Abstract

Dimethyl sulfide (DMS; CH_3SCH_3), a biogenically produced trace gas emitted from the ocean, accounts for a large fraction of natural sulfur released to the marine atmosphere. The oxidation of DMS in the marine boundary layer (MBL), *via* the hydrogen abstraction pathway, yields the short-lived methylthiomethylperoxy radical (MSP; CH_3SCH_2OO). In the remote MBL, unimolecular isomerization of MSP outpaces bimolecular chemistry leading to the efficient formation of hydroperoxymethyl thioformate (HPMTF; $HOOCH_2SCHO$). Here, we report the first ground observations and diurnal profiles of HPMTF mixing ratios, vertical fluxes and deposition velocities to the ocean surface. Average daytime HPMTF mixing ratios, fluxes, and deposition velocities were recorded at 12.1 pptv, -0.11 pptv m s^{-1}, and 0.75 cm s^{-1}, respectively. The deposition velocity of HPMTF is comparable to other soluble gas phase compounds (e.g., HCOOH and HNO_3), resulting in a deposition lifetime of 30 hours under typical windspeeds (3 m s^{-1}). A box model analysis incorporating the current mechanistic understanding of DMS oxidation chemistry, and geostationary satellite cloud imagery data suggests that the lifetime of HPMTF in the MBL at this sampling location is likely controlled by heterogenous loss to aerosol and uptake to clouds in the morning and evening.

62

1. Introduction

Emissions of dimethyl sulfide (DMS; CH_3SCH_3) from the oceans provide a significant source of natural reduced sulfur to the marine atmosphere.[1,2] The concerted mechanism of DMS oxidation leads to the formation of sulfur dioxide (SO_2) which can be further oxidized to sulfuric acid

67   (H_2SO_4), a precursor to new particle formation in the MBL, and methanesulfonic acid (MSA), a

68   contributor to particle growth through condensation. DMS oxidation is initiated through hydroxyl

69   (OH), nitrate (NO_3), bromine oxide (BrO), and chlorine (Cl) radicals, with OH oxidation expected

70   to dominate in the unpolluted marine boundary layer.[3,4] The OH-oxidation of DMS can proceed

71   through either an OH-addition mechanism forming MSA, methanesulfinic acid (MSIA) or

72   dimethylsulfoxide (DMSO), or through a OH abstraction mechanism, previously thought to lead

73   to SO_2 and ultimately sulfate (SO_4^-) production.[5] The fraction of OH addition/abstraction is

74   temperature dependent, with ~70% of OH-initiated oxidation of DMS in the summer MBL

75   proceeding *via* H-abstraction, rapidly producing the methylthiomethyl peroxy radical (MSP;

76   CH_3SCH_2OO) after recombination with atmospheric oxygen (O_2).[3] Until recently, it was assumed

77   that MSP either reacts with the hydroperoxyl radical (HO_2) to terminate as CH_3SCH_2OOH,

78   recombine with another peroxy radical (RO_2) or react with nitric oxide (NO) to largely produce

79   methyl thioformate (MTF; CH_3SCHO) or the radical CH_3SCH_2O, the latter of which terminates

80   as H_2SO_4 or MSA.

81

82   Theoretical studies have focused on the chemical fate of MSP in the pristine marine atmosphere

83   where NO, RO_2, and HO_2 are low (<10 pptv),[6,7] and bimolecular removal of MSP is slow.[8,9]

84   Quantum mechanical and kinetic calculations presented by Wu, et al. proposed a fast

85   intramolecular H-shift of MSP ($k_{H\text{-}shift,1}$ = 2.1 s^{-1} at 293 K), followed by combination with O_2 to

86   form $MSPO_2$. $MSPO_2$ then undergoes a second H-shift ($k_{H\text{-}shift,2}$= 150 s^{-1} at 293 K) and a recycling

87   of OH to produce hydroperoxymethyl thioformate (HPMTF; $HOOCH_2SCHO$), a

88   hydroperoxyenal.[9] The existence of this product was validated in a laboratory study, with the

89   authors also suggesting a MSP autoxidation rate as limited by the first H-shift ($k_{H\text{-}shift,1}$=0.23 s^{-1} at

90   293 K).[8] As of now, it is assumed that HPMTF is mainly removed through OH-oxidation at a

91   relatively slow rate ($k_{HPMTF+OH}$ = 1.4 x 10^{-12} cm^3 $molecules^{-1}$ s^{-1}) as determined through the Wu et

92   al. computational study. Most recently, HPMTF was observed in a global airborne study (the

93   NASA atmospheric tomography study; ATom) with observed concentration ratios of

94   DMS:HPMTF regularly at 1:1 during the day, demonstrating HPMTF as a major reservoir for

95   marine sulfur.[4] In the ATom study it was also noted that HPMTF is strongly anti-correlated with

96   observed clouds, proposing fast removal of HPMTF by cloud uptake.

