10 **Key Points:**

11 • The isotopic composition of central Andean precipitation records upstream precipitation,
12   local convection, and remote moisture sources

13 • Precipitation on the flank of the western central Andes is sourced from the Pacific Ocean

14 • Δ'^{17}O can separate evaporated and non-evaporated samples and provides key baseline
15   information for Andean paleoclimate and paleoaltimetry

16 **Abstract**

17 The isotopic composition of precipitation is used to trace water cycling and climate change, but
18 interpretations of the environmental information recorded in central Andean precipitation isotope
19 ratios are hindered by a lack of multi-year records, poor spatial distribution of observations, and
20 a predominant focus on Rayleigh distillation. To better understand isotopic variability in central
21 Andean precipitation, we present a three-year record of semimonthly $\delta^{18}O_p$ and δ^2H_p values from
22 15 stations in southern Peru and triple oxygen isotope data, expressed as $\Delta'^{17}O_p$, from 32
23 precipitation samples. Consistent with previous work, we find that elevation correlates
24 negatively with $\delta^{18}O_p$ and that seasonal $\delta^{18}O_p$ variations are related to upstream rainout and local
25 convection. Spatial $\delta^{18}O_p$ variations and atmospheric back trajectories show that both eastern-
26 and western-derived air masses bring precipitation to southern Peru. Seasonal d-excess$_p$ cycles
27 record moisture recycling and relative humidity at remote moisture sources, and both d-excess$_p$
28 and $\Delta'^{17}O_p$ clearly differentiate evaporated and non-evaporated samples. These results begin to
29 establish the natural range of unevaporated $\Delta'^{17}O_p$ values in the central Andes and set the
30 foundation for future paleoclimate and paleoaltimetry studies in the region. This study highlights
31 the hydrologic understanding that comes from a combination of $\delta^{18}O_p$, d-excess$_p$, and $\Delta'^{17}O_p$ data
32 and helps identify the evaporation, recycling, and rainout processes that drive water cycling in
33 the central Andes.

34 **1 Introduction**

35   The isotopic composition of precipitation ($\delta^{18}O_p$, $\delta^{17}O_p$, δ^2H_p, where δ is defined as
36 ($R_{sample}/R_{standard} - 1$)*1000, R is the ratio of heavy-to-light mass isotopes, and the subscript $_p$
37 refers to precipitation) and geologic materials that preserve precipitation isotope ratios are
38 valuable tracers of water cycling and climate change. In the Andes mountains, $\delta^{18}O_p$ and δ^2H_p
39 have been used to infer information about both modern and past water cycling (e.g., Fiorella et
40 al., 2015a; Poulsen et al., 2010) as well as past climate conditions (e.g., Hardy et al., 2003).
41 Nevertheless, uncertainties remain about the controls on modern $\delta^{18}O_p$, δ^2H_p, and $\delta^{17}O_p$ in the
42 Altiplano region (~ 12˚S to 22˚S and 63˚W to 74˚W, hereafter referred to as the central Andes)
43 because there are relatively few observations of $\delta^{18}O_p$ and δ^2H_p and no observations of $\delta^{17}O_p$
44 (Figure 1a; Valdivielso et al., 2020). Moreover, most previous studies of central Andean
45 precipitation isotope ratios focus primarily on either $\delta^{18}O_p$ or δ^2H_p and hydrologic processes
46 (e.g., rainout) associated with equilibrium fractionation and Rayleigh distillation (e.g.,
47 Gonfiantini et al., 2001). These studies do not leverage the additional information that comes
48 from a combination of $\delta^{18}O_p$ and δ^2H_p (d-excess$_p$; Dansgaard, 1964) and generally leave kinetic
49 fractionation processes (e.g., evaporation at a moisture source or moisture recycling) unexplored.
50 Additional observations of central Andean $\delta^{18}O_p$, δ^2H_p, and $\delta^{17}O_p$ and an expanded emphasis on
51 the isotopic signals of kinetic fractionation can improve understanding of water cycling,
52 paleoclimate, and mountain uplift in the central Andes (e.g., Bird et al., 2011; Garzione et al.,
53 2017).
54   The large-scale variability of central Andean $\delta^{18}O_p$ and δ^2H_p is primarily attributed to
55 Rayleigh distillation during rainout (Dansgaard, 1964; Fiorella et al., 2015a; Gat, 1996;
56 Gonfiantini et al., 2001; Jeffery et al., 2012; Rozanski et al., 1993; Sturm et al., 2007; Vimeux et
57 al., 2005). However, Rayleigh distillation does not account for all of the observed variability, and
58 central Andean $\delta^{18}O_p$ and δ^2H_p values can also reflect moisture recycling (Ampuero et al., 2020;
59 Salati et al., 1979), the intensity of upstream and local convective precipitation (Fiorella et al.,

60   2015a; Guy et al., 2019; Samuels-Crow et al., 2014a; Valdivielso et al., 2020; Vimeux et al.,
61   2005; Vimeux et al., 2011; Vuille et al., 2012; Vuille & Werner, 2005), and interactions between
62   Atlantic and Pacific moisture sources (Aravena et al., 1999). Elsewhere, a combination of $\delta^{18}O_p$
63   and d-excess$_p$ has been used to identify evaporation at a moisture source (e.g., Pfahl &
64   Sodemann, 2014), condensation from mixed-phase clouds (e.g., Bolot et al., 2013), and sub-
65   cloud evaporation (e.g., Froehlich et al., 2008), but to date studies of d-excess$_p$ in the central
66   Andes have received far less attention than those of $\delta^{18}O_p$ or δ^2H_p. Additional efforts to
67   understand d-excess variations in liquid water, water vapor, and ice cores can help explain the
68   evaporation and condensation processes that are recorded in central Andean $\delta^{18}O$ and δ^2H data
69   (e.g., Samuels-Crow et al., 2014b).
70   Triple oxygen isotope variations have recently emerged as another metric to track kinetic
71   fractionation in waters (e.g., Li et al., 2017) and geologic materials (e.g., Passey et al., 2014).
72   These variations, expressed as $\Delta'^{17}O$ (see Section 2.2 below), are useful because they add new
73   information to $\delta^{18}O$ and/or δ^2H records by quantitatively separating equilibrium and kinetic
74   fractionation (Barkan & Luz, 2007). Currently, however, measurements of triple oxygen isotope
75   ratios are rare and there are only a few published observations of surface water $\Delta'^{17}O$ (Aron et
76   al., 2021; Surma et al., 2018; Voigt et al., 2021) and structurally bonded gypsum water $\Delta'^{17}O$
77   (Herwartz et al., 2017) from the central Andes. Much like d-excess, water $\Delta'^{17}O$ measurements
78   can help identify the controls on $\delta^{18}O$ and δ^2H and enable better understanding of hydrologic
79   processes and climate conditions.
80   To better understand the environmental controls on precipitation isotope ratios in the
81   central Andes, we report on a three-year dataset of $\delta^{18}O_p$, $\delta^{17}O_p$, and δ^2H_p data from a previously
82   unstudied region in southern Peru (Figure 1b, Table S1). This dataset extends observations of
83    $\delta^{18}O_p$ and δ^2H_p from Bolivia (Fiorella et al., 2015a; Gonfiantini et al., 2001) into southern Peru
84   and fills a spatial gap across the northern Altiplano and western slope of the Peruvian Andes
85   (Figure 1a). We show that a combination of $\delta^{18}O_p$, d-excess$_p$, and $\Delta'^{17}O_p$ can differentiate
86   equilibrium and kinetic fractionation to constrain rainout, air mass sources, and moisture
87   recycling and improve understanding of water cycling and climate change in the central Andes.

