schemas in order to between field f of schemaR and field f' of schemaR' is benefit from record-level atomicity guarantees offered by most databases, without introducing new observable behav-correspondence function, denoted by  $R_{id} \rightarrow \overline{R_{id}}$ , relates iors. We elide the details of how anomalous access pairs are discovered, but note that existing tools [46] can be adapted for this purposeSection 6 provides more details about how this works in Atropos.

# Refactoring Database Programs

In this section, we establish the soundness properties on the space of database program refactorings and then intro-of tables{STUDENTCOURSE\_ST\_CNT0}L@@der the pair duce our particular choice of sound refactoring rules. Similar of value correspondencesCOURSETUDENTo\_avail, refactorings are typically applied by developers when mi- st\_co\_avail,  $\theta_1$ , any) and (COURSEOURSE\_ST\_CNT\_LOG grating traditional database programs to distributed database co\_st\_cnt , co\_cnt\_log ,  $\theta$ , sum), wher  $\theta_1(1) = \{100, 200\}$ , systems 28, 58. Our approach to repair can be thought of as automating this manual process in a way that eliminates The aggregator functionany: Val → Val returns a nonserializability anomalies.

ant that at every step in any history of a refactored program, contained by the set of tables bi. it is possible to completely recover the state of the data-storeWe define the soundness of our program refactorings usfor a corresponding history of the original program. To estabing a pair of refinement relations between execution histolish this property, we begin by formalizing the notion of a ries and between programs. An execution history where containment relation between tables.

Figure 7. An example illustrating value correspondences.

#### 4.1 Database Containment

Consider the tables in Figure 7, which are instances of the schemas from Section 2. Note that every fiel@@URSEan be computed from the values of some other field in either the STUDE Notin COURSE ST CNT 1 tables: co avail corresponds to the value of that co avail field of a record in STUDEN,Twhile co\_st\_cnt can be recovered by summing up the values of theo cnt log field of the records in COURSE\_ST\_CNT0\_W00seco\_id field has the same value as the original table.

The containment relation between a table (@@URSE that program's non-repeatable read anomaly from Figure 2. and a set of tables (eSTUDENandCOURSE\_ST\_CNT0)LOG We now turn to the development of an automated static re-is defined using a set of mappings called value correspondences [5]. A value correspondence captures how to compute a field in the contained table from the fields of the containing set of tables. Formally, a value correspondence defined as a tuple R, R, f,  $f\theta$ ,  $f\theta$  in which: (i) a total record every record of any instance of a set of records in any instance of R and (ii) a fold function on values, denoted by  $\alpha: \overline{\mathsf{Val}} \to \mathsf{Val}$  is used to aggregate a set of values. We say that a table X is contained by a set of table sunder a set of value correspondences, if V accurately explains how to compute X from  $\overline{X}$ , i.e.

For example, the table COURS Es contained in the set  $\theta_1(2) = \{300\}, \theta_2(1) = \{(1,11), (1,33)\} \text{ and } \theta_2(2) = \{(2,22)\}.$ deterministically chosen value from a set of values. The The correctness of our approach relies on being able to containment relation on tables is straightforwardly lifted to

 $h'_{fin} = (\Sigma', \Gamma)$  is a refinement of an execution (where

$$\begin{array}{c} (\text{intro } \rho) \\ \hline \hline V, (\overline{R}, \overline{T}) \leftrightarrow \overline{V}, (\overline{R} \cup \{\rho : \varnothing\} \overline{T}) \end{array} \qquad \begin{array}{c} (\text{intro } \rho : \overline{f}) \\ \hline R = \rho : \overline{f} & f \notin \overline{f} & R' = \rho : \overline{f} \cup \{f\} \\ \hline \overline{V}, (\{R\} \cup \overline{R}, \overline{T}) \leftrightarrow \overline{V}, (\{R'\} \cup \overline{R}, \overline{T}) \end{array}$$

$$\begin{array}{c} (\text{intro } \underline{v}) \\ \hline v \notin \overline{V} & \overline{T}' = \{t (\overline{a}) \{ [[c]]_v; \text{ return } [[e]]_v \} \mid t (\overline{a}) \{c; \text{ return } e\} \in \overline{T} \} \\ \hline \hline \overline{V}, (\overline{R}, \overline{T}) \leftrightarrow \overline{V} \cup \{v\}, (\overline{R}, \overline{T}) \end{array}$$

Figure 8. Refactoring Rules

 $h_{\text{fin}} = (\Sigma, 1), \text{ denoted by } h' \leq_V h, \text{ if and only if } \Gamma' \text{ and } \Gamma$ have the same collection of finalized transaction instances on the source table and field into use the target table of and there is a set of value correspondent which  $\Sigma$ is contained in  $\Sigma'$ , i.e.  $\Sigma \sqsubseteq_V \Sigma'$ . Intuitively, any refinement of a history h maintains the same set of records and spawns the same set of transaction instances laswith each instance producing the same result as it does in Lastly, we define a refactored program to be a refinement of the original program P, denoted by  $P' \leq_V P$ , if the following conditions are satisfied:

- (I) Every historyh' of P' has a corresponding historly in P such that h' is a refinement of h.
- (II) Every serializable history of P has a corresponding history h' in P' such that h' is a refinement of h.