97

98   Here we present observations of HPMTF mixing ratios ([HPMTF]; pptv), vertical fluxes (F_{HPMTF};

99   pptv m s^{-1}) and deposition velocities (v_d(HPMTF) = $F(HPMTF)$/[HPMTF]; cm s^{-1}) at a coastal site

100   in La Jolla, CA in the summer of 2018 as part of a study measuring the air-sea exchange of trace

101   gases at the ocean surface.[10] The observed diel profile in HPMTF is evaluated with a 0-D box

102   model that incorporates meteorological and chemical constraints from onsite measurements and

103   assimilated products, estimated rates of heterogenous uptake to aerosol particles, and the most

104   current understanding of the chemical rates that control production and loss of HPMTF. Our model

105   results suggest that the current recommendation for $k_{HPMTF+OH}$ is too slow and a rate constant closer

106   to the experimentally-determined OH-oxidation of MTF, which is structurally similar to HPMTF,

107   better matches our observations (k_{MTF+OH}=1.1 x 10^{-11} cm^3 $molecules^{-1}$ s^{-1}).[11] To validate the role

108   of cloud uptake in the lifetime of HPMTF ($\tau_{HPMTF} = \frac{[HPMTF]}{L_{HPMTF}}$, where L_{HPMTF} is the HPMTF loss

109   rate) remote sensing imagery from the Geostationary Operational Environmental Satellite-16

110   (GOES-16) was used to calculate cloud fractions over the La Jolla area. This analysis reveals a

111   consistent diel profile in cloud fraction, due to stratocumulus clearings common to the eastern

112   Pacific, that drives the observed diel profile in HPMTF. Through this analysis we propose that

113   heterogenous loss to aerosol particles and uptake to clouds play an important role in controlling

114   the lifetime of HPMTF at this coastal site in the morning and evening and are important

115   mechanisms to be considered in future models that include DMS oxidative chemistry.

116

117   **2. Materials and Methods**

118   **2.1 CIMS Detection of HPMTF.** Continuous measurements of HPMTF were made with a

119   chemical ionization time of flight mass spectrometer (CI-ToFMS, TOFWERK Inc. and Aerodyne

120   Research Inc.) utilizing iodide (I⁻) reagent ion chemistry.[12] A complete description of this

121   instrument can be found in Bertram et al. 2011.[13] Chemical ionization mass spectrometry (CIMS)

122   employing I⁻ chemistry has been used to quantify a wide number of oxidized organic and inorganic

123   compounds, as well as halogen species, at high sensitivities.[14–16] The HPMTF product ion is

124   detected as the adduct $I \cdot HOOCH_2SCHO^-$ and quantified at unit mass -m/Q 235 (where -m/Q is

125   negative mass to charge ratio). Potential compounds isobaric with HPMTF and the process to filter

126   those contaminant peaks are presented in the Supporting Information (SI). Determination of the

127   calibration factor of HPMTF was performed after the study period by way of a contained flow tube

128   experiment that generated OH radicals in the presence of DMS. A sensitivity of 1.17 ncps pptv⁻¹

129   was determined for an $I \cdot H_2O^-$: I⁻ of 0.63. Due to constant heating of the inlet and IMR, the

130   experimental $I \cdot H_2O^-$: I⁻ was kept close to 0.63 ± 0.02 More details on the experiment for

131   determining the sensitivity and its water dependence is presented in the SI (Figures S1-S2).[11,17–19]

132

133   **2.2 Concentration and Vertical Flux Measurements at Scripps Pier.** The summer 2018 flux

134   study performed at the Ellen Browning Scripps Memorial Pier (referred to herein as Scripps Pier)

135   is described extensively in Novak, et al. 2020,[10] but relevant details are outlined here. Scripps Pier

136 is a coastal Pacific site located in La Jolla, CA that has been previously used for flux studies of

137 trace gases (N_2O_5, SO_2), marking its suitability for observations of air-sea exchange.[20,21] The CI-

138 ToFMS employed I^- chemistry from July 24-August 03 2018 while deployed to the 330-m pier,

139 13-m above the mean lower tide level. Ambient air was sampled through a 20-m perfluroralkoxy

140 alkane (PFA) inlet manifold consisting of a sample line, an overflow line for zeroing, and a

141 calibration line for standard additions while held at a constant temperature of 40°C. When

142 quantifying the signal of HPMTF it is assumed no HPMTF is lost to the inlet, although it is possible

143 that an inlet this long could introduce irreversible wall partitioning effects. The inlet manifold was

144 mounted on a 6.1 m long boom and collocated with a Gil-Sonic HS-50 sonic anemometer

145 measuring 3-D winds. Data from both the CI-ToFMS and sonic anemometer were saved at a rate

146 of 10 Hz. Ambient air was collected for 30 minutes for calculating flux periods, followed by 2

147 minutes of zeroing with dry N_2 and 3 minutes of a standard addition of isotopically labeled

148 $H^{13}COOH$ by way of dilution of a custom permeation tube. Further detail on this experiment along

149 with figures of merit for HPMTF quantification can be found in the SI (Table S1).[13,22]

150

151 Air-to-sea fluxes of purely depositing compounds (i.e. HPMTF, HCOOH) were processed using

152 the eddy covariance (EC) technique, where flux (F) is calculated as the mean product of the

153 instantaneous variances of the vertical wind velocity (w) and ambient mixing ratios of a particular

154 compound (C) collected during a 30-minute averaging period:

$$F_C = \overline{w'C'} \tag{E1}.$$

156 For gases with high effective solubility, transfer across an air-liquid interface can be parameterized

157 as

$$F_C = -K_a \left(C_a - \frac{C_w}{K_H} \right) = -k_a(C_a) \tag{E2}$$

159   where K_a is the total transfer velocity that represents the limits of exchange across both sides of

160   the air-sea interface from the point of view of the air side, C_w and C_a are the waterside and airside

161   concentrations of compound C, respectively, K_H is the dimensionless Henry's law constant (M

162   atm^{-1}), and k_a is the solubility-independent air-side transfer velocity (cm s^{-1}). [23,24] K_a can be further

163   expressed in terms of the two single-phase transfer velocities, k_a and k_w, the former being the

164   solubility independent water-side transfer velocity:

$$K_a = [\frac{1}{k_a} + \frac{1}{k_w K_H}]^{-1} \tag{E3}$$

166   In the high solubility case $K_H \gg 1$ and $K_a = k_a$, which can be parameterized by physical constraints

167   that drive exchange (e.g. diffusivity of molecule in air, surface drag)[25], the airside transfer velocity

