## Abstract

200 words maximum

The industrial Haber-Bosch process for the production of ammonia ( $\text{NH}_3$ ) is crucial for modern society. The process has significant drawbacks, as it is highly energy intensive due to the inherent challenge of activating  $\text{N}_2$ , not sustainable due to substantial  $\text{CO}_2$  emissions, and requires large-centralized facilities. New strategies of sustainable  $\text{N}_2$  fixation, such as low-temperature thermochemical catalysis and (photo)electrocatalysis, have been pursued over the past few decades, but progress has been hindered by the lack of rigor and reproducibility in the collection and analysis of results. In this Primer, we provide a holistic step-by-step protocol, applicable to all nitrogen-transformation reactions, focused on verifying genuine  $\text{N}_2$  activation by accounting for all contamination sources. We compare state-of-the-art results from different catalytic reactions following the protocol's framework, and discuss necessary reporting metrics and ways to interpret both experimental and density functional theory results. This Primer covers various common pitfalls in the field, best practices to improve reproducibility and rigor, and cost-efficient ways to carry out rigorous experimentation. The future of nitrogen catalysis will require an increase in rigorous experimentation and standardization to prevent false positives from appearing in the literature, and help the field advance towards practical technologies for the activation of  $\text{N}_2$ .

## [H1] Introduction

### [H2] Importance of Ammonia for World Population Growth

Nitrogen is essential to all forms of life, and constitutes ~78 % of air in the form of dinitrogen ( $\text{N}_2$ ). However, the formidable strength of the  $\text{N}\equiv\text{N}$  triple bond (9.79 eV)<sup>1</sup> makes  $\text{N}_2$  fixation into biologically-available forms extremely difficult<sup>2</sup>.  $\text{N}_2$  fixation in nature occurs in two ways. Lightning can convert  $\text{N}_2$  in air to nitrous oxides ( $\text{NO}_x$ )<sup>3</sup>. More dominantly, nitrogenase enzymes can catalyze  $\text{N}_2$  reduction to ammonia ( $\text{NH}_3$ ) by a multi-electron transfer process. The latter process involves the hydrolysis of at least 16 equivalents of adenosine triphosphate (ATP) to produce 2 molecules of  $\text{NH}_3$  and at least 1 molecule of dihydrogen ( $\text{H}_2$ ), performing at up to 65% selectivity at 1 atm  $\text{N}_2$  in the absence of  $\text{N}_2\text{O}$  inhibitors<sup>4,5</sup>. Yet, biological  $\text{N}_2$  fixation is kinetically slow due to reliance on electron tunnelling<sup>6</sup> and is insufficient to sustain intensive modern agricultural practices<sup>7</sup>.

Prior to industrial production of  $\text{NH}_3$  by the Haber-Bosch process, natural fertilizers came in the form of caliche from Chile and guano from Peru<sup>8</sup>. In 1898, Sir William Crookes warned mass starvation as the biggest challenge of the 20<sup>th</sup> century<sup>9</sup>, instigating the burgeoning interest in industrial  $\text{N}_2$  activation. In 1903, the Birkeland-Eyde process became commercial<sup>7</sup>, utilizing electric arcs to fix atmospheric  $\text{N}_2$  into nitric acid ( $\text{HNO}_3$ ), based on a method used by Henry Cavendish in 1784<sup>10</sup>. In 1908, Fritz Haber managed to synthesize  $\text{NH}_3$  from  $\text{N}_2$  and  $\text{H}_2$  ( $\text{N}_{2(\text{g})} + 3\text{H}_{2(\text{g})} \rightleftharpoons 2\text{NH}_{3(\text{g})}$ ,  $\Delta G^\circ = -32.9 \text{ kJ/mol}$ <sup>11</sup>, eq. 1) on a table-top machine, but it suffered from remarkably slow kinetics under standard temperature and pressure<sup>8</sup>. To boost the formation rate of  $\text{NH}_3$  and tilt the equilibrium, Haber increased both temperature and pressure over an Os catalyst<sup>7</sup>. Subsequently, BASF bought the invention and Carl Bosch up-scaled the production in 1913<sup>7</sup> to the currently known Haber-Bosch process, which operates at 400-450 °C and 150-250 bar over a multi-promoted fused Fe catalyst<sup>12</sup>. A more active Ru-based supported catalyst was later developed, but was not as widely adopted due to cost and stability drawbacks<sup>13</sup>. Gerhard Ertl elucidated the molecular details of the catalytic  $\text{N}_2$  reduction to  $\text{NH}_3$  over Fe, enriching mechanistic understanding of the system<sup>14</sup>, and received a Nobel Prize in 2007 (Figure 1).

Today industrial  $\text{NH}_3$  production by the Haber-Bosch process is the backbone of modern society and is responsible for the population boom in the 20<sup>th</sup> century<sup>15-17</sup>. Current annual  $\text{NH}_3$  production exceeds 180 million metric tonnes<sup>18</sup> (Mt) globally, and its primary use is artificial fertilizers (~80 %<sup>19</sup>), sustaining two fifths of the global population<sup>20</sup>. Additionally,  $\text{NH}_3$  is the source of every N atom in all synthetic chemicals<sup>21</sup>, a key reactant in the chemical industry<sup>22</sup>, and a potential hydrogen energy carrier<sup>23,24</sup>. However,  $\text{NH}_3$  production from the Haber-Bosch process is energy and emission intensive. Nearly all the required energy and emissions in  $\text{NH}_3$  production originate from the generation of  $\text{H}_2$ , most commonly from natural gas via steam-methane reforming<sup>25</sup> ( $0.75\text{CH}_{4(\text{g})} + 1.5\text{H}_2\text{O}_{(\text{l})} \rightleftharpoons 3\text{H}_{2(\text{g})} + 0.75\text{CO}_{2(\text{g})}$ ,  $\Delta G^\circ = +98.0 \text{ kJ/mol}$ <sup>11</sup>, eq. 2). For the methane-fed process,  $\text{NH}_3$  production has a theoretical minimum energy input of 22.2 GJ/ $\text{t}_{\text{NH}_3}$  along with the stoichiometric emission 1.2  $\text{t}_{\text{CO}_2}/\text{t}_{\text{NH}_3}$ <sup>12</sup>. In comparison, modern  $\text{NH}_3$  production plants using the best available technology consume 28-33 GJ/ $\text{t}_{\text{NH}_3}$  and emit 1.6  $\text{t}_{\text{CO}_2}/\text{t}_{\text{NH}_3}$ <sup>12,25</sup> (although the global average is 2.9  $\text{t}_{\text{CO}_2}/\text{t}_{\text{NH}_3}$ <sup>26</sup> due to the use of coal and oil-based feedstocks<sup>12</sup>). At >180 Mt annually, global  $\text{NH}_3$  production therefore consumes about 1% of total world energy and emits 1.4% of global  $\text{CO}_2$  emissions<sup>25,27</sup>. Implementation of  $\text{CO}_2$  sequestration processes or other carbon offsets can reduce emissions but will add cost, plant complexity, and energy losses<sup>28</sup>. Reducing reliance on fossil fuels to address climate change challenges calls for sustainable alternatives for  $\text{NH}_3$  production.

## [H2] Concepts and challenges to decarbonize N<sub>2</sub> activation

Replacing the generation of H<sub>2</sub> by steam-methane reforming with renewable water splitting ( $3\text{H}_2\text{O}_{(l)} \rightleftharpoons 3\text{H}_{2(g)} + 1.5 \text{O}_{2(g)}$ ,  $\Delta G^\circ = +711.4 \text{ kJ/mol}^{11}$ , eq. 3) can eliminate CO<sub>2</sub> emissions associated with the Haber-Bosch process<sup>29</sup>, referred to as Gen 2 (Figure 1), resulting in an energy expenditure of  $\Delta G^\circ = +678.5 \text{ kJ/mol}^{11}$  for  $\text{N}_{2(g)} + 3\text{H}_2\text{O}_{(l)} \rightleftharpoons 2\text{NH}_{3(g)} + 1.5 \text{O}_{2(g)}$  (eq. 4). Operating the Haber-Bosch at reduced temperatures and pressures and coupling with renewable H<sub>2</sub> production via water electrolysis could make NH<sub>3</sub> production sustainable and reduce capital cost via smaller, local reactors. However, several major challenges need to be addressed<sup>30</sup>, including: synthesizing NH<sub>3</sub> at milder conditions (pressures of 20-40 bar) to cope with the intermittent and low-pressure influent of H<sub>2</sub> from water electrolysis; sustainable separation of pure N<sub>2</sub> from air, as N<sub>2</sub> is presently separated from O<sub>2</sub> by combustion of unreacted methane; and the discovery of low-temperature thermochemical catalysts to achieve high yield per pass at moderate pressures.

Electrochemical reduction of N<sub>2</sub> and H<sub>2</sub>O to make NH<sub>3</sub> is appealing, as NH<sub>3</sub> can be synthesized directly at the point of consumption, eliminating transportation cost and emissions and reducing issues of excess fertilizer run-off<sup>31,32</sup>. The energy expenditure of  $\Delta G^\circ = +678.5 \text{ kJ/mol}_{\text{N}_2 \text{ fixed}}$  (eq. 4) or 19.9 GJ/t<sub>NH<sub>3</sub></sub> for such process can be provided by using (photo)electrochemical systems powered by solar or wind (Gen 3, see Figure 1). This process can be made sustainable and economical,<sup>33,34</sup> where 40 m<sup>2</sup> of state-of-the-art solar cells operating at 20% efficiency are required to meet the average nutrient requirement of 100 kg of fixed nitrogen (expressed as monatomic N) per hectare of land per year, by assuming 5% electrical-to-NH<sub>3</sub> efficiency (the calculation neglects upstream and downstream separations, see Supplementary Information for details). The current densities will need to be comparable to those of the state-of-the-art electrolyzers to keep down capital costs; the US Department of Energy have a target<sup>35</sup> of 300 mA cm<sup>-2</sup><sub>geo</sub> at 90% Faradaic efficiency.

The reduction of N<sub>2</sub> can also be facilitated by non-thermal plasmas, where vibrational excitations of ground-state N<sub>2</sub> via collision with high-energy electrons can decrease the N<sub>2</sub> activation barriers<sup>36</sup>. Typically, microwave and dielectric barrier discharge (DBD) reactors have been used, where the NH<sub>3</sub> synthesis rate can be increased through heterogeneous catalysis<sup>37</sup>. Kim *et al.* have reported among the highest energy efficiencies of 25-35 g<sub>NH<sub>3</sub></sub> kWh<sup>-1</sup> (100-140 GJ t<sub>NH<sub>3</sub></sub><sup>-1</sup>) using a DBD reactor and promoted Ru catalyst<sup>38</sup>, but the challenges lie in the uncompetitive energy efficiency compared to commercial Haber Bosch (28-33 GJ t<sub>NH<sub>3</sub></sub><sup>-1</sup>) and NH<sub>3</sub> decomposition<sup>39</sup>. Additionally, recent reports suggest a mechanocatalytic method of NH<sub>3</sub> synthesis under (near) ambient conditions<sup>40,41</sup>, by ball-milling the catalysts under N<sub>2</sub> and subsequently introducing H<sub>2</sub>, showing early promise of comparable energy efficiency to the Haber-Bosch<sup>40</sup>.