88   **2 Background**

89   2.1 Central Andes topography, precipitation, and atmospheric circulation

90   The central Andes in southern Peru, Bolivia, and northern Chile are split into the Eastern
91   and Western Cordilleras, both of which reach over 6 km in height. The Altiplano lies between
92   the Cordilleras and has lower elevation (~4 km) and lower relief. A strong hydrologic gradient
93   extends across this region from the Amazon Rainforest, one of the wettest places on Earth, to the
94   Atacama Desert, one of the driest (Figure 2). Moisture transport from the Amazon Basin and
95   orographic uplift generate high precipitation rates (up to 6,000 mm/yr) on the flank of the
96   Eastern Cordillera (Garreaud, 2009), while the Western Cordillera flank is exceptionally dry (<
97   20 mm/yr) due to upwelling of cold waters from the coastal Humboldt current, large-scale
98   subsidence over the eastern Pacific Ocean, and orographic blocking from the Eastern Cordillera
99   (e.g., Garreaud et al., 2002; Rodwell & Hoskins, 2001; Vuille et al., 2000).
100   Seasonally, the central Andes are wetter during the austral summer (December to March)
101   and drier in the austral winter (June to September) (Figure 2). In the winter, upper-level (~200
102   hPa) circulation is dominated by subtropical westerly winds that restrict low-level (~850 hPa)
103   easterly moisture from reaching the Altiplano (Figures 2b and 2d). In the summer, the westerly

104 winds weaken and shift southward, and stronger easterly winds transport moisture toward the
105 central Andes. Simultaneously, intense summertime latent heating over the Amazon generates an
106 upper-level (~200 hPa) high pressure circulation feature known as the Bolivian High (Lenters &
107 Cook, 1997) that directs and intensifies near-surface moisture flow (Figure 2c). Orographic
108 blocking forms the South American Low Level Jet (SALLJ, Figure 2a), a low-level (~850 hPa)
109 barrier jet that transports moisture from the tropics to the subtropics and plays a critical role in
110 South American hydrology (e.g., Insel et al., 2010; Vera et al., 2006).
111   Infrequent, small (generally < 10 mm/event) summer storms occur on the western central
112 Andean slope when anomalously warm coastal sea surface temperatures break up the western
113 flank inversion layer (Aceituno, 1988). Although this localized feature is most commonly
114 associated with the negative phase of the El Niño Southern Oscillation (ENSO) and extreme
115 precipitation events along the tropical coastal western Andes (e.g., Quinn & Neal, 1987;
116 Takahashi & Martínez, 2019), it also generates episodic summertime precipitation on the western
117 flank (e.g., Garreaud et al., 2002; Vuille et al., 2000). Wintertime precipitation is very rare on the
118 western flank because sea surface temperatures are relatively cool and the inversion layer
119 remains stable (Figures 2b and 2d; Rutllant et al., 2003).

120 2.2 Isotope systematics

121   Relationships between isotopic compositions (e.g., $\delta^{18}O$ vs. δ^2H) are generally considered
122 to be linear, but mass-dependent isotope fractionation actually follows a power law relationship
123 that relates the fractionation factors (α) of coexisting phases (A and B) by a defined fractionation
124 exponent (θ) (Matsuhisa et al., 1978; Young et al., 2002):

126    $^*\alpha_{A\text{-}B} = (^*\alpha_{A\text{-}B})^\theta$ (1)

128 where * denotes a heavy mass number (e.g., ^{17}O, ^{18}O, ^2H). The value of θ is derived from mass
129 law theory (Criss, 1999; Matsuhisa et al., 1978; Young et al., 2002) and distinguishes
130 equilibrium (θ_{eq}) and kinetic (θ_{diff}) processes. These θ values are more familiar as the slopes that
131 relate isotopic compositions (α or δ values) during isotopic fractionation. Deviations in these
132 slopes (or position relative to them) indicate different roles of equilibrium and kinetic
133 fractionation on isotopic compositions.
134   The most familiar slope in isotope hydrology is the slope of the oxygen-hydrogen Global
135 Meteoric Water Line (GMWL) (Craig, 1961). This empirical value (8) integrates equilibrium
136 ($\theta_{eq} \approx 8$) and kinetic ($\sim 2.5 < \theta_{diff} < 8$; Gonfiantini et al., 2018) processes and establishes a
137 reference frame from which d-excess is defined (Dansgaard, 1964):

139   d-excess = $\delta^2H - 8*\delta^{18}O$.   (2)

141 A similar reference relationship differentiates triple oxygen isotope ratios during equilibrium and
142 kinetic fractionation and defines the $\Delta'^{17}O$ parameter (Barkan & Luz, 2007):

144    $\Delta'^{17}O = \delta'^{17}O - 0.528*\delta'^{18}O$.   (3)

146 The empirically determined slope of the triple oxygen isotope reference line (0.528) (Luz &
147 Barkan, 2010; Meijer & Li, 1998) integrates equilibrium ($\theta_{eq} = 0.529$; Barkan & Luz, 2005) and

148 kinetic (θ_{diff} = 0.518; Barkan & Luz, 2007) fractionation. The $\Delta'^{17}O$ definition requires δ'
149 notation (δ' = ln(δ/1000 + 1)*1000; Hulston & Thode, 1965; Miller, 2002) because mass-
150 dependent deviations from the triple oxygen isotope reference relationship are very small and
151 must be calculated from a reference frame that is exactly linear.