168   of a soluble compound is also considered its deposition velocity, ($k_a \cong v_d$ when $K_H \gg 1$). Exchange

169   velocities (v_{ex}, cm s^{-1}) were determined by dividing the flux by the averaged mixing ratio during a

170   particular flux period:

$$v_{ex} = \frac{F_C}{\bar{C}} \tag{E4}.$$

172   And v_d is defined as the inverse of v_{ex} ($v_d = -v_{ex}$). Individual flux periods were filtered based on

173   standard techniques for assessing air parcel sourcing, surface drag, and stationarity. A discussion

174   of EC calculations, quality assessment, and filter techniques can be found in the SI (Table S2;

175   Figures S3-S4).[21,26–31]

176

177   **2.3 Box Model Analysis.** A 0-D box model was built in MATLAB using the Master Chemical

178   Mechanism (MCM) v3.3.1 in the Framework for 0-D Atmospheric Modeling (F0AM) to assess

179   existing HPMTF chemical mechanisms.[18] In the model, we set the MSP autoxidation rate, that

180   produces HPMTF, as the temperature independent first H-shift as presented in Berndt et al. ($k_{H\text{-}}$

181     $_{shift,1} = 0.23$).[8] This production rate is used as it is the only published experimentally-observed value

182   to date and is fast enough to compete with the reaction of MSP and onsite NO. Model solutions

183   using all of the published values of $k_{H\text{-}shift,1}$ are presented in the SI. More details on the reaction

184   scheme and constraints used in the model are presented in the SI (Table S3; Figure S5).[20,32,33]

185

186   Meteorological inputs were acquired from the NOAA National Data Buoy Center (Stations LJPC1

187   and LJAC1) as well as from an onsite temperature and relative humidity data logger (OM-62,

188   Omega Engineering). Chemical constraints included measured $[O_3]$ and $[ClNO_2]$, an assumed

189   [OH] profile that followed the solar cycle and peaks at 4.0×10^6 molecules cm^{-3}, a constant

190   concentration of DMS (140 pptv) as determined by measurements at the same site in early

191   September 2019, a constant concentration of NO_2 (200 pptv) as determined from onsite

192   measurements (Figure S12), and constant concentrations of other major trace gases as listed in

193   Table S3. Dry deposition of HPMTF is set to 0.75 cm s^{-1} based on results from this study and a

194   static boundary layer height (BLH) of 800 m is used, based on consideration of its distance from

195   the shoreline (SI).[28,34,35] The model runs shown in the main text do not include anthropogenic VOC

196   or NO_3 oxidative reactions due to the large uncertainties the latter creates for coastal $[NO_3]$ that

197   may misrepresent nighttime HPMTF; a decision further explained in 4.1 and the SI.

198

199   Uptake of trace gases to marine aerosol particles is treated as heterogenous loss with a

200   unimolecular rate constant of:

$$k_{het} = \frac{\gamma A \bar{c}}{4} \tag{E5}$$

202   where γ is the dimensionless uptake coefficient, A is the particle surface area density (μm^2 cm^{-3}),

203   and $\bar{c}$ is the mean molecular speed of the molecule of interest (cm s^{-1}). A constant particle surface

204   area of 150 μm^2 cm^{-3} is used, based on published observations of typical coastal, marine aerosol

205   particle size distributions.[36–39] A complete table of base case model constraints are found in Table

206   S3 and the sensitivity of HPMTF to select constraints is presented in the SI (Figures S6-

207   S11).[6,7,20,40–42]

208

209   **3. Results**

210   **3.1 Summary of Select Measurements.** Figure 1 presents observations of HPMTF at Scripps Pier

211   from July 24 – August 3, 2018. The nighttime contribution of the isobaric compound N_2O_5 to

212   signal at -m/Q 235 was removed when $\tau(N_2O_5 + NO_3)$ was longer than 5 min, leaving an HPMTF

213   signal window from 600 – 2100 PDT (Figure S11).[43] The diurnal profile of HPMTF (Fig. 1a)

214   displays a rise after 600 PDT, concurrent with a change in winds from offshore (WD<180°) to

215   onshore (WD≥180°). HPMTF mixing ratios plateau from 1400-1600 PDT before falling to near

216   the detection limit by 2000 PDT. The diurnal profile in HPMTF peaks late in the afternoon before

217   rapidly being removed by sunset. Windspeed and thus DMS emission fluxes also peak in the late

218   afternoon which may partially account for the observed profile.[44] However, the decrease in

219   HPMTF past 1600 PDT cannot be explained by changes in windspeed or wind direction (Figure

220   S12), or by removal through OH oxidation (where $k_{HPMTF+OH}$ is on the order of 10^{-12}-10^{-11} cm^3

221   molecules^{-1} s^{-1} and $\tau_{HPMTF+OH} \approx 14$ hr)[4,8,9] or deposition to the ocean surface as measured in this

222   study ($\tau_{deposition} \approx 30$ hr).

Figure 1: Time series of a.) mixing ratios b.) fluxes, and c.) deposition velocities of HPMTF along with recorded d.) meteorological wind direction and wind speed. Mixing ratios are presented at a 30-sec resolution. Fluxes and v_d are presented as 30-min averages with errors as explained in the main text. Wind direction and speed are hourly averages. Diurnal averages of e.) mixing ratios, f.) flux, and g.) deposition velocities of HPMTF are also presented along with diurnal averages of h.) wind direction and wind speed.