Electrochemical oxidation of N<sub>2</sub> by electrolysis to fixate N<sub>2</sub> ( $\text{N}_{2(g)} + \text{H}_2\text{O}_{(l)} + 2.5\text{O}_{2(g)} \rightleftharpoons 2\text{HNO}_{3(aq)}$ ,  $\Delta G^\circ = +87.7 \text{ kJ/mol}$ , eq. 5) expends much less energy than  $\Delta G^\circ = +678.5 \text{ kJ/mol}$  for the reductive counterpart (eq. 3). Such processes can in principle replace the synthesis of NH<sub>3</sub> and subsequent oxidation of NH<sub>3</sub> by the Ostwald Process ( $2\text{NH}_{3(g)} + 4\text{O}_{2(g)} \rightleftharpoons 2\text{HNO}_{3(aq)} + 2\text{H}_2\text{O}_{(l)}$ ;  $\Delta G^\circ = -590.8 \text{ kJ/mol}^{11}$ , eq. 6) for the production of nitric acid, a primary commodity chemical of oxidized N<sub>2</sub><sup>42</sup>. The remarkable difference in the energy expenditure for N<sub>2</sub> fixation between reduction and oxidation can be noted clearly by standard potentials of electrochemical half-cell reactions plotted on the standard hydrogen electrode (SHE) scale and also on the absolute electron energy scale referenced to the free electron in vacuum<sup>43</sup>, as shown in Figure 2a. The standard potential for N<sub>2</sub> reduction ( $\text{N}_{2(g)} + 6\text{H}^+ + 6\text{e}^- \rightarrow 2\text{NH}_{3(g)}$ , 0.06 V<sub>SHE</sub>, -4.50 eV) is considerably higher than that of water splitting to generate O<sub>2</sub> ( $2\text{H}_2\text{O}_{(l)} \rightarrow 4\text{H}^+_{(aq)} + \text{O}_{2(g)} + 4\text{e}^-$ , 1.23 V<sub>SHE</sub>, -5.66 eV). The difference indicates the energy need of pumping electron energy from -5.66 eV to -4.50 eV for each electron

transferred, in agreement with standard reaction free energy of +678.5 kJ/mol for  $\text{N}_{2(\text{g})} + 3\text{H}_2\text{O}_{(\text{l})} \rightleftharpoons 2\text{NH}_{3(\text{g})} + 1.5\text{O}_{2(\text{g})}$  (with 6 electrons transferred). On the other hand, standard potential for  $\text{N}_2$  oxidation ( $\text{N}_{2(\text{g})} + 6\text{H}_2\text{O}_{(\text{l})} \rightarrow 2\text{NO}_3^-_{(\text{aq})} + 12\text{H}^+_{(\text{aq})} + 10\text{e}^-$ , 1.24  $\text{V}_{\text{SHE}}$ , -5.68 eV) is very similar to that of water splitting to generate  $\text{O}_2$  ( $2\text{H}_2\text{O} \rightarrow 4\text{H}^+ + \text{O}_2 + 4\text{e}^-$ , 1.23  $\text{V}_{\text{SHE}}$ , -5.67 eV), where minimum energy is required to activate  $\text{N}_2$  and  $\text{H}_2\text{O}$  to make  $\text{NO}_3^-$  from the thermodynamic standpoint.

The most technologically mature form of  $\text{N}_2$  oxidation is the Birkland-Eyde process, where the reaction between  $\text{N}_2$  and  $\text{O}_2$  to form nitric oxide (NO) is assisted by electric arc-generated hot plasma<sup>44,45</sup>. High-temperature thermal plasmas are not energy-competitive<sup>46</sup> and require rapid quenching to prevent NO decomposition back to  $\text{N}_2$ <sup>47</sup>. Researchers are paying increasing attention to the use of warm and cold (non-thermal) plasmas, as its theoretical energy consumption<sup>48</sup> is more than twice lower than that from  $\text{N}_2$  and  $\text{CH}_4$  (eq. 3), yet a technological bottleneck lies in low conversion to product<sup>49</sup>. More recently, a growing number of studies are dedicated to the electron and photon assisted conversion of  $\text{N}_2$  to nitrate ( $\text{NO}_3^-$ )<sup>50–56</sup> but seem to suffer significant kinetic limitations similar to the reductive counterpart.

## [H2] Origin to $\text{N}_2$ activation challenges

Activating  $\text{N}_2$  by reduction to make  $\text{NH}_3$  is kinetically difficult, which demands much more energy than what is needed thermodynamically to drive reactions at high rates to make these processes economical. Catalyzing  $\text{N}_2$  fixation has been limited largely by the cleavage of the  $\text{N}\equiv\text{N}$  bond due to the inertness of  $\text{N}_2$ <sup>2</sup>, i.e. the high triple bond strength (9.79 eV), high ionization potential (15.84 eV), low electron affinity (-1.90 eV), and nonpolarity. Ru is considered the most active elemental heterogeneous catalyst for thermochemical  $\text{NH}_3$  synthesis (i.e. the Haber-Bosch process). The energetics of the possible elementary steps are examined. The free energy profile for an associative mechanism on Ru(0001) terrace, which involves  $\text{N}_2$  bond cleavage via a hydrogenated intermediate (similar to nitrogenase<sup>6</sup>), is shown in Figure 2a. The protonation of adsorbed  $^*\text{N}_2$  to  $^*\text{N}_2\text{H}$  (step 1-2) has the largest thermodynamic barrier (1.02 eV). This is considered rate-limiting and prohibitively slow by invoking the Brønsted–Evans–Polanyi relationship<sup>57</sup>, which linearly correlates the activation barriers to the reaction energies. In contrast Ru(0001) step sites adsorb  $\text{N}_2$  more strongly than terrace sites and the thermodynamic barrier at the step sites for  $^*\text{N}_2$  to  $^*\text{N}_2\text{H}$  is much lower (~0.3 eV). In addition, the process can be understood commonly via a dissociative mechanism<sup>58–60</sup>, where  $\text{N}_2$  is cleaved upon adsorption into atomic N, and then hydrogenated to release  $\text{NH}_3$ . Although downhill in energy, the dissociation of  $\text{N}_2$  to  $2^*\text{N}$  has a significant activation barrier, and is revealed to occur only at step sites due to the prohibitively high activation barrier for  $\text{N}_2$  dissociation on terrace sites<sup>61,62</sup>. Experimentally, the activation barrier on a clean Ru(0001) single crystal (containing step site density of ~1%) is 0.4 eV and increases substantially to 1.3 eV when small amounts of Au, which preferentially decorate the steps, is introduced, thereby showing that the rate of  $\text{N}_2$  dissociation is completely dominated by steps<sup>62</sup>. There are also significant uphill steps for the reduction of  $^*\text{NH}_2$  to  $\text{NH}_{3(\text{g})}$  (step 6-8) at the step sites on Ru(0001), signifying the cost of creating free sites. The apparent activation energy is the sum of both the activation energy of the rate-limiting step and the cost of making free sites in a non-trivial manner<sup>61,63</sup>; this is the origin of the Sabatier principle.

Activating  $\text{N}_2$  by oxidation is equally challenging, and very few systematic investigations on the oxidative  $\text{N}_2$  fixation exist in literature<sup>67,68</sup>. A reasonable starting point would be to consider a series of hydroxylation-deprotonation steps as computed for  $\text{N}_2$  oxidation on rutile  $\text{RuO}_2$  (110)<sup>56</sup> in Figure 2a, which shows  $\text{N}_2$  activation is the most uphill step (1.86 eV), suggesting a substantial kinetic barrier for this reaction.

In interpreting free energy diagrams, an important distinction should be made between electrochemical and non-electrochemical steps. Electrochemical steps, such as those involving proton-electron transfers (i.e. all steps in Figure 2a except for N-N dissociation, adsorption and desorption), are affected by applied potential. The overpotential required to bring the most uphill electrochemical step downhill is plotted in Figure 2b (green) for associative N<sub>2</sub> reduction on transition metal terraces. In addition to the thermodynamic barrier, electrochemical steps can possess an additional barrier. For example, *Singh et al.* calculated the intrinsic electrochemical barrier (at  $\Delta G_{step} = 0$ ) for the  $*N + e^- + H^+ \rightarrow *NH$  step on transition metal terraces to be 0.7 eV regardless of the free energy difference between the two states ( $*N$  and  $*NH$ ), and thus insensitive to the metal identity<sup>66</sup>. We have used an intrinsic barrier of 0.7 eV for all proton-electron transfer steps in Figure 2a. Non-electrochemical steps, such as N-N dissociation (step 0-1 of the dissociative N<sub>2</sub> reduction, Figure 2a), adsorption (step 0-1 of the associative N<sub>2</sub> reduction/oxidation) and desorption (step 7-8 of N<sub>2</sub> reduction), are not affected by applied potential.

A feature of interest is the rate-limiting step, known as the maximum barrier along the reaction pathway whose rate is significantly slower than those of the other elementary steps, thus governing the rate of the overall reaction. The rate constant of the elementary step is given by  $\nu \exp(-\Delta G^\ddagger/k_B T)$  from transition state theory, where the prefactor  $\nu$  equals  $k_B T/h$  ( $\sim 10^{13} \text{ s}^{-1}$  at 25 °C). The rate of reaction for heterogeneous catalysis, expressed in  $\text{mol cm}_{cat}^{-2} \text{ s}^{-1}$ , is connected to the rate constant by multiplying with the concentrations of reactants if the first step is the rate limiting step, or by surface concentrations if the rate limiting step involves surface intermediates. This rate can be converted to the turnover frequency ( $\text{mol site}^{-1} \text{ s}^{-1}$ ) by dividing the site area density of the catalyst ( $\text{sites cm}_{cat}^{-2}$ ), to mass activity ( $\text{mol g}_{cat}^{-1} \text{ s}^{-1}$ ) by multiplying the specific surface area ( $\text{cm}_{cat}^2/\text{g}_{cat}$ ), and to geometric-area-normalized activity ( $\text{mol cm}_{geo}^{-1} \text{ s}^{-1}$ ) by multiplying the roughness factor ( $\text{cm}_{cat}^2/\text{cm}_{geo}^2$ ). To rationalize a catalyst's viability, one can calculate the rate constant to estimate the rate and establish the point at which the barrier becomes prohibitive.

In using the expression of  $\nu \exp(-\Delta G^\ddagger/k_B T)$ , we note that the errors due to the level of theory and a free energy correction of  $\sim 0.25 \text{ eV}$ <sup>67,68</sup> correspond to  $\sim 5$  orders of magnitude in rate. Generally, an active catalyst would have a turnover frequency greater than  $1 \text{ s}^{-1}$ , which corresponds to a barrier of 0.75 eV at room temperature. Therefore, free energy diagrams for electrochemical N<sub>2</sub> fixation under ambient conditions that involve an uphill step greater than 1.5 eV at the operating potential indicate non-viable catalysts, particularly if kinetic barriers have been neglected. However, a more quantitative and accurate description requires higher forms of simulation to capture the system's complexity, such as kinetic Monte Carlo simulation or microkinetic modelling; the latter shown in Figure 2b (red) for the thermochemical route of NH<sub>3</sub> synthesis. For the electrochemical route, we refer readers to ref<sup>66</sup> for the full microkinetic model.