3 Methods

152

153 3.1 Precipitation network and sample collection

154   This study includes data from a network of precipitation collection stations in southern
155 Peru that extends from the western Peruvian Amazon (~13˚S) to near the Pacific coast (~17˚S)
156 (Figures 1b and S1). Ten stations (San Gaban, Ollachea, Macusani, Ayaviri, Ichuña, Carumas,
157 Majes, Ayo, Orcopampa, and Santo Tomas) were installed in May and June 2016; eight stations
158 (Pampahuta, Ubinas, Quinistaquillas, Moquegua, Arequipa, Cotahuasi, and Puyca) were added in
159 November 2017. The final station (Calca) was installed in July 2018. This study includes
160 samples collected through May 2019 because travel restrictions associated with COVID-19
161 prevented travel after the 2020 rainy season. Isotopic data are not considered from Ichuña,
162 Orcopampa, or Puyca due to compromised samples or from Ayo due to a lack of rain. Additional
163 details about data quality and the stations are in Table S1 and Section 3.3.
164   Each precipitation collection station was managed by a local Peruvian observer and
165 collocated alongside SENAMHI (Servicio Nacional de Meteorología e Hidrología del Perú)
166 meteorological stations that record daily precipitation amount. Some SENAMHI stations also
167 record mid-day relative humidity and maximum and minimum or morning and afternoon
168 temperature. Temperature and relative humidity sensors (Onset HOBO, U23 Pro v2) were added
169 to stations that only record precipitation. Mean annual temperature (MAT) and mean annual
170 precipitation (MAP) from each site were extracted from the University of Delaware 0.5˚ monthly
171 gridded climate data (1960-1990 average) (Legates & Willmott, 1990a, 1990b).
172   Precipitation samples were collected at each site on the 1st and 15th of every month.
173 During the first year, samples were collected in 1.5 L HDPE bottles (McMaster Carr, 4280T37)
174 following the description in Gröning et al. (2012). This oil-free collection technique prevented
175 evaporation and simplified sample collection because station observers did not have to separate
176 the sample water from overlaying oil. Station observers poured the collected precipitation into 20
177 ml HDPE storage vials (Wheaton, 986716), capped the storage vials with PolyCone caps, and
178 cleaned and dried the collection bottle. After the first year, observers added mineral oil to the
179 collection bottles as another measure to prevent evaporation because we determined that the
180 traditional mineral oil technique is more reliable in remote locations and with non-expert
181 observers (Friedman et al., 1992; Scholl et al., 1996). Observers used a syringe to extract sample
182 water and cleaned, dried, and added a new layer of oil to the collection bottles between samples.
183   During annual site visits, we gathered the precipitation samples, cleaned and repaired the
184 collection equipment, and interviewed observers about local weather conditions. In the lab, we
185 transferred samples into 16 ml glass vials with PolyCone caps (The Lab Depot, 316018-2170)
186 for secure long-term storage. At most, samples were stored in HDPE vials for one year, so they
187 are not compromised by fractionation with the plastic containers (Spangenberg, 2012).

188 3.2 Isotopic analysis

189   The $\delta^{18}O$ and δ^2H values of every precipitation sample were measured using a Picarro
190 L2130-i with a high-precision vaporizer (A0211) and attached autosampler. Picarro

191 ChemCorrect software screened samples for organic contamination and normalized raw $\delta^{18}O$ and
192 δ^2H values to the VSMOW-SLAP scale with four in-house liquid standards that were calibrated
193 with USGS reference waters (USGS45, 46, 49, and 50). Analytical precision of repeat analyses
194 of deionized water was better than 0.1‰ and 0.3‰ for $\delta^{18}O$ and δ^2H, respectively. Assuming the
195 errors on $\delta^{18}O$ and δ^2H are independent, the analytical precision of d-excess is better than 0.4‰.
196   The $\delta^{18}O$ and $\delta^{17}O$ values of 32 precipitation samples were measured with a dual-inlet Nu
197 Perspective isotope ratio mass spectrometer (IRMS) using the cobalt(III) fluoride method
198 developed by Baker et al. (2002) and refined by Luz and Barkan (2005). Our methods are
199 described in Aron et al. (2021). Triple oxygen isotope values were normalized to the VSMOW-
200 SLAP scale using values of 0.0000‰ for $\delta^{18}O_{VSMOW}$ and $\delta^{17}O_{VSMOW}$ (Gonfiantini, 1978),
201 −55.5000‰ for $\delta^{18}O_{SLAP}$, and −29.6986‰ for $\delta^{17}O_{SLAP}$ (Schoenemann et al., 2013). The root-
202 mean-square error of the IRMS measurements, determined from replicate analyses of USGS
203 reference waters (Table S2), was 0.2‰ for $\delta^{17}O$, 0.3‰ for $\delta^{18}O$, and 6 per meg for $\Delta'^{17}O$. The
204 analytical precision of $\Delta'^{17}O$ is better than that of $\delta^{17}O$ and $\delta^{18}O$ because any fractionation that
205 occurs during sample preparation is related by a $\delta'^{18}O–\delta'^{17}O$ slope that is nearly equivalent to the
206 value of the reference slope (Barkan & Luz, 2007; Landais et al., 2006; Schoenemann et al.,
207 2013).

208 3.3 Isotopic data caveats

209   We collected and analyzed $\delta^{18}O$ and δ^2H from a total of 451 precipitation samples (Table
210 S1). From this, we removed 12 samples with negative d-excess$_p$ values that are likely affected by
211 evaporation and 130 samples from five sites that we suspect were collected from tap or surface
212 water sources. The probable tap or surface water samples were easily identifiable from site-
213 specific timeseries with less than 1‰ of seasonal $\delta^{18}O_p$ variation (seasonal $\delta^{18}O_p$ variation is at
214 least 5‰ at most sites). All the measured $\delta^{18}O$ and δ^2H data are reported in Table S3, but data
215 from the excluded samples are flagged as unreliable.
216   Data are also missing or incomplete from three other sites. First, data from Macusani are
217 missing from May 2018 to May 2019 because the observer did not record collection dates on the
218 sample vials. Second, sample collection lasted only one year (June 2017 to May 2018) in Cusco.
219 Third, the observer in Majes was not available during the 2019 site visit, so isotopic data from
220 this site only extend until May 2018.
221   After screening for compromised and/or improperly collected samples, the final dataset
222 contains 309 precipitation samples (Table S1).

223 3.4 Air mass trajectories

224   We used the Hybrid coordinate Single Parcel Lagrangian Integrated Trajectory model
225 (HYSPLIT; Draxler & Hess, 1998) and 0.5˚ Global Data Assimilation System (GDAS)
226 meteorological data to compare eastern and western moisture sources at San Gaban, Ayaviri,
227 Santo Tomas, Cotahuasi, Ubinas, Majes, and Moquegua. At each site, ten-day atmospheric back
228 trajectories were initiated at 0, 6, 12, and 18 UTC (the availability of GDAS data) from 1,000 m
229 above ground level. We chose the initiation height based on previous back trajectory analyses in
230 the central Andes (e.g., Fiorella, et al., 2015a; Vimeux et al., 2011). Parcel vertical velocities
231 were determined from GDAS wind fields. To separate winds on wet and dry days, we analyzed
232 the trajectories in two ways: an 'all days' analysis that included trajectories from every day