The diurnal profile of F_{HPMTF} (Figure 1f) follows that of [HPMTF] and windspeed, rising throughout the day, coming to a peak near 1400 PDT and plateauing until 1600 PDT before decreasing to the limit of no net surface exchange. The diurnal profile of v_d(HPMTF) is fairly static from 600-2100 PDT, with a daytime (900-1800 PDT) average of 0.75 cm s^{-1}; comparable to that of a highly soluble molecule such as nitric acid (v_d= 0.5-2.0 cm s^{-1}).[45,46] The daily maximum HPMTF deposition flux ranged from 0.07-0.21 pptv m s^{-1} (5.26 ×10^8 molecules cm^{-2} s^{-1}) with daytime v_d(HPMTF) maxima ranging from 0.73-1.7 cm s^{-1}. Temporal profiles of surface horizontal wind at 10-m (U_{10}) were consistent throughout the observation period; offshore winds were sustained until around 700 PDT, on average, switching to onshore winds until the early morning.

3.2 Deposition Velocities of HPMTF. The air-side transfer velocity term (k_a) in E2 can be expressed in terms of resistances to deposition

$$k_a^{-1} = r_{turbulence} + r_{diffusion} + r_{surface} \tag{E5}$$

where $r_{turbulence}$ is the aerodynamic resistance, $r_{diffusion}$ is the resistance posed by diffusivity in air, and $r_{surface}$ is the resistance to air–sea gas transfer arising from physical–chemical interactions on a molecular scale layer at the surface. The resistance to turbulence can be approximated by the momentum transfer velocity (k_{mom}, cm s^{-1}):

$$r_{turbulence}^{-1} = k_{mom} = \frac{F_{mom}}{\bar{\rho} U_{10}} \tag{E6}$$

where F_{mom} is the momentum flux (kg m^{-2} s^{-2}) and $\bar{\rho}$ is the density of air (kg m^{-3}). The momentum flux during this study was calculated through the EC method for the vertical (w) and zonal (u) winds and the meridional (v) and zonal winds:

$$F_{mom} = \bar{\rho} \sqrt{\overline{(w'u')^2} + \overline{(v'u')^2}} \tag{E7}.$$

To better understand the processes controlling the air to sea deposition of HPMTF, we compare the U_{10} dependences of v_d(HPMTF), k_{mom}, and the v_d of the water soluble molecule formic acid (HCOOH; K_H=5600 M atm^{-1})[24,47] also measured in this study (Figure 2). The observed v_d(HPMTF) reaches a maximum of 1.7 cm s^{-1} and above windspeeds of 5 m s^{-1} v_d(HPMTF) no longer exhibits values above 0.7 m s^{-1}. These high windspeed periods were primarily associated with air parcels received from La Jolla Cove (220° > WD ≥ 180°), which may have impacted flow characteristics and biased the measured flux low. Although the data presented in Figure 2a are filtered for coastal influence (WD < 220° were removed), this turnaround at high U_{10} is exhibited at higher

259 windspeeds in both v_d(HPMTF) for the July observation period and k_{mom}
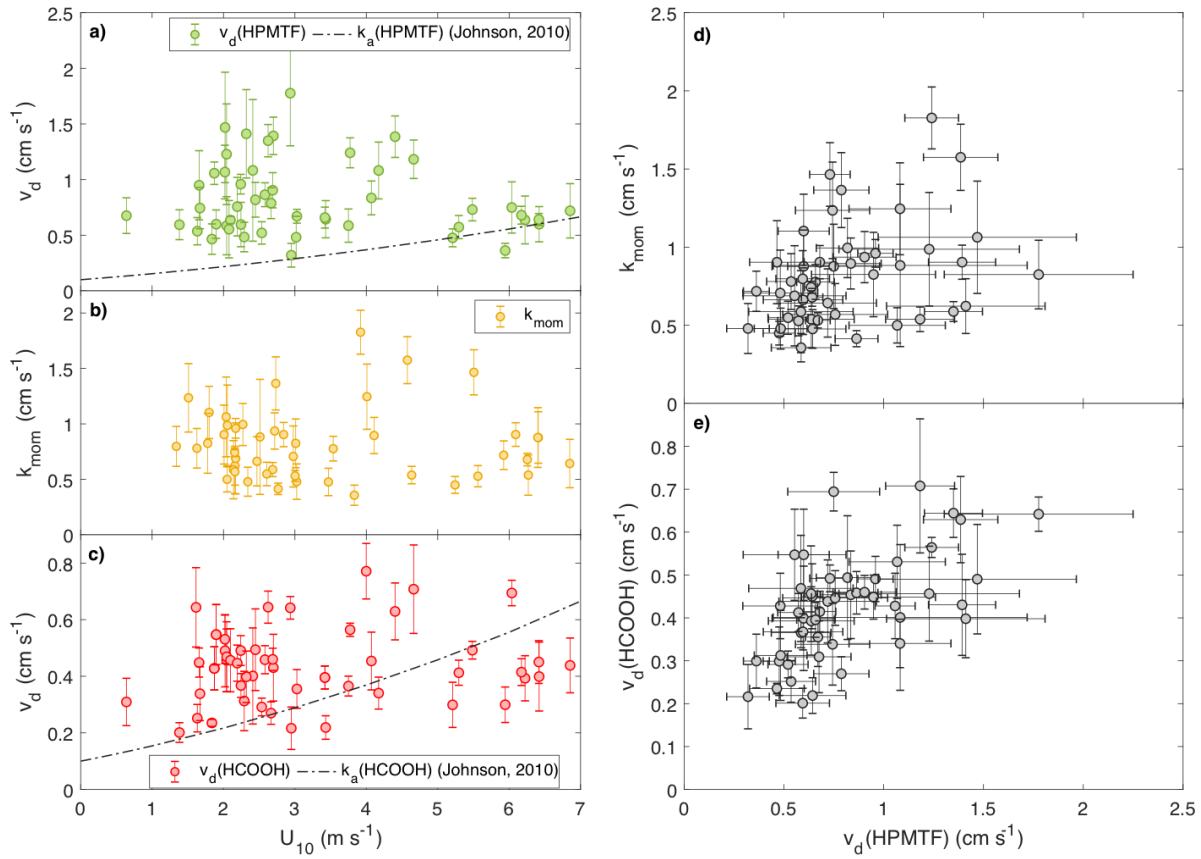