The difficulty of finding catalysts with fast kinetics for N<sub>2</sub> fixation can be explained by the “scaling relations”<sup>69</sup>, where the energetics of different elementary steps shown in Figure 2a cannot be controlled independently on a given surface. Such scaling relations can be manifested in the volcano dependence of catalytic activity on the adsorption energy of surface reaction intermediates. For example, the catalyst activity, computed via mean-field kinetic model of the dissociative mechanism, exhibits a volcano dependence on the N adsorption energy (Figure 2b, red)<sup>69</sup>. On the right side of the volcano for weak-binding surfaces, N<sub>2</sub> dissociation is rate-limiting, while on the left side for strong-binding surfaces there is a low barrier for N<sub>2</sub> dissociation, but the surface is poisoned by N species. Fe, Ru and CoMo alloy exhibit the highest activity and further enhancement can be achieved by using alkali (electronic) promoters<sup>70,71</sup>.

However, efficient, low-pressure Haber Bosch requires more active catalysts beyond the constraints set by the volcano<sup>72</sup>.

Scaling relations also constrain electrochemical N<sub>2</sub> reduction. The overpotential needed to have all the elementary reaction steps downhill for the associative mechanism (Figure 2b, green), exhibit a volcano relationship with the N binding energy on metal surfaces<sup>73,74</sup>. More importantly, electrochemical N<sub>2</sub> reduction in aqueous electrolytes has to compete with electrochemical H<sub>2</sub> evolution as both reactions have similar standard potentials and electron energy on the absolute energy scale (Figure 2a). Unfortunately, the kinetics of water reduction to produce H<sub>2</sub> is much faster than that reduction of N<sub>2</sub> to NH<sub>3</sub>, as seen in the comparatively lower overpotential for H<sub>2</sub> evolution (Figure 2b), translating to many orders of magnitude difference in the estimated rate (Figure 2b, green). In addition, the bond strength of any given metal surface to H (a sole intermediate of H<sub>2</sub> evolution) is stronger and linearly correlates with N-containing intermediates of N<sub>2</sub> reduction<sup>33</sup>, indicates that the surface will be poisoned by \*H<sup>75</sup>, likely responsible for negligible NH<sub>3</sub> reported in aqueous systems<sup>76,77</sup>. A study on wider N<sub>2</sub> electrooxidation trends are unavailable, but we expect a similar scaling relation between the reactant activation and subsequent hydroxylation or desorption steps, and scaling with \*O<sub>2</sub> intermediates of the competing O<sub>2</sub> evolution.

Alternative strategies have been explored to overcome the activity and selectivity challenges in N<sub>2</sub> reduction. In thermochemical NH<sub>3</sub> catalysis, Chen *et al.* have demonstrated excellent activities using transition metal-LiH composite catalysts, where two active centers are present; transition metal sites to cleave the N<sub>2</sub> bond, and LiH to aid N hydrogenation and subsequent NH<sub>3</sub> desorption<sup>78</sup>. In electrochemical NH<sub>3</sub> synthesis, the lithium-mediated approach has emerged, where the N<sub>2</sub> reacts with metallic Li to form Li<sub>3</sub>N, followed by nitride protonation to evolve NH<sub>3</sub>, including continuous lithium-mediated N<sub>2</sub> reduction in non-aqueous solvents<sup>79-82</sup> or a lithium-nitride cycling scheme<sup>83,84</sup> (Figure S2, see Supplementary Information). The Li-mediated approach has decoupled reactant activation and subsequent protonation steps, where the non-aqueous solvents and the in situ formation of protective solid-electrolyte-interphase (SEI) layer restrict proton availability to the active site<sup>82,83</sup>, potentially responsible for the high yields.

## [H2] The need for a strict protocol

Progress in (photo)electrochemical N<sub>2</sub> fixation can benefit from developing a more rigorous protocol of measurements and product quantification, as state-of-the-art yields of NH<sub>3</sub> (and NO<sub>3</sub><sup>-</sup>) from these processes are significantly lower than thermochemical NH<sub>3</sub> production (see Results.) while contamination (possible sources summarized in Table 1) can be present at similar or greater concentration levels than the measured product<sup>76</sup>. In addition, the NH<sub>3</sub> yields for low-temperature and/or low-pressure thermal catalysis exponentially drops, and accurate activity measurements can suffer from adventitious N contamination, N and/or H leaching, and non-catalytic NH<sub>3</sub> generation<sup>85</sup>, where such uncertainties in catalytic activity measurements can propagate into subsequent kinetic analyses.

The field has been plagued with false positives. The first observation of electrochemical N<sub>2</sub> fixation was in 1807 by Sir Humphry Davy, who reported production of NH<sub>3</sub> and HNO<sub>3</sub> by passing current through distilled water<sup>86</sup>, but was proven non-reproducible some 90 years later<sup>87</sup>. In 1995, Boucher *et al.* demonstrated inability to reproduce reported photochemical NH<sub>3</sub> synthesis using TiO<sub>2</sub> under rigorous measurements<sup>88</sup>. More recently, Shipman *et al.* retested Sn(II) phthalocyanine catalysts in 2017 for electrochemical N<sub>2</sub> reduction, concluding that the NH<sub>3</sub> measured arose from decomposition of their catalyst<sup>89</sup>. Litch *et al.* retracted their work on nanoscale Fe<sub>2</sub>O<sub>3</sub> in molten hydroxide from *Science* in 2020, citing adventitious NH<sub>3</sub>

synthesis from trace  $\text{NO}_x^-$  contaminants in their electrode material. MacFarlane, Simonov, and coworkers retested and reported no electrochemical activity for  $\text{VN}^{90}$ , and Bi and Au catalysts<sup>91</sup>, reported previously to have high activity<sup>92–94</sup>, after accounting for N leeching from the VN catalyst and properly cleaning the supplied  $\text{N}_2$  gas for  $\text{NH}_3$  and  $\text{NO}_x$  impurities.

The ubiquity of contamination sources calls for an exceptional scrutiny. In this Primer, we introduce a general protocol focused on confirming genuine activation of inert  $\text{N}_2$  and elaborate details in performing catalytic measurements (Experimentation). We then evaluate state-of-the-art results, primarily focused on (photo)electrochemical and thermochemical systems using the protocol's framework and discuss best practices in reporting and interpreting both experimental and DFT data (Results). The potential uses of these  $\text{N}_2$  activation reactions is discussed in the context of current practices, highlighting the importance of research in these areas (Applications), and we explore factors affecting reproducibility, thereby establishing reporting standards (Reproducibility and Data Deposition). Finally, we discuss ways to overcome cost-limitations of performing repeated isotope-labelled experiments (Limitations and Optimizations) and outline future directions in  $\text{N}_2$  catalysis research including community-wide adoption of rigorous protocol, in situ measurements for mechanistic understanding and field-specific needs (Outlook).

## [H1] Experimentation

A general protocol for carrying out electrochemical, photo(electro)chemical, and thermochemical  $\text{N}_2$  activation experiments is presented, which can be extended to apply across all  $\text{N}_2$  activation fields. This is followed by an in-depth discussion of the experimental setups and necessary measurements, and various different methods of product detections to determine successful product synthesis.

### [H2] General protocol for $\text{N}_2$ reduction and oxidation reactions

We propose a general protocol shown in Figure 3, to holistically account for various contamination sources, applicable to any  $\text{N}_2$  activation reactions, which is based on the principle that one should always be wary of contamination.

The first step involves the experiment setup and it is run with  $\text{N}_2$ . If no product is measured, re-iterations with new parameters or catalysts is necessary, until the desired product is detected. Next, one must measure or estimate the total equivalent N mass of the system,  $mass_{sys}$ , to account for possible contamination sources, which includes  $mass_{N,cat}$ ,  $mass_{N,electrolyte}$ ,  $mass_{N,absorber}$  and  $mass_{N,gas}$ . Precise definitions of these terms are outlined in Box 1.

For successful synthesis, the amount of N in the product measured must exceed the amount of N in  $mass_{sys}$  by a factor of 2 ( $mass_{prod} > 2 mass_{sys}$ ) to account for unexpected sources of contamination, and one must in this case ensure that  $mass_{prod}$  is well above  $mass_{N,cat}$ . The product concentration ( $C_{prod}$ ) in the electrolyte or gas stream must be higher than 100 ppm, based on olfactory detection of  $\text{NH}_3$ , to exclude unaccounted sources of contamination (e.g. glassware, breath, laboratory air, etc.), as the reported yield above 100 ppm would easily be detectable by olfaction<sup>95</sup>, and far greater than common source of contamination in the lab.

If both these criteria are met, repeated testing is necessary with independently prepared samples to confirm reproducibility. If these criteria were not met, the measured yield of product might stem from contamination, and further evidence of successful synthesis via quantifiable isotope-labelling experiments is necessary. First, one must test using an inert gas (e.g. Ar or pure  $\text{H}_2$ ) and  $\text{N}_2$  in the absence of driving

force. These conditions can range from operating an open circuit potential for electrochemical systems, under dark illumination for photo(electro)chemical systems, or without applied heat for thermochemical systems, which is essential to account for sources of contamination in the experimental set-up, as this should give no or significantly less product compared to  $N_2$  with a driving force. Repeated identical testing of independently prepared batches follows, to ascertain reproducibility, and determine the level of inherent contamination in the system (if any). Additionally, a stability test is needed to eliminate the possibility of non-catalytic generation of the product, such as N-leeching from an N-containing catalyst. Once all sources of contamination were accounted for, quantitative isotopic labelling experiments is necessary. In detecting the product, two separate quantification techniques must be used, where at least one of them is isotopically sensitive, and these two methods must show repeated and reproducible overlap between the use of  $^{14}N_2$  and  $^{15}N_2$  over multiple points (see Results). It is important to include a proper gas cleaning procedure, as isotope labelled  $^{15}N_2$  gas can contain significant amounts of  $NO_x$  and  $NH_3$  impurities<sup>96</sup>.

In thermal catalysis, kinetics parameters, such as activation energy and reaction orders in the kinetic regime, are a key metric to report. It is important that the kinetics measurements are carried out far from the equilibrium to avoid the reaction reversing, where mass and heat transfer limitations are minimized. Kinetic measurements to extract activation energy and reaction orders are extremely beneficial for elucidating the reaction mechanism. In particular, the effect of  $NH_3$  concentration on the reaction orders and the apparent activation energy must be accounted for (see Results). Electrochemical and photo(electro)chemical systems can also benefit from kinetic measurements, although this is not common in the literature. These measurements are difficult to obtain, as reliable determination of the partial current density toward  $NH_3$  for a given system might be highly inaccurate, due to a historic contamination issues in the field. With rigorous experimentation, measuring parameters such as the pH dependence of the  $N_2$  reduction activity might provide insights on the reaction path and mechanism<sup>97</sup>. The only published and proven work reporting kinetic measurements have investigated the effect of proton and  $N_2$  concentration and their respective reaction orders in the lithium-mediated system<sup>81</sup>. In addition, Tafel analysis can be a powerful tool for elucidating rate determining steps, but overly simplified assumptions will lead to inaccurate description of the electrocatalysis<sup>98</sup>, and researchers should apply caution when interpreting Tafel slopes as they may contain many artefacts<sup>99</sup>. Furthermore, when including kinetic measurements, great care should be taken with reporting a clear definition of the kinetic parameters and kinetic models used<sup>100</sup>.