233   during the study period and a 'rainy days' analysis that only included the trajectories initiated on
234   days when rain fell at each site.
235   We then used the Lagrangian tracer developed by Sodemann et al. (2008) to determine
236   the humidity contribution from each grid cell along the moisture trajectories and calculate
237   moisture footprints for each site (Figure S2). This iterative tracer links precipitation to remote
238   evaporation sources by tracking increases in planetary boundary layer specific humidity and
239   diagnoses the humidity contribution from each point along a trajectory. HYSPLIT-extracted
240   boundary layer heights were doubled, as prior work with this tracer has suggested that using
241   unscaled boundary layer heights may underestimate moisture contributions from shallow
242   convection (Aemisegger et al., 2014; Fiorella et al., 2018; Sodemann et al., 2008). The ten-day
243   trajectories used in this study were sufficiently long to determine moisture source locations for
244   85-95% of the total parcel moisture.
245   Finally, we determined the large-scale contribution of eastern and western air masses to
246   precipitation in southern Peru by estimating the humidity contributions from two zones separated
247   by the spine of the Western Cordillera: an eastern zone that includes humidity sourced from the
248   Atlantic Ocean, Amazon Basin, eastern Andean flank, and the Altiplano and a western zone that
249   includes humidity from the Pacific Ocean and western Andean flank. The ratio of eastern and
250   western air masses was determined at each site by summing the monthly humidity contributions
251   from each zone and dividing by the total moisture footprint across both zones. Because rain did
252   not fall equally across the study region, we report the moisture flux ratios as quarterly seasonal
253   averages among water years (a water year is defined as June to May to keep the summer rainy
254   season intact). This approach is not intended to differentiate tropical versus extratropical air
255   masses and is not well suited to identify small-scale circulation features along the Andean flanks
256   or Altiplano due to the spatial and temporal scale of the GDAS data.

257 **4 Results**

258 4.1 Precipitation $\delta^{18}O$, δ^2H, and d-excess

259   Values of $\delta^{18}O_p$ in southern Peru range from –29.3 to 2.0‰, δ^2H_p ranges from –216.1 to
260 35.2‰, and d-excess ranges from 0.2 to 41.8‰ (Figure 3a, Table S3). $\delta^{18}O_p$ and δ^2H_p are
261 strongly correlated (Pearson's r > 0.99) and cluster on or near the $\delta^{18}O$-δ^2H GMWL, although
262 the slope (8.1) and intercept (15.8) through $\delta^{18}O_p$ and δ^2H_p are slightly higher than the reference
263 values (8 and 10, respectively). Because $\delta^{18}O_p$ and δ^2H_p are so strongly correlated, the following
264 results and discussion focus only on $\delta^{18}O_p$ and d-excess$_p$.
265   Values of $\delta^{18}O_p$ and d-excess$_p$ varied on semimonthly to interannual timescales across the
266 study region (Figure 4). The most pronounced temporal variation was a seasonal pattern on the
267 eastern flank and Altiplano with lower rainy season (DJFM) $\delta^{18}O_p$ (–26.0 to –3.3‰, amount-
268 weighted average –14.9‰) and d-excess$_p$ (2.4 to 33.6‰, amount-weighted average 14.6‰)
269 values and higher dry season (JJAS) $\delta^{18}O_p$ (–21.1 to 2.0‰, amount-weighted average –7.5‰)
270 and d-excess$_p$ (8.6 to 38.8‰, amount-weighted average 16.0‰) values. Seasonal $\delta^{18}O_p$ and d-
271 excess$_p$ variability cannot be assessed on the western flank because precipitation only fell during
272 the wet season, but in general western flank $\delta^{18}O_p$ (–16.7 to 1.2‰, amount-weighted average –
273 6.7‰) values were higher and d-excess$_p$ (0.2 to 27.0‰, amount-weighted average 11.3‰) values
274 were lower than those on the Altiplano or eastern flank (Figures 4 and 5).

275   Spatially, wet season amount-weighted $\delta^{18}O_p$ correlated negatively with elevation (r = –
276 0.82, p < 0.001, Figures 5b and 6a) and latitude (r = –0.72, p < 0.005, Figure 6c) and exhibited
277 weaker correlations with MAP (r = –0.22, p = 0.67, Figure 6b) and longitude (r = –0.12, p =
278 0.46). We report and show (Figures 5 and 6) amount-weighted averages from the wet season
279 because dry season precipitation data do not exist on the western flank and most of the Altiplano.
280 However, the relationships between amount-weighted annual $\delta^{18}O_p$ and elevation (r = –0.84),
281 latitude (r = –0.70), longitude (r = –0.13), and MAP (r = –0.20) are nearly identical to those that
282 only consider wet season data because most precipitation fell during the wet season. Stepwise
283 multiple linear regression models with elevation, latitude, longitude, and MAP as possible
284 predictor variables (Bowen & Wilkinson, 2002; Lechler & Niemi, 2011) confirm that elevation
285 and latitude were the dominant controls on $\delta^{18}O_p$ (Table S4). Each regression model was
286 assessed with the Akaike information criterion (AIC), with lower AIC scores indicating a
287 balance between goodness of model fit with model parsimony.
288   Isotopic lapse rates were determined by linear regression through amount-weighted rainy
289 season $\delta^{18}O_p$ from San Gaban, Ollachea, and Macusani on the eastern flank and Moquegua,
290 Quinistaquillas, Carumas, Ubinas, Arequipa, Majes, and Cotahuasi on the western flank. The
291 eastern flank $\delta^{18}O_p$ lapse rate, –2.8 ± 0.2‰/km, was determined from precipitation collected at
292 three closely-located sites that span over 3.6 km of elevation, but this lapse rate does not change
293 if $\delta^{18}O_p$ data from Cuzco, Calca, Ayaviri and/or Santo Tomas are also included in the regression
294 analysis. The western flank $\delta^{18}O_p$ lapse rate was determined from all the available rainy season
295 western slope precipitation data because rain events in this region are very rare. This $\delta^{18}O_p$ lapse
296 rate is nearly identical when derived from all the western flank sites (–4.5 ± 1.2‰/km) and from
297 the four sites (Moquegua, Quinistaquillas, Carumas, and Ubinas) in the Moquegua region (–4.3 ±
298 1.8‰/km). However, due to the small number of samples, interannual variability of western
299 flank $\delta^{18}O_p$ lapse rates was high, ranging from –1.9‰/km in 2017 to –5.5‰/km in 2019, and the

300 uncertainty of the lapse rate (1.2‰/km) is an order of magnitude greater than that on the eastern
301 flank (0.2‰/km).
302   Amount-weighted wet season d-excess$_p$ values ranged from 5.0 to 22.1‰ and are poorly
303 correlated with elevation (r = 0.34, p = 0.24, Figures 5c and 6d), latitude (r = 0.16, p = 0.60,
304 Figure 6f), or MAP (r = 0.07, p = 0.82, Figure 6e). Unfortunately, the observer at Carumas did
305 not collect samples properly after 2017, so it is difficult to assess the noticeably high (22.1‰) d-
306 excess$_p$ value at this site. Excluding this value, amount-weighted DJFM d-excess$_p$ was highest at
307 Macusani (17.3‰) and decreased across the Altiplano from the Eastern Cordillera towards the
308 Western Cordillera, with lower values on the western flank (5.0 to 13.3‰) than on the Altiplano
309 or eastern flank (12.4 to 17.3‰) (Figure 5c).