Figure 2: Dependence of a.) v_d(HPTMF), b.) k_{mom}, and c.) v_d(HCOOH) on 10-m windspeed. Calculations of k_a, following the method of Johnson, et al. 2010, are included in panel c for a sea surface temperature of 20°C and an ocean salinity of 35 practical salinity units (PSU).[25] Regressions of d.) k_{mom} and e.) v_d(HCOOH) against v_d(HCOOH) are in good agreement implying fast air-side transfer.

265 (Fig. 2b), suggesting an increase in $r_{turbulence}$ (E5-6) concurrent with these periods of higher

266 windspeed at this site. Since k_{mom} and v_d are close in scale beyond a U_{10} of 2 m s^{-1}, it is possible

267 that v_d(HPMTF) is mainly limited by $r_{turbulence}$, maintaining a low barrier imposed by solubility

268 (Figure 2b). Included in Figure 2a is the windspeed dependence of parameterized k_a (E2) using the

269 temperature- and salinity-dependent method of Johnson, 2010, where k_a is calculated using a sea-

270 surface temperature of 20°C and ocean salinity (35 PSU).[25]

271

272   The v_d(HPMTF) is comparable to v_d(HCOOH) (Fig. 2c), with HCOOH a highly soluble molecule

273   expected to deposit at the airside limit (v_d(HCOOH)$_{max,obs}$ = 0.77 cm s^{-1}). Also included in Figure

274   2c is the parameterized k_a of HCOOH following the parameterization of Johnson, et al. 2010.[25]

275   There is good agreement between measured v_d(HCOOH) and k_a(HCOOH), suggesting that the

276   measurements fall in line with this numerical scheme and the parameterization can be used to infer

277   a low water-side resistance of HPMTF at this site. Figures 2d and 2e present reasonable agreement

278   of v_d(HPMTF) with k_{mom} (m=0.90; R^2=0.43) and good agreement of $\underline{v_d}$(HCOOH) and v_d(HPMTF)

279   (m=0.48; R^2=0.60). We present the relationship of $\underline{v_d}$(HCOOH) and v_d(HPMTF) to highlight that

280   HPMTF deposition closely resembles another known soluble molecule, HCOOH. However as

281   HCOOH has a comparably high solubility to HPMTF and a lower molecular weight, it is expected

282   that $\underline{v_d}$(HCOOH)   would   be   equal   or   greater   than v_d(HPMTF),   with   expected

283    $\underline{v_d}$(HCOOH):v_d(HPMTF) on the order of 1:1 and greater rather than the observed 0.48:1. The

284   comparison of these three transfer velocities imply that HPMTF: 1) deposits rapidly to the ocean

285   surface at the air side resistance limit (i.e. limited by $r_{turbulence}$), 2) is very subsaturated in the ocean

286   surface waters, and 3) must have a high solubility (K_H>>1) or fast chemical conversion in ocean

287   surface water. These implications call for the necessity of experimental determinations of K_H to

288   further validate these claims.

289

290   **4. Discussion**

291   To assess the relevant chemistry and physics that determine the HPMTF diurnal profile, we utilize

292   a 0-D chemical box model that incorporates known gas phase and heterogeneous production and

293   loss processes. The base model framework is described in section 2.3 and the base case parameters

294   are outlined in Table S3. In the discussion that follows, we present model solutions to validate

295   potential gas phase and heterogeneous loss processes. To incorporate cloud chemistry, we first

296   describe a novel approach for modeling cloud chemistry based on geostationary satellite imagery.

297   We then present the potential role for cloud uptake as an HPMTF loss process. The box model

298   analysis is performed for July 26, 2019, a day that presents a typical HPMTF and regional cloud

299   fraction profile for the study period. Sensitivities of this model to select ambient mixing ratios of

300   key precursors, chemical rate constants, and physical parameters are presented in the SI.

301

302   **4.1 Potential HPMTF Loss Mechanisms: Oxidation and Heterogenous Uptake.** Currently,

303   there are three prior studies of the chemical production and loss of HPMTF, where P_{HPMTF} is

304   limited by a first intramolecular H-shift of MSP, and the reaction rate for the gas-phase reaction

305   of HPMTF with OH has been calculated. As noted previously, Wu et al (2015) calculated $k_{H\text{-}shift,1}$

306   of 2.1 s^{-1}, Berndt et al. (2019) measured $k_{H\text{-}shift,1}$ of 0.23 s^{-1}, and Veres et al. (2020) calculated $k_{H\text{-}shift,1}$

307    $_{shift,1}$ of 0.041 s^{-1}, all at temperature of around 293 K.[4,8,9] In this analysis we use the Berndt et al.

308   calculation of $k_{H\text{-}shift,1}$, as it is currently the only experimentally-determined value to date. Figure

309   S9 presents model sensitivity to the other $k_{H\text{-}shift,1}$ values along with the concurrent changes in

310   experimental HPMTF calibration factors that would arise from utilizing a different $k_{H\text{-}shift,1}$.