The first condition ensures that does not introduce any new behaviors over, while the second ensures that does not remove any desirable behavior exhibited By

#### 4.2 Refactoring Rules

We describe Atropos's refactorings using a relation⊆  $\overline{V} \times P \times \overline{V} \times P$ , between programs and sets of value correspondencesThe rules in Figure 8 are templates of the three categories of transformations employed by Atropos. These categories are: (1) adding a new schema to the program, captured by the rule (intro $\rho$ ); (2) adding a new field to an existing schema, captured by rule (intro  $\rho$ .); and, (3) relocating certain data from one table to another while modifying the way it is accessed by the program, captured by the rule (intro v).

The refactorings represented by (intro v) introduce a new value correspondence and modify the body and return expressions of a programs transactions via a rewrite function, [[.]],. A particular instantiation of [.]], must ensure the same data is accessed and modified by the resulting sound transformations do not introduce any new anomalies. program, in order to guarantee that the refactored program refines the original. At a high-level, it is sufficient f[[r]], to ensure the following relationship between the original ( and refactored programs P():

- (R1)P' accesses the same data Paswhich may be maintained by different schemas:
- (R2) P returns the same final value as
- (R3) and, P properly updates all data maintained by

To see how a rewrite function might ensure R1 to R3, con- $\frac{1}{2}$ A complete formalization of all three refactoring rules, their correctness sider the original (top) and refactored (bottom) programs presented in Figure 9. This example depicts a refactoring of this paper [47].

transactionsgetSt and setSt to utilize a value correspondence fromem\_addito st\_em\_addir, moving email addresses to the STUDENtable, as described in Section 2. The select commands1andS3in getS remain unchanged after the refactoring, as they do not access the affected table. However, the queryS2 which originally accessed the MAILtable is redirected to the STUDENT table.

More generally, in order to take advantage of a newly added value correspondence[[.]] v must alter every query instead, so that the new query accesses the same data as the original. This rewrite has the general form:

$$[[x := SELEC]^T FROM WHER D]_v = x := SELEC]^T FROM WHERE redirects. (1)$$

Intuitively, in order for this transformation to ensure R1, the redirect function must return a new where clause on the target table which selects a set of records corresponding to set selected by the original clause.

In order to preserve R2, program expressions also need to be rewritten to evaluate to the same value as in the original program. For example, observe that the turn expression in getSt is updated to reflect that the records held in the variable y now adhere to a different schema.

The transformation performed in Figure 9 also rewrites the update U2 of transactionsetSt. In this case, the update is rewritten using the same redirection strategy **32**( so that it correctly reflects the updates that would be performed by the original program to the EMAIL record.

Taken together R1 - R3 are sufficient to ensure that a particular instance of intro v is sound:

Theorem 4.1. Any instance of introv whose instantiation of  $[[\cdot]]_v$  satisfies R1 – R3 is guaranteed to produce a refactored program that refines the original, i.e.

$$\forall_{P,P',V',vww} (V,) P \rightarrow (V \cup \{v\}, P') \Rightarrow P' \leq_{V \cup \{v\}} P$$

Although our focus has been on preserving the semantics of refactored programs, note that as a direct consequence of our definition of program refinement, this theorem implies that

We now present the instantiations of v used by Atropos, explaining along the way how they ensure R1-R3.

4.2.1 Redirect Rule. Our first refactoring rule is parameterized over the choice of schemas and fields and uses the aggregatorany. Given data store state  $\Sigma$  and  $\Sigma$ , the record correspondence is defined  $\mathbf{a}\hat{\mathbf{g}}: \mathbf{r}' \in \mathbf{r}' \mid \mathbf{r}' \in \mathbf{r}'$  $R'_{\mathsf{d}} \wedge \forall_{f \in R_{\mathsf{d}}} \forall_{n} \cdot \Sigma(r \cdot) \not \sqcup n \Rightarrow \Sigma'(r' \cdot \hat{\theta}(f)) \Downarrow n \}$ . In essence,

criteria, and proofs of soundness is presented in the extended version of

Figure 9. A single program refactoring step, where (EMAILem addr) = STUDENTEM addr

the lifted function  $\theta$  identifies how the value of the primary key f of a recordr can be used to constrain the value of field  $\hat{\theta}(f)$  in the target schema to recover the set of records corresponding tor, i.e.  $\theta(r)$ . The record correspondences from Section 4.1 were defined in this manner, where

$$\hat{\theta}_1$$
(COURS£6\_id) ≡ STUDENST\_co\_id , and  $\hat{\theta}_2$ (COURS£6\_id) ≡ COURSE\_CO\_ST\_CNTcol\_00G