## [H2] Experimental setup

### [H3] Electrochemical measurements

Electrochemical measurements are typically conducted in a cell setup as depicted in Figure 4a, into which gas streams are introduced. As feed gases ( $Ar$ ,  $^{14}N_2$ , and  $^{15}N_2$ ) can contain significant amounts of activated N-species (such as  $NH_3$ ,  $NO_x$  and  $N_2O$ ) as contaminants<sup>96,101</sup>, the gas must be cleaned prior to use, using a reduced Cu catalyst and freeze trap<sup>76</sup> or commercial gas purifiers. One can also chose to not clean the gas, but measure all the N-containing contaminants, and include them in the value for  $mass_{N,gas}$ . In the electrochemical cell, depending on the desired reaction, the working electrode (WE) will either facilitate  $N_2$  reduction or oxidation, while the counter electrode (CE) runs the respective counter reaction, and the reference electrode (RE) determines the potential at the surface of both other electrodes. In aqueous electrolytes, numerous commercial REs are available<sup>102</sup> and should be calibrated against the reversible hydrogen electrode (RHE) by measuring the equilibrium potential for  $H_2$  oxidation and evolution on a Pt electrode. Alternatively, a well-known RE such as saturated calomel electrode (SCE) in aqueous electrolytes, or Li in non-aqueous electrolytes can be utilized, with a conversion to RHE. Calibrating the RHE in non-aqueous electrolytes can be challenging<sup>103</sup>, but is possible, since the  $H_2$  oxidation and evolution

potential is measurable for lithium-mediated  $\text{N}_2$  reduction<sup>80</sup>. When measuring  $\text{N}_2$  reduction in non-aqueous electrolytes, researchers can use the same REs as those used in the battery literature, such as metallic Li<sup>104</sup>, and calibrate the RE to the RHE scale in their electrolyte of choice in a separate measurement.

As activated N-species is ubiquitous in the environment, electrochemical and photo(electro)chemical systems are prone to contamination. Possible sources of contamination are shown in Table 1, along with a recommended method of elimination. Specifically, the commonly used Nafion membrane has been shown to contaminate the setup<sup>76,105,106</sup> and degrade in the presence of  $\text{NH}_3$ <sup>107,108</sup>, so extra care must be taken if using this membrane. Control experiments, such as testing using Ar with a driving force and  $\text{N}_2$  without a driving force with time-dependent experiments, are needed. All adventitious sources of activated  $\text{N}_2$  can be avoided by the use of purified isotopically labelled  $^{15}\text{N}_2$ , and the subsequent measurement of  $^{15}\text{NH}_3$  or  $^{15}\text{NO}_x$  by an isotope sensitive method<sup>76,77</sup>. Liquid samples from the electrolyte should be investigated, repeated for reproducibility, and quantified via at least two separate methods, and the yield produced using  $^{15}\text{N}_2$  must be comparable to the yield measured with  $^{14}\text{N}_2$ .

Chronopotentiometric (CP) and/or chronoamperometric (CA) measurements show the stability of the system over time, and representative data for these should be reported, with a description of whether Ohmic correction is utilized. Once the synthesized product is detected (see Experimentation), the product yield and Faradaic efficiency can be calculated as a function of potential vs RHE, enabling the determination of the optimum for each of these factors in the system. Moreover, the difference between the operating potential and the equilibrium voltage approximates the overpotential, a critical figure-of-merit. The overpotential for  $\text{N}_2$  reduction to  $\text{NH}_{3(\text{g})}$  is pH and electrolyte independent. The Nernstian shift in the equilibrium potential occurs due to a change in product and reagent concentrations that affect the overall pH of the solution, and can be taken into account via the actual amount of  $\text{NH}_3$  produced. Relative to standard conditions, the equilibrium concentration of  $\text{NH}_{3(\text{aq})}$  or  $\text{NH}_4^+_{(\text{aq})}$  can be determined by thermodynamic data (solvation energy) or measured directly via NMR<sup>109</sup>. At pH = 0 the difference between the standard equilibrium potential  $\text{N}_{2(\text{g})}/\text{NH}_4^+_{(\text{aq})}$  is 0.27 V vs RHE, while at pH = 14 the standard equilibrium potential of  $\text{N}_{2(\text{g})}/\text{NH}_{3(\text{aq})}$  is ~0.1 V vs RHE<sup>11</sup>. However, this Nernstian shift is insignificant when there is a large overpotential for  $\text{N}_2$  reduction, such as the case of non-aqueous lithium-mediated  $\text{NH}_3$  synthesis.

### [H3] Thermochemical measurements

Thermochemical measurements are usually conducted in a fixed-bed flow system as shown in Figure 4b, where the catalyst is loaded into the reactor and pretreated under specified conditions. The reactant gases ( $\text{N}_2$  and  $\text{H}_2$ ) are passed over the catalyst bed with a certain space velocity, where the reaction rates are not limited by gas transport. The reactant gases may need purification by in-line gas purifiers to reduce the content of impurities (e.g.  $\text{H}_2\text{O}$ ,  $\text{O}_2$ ,  $\text{CO}_2$ ) to ppt-level, as these might affect the surface of the active catalyst e.g. via poisoning. The measurements should be conducted under steady-state conditions as a function of temperature and pressure. The produced  $\text{NH}_3$  is typically trapped in a downstream diluted sulfuric acid solution, which is then quantified by using ion chromatography or a conductivity meter (see Experimentation). Once the amount of produced  $\text{NH}_3$  is determined, the related kinetic parameters (e.g.,  $\text{NH}_3$  synthesis rate and yield) can be obtained.

Reactors made of stainless steel are commonly employed for pressurized reactions. Transition metals (e.g. Fe, Cr, Ni) in the reactor may not be inert, and could interfere in the  $\text{NH}_3$  synthesis through interacting with the catalyst. It is recommended to use a reactor made of, or lined with, inert material such as quartz to

exclude the contribution of a “reactive reactor”<sup>110</sup>. A blank test (without catalyst loading) should be performed prior to catalyst evaluation, to make sure there is no detectable NH<sub>3</sub> contamination present in the system. In addition, benchmark catalysts, such as Cs-promoted Ru/MgO should be prepared and tested, with an activity comparable to that previously reported (Cs–Ru/MgO with 3–6 wt.% Ru loading should have an NH<sub>3</sub> formation rate from 8–14 mmol g<sub>cat</sub><sup>-1</sup> h<sup>-1</sup> at 400 °C and 10 bar)<sup>111–113</sup>. These two experiments are important for validating the testing system.

## [H2] Product detection and Isotope Labelling

### [H3] Non-isotopic product detection

**UV-Vis spectroscopy** allows the fast and easy quantification of NH<sub>3</sub> through the colorimetric reactions of either indophenol blue or Nessler’s reagents, with a limit of detection down to 10 ppb (~0.5 μM) NH<sub>3</sub> (Figure 5 a, b). The method induces a chemical reaction between NH<sub>3</sub> and the reagents of choice, leading to the formation of a colorful dye that is quantifiable via UV-vis spectroscopy with a peak value at 625 nm for indophenol blue and 425 nm for Nessler’s reagents<sup>114</sup>. Despite the simplicity of these techniques, interferences in the chemical reaction forming the colorful dye may be caused by the presence of different ions in the media (Fe<sup>3+</sup>, Co<sup>2+</sup> to S<sup>2-</sup>, etc.), the reaction time, and diverse pH conditions, which may impede accurate quantification of NH<sub>3</sub><sup>115</sup>. Nevertheless, some of these can be overcome by e.g. utilizing Seignette reagent (also known as Rochelle salt), which allows the analysis of samples with high salinity<sup>116</sup>. The salicylate method (similar in principle to indophenol) is also commonly used to detect NH<sub>3</sub>. Recently, Giner-Sanz *et al.* show a convenient methodology to correct the effect of strong Fe III interference by using an interference model requiring only three experimental curves<sup>117</sup>.

The Griess assay is widely adopted for the quantification of NO<sub>2</sub><sup>-</sup>. To quantify NO<sub>3</sub><sup>-</sup>, the sample can be reduced to NO<sub>2</sub><sup>-</sup> using Zn powder<sup>118</sup>. However, the Griess method suffers from a comparatively high limit of detection of 500 ppb (~10 μM), and interferences with Fe<sup>3+</sup>, Cu<sup>2+</sup>, S<sup>2-</sup> or I<sup>-</sup>, and should be used with caution.

**Conductivity meter** provides a facile and widely adapted method in thermochemical reactions for quantifying NH<sub>3</sub> in a limit of detection of 1 ppm (Figure 5a, c). The concentration of NH<sub>3</sub> from the outlet gas trapped in a diluted sulfuric acid solution can be determined by measuring the decrease in ion conductivity (corresponding to the conversion of H<sup>+</sup> to NH<sub>4</sub><sup>+</sup>) of the solution. A correlation/calibration curve of the change of conductivity and the amount of NH<sub>3</sub> produced should be determined under a given temperature and concentration of the solution. As both of these parameters have strong influences on the ion conductivity in the solution<sup>119</sup>, it is important to maintain a constant temperature and concentration of the solution in each measurement.

### [H3] Isotopic Product detection

**Nuclear Magnetic Resonance (NMR)** is a useful technique for determining the chemical composition of a sample, and can accurately detect NH<sub>3</sub> down to 50 ppb (~3 μM), as shown in Figure 5a, d. It utilizes the magnetic properties of nuclei with non-zero spin and non-zero magnetic dipole moment. The sample composition can be determined based on the characteristic radio frequency (RF) pulse required for the excitation of the nuclei<sup>120</sup>. As the area of the signal is proportional to the number of nuclei affected by the applied RF pulse, the concentration of the sample can be inferred based on calibration curves. <sup>1</sup>H NMR can be used to differentiate isotopes of <sup>14</sup>NH<sub>3</sub> and <sup>15</sup>NH<sub>3</sub>. Due to the difference in spin between <sup>14</sup>N and <sup>15</sup>N, the scalar interaction of <sup>1</sup>H will lead to respectively a triplet peak with a characteristic spacing of 52 Hz, and a

doublet peak with a splitting of 73 Hz. For non-aqueous systems, the use of organic solvents might interfere with the detection of the  $\text{NH}_3$  signal, however, different methods for solvent signal suppression are reported in the literature<sup>76,121</sup>.

The quantification of  $^{14}\text{NO}_3^-$  and  $^{15}\text{NO}_3^-$  can be performed using N-NMR, but the low production yield of the experiment, coupled with the unfavorable NMR properties of  $^{15}\text{N}$  (i.e. low gyromagnetic ratio and long T1 relaxation constants)<sup>122</sup>, implies that long-duration electrochemical experiments must be performed to allow reproducible quantification at multiple points. One study covering  $\text{N}_2$  oxidation has used  $^{15}\text{N}$ -NMR<sup>56</sup>, requiring >100 ppm concentration of  $\text{NO}_3^-$  for detection, which was achieved via a 50 hour experiment. Finding a more convenient isotopic  $\text{NO}_3^-$  detection method is therefore a gap that must be addressed to enable development in the field of electrochemical  $\text{N}_2$  oxidation.