310 4.2 Triple oxygen isotope ratios

311   Precipitation samples from San Gaban (n = 9), Ollachea (n = 2), Macusani (n = 6), Santo
312 Tomas (n = 3), Ayaviri (n = 6), Carumas (n = 2), and Majes (n = 4) were selected for triple
313 oxygen analysis to explore $\Delta'^{17}O_p$ relationships with d-excess$_p$, $\delta^{18}O_p$, elevation, MAP, and
314 latitude (Figures 6 and 7). Among this subset of samples, $\delta'^{18}O_p$ ranges from –28.3 to –0.2‰,
315 $\delta'^{17}O_p$ ranges from –14.9 to –0.1‰, and $\Delta'^{17}O_p$ ranges from 1 to 55 per meg (Figures 3b and 7a,
316 Table S2). Although $\delta'^{18}O_p$ and $\delta'^{17}O_p$ are very well correlated (r > 0.99999) and appear to plot
317 exactly on the reference relationship (Figure 3b), the slope (0.5275 ± 0.0003) of the observed
318 $\delta'^{18}O_p$-$\delta'^{17}O_p$ regression line is slightly lower than that of the reference line (0.528). These small,
319 mass-dependent $\delta'^{18}O$ and $\delta'^{17}O$ deviations from the reference line are not visible in Figure 3b,
320 but become apparent when triple oxygen isotope data are shown as $\delta'^{18}O$ versus $\Delta'^{17}O$ (Figure
321 7a). This isotope space is analogous to plots of $\delta^{18}O$ versus d-excess (Figure 7b) and is an easier
322 way to visualize isotopic compositions that vary on different orders of magnitude (1‰ is equal to
323 1,000 per meg).
324   Similar to most previously published water triple oxygen isotope data, $\Delta'^{17}O_p$ is slightly
325 anticorrelated with $\delta'^{18}O_p$ (r = –0.26, Figure 7a) and positively correlated with d-excess$_p$ (r =
326 0.46, Figure 7c). In general, $\Delta'^{17}O_p$ was higher on the Altiplano (29 to 55 per meg) and lower on
327 the dry western flank (1 to 35 per meg). Site-specific $\Delta'^{17}O$ variation was larger on the western
328 flank (17 per meg $\Delta'^{17}O_p$ range at Carumas, 27 per meg at Majes) than on the eastern flank (12
329 per meg at San Gaban, 2 per meg at Ollachea). Across the study region, $\Delta'^{17}O_p$ was moderately
330 positively correlated with elevation (r = 0.57, Figure 6g) and latitude (r = 0.41, Figure 6i) and
331 uncorrelated with MAP (r = –0.07, Figure 6h). This dataset is not well suited to evaluate
332 temporal $\Delta'^{17}O_p$ variability (Figure S3) and seasonal $\Delta'^{17}O_p$ variability should be the focus of
333 future work.

334 4.3 Atmospheric moisture transport

335   The ratio of eastern- versus western-sourced air masses differs in the 'all days' (Figure 8,
336 yellow squares) and the 'rainy days' (Figure 8, blue circles) analyses, but both reveal a dominant
337 easterly source of water vapor on the eastern flank and a mixture of eastern and western sourced
338 air masses on the central Altiplano and western flank (Figures 8 and S2). Across the study
339 region, the 'all days' eastern moisture flux ratio decreased from > 99% on the eastern flank
340 (Figure 8a), to ~ 75% on the central Altiplano (Figures 8b and 8c), ~ 30% high on the western
341 flank (Figures 8d and 8e), and < ~ 10% at low elevation on the western flank (Figures 8f and 8g).
342 The moisture flux ratio is more variable when calculated from the 'rainy days' trajectories, but

343 still shows that > 95% of the water vapor in San Gaban originated from the Atlantic Ocean and
344 Amazon Basin (Figure 8a). The eastern-sourced 'rainy days' moisture flux ratio was also
345 dominant at the high elevation sites during the 2018 and 2019 water years. During the 2017
346 water year, the contribution of western-sourced air masses to the high elevation sites was higher,
347 ranging from ~40% to more than 70% (Figures 8b-8e).
348   Finally, it is interesting to compare the 'all days' and 'rainy days' moisture flux ratios on
349 the western flank. For example, the 'all days' ratios show a dominant contribution from western-
350 sourced air masses at high (Cotahuasi and Ubinas, ~ 75% of air masses) and low (Majes and
351 Moquegua, > 90% of air masses) elevation. Such a clear distinction between air mass source
352 regions disappears among the western flank 'rainy days' moisture flux ratios (Figures 8b-8e).
353 This suggests that dry winds on the western flank of the central Andes originate predominantly
354 from the Pacific Ocean, whereas the air masses that bring precipitation to this region are sourced
355 from a combination of both eastern and western regions.

5 Discussion

356

5.1 Controls on central Andean $\delta^{18}O_p$

357

358   The seasonal $\delta^{18}O_p$ pattern observed on the eastern flank and Altiplano in southern Peru
359 is consistent with previous studies from the central Andes (Figure 9a; Aravena et al., 1999;
360 Fiorella et al., 2015a; Fritz et al., 1981; Gonfiantini et al., 2001; Guy et al., 2019) and is related
361 to a number of hydrologic processes that contribute to lower $\delta^{18}O_p$ values during the summer
362 rainy season. First, during the wet season, high upstream precipitation in the Amazon Basin
363 decreases the isotopic composition of vapor that is advected to the central Andes (Fiorella, et al.,
364 2015a; Guy et al., 2019; Vimeux et al., 2005, 2011). Second, rainy season deep convection and
365 downdrafts from aloft entrain isotopically light vapor from the upper and middle troposphere and
366 decrease $\delta^{18}O_p$ values (Blossey et al., 2010; Galewsky et al., 2016; Moore et al., 2014; Risi et al.,
367 2008; Samuels-Crow et al., 2014a; Worden et al., 2007). Although small, localized convective
368 cells can entrain near-surface vapor with relatively high isotopic compositions (e.g., Aggarwal et
369 al., 2016; Kurita, 2013), the high elevation Altiplano and intense daytime heating across the
370 Amazon Basin lead to the development of deep convective cells (Garreaud et al., 2009) that
371 decrease $\delta^{18}O_p$ values in this region. Third, water droplets likely undergo less sub-cloud
372 evaporation and less heavy isotope enrichment during the wet season when relative humidity is
373 high and the air column is closer to saturation than during the dry season.
374   The interannual variations of central Andean $\delta^{18}O_p$ are often linked to ENSO (e.g., Vuille
375 & Werner, 2005), but our study duration is short and occurred during weak ENSO conditions
376 (National Weather Service, Climate Prediction Center) and we do not observe consistent
377 interannual $\delta^{18}O_p$ patterns (Figures 4a, 4b, and 5b). Interestingly, the relatively strong
378 contribution of western-sourced water vapor during the 2017 water year (Figures 8b-8g and
379 Figure S2), which is likely related to the strong El Niño event that occurred off the coast of Peru
380 and Ecuador in early 2017 (Garreaud et al., 2018; Peng et al., 2019), is not evident in the western
381 flank or Altiplano $\delta^{18}O_p$ data (Figures 4 and 5). Although this precipitation record is too short to
382 comment substantially on interannual $\delta^{18}O_p$ variability, the absence of a clear ENSO-$\delta^{18}O_p$
383 relationship shows that even strong El Niño events are not always reflected in local precipitation
384 isotope ratios. Instead, it is possible that rainout over the Andes overwrites $\delta^{18}O_p$ anomalies
385 related to Pacific Ocean conditions and/or regional atmospheric circulation (Hurley et al., 2019;
386 Thompson et al., 2017).