Defining the record correspondence this way ensures that if agrows and cannot be statically identified. recordr is selected i\(\mathbb{Z}\), the corresponding set of record\(\mathbb{Z}\) in can be determined by identifying the values that were used toging schema for the target schema logging schema for selectr, without depending on any particular instance of the tables. Our choice of record correspondence function makes target schema I og R has a primary key field, correspondthe definition of [[·]] for select statements a straightforward instantiation of (1) with the following definition of (2) with the following definition of (2) with the following definition of (3) with the following definition of (1) with the following definition of (2) with the following definition of (3) with the following definition of (3) with the following definition of (4) with the following definiti

redirect( 
$$\phi$$
,  $\lceil \hat{\theta} \rceil$ )  $\equiv \lim_{f \in \phi_{\text{Bld}}} \text{this } .\hat{\theta}(f) = \phi[f]_{\text{exp}}$  (2)

The one wrinkle in this definition ofedirect is that it is only defined when the where claus is well-formed i.e.  $\phi$  only consists of conjunctions of equality constraints on primary key fields. The expressions used in such a constraint be utilized to determine the final value of each record, by is denoted by  $\phi[f]_{exp}$ . As an example, the where clause of command \$2) in Figure 9 (left) is well-formed, where  $\phi$ [em\_id]<sub>exp</sub>  $\equiv$  x .st\_e\_id . However,the where clause in (S2) after the refactoring step is not well-formed, since it does not constrain the primary key of the TUDENtable. This restriction ensures that only queries that access a singletion of [[·]] for the logger rule usingsumas an aggregator. record of the original table will be rewritten Expressions using variables containing the results of such queries are rewritten by substituting the source field name with the target field name, e.**g**[at  $^{1}(x)$ ]  $_{v} \equiv$  at  $^{1}(x)$ .

Redirecting updates is similarly defined using the definition of redirect( $\phi$ ,  $\partial$ ) from 2:

```
[[UPDATR SET f = e WHER f]]_v \equiv
UPDATR SET (f' = [[e]]_v) WHERE redirect(\phi, \phi)
```

4.2.2 Logger Rule. Unfortunately, instantiating intro v is not so straightforward when we want to utilize value correspondences with more complicated aggregation functions than any. To see why, consider how we would need to modify an UPDAT when  $\alpha \equiv$  sum is used. In this case, our rule transforms the program to insert a new record corresponding to each update performed by the original program. Hence, the set of corresponding records in the target table always

We enable these sorts of transformations by using logsource schem $\mathbf{R}$  and the field f is defined as follows: (i) the ing to every primary key field of the original schemaR(); (ii) the schema has one additional primary key field, denoted by LogRlog\_id, which allows a set of records in LogRto represent each record in and (iii) the schemal og Rhas a single field corresponding to the original field. f, denoted by Log R. f.

Intuitively, a logging schema captures the history of updates performed on a record, instead of simply replacing old values with new ones. Program-level aggregators can then observing all corresponding entries in the logging schema. The schemaCOURSE\_CO\_ST\_CNTrolro Section 2 is an example of a logging schema for the source schema and field COURSDE\_st\_cnt.

Under these restrictions we can define an implementa-This refactoring also uses a lifted function for its value correspondence, which allows [[·]] to reuse our earlier definition of redirect . We defind[] on accesses to to use program-level aggregators, e.[(x .)],  $\equiv sum(x .)$ .

Finally, the rewrittenUPDATcommands simply need to log any updates to the field, so its original value can be recovered in the transformed program, e.g.

```
[[UPDATR SET f = e + at^{1}(x .)]WHER f_{1}]_{v} \equiv UPDATR
   SETf = [[e]]_vWHERE redirect(p, \theta) \land R.log_id = uuid().
```

Having introduced the particular refactoring rules instantiated in Atropos, we are now ready to establish the soundness of those refactorings:

Theorem 4.2. The rewrite rules described in this section sat 6 isfy the correctness properties (R1), (R2) and (R3).