## [H1] Results

A state-of-the-art overview of the electrochemical, photo(electro)chemical, and thermochemical  $\text{N}_2$  activation fields is presented, applying the protocol from the Experimentation section to determine levels of contamination. Important reporting metrics and issues hindering progress in the field is covered in this section, along with interpretation of both experimental and density functional theory results.

### [H2] Evaluation of $\text{N}_2$ Catalysis Experiments

Figure 6a depicts the yields of the product ( $mass_{prod}$ ), namely  $\text{NH}_3$  for  $\text{N}_2$  reduction and  $\text{NO}_3^-$  for  $\text{N}_2$  oxidation, relative to the size of the system from which N-contaminants may originate ( $mass_{sys}$ ). Thermochemical systems typically produce several orders of magnitude more  $\text{NH}_3$  (especially at temperatures >300 °C) compared to  $mass_{sys}$ . As a result, these systems can cross the  $mass_{prod} > 2 mass_{sys}$  line within the first few hours of experimentation, and have experimental durations upwards to 100 hours. (See Supplementary Information for a demonstration) The ease with which thermochemical experiments surpass the size of the system explains why contamination issues are not typically prevalent in thermal catalysis, and also inherently points towards an intrinsically high catalyst activity.

In contrast, electrochemical, photochemical, and photoelectrochemical experiments typically show yields of  $\text{NH}_3$  or  $\text{NO}_3^-$  in orders of magnitude less than the size of the system. None of these catalytic systems fulfill the  $mass_{prod} > 2 mass_{sys}$ , and would require several orders of magnitude longer experimentation (with proper gas cleaning) to produce more product, and thereby move vertically up to cross the criteria of  $mass_{prod} > 2 mass_{sys}$ . We note some suspiciously high reported yield rates from recent (photo)electrochemical studies (Figure 6d), including the Bi point<sup>94</sup> operating at only -0.7  $\text{V}_{\text{RHE}}$  which reported higher production rates than some highly active thermochemical catalysts operating at elevated pressure and temperature conditions. This should have raised some concerns due to the high computed barrier in the same paper (>2 eV) and the selectivity challenge against  $\text{H}_2$  evolution (See Figure 2a). As the flagged point has been shown as non-reproducible<sup>91</sup>, this example serves to highlight how adventitious N sources can lead to non-genuine  $\text{N}_2$  fixation and inflate the reported yield rates in literature. Comparison of the reported intrinsic activity i.e. turnover frequency with thermochemical catalysts also shows this conclusion (see Figure S3 in Supplementary Information) and can be used to screen potential false positives. In most cases, the catalytic activity of electro/photocatalysts are much lower than the thermal counterpart and thus require hundreds of hours of experimentation to surpass the  $mass_{sys}$  (see Supplementary Information for demonstration). Therefore, quantitative isotope-labelling experiments, along with a proper gas-cleaning protocol, is a convenient and unambiguous way to verify genuine  $\text{N}_2$  fixation, thereby proving the origin of the activated N.

As of now, non-aqueous electrolytes are the only known conditions in which genuine electrochemical N<sub>2</sub> reduction under standard temperature and pressure is reliably demonstrated<sup>76,81,82</sup>. Several generations of breakthroughs are still needed to enhance reaction kinetics and achieve viable photo- and (photo)electro-catalytic performances for commercial application<sup>123</sup>. Advances in catalyst and electrolyte design are therefore required<sup>124</sup>, but low concentrations of  $mass_{prod}$ <sup>76,125</sup> in these fields means a rigorous experimental protocol must be followed to ensure the integrity of reported experimental results.

The current goal in thermochemical NH<sub>3</sub> production is to decrease the temperature and pressure, enabling milder operational conditions compared to current Haber-Bosch plants<sup>29</sup>. However, lowering the temperature leads to an exponential decrease in the formation rate, which increases the possibility of contamination, particularly if the catalyst contains activated N. The  $mass_{prod}$  for these low-temperature systems also becomes so low, that they fall below the  $mass_{prod} > 2\ mass_{sys}$  threshold and are comparable to some of the more active electrochemical systems, necessitating isotope measurements. We note that the integrity of the reported formation rate must be rigorously evaluated especially at the low production points, because if the activity measurement is based on incorrect yields of NH<sub>3</sub>, the error will propagate to the subsequent kinetic analysis.

## [H2] Electrochemical and Photo(electro)chemical N<sub>2</sub> Reduction and Oxidation

### [H3] Reporting metrics of experimental results

To measure the catalytic performance, CA and/or CP measurements are carried out, the product concentration determined, enabling a calculation of the yield and Faradic efficiency of the process. Typically a metric such as the partial current density or formation rate is plotted as a function of applied current or potential, and the Faradaic efficiency is overlaid on a separate y-axes, displaying the maximum performance of the system (Figure 7a)<sup>79</sup>. In photoelectrochemical systems, incident photon-to-current efficiency should be calculated utilizing a monochromatic light source<sup>126</sup>. All experiments should be repeated several times, from at least three independent batches of experiments to allow appropriate determination of a mean and its associate standard deviation. Representative CA or CP graphs should also be shown, as this illustrates the catalyst stability with time (Figure 7b). In the case of powder photocatalysis, the amount of product formed should be plotted versus time, and a production value per hour and gram catalyst can be extracted. The amount of product formed must be correlated with the amount of incident photons reaching the reaction vessel by calculating the average quantum yield (or quantum efficiency), which is measured with monochromatic light sources or cut-off filters at a given wavelength<sup>127,128</sup>.

As rigorous product detection is key to appropriately evaluating activity of (photo)electrochemical catalysts, product concentrations should be verified using at least two independent detection methods, and must show quantitative agreement with each other over multiple points<sup>129</sup>. Typically, this is shown by comparing results from colorimetric methods with results from isotope labelled experiments<sup>76</sup>. This should demonstrate that the amount of product measured using appropriately cleaned <sup>15</sup>N<sub>2</sub> (seen in Figure 7c) can reproduce quantitatively the amount measured using <sup>14</sup>N<sub>2</sub> over numerous points, as shown in Figure 7d, and that there is a linear increase in detected product as a function of time or charge passed.

### [H3] Issues hindering progress in (photo)electrochemical N<sub>2</sub> activation

Due to the selectivity challenge and the activity issue, reported yields and Faradaic efficiencies are very low, both for electrochemical N<sub>2</sub> reduction and oxidation. The reported partial current densities towards NH<sub>3</sub> are  $< \sim 1\ \text{mA}/\text{cm}_{\text{geo}}^2$  with reported Faradaic efficiency up to 60%. However, NH<sub>3</sub> is ubiquitous in the environment<sup>130</sup> in concentrations similar to or greater than those reported, so great care must be taken with

experimentation to avoid false positives. Many reports in Figure 6b now include isotopic labelling experimentation (crossed points), which is a shift towards utilizing isotopes that has occurred over the previous 2 years<sup>76</sup>. Unfortunately, many of the reports only do isotopic labeling of a single experiment<sup>94,131–137</sup>, which does not demonstrate reproducibility, as this is not enough to prove beyond doubt that synthesis of the product takes place. Also, the isotopically labelled gas typically contains  $^{15}\text{NH}_3$  and  $^{15}\text{NO}_x$  impurities<sup>96</sup>, and most of these new reports do not clean the gas prior to measurements, or clean it incorrectly<sup>101</sup>. Many of these reports are aqueous systems (non-stared), which typically suffer from low selectivity due to the competing  $\text{H}_2$  evolution reaction<sup>33</sup>, and could therefore easily be contaminated. The flagged Bi report<sup>94</sup> demonstrates the possibility of inflated yield rates due to contamination: we therefore urge researchers to reexamine high catalytic activity results via a rigorous experimentation<sup>76,101</sup> (see Experimentation). The Li-mediated system (denoted  $\text{Li}_x\text{N}/\text{xx}$ ) was initially discovered by Tsuneto *et al.*<sup>138,139</sup>, and has recently gained renewed interest, as it has been proven to work via rigorous isotope sensitive experimentation<sup>76</sup>. This system is displaying comparatively increased partial current density towards  $\text{NH}_3$ <sup>81</sup>, however, it requires very negative potentials, due to the necessity of Li plating, making it energy inefficient.

For  $\text{N}_2$  oxidation (squares, Figure 6b), the partial current densities to  $\text{NO}_3^-$  are less than  $\sim 10 \mu\text{A}/\text{cm}_{\text{geo}}^2$ <sup>50</sup>, and the highest activity catalysts tend to correspond to Faradaic efficiencies  $< \sim 1\%$ <sup>56,140</sup>. The field of electrochemical  $\text{N}_2$  oxidation is novel and small, with only a handful of published papers<sup>50–52,56,140</sup>. However, there is hope of a significant increase in the selectivity, as  $\text{H}_2$  evolution is not a competing reaction to  $\text{N}_2$  oxidation, as it is with  $\text{N}_2$  reduction. More theory to elucidate the reaction mechanisms is needed, along with a standardization and rigor regarding measurement, as the yields and product concentrations are still very low.

In the case of photon-driven  $\text{N}_2$  fixation, there is a general lack of rigorous testing<sup>115</sup>. Hirakawa *et al.* showed that activity of titania is highly dependent on supplier, a fact that has been attributed to differences in oxygen vacancy abundance<sup>141</sup> or carbon contaminants<sup>142</sup>. Nonetheless, reports of photochemical  $\text{N}_2$  fixation on titania and numerous other materials have been growing exponentially<sup>64,115</sup>. Literature results in photochemical  $\text{N}_2$  fixation must be viewed in the context of experimental rigor, which includes not only mere isotope labelling experiments but also tangible efforts to account for contamination sources including the elimination of  $^{15}\text{NH}_3$  and  $^{15}\text{NO}_x$  impurities in gas streams. The necessity of isotope-labelled experiments is due to the inherent measurement challenges similar to those within electrochemical systems. For instance, some of the most widely utilized semiconductor photocatalysts for  $\text{N}_2$  reduction are based in carbon nitride materials<sup>143,144</sup>, which display plenty of amine terminal moieties and a general high N content that can lead to meaningful amounts of  $\text{NH}_3$  upon degradation<sup>145</sup>. Additionally, residual alcohols, amines, organic solvents can interfere with  $\text{NH}_3$  quantification which lead to unreliable determination of  $\text{NH}_3$  yields<sup>115,146</sup>. Thus far, we are not aware of any photochemical studies in which isotope labelling shows quantitative agreement between  $^{14}\text{N}_2$  and  $^{15}\text{N}_2$  over multiple points (i.e. as a function of illumination time), along with proper gas cleaning to scrub away  $^{15}\text{NH}_3$  and  $^{15}\text{NO}_x$  impurities. Nonetheless, theoretical works suggest that photo-excited holes or electrons may facilitate N fixation more easily than metal electrodes, as the adsorbates at the electrodes may not be in equilibrium with the charge carriers<sup>33</sup>.