387   Site-to-site correlations of concurrent semimonthly $\delta^{18}O_p$ values (Table S5) reflect a
388   combination of synoptic- and local-scale controls on $\delta^{18}O_p$ in southern Peru. Strong correlations
389   between eastern flank and eastern Altiplano $\delta^{18}O_p$ values indicate synoptic-scale moisture
390   transport, whereas weaker correlations among western flank sites result from sporadic and small-
391   scale precipitation events (Figure 4). Large (up to 15‰) variations between concurrent
392   semimonthly $\delta^{18}O_p$ values on the Altiplano point to local-scale $\delta^{18}O_p$ controls such as convection
393   and near-surface convergence (Garreaud et al., 2003; Kumar et al., 2019; Romatschke & Houze,
394   2010), ridges and valleys that funnel moisture (Giovannettone & Barros, 2009), or the addition
395   of water vapor from evaporation of lakes or other surface water (Pillco Zolá et al., 2019).

396   Our analysis of regional $\delta^{18}O_p$ controls shows that 1) elevation is a dominant control on
397    $\delta^{18}O_p$ values (Figure 6a, Table S4) and 2) central Andean $\delta^{18}O_p$ values are not correlated with
398   local precipitation amounts on annual (r = –0.06, our data), rainy season (r = –0.05, all monthly
399   data), monthly (r = –0.08, all monthly data), or semimonthly (r = 0.13, our data) time scales
400   (Figure 6b). Although our dataset only contains data from three years, these results are consistent
401   with previous work from the central Andes and suggests that local precipitation rates are often
402   poor predictors of precipitation isotope ratios in the central Andes (e.g., Vimeux et al., 2005).
403   There is a clear seasonal signal in $\delta^{18}O_p$ with lower values during the rainy season and higher
404   values during the dry season (Figures 4a and 9a), but individual $\delta^{18}O_p$ values are more closely
405   tied to upstream rainout, evapotranspiration, moisture convergence, and cloud type than local
406   precipitation amount in the central Andes (Konecky et al., 2019). The statistically significant
407   latitude-$\delta^{18}O_p$ relationship (Table S4) in southern Peru is unique in the central Andes (Figure 6c)
408   and is opposite in sign from the global trend because the global latitude-$\delta^{18}O_p$ relationship is
409   related to progressive rainout during poleward moisture transport (Bowen et al., 2019) whereas
410   the latitude-$\delta^{18}O_p$ relationship in southern Peru reflects a contribution of eastern- and western-
411   derived water vapor (Figure 8).

412   5.2 Hydrologic interpretations of d-excess and $\Delta'^{17}O$

413   To this point, interpretations of isotopic variability have mainly focused on large-scale
414   circulation patterns, rainout, and convection. However, processes such as evaporation, moisture
415   recycling, and in-cloud microphysics also affect the isotopic composition of precipitation but are
416   poorly constrained with $\delta^{18}O_p$ alone. Here, we show how d-excess and $\Delta'^{17}O$ complement $\delta^{18}O$
417   to provide new hydrologic insights in the central Andes.

418   We observe high (>10‰) d-excess$_p$ values and two primary types of d-excess$_p$ variation:
419   1) a consistent 5-10‰ seasonal cycle with higher (> ~ 15‰) d-excess$_p$ values in the dry season
420   and lower (~ 10-15‰) d-excess$_p$ values in the wet season and 2) infrequent very high (>25‰)
421   dry season d-excess$_p$ values on the Altiplano (Figures 4c, 4d, and 9b). Regardless of season or
422   location, d-excess is unrelated to elevation, MAP, or latitude (Figures 6d-6e) because it is
423   primarily sensitive to kinetic fractionation.

424   The seasonal d-excess$_p$ pattern records relative humidity above the surfaces of remote
425   Atlantic moisture sources and in the atmosphere above precipitation stations as well as
426   land-atmosphere water fluxes from the Amazon (Salati et al., 1979). During the rainy season, d-
427   excess$_p$ values from ~ 10 to 15‰ are consistent with Rayleigh distillation and moisture recycling
428   across the Amazon Basin (Ampuero et al., 2020; Salati et al., 1979). During the dry season,
429   lower relative humidity above the tropical Atlantic increases kinetic fractionation during
430   evaporation and results in higher vapor d-excess (Pfahl & Sodemann, 2014). Downstream