Corollary 4.3. (Soundness) Any sequence of refactorings pe formed by Atropos is sound, i.e. the refactored program is a refinement of the original program.

Proof.Direct consequence of theorems 4.1 and 4.2.

# Repair Procedure

Figure 10 presents our algorithm for eliminating serializability anomalies using the refactoring rules from the previous section. The algorithmepair ) begins by applying an anomaly detectorO to a program to identify a set of anomalous access pairs. As an example, consident from our running example. For this transaction, the anomaly oracle identifies two anomalous access pairs:

(U3{st\_co\_id ,st\_reg} ,U4{co\_avail}) (
$$\chi$$
1) (S5{co st cnt} ,U4{co st cnt}) ( $\chi$ 2)

The first of these is involved in the dirty read anomaly from Section 2, while the second is involved in the lost update anomaly.

```
Function: repair(P)
  \overline{\chi} \leftarrow O(P); P \leftarrow \text{pre\_process}(P, \overline{\chi})
  for \chi \in \overline{\chi} do
         if try_repair( P, \lambda) = P' then P \leftarrow P'

Figure 11. Repair steps of transaction regSt

repair them one by one usingry\_repair . This function attempts to eliminate a given anomaly in two different ways: either by merging anomalous database commands into a single command, and/or by removing one of them by making it obsolete. In the remainder of this section, we present these two strategies in more detailusing the running example from Figure 11.

We first explain the merging approach. Two database commands can only be merged if they are of the same kind (e.g. both are selects and if they both access the same schema. These conditions are checked in lines 2-3. Funtationnerge attempts to merge the commands if it can establish that their where clauses always select the exact same set of records, i.e. condition (R1) described in Section 4.2.

Unfortunately, database commands involved in anomalies The repair procedure next performs a pre-processing phase rarely on the same schema and cannot be merged as they table in the refactored program and thus mergeable. This is dences between the two schemas using the redirect rule. such that c2 is redirected to the same table as The record

correspondence is constructed by analyzing the commands' Table 1. Statically identified anomalous access pairs in the where clauses and identifying equivalent expressions used original and refactored benchmark programs

in their constraints. If redirection is success toly, merge is invoked on the commands and the result is returned (line 6).

For example, consider commands and U42 in Figure 11 (top), which are involved in the anomaly. By introducing a value correspondence fro@OURSESTUDENAtropos refactors the program into a refined version whell 2 is transformed into U.2 and is mergeable with U3.

Merging is sufficient to fix  $\chi_1$ , but fails to eliminate  $\chi_2$ . The repair algorithm next tries to translate database updates into an equivalent insert into a logging table using the try logging procedure. This procedure first introduces a new logging schema (using the intro rule) and then introduces fields into that schema (using intro .). It then attempts to introduce a value correspondence from the schemaused by an implementation of the repair algorithm build a involved in the anomaly to the newly introduced schema using the logger rule. The function returns successfully if such a translation exists and if the select command involved code. For example, in Figure 11, a value correspondence from in the anomaly becomes obsolete, i.e., the command is dead COURSE the logger table OURSE CO STISCINTFoduced. which translates thepdate command involved in the anomaly to aninsert command. The select command is obsolete in the final version, since variable is never used.

Once all anomalies have been iterated over, Atropos performs a post-processing phase on the program to remove any remaining dead code and merge commands whenever possible. For example, the transactions St is refactored into its final version depicted in Figure 3 after post-processing. Both anomalous accesses (and  $\chi_2$ ) are eliminated in the final version of the transaction.

# **Implementation**

Atropos is a fully automated static analyzer and program repair tool implemented in Java. Its input programs are written come from the ten benchmarks defined in the OLTPBench in a DSL similar to the one described in Figure 5, but it would project [18]. We did not consider the remaining four benchbe straightforward to extend the front-end to support popular database programming APIs, e.g. JDBC or Python's DB-alies. The last three programs are drawn from papers that API. Atropos consists of a static anomaly detection engine and a program refactoring engine and outputs the repaired program. The static anomaly detector in Atropos adapts existing techniques to reason about serializability violations over abstract executions of a database application [9]. In this approach, detecting a serializability violation is reduced to checking the satisfiability of an FOL formula constructed from the input program. This formula includes variables for each of the transactional dependencies, well as the visibility and global time-stamps that can appear during a program's execution. The assignments to these variables in repair each benchmark is presented in fliene(s) column. any satisfying model can be used to reconstruct an anoma-The time spent on analysis dominates these numbers; lous execution. We use an off-the-shelf SMT solver,1ZB [ to check for anomalies in the input program and identify a