## [H2] Thermochemical N<sub>2</sub> Reduction

### [H3] Reporting metrics of experimental results

To evaluate a catalyst, the effects of temperature, pressure, and space velocity on catalytic activity as well as stability testing should be done. The typical reports of catalytic performance are shown in Figure 8. A temperature-dependent activity test within a certain temperature range (e.g. 250-400 °C) should be conducted, and a benchmark catalyst (Cs-Ru/MgO) should also be tested under identical condition. Special care should be given to the measurement of low-temperature activity (temperatures below 250 °C). For some of N-containing catalysts, such as nitrides, amides, imides and N-doped carbonaceous support, the catalysts should be reduced/pretreated under H<sub>2</sub> or H<sub>2</sub>/N<sub>2</sub> at elevated temperature long enough to remove any reactive species from the catalyst. The stability is also crucial for evaluating the performance of a catalyst, and the activity data is meaningful only if there is stable performance. A life-time evaluation should show NH<sub>3</sub> production that is greater than the amount of N in the system, moreover, NH<sub>3</sub> concentration in the outlet gas should be greater than 100 ppm. Otherwise, isotope sensitive measurements are necessary.

Kinetic measurement should be conducted under conditions far from the thermodynamic equilibrium and in the absence of mass and heat transfer limitations (Figure 8c). From the power-law rate equation,  $r = kP_{\text{NH}_3}^\alpha P_{\text{N}_2}^\beta P_{\text{H}_2}^\gamma$ , where  $r$  is the reaction rate,  $k$  is the rate constant,  $P$  is the partial pressure of the reactants or product,  $\alpha$ ,  $\beta$ , and  $\gamma$  are the reaction orders with respect to NH<sub>3</sub>, N<sub>2</sub>, and H<sub>2</sub>,<sup>147,148</sup> the reaction rate is affected by the partial pressures of all gaseous components (N<sub>2</sub>, H<sub>2</sub> and NH<sub>3</sub>). The reaction order of NH<sub>3</sub> ( $\alpha$ ) should be measured by changing the flow rate ( $F$ ) of reactant gas while keeping the N<sub>2</sub> and H<sub>2</sub> partial pressure constant. The reaction order of NH<sub>3</sub> ( $\alpha$ ) could be obtained by plotting  $\log(P_{\text{NH}_3})$  (or  $\log(C_{\text{NH}_3})$ ,  $C_{\text{NH}_3}$  is the NH<sub>3</sub> outlet concentration) vs.  $\log(1/F)$ . The reaction order of N<sub>2</sub> ( $\beta$ ) should be determined by plotting  $\log(r) - \gamma \log(P_{\text{H}_2}) - \alpha \log(P_{\text{NH}_3})$  vs.  $\log(P_{\text{N}_2})$ . Because the partial pressure of H<sub>2</sub> will not change significantly during catalytic testing,  $\gamma \log(P_{\text{H}_2})$  can be regarded as a constant. The  $\beta$  could be obtained by plotting  $\log(r) - \alpha \log(P_{\text{NH}_3})$  vs.  $\log(P_{\text{N}_2})$  (Figure 8b). However, the term  $\alpha \log(P_{\text{NH}_3})$  should not be omitted unless  $\alpha$  is close to zero or NH<sub>3</sub> partial pressure is kept constant. Only under such circumstance can  $\beta$  be obtained by directly plotting  $\log(r)$  vs.  $\log(P_{\text{N}_2})$ . The similar method is applied when determining  $\gamma$ . Calculating this result without keeping the NH<sub>3</sub> partial pressure constant may lead to a problematic interpretation of the reaction mechanism.

Generally, the N<sub>2</sub> order is positive and close to unity for the conventional oxide or carbon supported catalyst because the rate-determining step of these catalysts is the N<sub>2</sub> activation. However, H<sub>2</sub> and NH<sub>3</sub> orders can differ for various catalysts. For the iron-based catalysts, the H<sub>2</sub> order is positive and the NH<sub>3</sub> order is negative because of the strong adsorption of N<sup>149,150</sup>. For some of the Ru-based catalysts, the H<sub>2</sub> order can be negative, due to being strongly inhibited by hydrogen<sup>151</sup>.

The apparent activation energy ( $E_a$ ), in theory, should be determined by plotting  $\ln(k)$  vs.  $1/T$ , rather than  $\ln(r)$  vs.  $1/T$ , mainly because the variation of NH<sub>3</sub> partial pressure has influence on the reaction rate according to the power-law rate equation. Thus,  $E_a$  should be measured at a constant NH<sub>3</sub> pressure. As shown in Figure 8d, the apparent  $E_a$  calculated at constant NH<sub>3</sub> pressure were greater than those determined at constant flow rate over RuCl<sub>3</sub>/γ-Al<sub>2</sub>O<sub>3</sub> catalysts<sup>152</sup>. Thus, the importance of NH<sub>3</sub> partial pressure should be considered in the kinetic measurements, as it could otherwise lead to inaccurate values.

### [H3] Issues hindering progress in thermochemical N<sub>2</sub> reduction

Generally, catalysts operated at lower temperature are associated with a lower NH<sub>3</sub> synthesis rate. More recently, reactive catalytic materials have been employed for thermal NH<sub>3</sub> synthesis (Figure 6c). Some of

the materials such as electrides<sup>111</sup>, hydrides<sup>78</sup>, nitrides<sup>153</sup>, and oxy-hydrides<sup>154</sup> have been found effective in promoting/synergizing with transition metals, making early- and/or late-transition metals highly active. Some of the transition metal hydrides alone were also found to be catalytic active<sup>155,156</sup>. Those materials, however, have dynamic responses to the reacting environment. A recent neutron scattering investigation reveals formation of H-containing species in the C12A7:e<sup>-</sup> lattice under reaction conditions<sup>157</sup>. The TiH<sub>2</sub> shows the potential nitridation of the surface during the reaction<sup>155</sup>. The VH<sub>0.39</sub> is most likely converted into VH<sub>0.44</sub>N<sub>0.16</sub> under reaction conditions, which is the stable active composition<sup>156</sup>. Amides, hydrides and nitrides of alkali/alkaline earth/rare earth metals can also react with H<sub>2</sub>, N<sub>2</sub> and/or NH<sub>3</sub><sup>158</sup>. Moreover, catalyst made of coordination-unsaturated transition metal atoms or clusters may alter its chemical composition or physical state in response to the reacting environment. Characterization on a catalyst quenched from reaction would be more meaningful to provide information on the composition and chemical state of active phase/site. However, this has yet to be fully addressed.

Adventitious N source can also be significant when claiming catalytic activity with NH<sub>3</sub> concentration below 100 ppm or  $mass_{prod} < 2\ mass_{sys}$ . In addition to the possible sources of contamination discussed in electrochemical N<sub>2</sub> reduction/oxidation reactions, attention should also be given to reactive catalysts that would build up lattice or surface N species in situ under N<sub>2</sub>- or NH<sub>3</sub>-rich atmosphere and elevated temperatures. Those N species have a chance to convert to NH<sub>3</sub> in a non-catalytic way when reaction condition allows (e.g., H<sub>2</sub>-rich environment or low temperature), which may result in a false-positive, thus calling for verification via isotope labelling in the activity test as suggested.

## [H2] Reporting and interpreting density functional theory results

Quantum mechanical simulations, typically based on density functional theory (DFT), are useful in understanding the mechanisms of N<sub>2</sub> activation. In this section, best practices in creating free energy diagrams, assessing active site stability, and rationalizing free energy diagrams are discussed.

### [H3] Creating free energy diagrams

When creating free energy diagrams, it is critical to ensure that the initial and final states correspond to gas-phase N<sub>2</sub> and gas-phase/aqueous products respectively (for liquid-phase systems vapor pressure of N<sub>2</sub> can be used) so the overall reaction energy is independent of the catalytic material. For electrochemical free energy diagrams, a convenient model of applied potential is the computational hydrogen electrode (CHE) model<sup>159</sup>, but more sophisticated models of applied potential may provide more accurate energies<sup>160,161</sup>.

Considering the free energy of species, rather than just the energy obtained directly from DFT, is critical whenever computed energies are compared to experimental values<sup>162</sup>. At 0 K, the free energy consists of the energy obtained from DFT and the zero point energy. The temperature-dependent free energy includes additional contributions from enthalpy and entropy, which can be computed through statistical mechanics (we refer the readers consult standard DFT textbook<sup>163</sup> for how each term is calculated). As an approximate upper bound, the entropy can be computed by assuming the adsorbate acts as a harmonic oscillator, which can lead to over-estimation in the case of low-frequency modes since the entropy diverges as frequency goes to zero for a harmonic oscillator, calling the need of rigorous treating and reporting of low-frequency modes<sup>164</sup>. Compared to the DFT energies, the inclusion of all free energy terms generally causes surface states to be less favorable due to the vibrational energy of the adsorbed states and the loss of entropy as they are bound to the surface. For example, the \*N<sub>2</sub>H surface species gains 0.16 eV to be adsorbed on Ru (211) when considering only the DFT energy (Figure 9a orange). However, it is destabilized by 0.67 eV

due to the entropy loss relative to the gas phase and by 0.16 eV due to changes in the zero-point energy of the bonds, leading to an energy penalty of +0.62 eV for adsorption (Figure 9a black). This increase reveals that not considering the relevant free energy can lead to qualitatively incorrect conclusions of thermodynamic driving force for elementary reaction steps and what the rate-limiting steps are.

### [H3] Assessing Active Site Stability

The feasibility of an active site model can be assessed in terms of at least two criteria: stability and reactivity. An active site's stability should be assessed by computing its surface energy using ab initio thermodynamics<sup>159</sup>. In general, activity and reactivity are related by a non-linear "volcano plot" relationship and sites that are more reactive tend to be less stable. Therefore, it is necessary to find a trade-off between reactivity and stability<sup>165,166</sup>. Figure 9b shows an example of an activity-stability plot for surfaces toward O<sub>2</sub> reduction reaction on a number of Pt (111)-derived surfaces, where predicted current density represents activity and surface energy represents stability. The most relevant surfaces form a Pareto-optimal frontier along the activity/stability axes. Surfaces on the Pareto-optimal line represent optimal trade-offs between activity and stability, whereas surfaces below the line are sub-optimal. Surfaces further to the right are less stable and thus more challenging to generate under the atmospheric conditions used as the reference state. However, the stoichiometry active sites can vary, and their relative stability will vary depending on the chemical potential of the environment. Therefore, it is critical to consider the relevant chemical potentials when assessing active site stability. Competitive adsorption is also an important component of active site stability. For example, analysis of N<sub>2</sub> adsorption free energy often assumes that there is no competitive adsorption from abundant spectator species such as H\*, which may prohibit adsorption and reaction<sup>73</sup>. Surface phase diagrams provide a useful tool to assess stability and coverage of competing intermediates as a function of chemical potential<sup>167</sup>.