431   condensation retains this signal, resulting in higher ($> \sim 15‰$) dry season d-excess$_p$ values
432   (Figures 5c and 9b). Subcloud evaporation, which is more likely in the winter when the
433   atmosphere is drier, may also play a role in the higher winter d-excess$_p$ values if precipitation
434   condenses from reevaporated vapor (e.g., Risi et al., 2008). Evapotranspiration from the Amazon
435   Basin may amplify this d-excess$_p$ seasonality if the bare-ground evaporation flux increases
436   during the dry season (Pattnayak et al., 2019).
437   The very high (>25‰) Altiplano d-excess$_p$ values are uncommon in tropical
438   precipitation, but are occasionally observed in the central Andes (Fiorella et al., 2015a; Guy et
439   al., 2019; Vimeux et al., 2011) and other high elevation regions (Liotta et al., 2006). Guy et al.
440   (2019) also observed high (>30‰) event-scale d-excess$_p$ values on the eastern margin of the
441   Altiplano in 2016 and 2017. Such elevated d-excess$_p$ values likely reflect kinetic fractionation
442   during ice crystal formation and deep convection over the central Andes (Bolot et al., 2013;
443   Jouzel & Merlivat, 1984), low temperature condensation from upper troposphere water vapor
444   (Bony et al., 2008; Galewsky et al., 2016; Samuels-Crow et al., 2014b), and/or a non-linear
445   isotope effect in air parcels that have experienced strong rainout (Dütsch et al., 2017; Jouzel &
446   Merlivat, 1984).
447   This study reports the first $\Delta'^{17}O_p$ data from the central Andes. Controls on $\Delta'^{17}O_p$
448   variation are not yet well established, so as a starting point we base explanations of $\Delta'^{17}O_p$
449   variation on our understanding of d-excess$_p$. In the same way d-excess records information about
450   kinetic fractionation, we expect that $\Delta'^{17}O$ records information about evaporation, relative
451   humidity near precipitation collection sites and above remote moisture sources,
452   evapotranspiration and moisture recycling across the Amazon Basin, ice crystal formation,
453   and/or condensation that incorporates upper troposphere water vapor. We also consider the role
454   of air mass mixing, which produces a non-linear response in $\Delta'^{17}O$ because $\Delta'^{17}O$ is defined from
455   logarithmic δ' values (Equation 2). A similar signal of mixing is likely less clear in d-excess
456   because d-excess is defined from δ values (Equation 1) and the mixing response is linear.
457   The clearest findings from the triple oxygen isotope data are that 1) the range of $\Delta'^{17}O_p$
458   values ($\sim$ 20 to 40 per meg) in southern Peru is consistent with previous observations from other
459   tropical and mid-latitude regions and 2) precipitation $\Delta'^{17}O$ values are less variable than those
460   from surface water (Figure 7). A similar, more familiar distinction between precipitation and
461   surface water is also observed in d-excess (Figures 7b and 7c) because surface waters are
462   typically more evaporated than precipitation.
463   Interpretations of the variations among $\Delta'^{17}O_p$ observations are less clear. Most $\Delta'^{17}O_p$
464   values cluster around 20 to 40 per meg due to kinetic fractionation that occurs as water vapor
465   diffuses through unsaturated air during the initial evaporation from moisture sources (Aron et al.,
466   2021; Luz & Barkan, 2010). The same process results in d-excess$_p$ values from $\sim$10 to 20‰ for
467   these samples. These $\Delta'^{17}O_p$ and d-excess$_p$ values are higher than those of seawater (0 per meg
468   and 0‰, respectively) because kinetic fractionation slopes are shallower than the slopes of the
469    $\delta'^{18}O–\delta'^{17}O$ and $\delta^{18}O–\delta^2H$ reference relationships and evaporated vapor $\delta^{18}O$, $\delta^{17}O$, and δ^2H
470   values fall above the reference lines. Positive $\Delta'^{17}O$ and d-excess values are then conserved
471   through downstream condensation (Aron et al., 2021; Luz & Barkan, 2010). However, while the
472   10‰ d-excess$_p$ range in Figures 5 and 9 is interpretable, patterns among the $\Delta'^{17}O_p$ data from 20
473   to 40 per meg are not clearly related to seasonality, location, or moisture recycling and it is hard
474   to definitively isolate competing fractionating processes within this 20 per meg range. For
475   example, it is tempting to attribute some of the higher ($\sim$30 to 40 per meg) values at San Gaban
476   to moisture recycling from the Amazon Basin or link regional $\Delta'^{17}O_p$ variability to eastern and

477 western moisture sources, but these interpretations are not yet clear from the $\Delta'^{17}O_p$ data and
478 require further study.

479 Beyond the clustered $\Delta'^{17}O_p$ data from 20 to 40 per meg, we observe a few high (> 40 per
480 meg) $\Delta'^{17}O_p$ values from sites located on the eastern margin of the Altiplano and two samples
481 from Majes with relatively low (< 10 per meg) $\Delta'^{17}O_p$ values (Figures 7a and S3). The samples
482 with high $\Delta'^{17}O_p$ values also have high (> 25‰) d-excess$_p$ values (Figure 7c), so it is likely that
483 these $\Delta'^{17}O_p$ values are related to kinetic fractionation during ice crystal formation and/or
484 condensation that incorporates upper troposphere water vapor. Future work to evaluate $\delta'^{17}O$ and
485 $\delta'^{18}O$ during ice crystal formation and additional observations of $\Delta'^{17}O_p$ variability through the
486 troposphere can test these interpretations (Risi et al., 2013). It is unlikely that the high $\Delta'^{17}O_p$
487 values are related to air parcels that have experienced strong rainout because $\Delta'^{17}O$ and d-excess
488 typically diverge at low $\delta^{18}O$ values (Aron et al., 2021). The low $\Delta'^{17}O_p$ values at Majes are not
489 related to evaporation (d-excess$_p$ of these samples is ~ 15‰) and instead could be indicative of
490 air mass mixing on the western flank (Figure 8f).

491 Initial central Andean $\Delta'^{17}O_p$ results show the promise of this type of measurement in
492 isotope-based studies of hydrology and climate. Primarily, these data clearly show that $\Delta'^{17}O$ can
493 separate evaporated samples from non-evaporated samples (Figure 7). This sensitivity has
494 exciting applications in paleoclimate studies, which have long been limited by a singular focus
495 on either $\delta^{18}O$ (e.g., pedogenic carbonates) or δ^2H (e.g., leaf waxes or volcanic glass). The
496 central Andes are a prime region of interest for future triple oxygen isotope studies because the
497 history of Andean uplift is uncertain and many of the archives that are used to infer
498 paleoaltimetry are from arid regions subject to a high degree of evaporation (Fiorella et al.,
499 2015b). In this context, $\Delta'^{17}O$ will be a useful metric to differentiate isotopic signals that record
500 information about paleoclimate conditions from those that reflect uplift or mountain building
501 (Rech et al., 2019). Specifically, $\Delta'^{17}O$ can help diagnose evaporation on the Altiplano and
502 Atacama Desert and may also contain new information about large-scale changes in moisture
503 recycling and atmospheric circulation associated with the evolution of the Amazon Rainforest
504 and uplift of the Andes mountains. Alongside these geologic applications, future hydrologic
505 $\Delta'^{17}O$ studies should further evaluate the range of unevaporated $\Delta'^{17}O_p$, temporal $\Delta'^{17}O_p$
506 variation, and the relationship between $\Delta'^{17}O_p$ and elevation. These future studies are important
507 because the positive correlation between $\Delta'^{17}O_p$ and elevation is almost certainly biased by the
508 very high $\Delta'^{17}O_p$ values on the Altiplano (Figure 6g) and will likely weaken with future
509 observations (Bershaw et al., 2020). Similarly, the trend between latitude and $\Delta'^{17}O$ (Figure 6i) is
510 largely related to water types because lakes tend to have lower $\Delta'^{17}O$ values than precipitation
511 and will also likely weaken with additional observations from this region.

512 5.3 Implications of western-derived air masses

513 Atmospheric back trajectories and isotopic data show an important role of western-
514 sourced water vapor in southern Peru. A similar moisture source has been inferred from $\delta^{18}O_p$ in
515 northern Chile and the Atacama Desert (Aravena et al., 1999; Herrera et al., 2018; Valdivielso et
516 al., 2020), but is generally disregarded in modern central Andean water budgets (e.g., Garreaud,
517 1999) and is not considered in most reconstructions of Andean paleoaltimetry (e.g., Garzione et
518 al., 2006). Our $\delta^{18}O_p$, d-excess$_p$, and moisture flux results show that western-sourced moisture
519 may play an important hydrologic role in the dry western central Andes and may contribute to
520 steep $\delta^{18}O_p$ lapse rates (−4.4 ± 1.1‰/km in southern Peru (this study) to ~−10‰/km in northern

521 Chile (Aravena et al., 1999; Fritz et al., 1981)) on the western flank where low elevation Pacific
522 sourced water vapor (high $\delta^{18}O$) mixes with high elevation Atlantic sourced water vapor (low
523 $\delta^{18}O$). Our results suggest that this moisture source should be considered in regional hydrologic
524 assessments and paleoaltimetry reconstructions.