set of anomalous access pairs. These access pairs are then repaired version of the input program.

### Evaluation

- 1. Effectiveness: Does schema refactoring eliminate serializability anomalies in real-world database applications? Is Atropos capable of repairing meaningful concurrency bugs?
- 2. Performance: What impact does Atropos have on the performance of refactored programs? How does Atropos compare to other solutions to eliminating serializability anomalies, in particular by relying on stronger database-provided consistency guarantees?

#### 7.1 Effectiveness

To assess Atropos' effectiveness, we applied it to a corpus of standard benchmarks from the database community. Table 1 presents the results for each program. The first six programs marks because they do not exhibit any serializability anomdeal with the consistency of distributed systems, [27, 53].

The first four columns in Table 1 display the number of transactions (#Txns), the number of tables in the original and refactored schemas (#Tables), and the number of anomalies detected assuming eventually consistent guarantees for the original (EC) and refactored (AT) programs. For each benchmark, Atropos was able to repair at least half the anomalies. and in many cases substantially more, suggesting that many serializability bugs can be directly repaired by our schema refactoring technique. The total time needed to analyze and pairing programs took under 50ms for every benchmark.

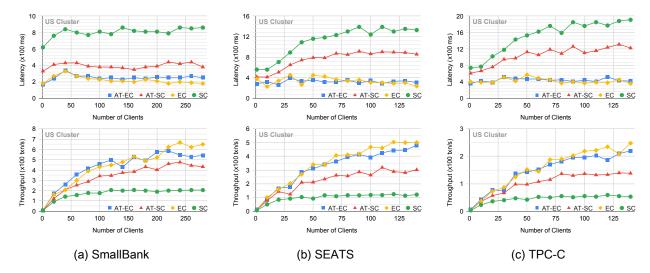

Figure 12. Performance evaluation of SmallBan&EATS and TPC-C benchmarks running on US cluster (see the extended version [47] for experimental results for local and globally distributed clusters).

#### 7.3 Discussion

It is well-known that some serializability anomalies cannot be eliminated without database-level enforcement of strong ploy conflict-driven learning [2] or related mechanisms to isolation and consistency semantic [9]. In particular, if a write operation (W) that depends on the value returned by R, it cannot be eliminated without synchronization between clients. For example, the write check transaction in that directly informs the structure of the target program. the Smallbank benchmark includes an anomaly caused by Identifying serializability anomalies in database systems

Furthermore, our evaluation shows that the combiample, to safely develop applications for eventually-consistentiation of Atropos and stronger database-provided consisdistributed environments, conflict-free replicated data-types (CRDTs)49 have been proposed. CRDTs are abstract data-offer strong serializability guarantees with less performance types (e.gsets,counters) equipped with commutative operations whose semantics are invariant with respect to the order in which operations are applied on their state. Alternatively, there have been recent efforts which explore enriching We thank our shepherd, Dr. Kapil Vaswani, and the anonyspecifications rather than applications, with mechanisms that characterize notions of correctness in the presence of replication [29, 50], using these specifications to guide safe implementations. These techniques, however, have not been applied to reasoning on the correctness of concurrent relational database programs which have highly-specialized structure and semantics, centered on table-based operations [1] 2020. TPC-C Benchmark. http://www.tpc.org/tpc\_documents\_ over inter-related schema definitions, rather than controland data-flow operations over a program heap.

The idea of altering the data structures used by a client program, rather than changing its control flow, is reminiscent of the data-centric synchronization proposed by Dolby et al. [19], which considers how to build atomic sets with associated units of work. The context of their investigation, concurrent Java programs, is quite different from ours; in particular, their solution does not consider sound schema refactorings, an integral part of our approach.

# Conclusions and Future Work

There are several interesting future directions for Atropos. In particular, our repair algorithm greedily identifies the first refactoring that eliminates an anomaly. Integrating a cost model into this search could result in repaired programs with even better performance. In addition, though we were not

mattered in our experiments, investigating the potential of merits further investigation.

The techniques presented in this paper operate solely on another; cycles in the graph indicate a possible serializabil- the database parts of some larger program. Our refactorings are guaranteed to soundly preserve the semantics of these more holistic refactoring approach, which considers both the Various techniques have been developed to discover these database parts and the surrounding application, may offer ments.

We have presented Atropos, an approach for automatitributed databases. By altering the data layout (i.e. schemas) of the underlying database and refactoring the client propair many statically identified anomalies in those clients. Our experimental results showcase the utility of this approach, showing that the refactored programs perform comparably An alternative approach to eliminating serializability anom- to the original programs, while exhibiting fewer serializabiltency semantics, enables clients of distributed databases to impact than stronger consistency semantics alone.