### [H3] Rationalizing free energy diagrams

When reading free energy diagrams, a distinction should be made between electrochemical steps and non-electrochemical steps. The thermodynamic barrier  $\Delta G_{step}$ , which is the most uphill step in free energy along the reaction pathway, can be set as a lower bound for the true activation energy,  $\Delta G^\ddagger$ . As mentioned, a free energy diagram for electrochemical N<sub>2</sub> fixation with a thermodynamic barrier greater than  $\Delta G_{step} = 1.5$  eV under ambient conditions should be treated with skepticism.

Moreover, it is also important to consider the adsorption free energy of the inert N<sub>2</sub> molecule, an essential first step of N<sub>2</sub> fixation. N<sub>2</sub> physisorbing to the surface corresponds to an energy penalty of 0.67 eV<sup>168</sup> at 25 °C owing to the gas-phase entropy loss, and thus must be compensated by an enthalpic gain. To assess the point where N<sub>2</sub> adsorption becomes rate-limiting, we resort to collision theory to obtain the rate of collisions between a gas and a surface<sup>63</sup>. Thus, the number of successful collisions per unit time per area becomes:

$$r \sim \frac{P_{N_2}}{N_A \sqrt{2\pi m k_B T}} \exp\left(-\frac{\Delta G_{*N_2}}{k_B T}\right) [\text{mol}_{N_2} \text{ cm}_{\text{geo}}^{-2} \text{ s}^{-1}]$$

where  $P_{N_2}$  is the partial pressure of N<sub>2</sub>,  $m$  is the mass of N<sub>2</sub>,  $k_b$  is the Boltzmann constant,  $T$  is the temperature,  $N_A$  is the Avogadro constant, and  $\Delta G_{*N_2}$  is the thermodynamic N<sub>2</sub> adsorption free energy, which is a lower bound for the true adsorption barrier. To obtain the number of successful collisions per site per second, the rate can be multiplied by the Avogadro constant ( $N_A$ ) and divided by the site density  $N_o$ . Using a typical site density<sup>63</sup> of  $N_o = 1.5 \times 10^{15}$  sites/cm<sub>geo</sub><sup>2</sup> and 1 bar of N<sub>2</sub>, the barrier corresponding to 1 successful collision per site per second (i.e. turnover frequency of 1 s<sup>-1</sup>) becomes roughly 0.5 eV at 25 °C. In the case of aqueous solutions, the collision rate can be estimated by using the concentration of dissolved N<sub>2</sub> at standard conditions ( $P_{N_2} = 0.012$  bar), leading to the requirement that the N<sub>2</sub> adsorption free energy should be below 0.35 eV to ensure that N<sub>2</sub> adsorption is not rate limiting.

## [H1] Applications

Electrochemical, photo(electro)chemical and thermochemical  $N_2$  fixations have primarily been discussed in this Primer due to the size of interest and research efforts in these fields, and the possibilities they offer to sustainably produce high value N-containing chemicals. Particularly power-to- $NH_3$  is an attractive process, as  $NH_3$  is not only a fertilizer, but can also be used to power an  $NH_3$ -based economy, since it forms a liquid under light pressure and cooling, thereby providing a carbon-free and energy-rich fuel. This fuel can be transported and stored much easier and safer than liquid  $H_2$ , the only other viable carbon-free green fuel, and comparatively,  $NH_3$  even contains a higher volumetric energy density. It can therefore provide power-plants a sustainable fuel for the generation of electricity, it can be used as fuel in gas turbines and power generators, or the  $NH_3$  can be split, thereby providing a source of  $H_2$  gas for fuel-cell based vehicles and marine transportation<sup>169,170</sup>. Centralized production of  $NH_3$  via the Haber-Bosch process is currently slowly replacing the  $H_2$  supplied via steam-reformed methane (called brown  $NH_3$ ) to water electrolysis driven by solar- and wind-powered electricity (Gen 2, Figure 1)<sup>28</sup>. These electrified Haber-Bosch facilities would significantly reduce the carbon footprint of  $NH_3$  production<sup>29</sup>, and with the addition of e.g.  $NH_3$  pipelines, the ease of storage and distribution could lead to the envisioned  $NH_3$  economy. Thermochemical  $N_2$  reduction is a crucial key point, as lowering the required pressure and temperatures of the Haber-Bosch process enables smaller and thereby cheaper production facilities<sup>11</sup>. For fully decentralized  $NH_3$  production of e.g. 1 device per farm or greenhouse for fertilizer production, significant breakthrough in electrochemical or photo(electro)chemical  $N_2$  activation (Gen 3, Figure 1) is necessary<sup>171</sup>. These processes would completely eliminate the dependence on Haber-Bosch on a local scale, as the only inputs should be air, water, and renewable electricity on a small-scale device. Breakthroughs on this scale would also lead to electricity storage as  $NH_3$ , aiding the intermittency issue of renewable electricity sources, and more advances in overall power-to-X technologies, as more infrastructure and reliance on blue  $NH_3$  will increase understanding of general electricity conversion, energy storage, and reconversion pathways. Overall, progress in the  $N_2$  activation reactions has the capability of shaping a future without dependence on fossil fuels, as  $NH_3$  is one of the leading choices for a carbon-free fuel.

## [H1] Reproducibility and data deposition

### [H2] The importance of reproducibility

Ensuring complete account and mitigation of contamination sources is key to improving reproducibility in  $N_2$  activation. Given the ubiquity of N-impurities, results of catalytic performance must be accompanied with experimental details showing how contamination sources have been mitigated. Reporting the actual product concentrations and the measured concentrations in control experiments is also recommended, along with the electrolyte volume and the mass and surface area of the catalyst used, as these can be a telling factor toward contamination. More vitally, we emphasize the need to perform complete isotope-labelling experiments, with time-dependent product quantification and proper cleaning of the  $^{15}N_2$  gas steams, to ensure unambiguous certainty of successful  $N_2$  fixation. Additionally, more rigor needs to be applied in performing electrochemical and photo(electro)chemical measurements and their product detection measurements, especially when the reported selectivity is close to zero. For electrochemical measurements, the pre- and post-test Ohmic resistance can differ substantially due to bubble formation, temperature variance, etc., and thus the shift in potential should be properly adjusted<sup>76</sup>. Similarly, in thermochemical studies, catalyst preparation-pretreatment and activity measurements are two main factors influencing the reproducibility of the experiments. Experimental details associated with these must be reported.

It is vital that one demonstrates  $n \geq 3$  reproductions of the reported data, which include at least three repeated measurements in product detection for each catalytic activity point, three independent activity testing, and three independently prepared catalyst batches. The mean and spread of each data point must be reported, acknowledging errors from activity measurements and product detection, with the appropriate number of significant figures. This is significant as several studies report an excessive number of digits beyond the accuracy usually attainable in catalysis.

## [H2] Data deposition and reporting

Transparency in reporting and data deposition are essential. Useful figures of merit regarding the catalytic performance and details of the experimental conditions, as elaborated in Table 2, must be reported to enable thorough assessment of the experimental rigor and aid comparisons of data collected under different conditions. Extra care must be given for electrochemical, photochemical, photoelectrochemical, and low-temperature thermochemical systems by clearly reporting the gas purity, the cleaning procedure of the gas (especially  $^{15}\text{N}_2$  used in isotope-labelling experiment), and the actual concentration of the measured product. Ultimately, these efforts are aimed at evaluating the  $mass_{prod}$  relative to the  $mass_{sys}$  of the experiments. Kinetic measurements such as the determination of reaction orders and activation energy may be required according to the need of research. Lastly, pre- and post-measurement (and/or in situ) characterization of the catalyst may be necessary, to ascertain changes associated with the reaction conditions.

In a move towards open data, we also request the sharing of raw calibration and test data associated with catalytic activity measurements, the relevant data analysis scripts where possible, and results such as converged atomic coordinates and vibrational frequencies when a DFT calculation is performed.

## [H1] Limitations and Optimizations

### [H2] Cost of isotope experiments

For repeated isotope labelled experiments, the cost of  $^{15}\text{N}_2$  can unfortunately be prohibitively expensive, as a single long-term experiment can easily cost upwards to 2,300 USD for 5 L. This can be circumvented by introducing a glass circulation pump. Once a high enough  $^{15}\text{N}_2$  atmosphere is achieved in the system, the glass pump will continuously circulate the gas, without the need to supply more throughout the experiment. Furthermore, the circulation pump has the added benefit of not introducing contaminants over time, if the gas stream contains any  $\text{NH}_3$  or  $\text{NO}_x$  species, decreasing the possibility of false positives. The glass circulation pump can be made in-house<sup>172</sup> as seen in Figure 10a, or bought commercially.

Isotopically labelled  $^{15}\text{N}_2$  can contain significant amounts of both  $^{15}\text{NH}_3$ , and  $^{15}\text{NO}_x$  species that reduce easily, leading to isotopically labelled contamination<sup>96</sup>. We do not advocate the use of aqueous solutions to clean  $\text{N}_2$ , as they would not trap all contaminants<sup>173</sup>. The residence time of the bubbles compared to the diffusion time inside the bubbles would need to be ideal, with certain probability of uptake. The bubbles need to be tiny, so they rise slowly and have fast internal mixing and large surface/volume ratio<sup>101</sup>. Furthermore, it is unclear how  $\text{NO}_x$  species would be trapped in acid<sup>133</sup>. We found that a home-made reduced Cu catalyst combined with a freeze trap to be efficacious for removing impurities, on the basis of the measured level of all  $\text{NH}_3$  and  $\text{NO}_x$  impurities removed before and after the cleaning<sup>76</sup>. The reduced Cu catalyst will catch all  $\text{NO}_x$  species, while the cold trap freezes out  $\text{NH}_3$ . Commercial gas purifiers down to ppt per volume fraction (pptV) level are also available for purchase. A complete home-built and inexpensive system for both the glass circulation pump and the reduced Cu catalyst is shown in Figure 10b.

## [H2] Access to NMR

NMR is the most commonly reported technique for isotope labelling experiments, as it can distinguish between  $^{14}\text{NH}_3$  and  $^{15}\text{NH}_3$ . Not all will have access to a high-field 800 MHz NMR, but the use of the more commonly available 400 MHz NMR can achieve similar sensitivity, covered in more detail in Reference<sup>76</sup>.

## [H1] Outlook

### [H2] Adoption of standardized test protocols for $\text{N}_2$ activation

$\text{N}_2$  reduction and oxidation at low temperature and pressure are reactions with immense technological significance. Unfortunately, much published research lacks rigorous and standardized testing, leading to possible contamination of results and false positives. The possibility of contamination is particularly prominent for reports with low product formation rates, spanning all electrochemical and photo(electro)chemical systems to date, as well as some low temperature thermochemical systems. The only conclusive proof of successful  $\text{N}_2$  activation is via repeated and quantified isotope labelled testing with proper gas cleaning. In this Primer, our objective is to define the cut-off necessitating the use of the crucial  $^{15}\text{N}_2$  quantitative isotope labelling experimentation for all  $\text{N}_2$  activation reactions. The cut-off is defined at  $\text{mass}_{\text{prod}} > 2 \text{ mass}_{\text{sys}}$ , where  $\text{mass}_{\text{sys}}$  is based on experimentally measured N in the system. Furthermore, the concentration of the product must also exceed 100 ppm, far above the olfactory detection of  $\text{NH}_3$ , to circumvent contamination from other sources. This will prevent false positives from reaching publication, as these results hinder development of the  $\text{N}_2$  activation field.