311

312   Loss of HPMTF by OH oxidation has only been explored in the computational study by Wu et al.,

313   with a $k_{HPMTF+OH}$ of 1.4 x 10^{-12} cm^3 molecules^{-1} s^{-1}. At an upper limit we can expect the rate of

314   oxidative loss of HPMTF to OH to be much slower than that of C5-HPALD, a hydroperoxyenal

315   that is formed from isomerization and decomposition of isoprene hydroperoxyl radicals (ISO$_2$),

316   the isoprene analogues of MSP. An experimentally-derived $k_{C6\text{-}HPALD+OH}$ was determined to be 5.1

317   x 10^{-11} cm^3 molecules^{-1} s^{-1} at 296 $\pm$ 2 K, serving as an upper bound for model sensitivity to HPMTF

318   loss to OH, as we expect C5-HPALD to react with OH faster than HPMTF due to the presence of

319   double bonds in C5-HPALD that are absent in HPMTF.[48] The Wu, et al. rate constant for reaction

320   with OH can also be compared to an experimentally-determined rate for the OH-oxidation of MTF,

321   a sulfur-containing molecule structurally similar to HPMTF in that the hydroperoxide group is

322   replaced with a methyl group (k_{MTF+OH} = 1.11 ± 0.22 x 10^{11} cm^3 molecules^{-1} s^{-1} at 298 K).[11].

323

324   Figure 3a presents model solutions of HPMTF using rate constants for oxidative removal by OH

325   of either $k_{HPMTF+OH}$ as calculated in Wu et al. (red line), k_{MTF+OH} (green line), or $k_{HPALD+OH}$ (blue

326   line) all in units of cm^3 molecules^{-1} s^{-1}. In this implementation of the model no heterogenous loss

327   is considered, with L_{HPMTF} only driven by chemical loss to OH and dry deposition. From Figure

328   3a, it is evident that the currently used $k_{HPMTF+OH}$ of 1.4 x 10^{-12} cm^3 molecules^{-1} s^{-1} is likely too

329   slow to replicate observations, with the model solution over a factor of 3 larger than observations

330   at the observed peak in [HPMTF]. Model solutions that use $k_{HPMTF+OH}$=k_{MTF+OH} are a factor of 2

331   larger than observed peak [HPMTF], also implying that this rate would be too slow if it is assumed

332   that L_{HPMTF} is solely due to gas-phase reactions and dry deposition. When using a

333     $k_{HPMTF+OH}$=$k_{HPALD+OH}$, model [HPMTF] underpredicts the observed peak [HPMTF]. Each of the

334   modeled series in Fig. 3a fail to replicate the shape of the diel profile of observed [HPMTF] which

335   consists of a small peak around 1000 PDT due to Cl-initiated oxidation of DMS, a second peak

336   around 1300 PDT, due to OH-initiated oxidation, and a fast decline from 1600-1800 PDT. This

337   failure to replicate [HMPTF] in the morning and late afternoon implies that τ_{HPMTF} is not solely

338   controlled by gas-phase loss to OH and that another loss route must be present at this site.

339

340   Other gas-phase oxidative loss routes of HPMTF that can be considered are loss to O_3 and NO_3.

341   Reactions of O_3 with C6-HPALD indicate that the chemical lifetime of C6-HPALD due to OH is

342   over 200 times shorter than that of C6-HPALD to O_3 (at $[OH] = 4 \times 10^6$ molecules cm^{-3} and $[O_3]$

343   = 30 ppbv).[48] Due to the presence of a more O_3-reactive carbon-carbon double bond in a C6-

344   HPALD that is absent in HPMTF, it is expected that HPMTF ozonolysis proceeds very slowly,

345   with a lifetime of HPMTF against O_3 more comparable to DMS (148 days).[49] Daytime loss of

346   HPMTF to NO_3 is negligible due to the short photolysis lifetime of NO_3, however it can play a

347   role in nocturnal loss of HPMTF that currently has not been explored. The analysis presented here

348   does not account for nocturnal chemistry of NO_3 that may be important in coastal DMS oxidation

349   chemistry. A final consideration for chemical loss is through photolysis of the aldehyde group. We

350   expect that this pathway is considered to have a small impact on the diel profile of [HPMTF] based

351   on experimentally-determined MTF photolysis lifetime of 3.7 days at the equator and 5.4 days at

352   40ºN [11]. However, there is no experimentally measured HPMTF photolysis rate.

353

Figure 3: a.) Box-model simulations of HPMTF as a function of the implemented HPMTF + OH rate
constant ($k_{HPMTF+OH}$; cm^3 molecules^{-1} s^{-1}) , where $k_{HPMTF+OH}$ is set equal to: k_{MTF+OH} (green line), $k_{C6\text{-}HPALD+OH}$
(blue line), and the Wu, et al. computationally-derived $k_{HPMTF+OH}$ (red line). b.) Box-model simulations of
HPMTF as a function of the implemented heterogenous uptake coefficient (γ), where γ ranges from 0.001-
0.03 and $k_{HPMTF+OH}$=1.11 x 10^{-11}. Measurements of HPMTF on July 26th, 2018 are shown as black dash-
dots.

360

361   The box-model fails to replicate the diurnal profile and magnitude of HPMTF using only gas-

362   phase loss processes, suggesting an important role of heterogenous or multiphase chemistry. To

363   date, there are no experimental studies of the heterogeneous reactions of HPMTF to constrain the

364   model. To assess the sensitivity of HPMTF to γ_{HPMTF}, we set an upper and lower limit of 0.001

365   and 0.03 to span a reasonable range of reactive uptake coefficient for comparable molecules.