525 **6 Conclusion**

526 We report on a new three-year record of semimonthly $\delta^{18}O_p$, d-excess$_p$, and $\Delta'^{17}O_p$ from
527 southern Peru to improve our understanding of water cycling and isotopic variation in the central
528 Andes. We observe a strong negative $\delta^{18}O_p$ relationship with elevation and a seasonal $\delta^{18}O_p$
529 cycle related to upstream precipitation and local deep convection. These findings are consistent
530 with previous work and are generally explained by equilibrium isotope fractionation. Kinetic
531 fractionation is much less commonly considered in interpretations of central Andean
532 precipitation isotope ratios, but can be quantified with d-excess and $\Delta'^{17}O$. Seasonal variations of
533 d-excess$_p$ reflect moisture recycling, relative humidity above precipitation collection stations and
534 at remote moisture sources, and regional evapotranspiration. This study reports the first $\Delta'^{17}O_p$
535 data from the central Andes and results clearly show that $\Delta'^{17}O$ differentiates evaporated and
536 non-evaporated samples. This sensitivity has immense potential to quantify evaporation in
537 paleoclimate studies and address outstanding questions about uplift and long-term climate
538 change in the Andes. Although the modern hydrologic applications of $\Delta'^{17}O_p$ will require future
539 work, our results show that d-excess$_p$ and $\Delta'^{17}O_p$ complements $\delta^{18}O_p$ data and record new
540 information about water cycling. Together, these results highlight the utility and untapped
541 potential of precipitation isotope ratios to understand water cycling, hydrologic conditions, and
542 climate change in the central Andes.

564   Figure 1. Spatial distribution of $\delta^{18}O_p$ and δ^2H_p observations in the central Andes (a) and this
565   study (b). No previous studies have reported $\delta^{17}O_p$ from this region.

566

567   Figure 2. Mean 1989-2019 seasonal climatologies of the central Andes from ERA5 reanalysis
568   data (Hersbach et al., 2020). Panels a and b show 850 hPa winds (vectors, m/s) and total daily
569   precipitation (mm/day); c and d show 200 hPa winds (vectors, m/s) and total column rainwater
570   (kg/m^2). The panels highlight summer (a and c) and winter (b and d) conditions. The geographic
571   bounds of the central Andes are noted with a dotted box in b.

572

573   Figure 3. Semimonthly precipitation (colored by site) $\delta^{18}O$ versus δ^2H (a) and $\delta'^{18}O$ versus $\delta'^{17}O$
574   (b) with respect to the $\delta^{18}O$-δ^2H (Craig, 1961) and $\delta'^{18}O$-$\delta'^{17}O$ (Luz and Barkan, 2010) meteoric
575   water lines, respectively. Panel b contains a subset of 32 samples from panel a.

576

577   Figure 4. Timeseries of semimonthly $\delta^{18}O_p$ (‰; a, b) and d-excess$_p$ (‰; c, d) from June 2016
578   through May 2019. Gray vertical bars indicate the rainy season (DJFM). For clarity, the data are
579   separated into Eastern and Altiplano sites (a, c) and Western sites (b, d) and are colored by site
580   location. Eastern and Altiplano sites received dry season precipitation; western sites typically did
581   not. Missing data indicate rain did not fall during the collection period or the observer did not
582   collect a sample.

583

584   Figure 5. Elevation profile along the A-B-C transect (a) and spatiotemporal variability of average
585   amount-weighted rainy season $\delta^{18}O_p$ (b) and d-excess$_p$ (c) in southern Peru. Blue sites fall on or
586   near the elevation profile; an elevation profile through the yellow sites is not shown, but the
587   dominant topographical features through these sites are the same as those along the A-B-C
588   transect. In b and c, the filled circles represent the multiyear average $\delta^{18}O_p$ and d-excess$_p$ values,
589   respectively; the open symbols show data from 2017 (square), 2018 (diamond), and 2019
590   (triangle). Relatively invariant d-excess$_p$ values and an inverse elevation-$\delta^{18}O_p$ relationship point
591   to Rayleigh distillation on both flanks from eastern and western-derived air masses.

592

593   Figure 6. Scatterplots of central Andean amount-weighted wet season $\delta^{18}O_p$, d-excess$_p$, and
594   $\Delta'^{17}O$ variation with elevation (a, d, g), MAP (b, e, h), and latitude (c, f, i). In panels a through f,
595   color differentiates $\delta^{18}O_p$ references, the solid black line shows the best fit linear regression
596   through data from all studies, and the dotted line shows the best fit linear regression through data
597   from this study. In panels g through i, shape differentiates references and color differentiates
598   water type.

599

600   Figure 7. Scatterplots of $\delta'^{18}O$ versus $\Delta'^{17}O$ (a), $\delta^{18}O$ versus d-excess (b), and d-excess versus
601   $\Delta'^{17}O$ (c) from this study (filled circles) and published precipitation (open circles) and surface
602   waters (open diamonds) in the tropics and mid-latitudes. The open black diamonds show surface
603   water data from the central Andes (Aron et al., 2021; Surma et al., 2018; Voigt et al., 2021). The
604   open gray diamonds show surface water data from locations other than the central Andes
605   (Affolter et al., 2015; Bergel et al., 2020; Bershaw et al., 2020; Gázquez et al., 2017; Li et al.,
606   2017; Luz & Barkan, 2010; Nava-Fernandez et al., 2020; Passey & Ji, 2019; Surma, et al., 2015;
607   Tian et al., 2021). The open circles show precipitation data (Affolter et al., 2015; Gázquez et al.,
608   2017; Landais et al., 2010; Luz & Barkan, 2010; He et al., 2021; Surma et al., 2018; Tian et al.,
609   2021; Tian & Wang, 2019; Uechi & Uemura, 2019). Error bars on $\Delta'^{17}O$ show the standard

610 deviation of multiple replicate analyses of each sample. There are more points in a than b or c
611 because some published $\Delta'^{17}O$ studies do not include δ^2H data.
612
613 Figure 8. Timeseries of eastern (filled symbols) and western (open symbols) moisture flux ratios
614 at San Gaban (a), Santo Tomas (b), Ayaviri (c), Cotahuasi (d), Ubinas (e), Majes (f), and
615 Moquegua (g). The points represent the ratio of eastern versus western moisture at each site
616 determined from atmospheric back trajectories and the Sodemann et al. (2008) humidity tracer.
617 The yellow points were calculated from trajectories initiated on every day of the study period;
618 the blue points were calculated with trajectories only from rainy days only. Gray vertical bars
619 indicate the DJF rainy seasons.
620
621 Figure 9. Timeseries of monthly $\delta^{18}O_p$ (a), d-excess$_p$ (b), and precipitation (c) from this study
622 (circles), Fiorella et al., 2015a (triangles), and Guy et al., 2019 (squares) colored by site-specific
623 elevation. Vertical gray bars mark the DJFM rainy season.