366   Figure 3b shows the results of these sensitivity runs, with model and measurements best agreeing

367   near γ_{HPMTF} =0.005 at peak [HPMTF]. Based on the implied high solubility and/or ocean surface

368   reactivity from the v_d(HPMTF) measured in this study, it is plausible that γ_{HPMTF} would be within

369   this magnitude for faster uptake. However, this route still cannot explain the apparent short

370   atmospheric lifetime of HPMTF in the morning and late afternoon shown in the observations. In

371   the following section we explore the potential for cloud uptake of HPMTF as a controlling loss

372   mechanism.

373

374   **4.2 Assessing the Influence of Marine Clouds on HPMTF.** Clouds can serve as efficient sinks

375   for water-soluble species that undergo reactions within the cloud droplet. As discussed by Veres

376   et al. (2020), HPMTF mixing ratios were found to be consistently depleted when passing through

377   the cloud layer, suggesting HPMTF may undergo irreversible uptake to cloud droplets.[4] The

378   overall lifetime for cloud processing of species with irreversible uptake in the turbulently mixed

379   boundary layer is controlled by the rate of mixing into the cloud layer and the residence time within

380   the cloud layer.[50] Once a parcel is mixed into the cloud layer, uptake is limited by gas phase

381   diffusion to droplet surfaces, with lifetimes on the order of 5 s for HNO_3 in fair weather cumulus

382   clouds.[51] Holmes et al. have implemented a revised scheme for cloud uptake in a global transport

383   which included cloud spatial information and explicitly treated the mixing rate of parcels into

384   clouds.[50] In that study, the loss rates of N_2O_5 to clouds was found to be limited by the mixing rate

385   of boundary layer air parcels into clouds, with the lifetime of N_2O_5 within the cloud layer found to

386   be 10 s.

387

388   Stratocumulus clouds within the turbulent MBL are a common feature over cooler regions of the

389   subtropical and mid-latitude oceans, where mean annual coverage can exceed 50%.[52] Globally,

390   stratus and stratocumulus clouds are typically present over 10-70% of the MBL, suggesting loss

391   to clouds within the MBL to be a potentially significant term in reactive trace gas budgets. Based

392   on imagery of clouds and surfaces from the geostationary satellite GOES-16[53], we suggest that

393   HPMTF undergoes cloud uptake due to the presence of clouds over coastal southern California.

394

395   Imagery from GOES-16 reveals a diurnal pattern in cloud cover over the southern coast of

396   California for the July 24 – August 3, 2018 period. An example of this is shown in Figure 4a,

397   where true color imagery of the contiguous United States (CONUS) cropped to southern California

398   on July 23rd, 2018 is shown. A clear-sky period with cities labeled for regional clarity is shown

399   along with a red box denoting a pixel counting region around the measurement site. Images

400   cropped to the same domain for July 26th at 700, 1400, and 1800 PDT (Fig. 3b-d) were converted

401   from color to gray scale to discriminate between cloud, land, and water based on gray scale value

402   (GV=0-256). Examples of the discernment of land, ocean, and cloud from this analysis are shown

403   in the SI (Figure S14-S15). The imagery in Figure 4b-d shows a clear diel profile in cloud cover,

404   where at 700 PDT (Fig. 4b) there is presence of stratocumulus clouds over Scripps Pier and most

405   of southern CA. By 1400 PDT (Fig. 4c) the clouds have mostly cleared from the measurement site,

406 and by 1800 PDT (Fig. 4d) the clouds have returned, displaying a diurnal profile that is typical of

407 stratocumulus clearings in the summertime eastern Pacific.[52,54–56]

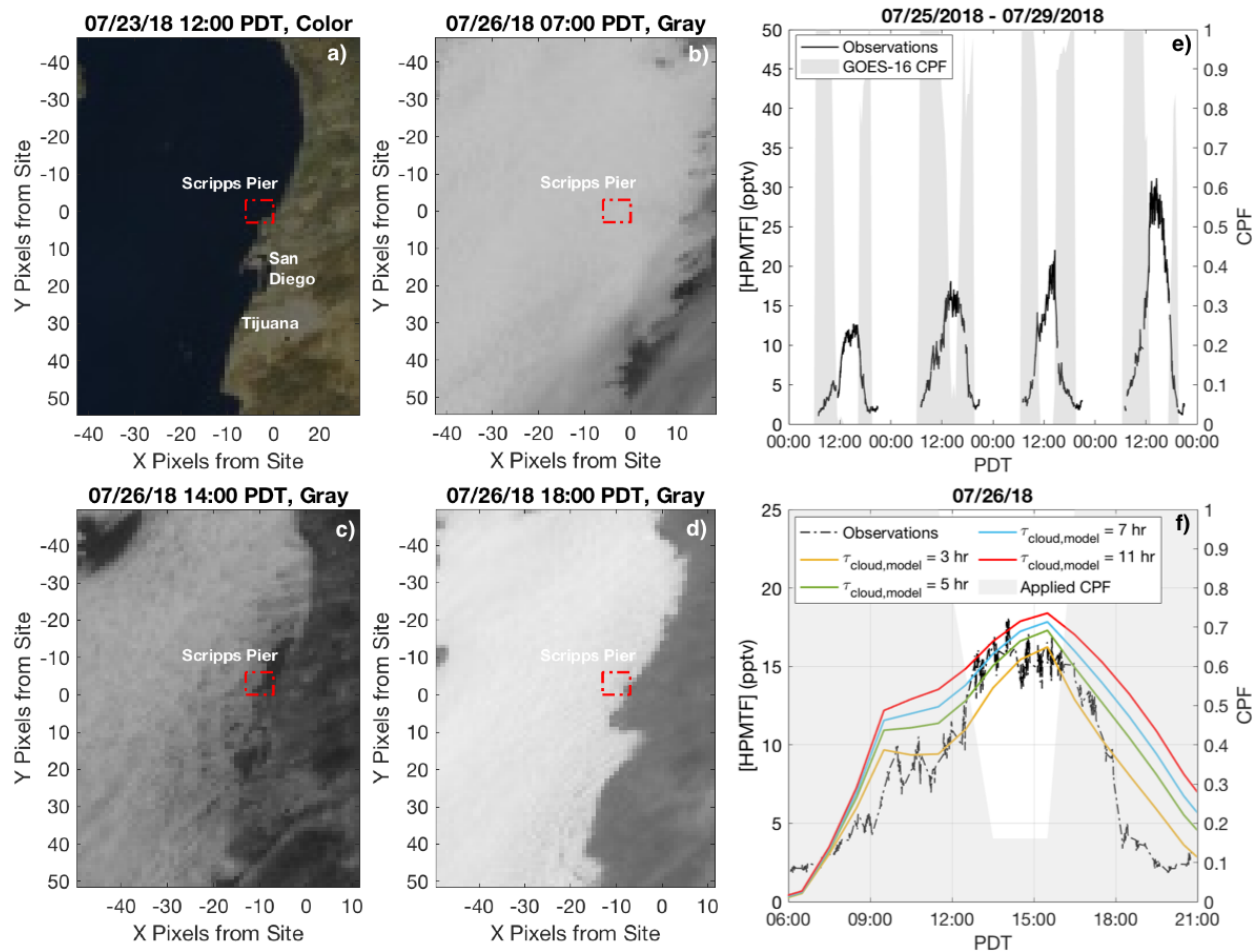

Figure 4: Images from GOES-16 over coastal southern California show varying amounts of cloud cover over Scripps Pier throughout the day. a.) A color reference of a clear sky day on 07/23/18 is presented for clarity. Comparison of grayscale images from b.) 700, c.) 1400, and d.) 1800 PDT on 07/26/18 show cloud cover during the morning and early evening but little cloud cover during the afternoon within a 49 pixel^2 domain (red box). Pixels in this region are ~0.7 km. e.) A time series of the cloud pixel fraction (CPF) within the 49 pixel^2 domain compared to the [HPMTF] time series from July 25-29, 2018 reveals an anticorrelation of [HPMTF] with cloud cover. f.) Box model simulations of 07/26/18 that implement a cloud uptake loss pathway at the timescale of τ_{cloud} show a strong influence of clouds on τ_{HPMTF} in the morning and late afternoon. A modified CPF is applied (grey area) based on domain sensitivity tests (Figure S16).

419 Pixels were counted within a counting domain for 25-minute averages of imagery and hourly

420 thresholds of GV for clouds (e.g. GV$_{cloud,17PDT}$ ≥ 160) were used to determine the fraction of clouds

421 in each time point (CPF; cloud pixel fraction). Figure 4e shows CPF for July 25-29, along with

422 measured [HPMTF] and highlights a clear anticorrelation between [HPMTF] and CPF suggesting

423 the influence of clouds on measured HPMTF. CPFs were used in a box model to assess the impact

424 of cloud uptake on the HPMTF profile by applying a time-dependent cloud uptake lifetime (τ_{cloud})

425 that is scaled by observed CPF. Figure 4f shows the model solutions using base case constraints

426 and an applied τ_{cloud} from 3-11 hrs. Upon comparison of model to measurements, τ_{cloud} would

427 need to be relatively fast (3-5 hours) to best match the observations. When τ_{cloud} exceeds 7 hours,

428 cloud uptake has minimal effect on HPMTF loss and no longer controls τ_{HPMTF}. Details on GOES-

429 16 imagery, GV cloud thresholding, selection of counting region, and applied CPF profile are

430 presented in the SI (Figure S14-S16). The observed diel profile in HPMTF is reproduced when we

431 apply a time-dependent HPMTF loss to clouds indicating that HPMTF cloud uptake likely dictates

432 τ_{HPMTF} in the cloudy MBL. Future field observations should target HPMTF chemistry in both

433 cloud free and cloudy regions.

434

435 **4.3 Model Outlook**

436 At this time, accurate chemical modeling of the diel profile in HPMTF is limited by the lack of

437 laboratory constraints on HPMTF loss rates, both in the gas-phase and *via* heterogeneous and

438 multiphase reactions. In this study, τ_{cloud} was not directly measured but rather determined by

439 comparison to chemical observations. Vertical airborne flux measurements of HPMTF in cloudy

440 environments will prove useful for validating this loss pathway. Although this study uses a reliable

441 estimate of aerosol surface at this site, the heterogenous loss of HPMTF to marine aerosol is still

442 a large unknown variable that can drastically modify model solutions within a plausible range of

443 γ_{HPMTF} (Figure 3b) which can then impact other estimations of HPMTF loss processes. Detailed

444   studies of reactive uptake of HPMTF to aerosol are required to better predict the fate of HPMTF

445   over the ocean surface.

446

447   Due to the existence of only a few published HPMTF lab studies, the kinetics involving HPMTF

448   are still prone to uncertainty and require validation through comparison to published studies of

449   analogous molecules. The required constraints on $k_{H\text{-}shift,1}$ and $k_{HPMTF+OH}$ utilized in this case study

450   bring two major implications. The first is that the isomerization of MSP may be slow enough that

451   bimolecular reactions of MSP in coastal regions, where RO_2 and NO have the potential to be

452   sufficiently high enough, may limit the production of HPMTF. The second implication is that loss

453   through OH may be faster than recently published rates, leading to an additional route for

454   overprediction of HPMTF. The ambient observations presented in this analysis may prove useful

455   in the future model evaluations of HPMTF production and loss processes as determined in

456   laboratory studies.