Beyond electrochemical, photo(electro)chemical and thermochemical systems, efforts on non-thermal plasma  $\text{N}_2$  fixation have been pursued in recent years<sup>174</sup>. Generally, the plasma-driven  $\text{N}_2$  fixation studies report product concentrations of hundreds of ppm and up to ~5% of the gas stream<sup>37</sup>, diminishing the detrimental contribution of labile N-species in various contamination sources. However, with the field's primary focus on racing toward higher energy efficiency, several studies using dielectric barrier discharges as the most common plasma source show worryingly low  $\text{NH}_3$  production ( $C_{\text{prod}} < 100 \text{ ppm}$ )<sup>36</sup>, possibly dipping into the range of contaminants. Moreover, the mechanochemical method of  $\text{NH}_3$  synthesis has emerged as a new direction for  $\text{N}_2$  activation<sup>40,41</sup>. The reported  $\text{NH}_3$  yields are similarly high, but the field can benefit from the critical assessment of the potential size of N-contaminants. We suggest researchers also adapt the protocol in this Primer by comparing the product mass ( $\text{mass}_{\text{prod}}$ ) with the total equivalent N mass of the system ( $\text{mass}_{\text{sys}}$ ) and performing quantitative isotopic-labelling verification technique at the low-yield data points to warrant genuine  $\text{N}_2$  fixation.

### [H2] Mechanistic insight via in-situ measurements

Our insight into the reaction mechanisms on  $\text{N}_2$  reduction has largely been built on theoretical investigations<sup>69,73,175</sup>. In-situ and in-operando techniques to probe intermediate species can validate or challenge established paradigm, and inform valuable insights into future catalyst designs (Box 2). However, adoption of the rigorous protocol takes precedence to ensure what is being detected is not associated with the presence and redox processes of adventitious N sources.

### [H2] Perspective to achieve commercialization

The emerging false positives and likely unreliability of many prior publications in the field of  $\text{N}_2$  fixation have undoubtedly injured the reputation of the field. In the immediate future, the scientific community should aim to restore the field's integrity and eliminate the emergence and propagation of unreliable results. In our view, this can be achieved through increased rigor of experimental practices, increased efforts to reproduce reported results, increased cross-pollination of knowledge and best practices across laboratories, and a more deliberate regard toward fundamental concepts and principles.

In the next 5-10 years, we anticipate researchers will focus on addressing the field-specific needs (Box 3), and ultimately finding breakthrough catalysts with practically relevant and reliably demonstrated yield rates, selectivity, stability and energy efficiency to enable industrial deployment of sustainably-produced ammonia. The obsessive pursuit of breakthrough results must go hand in hand with robust fundamental studies unveiling the identification of true reaction mechanisms and active sites and reaction kinetics, aided by experimental mechanistic studies and quantum chemistry or other computational methods. Ultimately, concerted efforts from experimental and theoretical communities will be key to discovering a practical solution to decarbonize the fixation of  $N_2$ .

## Boxes

### [bH1] Box 1. Sources of system N mass

<i>mass<sub>N,cat</sub></i>	The amount of measured N in the catalyst and support, which must be experimentally determined. This measure is important, even if the catalyst does not intrinsically contain N, as substantial levels of NO <sub>3</sub> <sup>-</sup> and nitrides can contaminate commercial metal sources <sup>106,176,177</sup> , despite manufacturer's claims otherwise. We recommend the simple 2 step procedure by Chen <i>et al.</i> <sup>177</sup> of alkaline and acidic treatment of the catalyst, followed by HPLC or UV-vis analysis, or any equivalent method for determining N-content. Special care should be taken regarding N-buildup on the catalyst if pretreated with an N-containing procedural step. These N-species could contaminate the catalyst, and convert to NH <sub>3</sub> in a non-catalytic way <sup>178,90</sup> . We therefore recommend examining the N-content of the catalyst as bought, after any pre-treatment, and after catalysis. If the N-content of the catalyst is not explicitly experimentally determined, one should consider <i>mass<sub>N,cat</sub></i> as at least 25% of the whole mass of the catalyst, unless the catalyst is intrinsically N-containing (e.g. a nitride), in which case 100% of the mass should be considered.
<i>mass<sub>N,electrolyte</sub></i>	The measured amount of N in the electrolyte. Electrochemical and photo(electro)chemical systems submerge the catalyst in electrolyte, and if the electrolyte itself contains N species, these must be considered as sources of contamination, due to possible electrolyte breakdown. However, the electrolyte itself may also be contaminated, as chemicals and membranes (e.g. Nafion) readily soak up NH <sub>3</sub> from the surroundings <sup>76</sup> , and both NO <sub>x</sub> and NH <sub>3</sub> blank measurements of the electrolyte should be included with each batch of electrolyte.
<i>mass<sub>N,absorber</sub></i>	The measured amount of N in the photoabsorber present in photo(electro)chemical system. This may contain sources of activated N as a contaminant, and should be determined experimentally.
<i>mass<sub>N,gas</sub></i>	The total calculated N impurities of the N <sub>2</sub> gas stream <sup>96,101</sup> . If the purity of the N <sub>2</sub> is e.g. 99.999%, one must consider 0.001% of the total gas used to be 100% contamination, and calculate the mass of this based on flow rate and duration. Alternatively, a proper gas cleaning procedure, with reported NH <sub>3</sub> and NO <sub>x</sub> contamination of the gas before and after cleaning can be used.

### [bH1] Box 2. In-situ and operando techniques for N<sub>2</sub> fixation

<b>Surface enhanced infrared spectroscopy (SEIRAS)</b>	SEIRAS can detect many of the adsorbates in electrochemical N <sub>2</sub> fixation in operando. The IR adsorption peaks can be attributed to vibrational modes of reaction intermediates, and these signals can be enhanced on metal surfaces by the SEIRA effect <sup>179</sup> . Several studies have attempted SEIRAS for electrochemical N <sub>2</sub> reduction <sup>180,181</sup> , but contributions from contamination to the detected species are highly probable. Nonetheless, Matsui et al. have demonstrated successful <i>in-situ</i> FTIR spectroscopy for electrochemical NH <sub>3</sub> oxidation on Pt electrode <sup>182</sup> . Here, various bands, detected at different voltages, were ascribable to the HNH bending mode of *NH <sub>3</sub> , NH <sub>2</sub> wagging mode of *N <sub>2</sub> H <sub>4</sub> , absorption of NO bridged species and HOH bending mode of *OH groups.
<b>Electron Paramagnetic</b>	EPR allows the monitoring on paramagnetic species as a function of potential in an electrochemical process, detectable upon rapid freezing of the electrodes. EPR spectra have detected nitrous oxides in redox processes in biomolecules <sup>183</sup> and

<b>Resonance Spectroscopy (EPR)</b>	during alcohol oxidation. <sup>184</sup> . Electrochemical EPR could potentially detect absorbed paramagnetic *NO species formed during N <sub>2</sub> oxidation.
<b>N<sub>2</sub> isotopic exchange reaction (N<sub>2</sub>-IER)</b>	N <sub>2</sub> -IER ( <sup>15</sup> N <sub>2</sub> + <sup>14</sup> N <sub>2</sub> → 2 <sup>15</sup> N <sup>14</sup> N) has been used to probe the reaction mechanisms and the rate-determining step of the thermochemical NH <sub>3</sub> synthesis, by introducing <sup>14</sup> N <sub>2</sub> / <sup>15</sup> N <sub>2</sub> gas mixtures and monitoring the <sup>14</sup> N <sub>2</sub> , <sup>15</sup> N <sub>2</sub> and <sup>14</sup> N <sup>15</sup> N gas phase composition. Successful examples of N <sub>2</sub> -IER for NH <sub>3</sub> synthesis have been reported on Fe <sup>185</sup> and Ru <sup>186,187</sup> confirming N <sub>2</sub> dissociation as the rate-determining step. A N <sub>2</sub> -IER study on cobalt molybdenum nitride <sup>188</sup> demonstrates the possible participation of lattice N in a Mars-van Krevelen mechanism.
<b>Steady State Isotopic Transient Kinetic Analysis (SSITKA)</b>	SSITKA is performed under steady-state conditions and involves introducing a step change in the isotopic content of the reactant and monitoring the transient responses of the isotopically labeled species <sup>189</sup> SSITKA has been used to study the kinetics of NH <sub>3</sub> synthesis on commercial Fe <sup>190</sup> and Ru <sup>191–194</sup> catalysts. A study on commercial Fe catalysts reveals *N as the most abundant reactive intermediate <sup>190</sup> . The role of potassium promoter over Ru catalysts, investigated by SSITKA, is revealed to induce surface site heterogeneity on Ru/SiO <sub>2</sub> , creating super-active sites responsible for enhanced catalytic activity <sup>191</sup> .

### [bH1] Box 3. Field-specific progress, needs, and insight

Thermochemical N <sub>2</sub> reduction	The thermochemical N <sub>2</sub> reduction reaction is the most advanced in terms of technological readiness, as there are a variety of newly developed catalysts shown to produce NH <sub>3</sub> at low pressures (1-10 bar) and low temperatures (< 300 °C). However, this type of reaction would still require higher operation temperatures (compared to ambient conditions) and pure H <sub>2</sub> as the feed gas, necessitating an additional clean H <sub>2</sub> production step. Increased focus is on exploring unconventional, highly active, and electron-rich materials as catalysts or catalyst supports in the aim of optimizing the reaction rate, decreasing the temperature even further. In the meantime, efforts should be devoted to the elucidation of active site and reaction mechanism. As a bellwether reaction, any progresses in fundamental insight and/or practical transformation in thermochemical NH <sub>3</sub> synthesis would have profound impact on the field of heterogeneous catalysis.
Electrochemical and photo(electro)chemical N <sub>2</sub> reduction	Reactions that use protons in lieu of H <sub>2</sub> have also been gaining increased attention. The requirements for high yields comparable to the Haber-Bosch process or even to thermochemical systems is not necessary, as the focus is on creating completely decentralized systems <sup>28</sup> . Unfortunately, there is a strong need to validate the aqueous results using rigorous protocols <sup>76,101</sup> , in light of the sheer selectivity challenge against H <sub>2</sub> evolution in aqueous environments as revealed by theory and the ubiquity of N-containing contaminants. Once these systems are experimentally validated, efforts towards increased catalytic activity, selectivity, and number of active sites can be considered <sup>124</sup> . The non-aqueous Li-mediated N <sub>2</sub> reduction process have been proven to work, achieving the highest reported energy efficiencies in the literature. However, this system has significant kinetic challenges due to sluggish mass-transport limitations, which needs to be overcome for practical commercial use.
Electrochemical N <sub>2</sub> oxidation	Electrochemical aqueous N <sub>2</sub> oxidation is piquing the curiosity of the scientific community. Nonetheless, we consider this field to still be in its infancy, with ample opportunity for fundamental insight and step improvements to catalyst performance.

## Tables

**Table 1** Common sources of contamination of electrochemical and photo(electro)chemical systems and the suggested method of elimination. Methods adapted from Liu et al.<sup>106</sup>

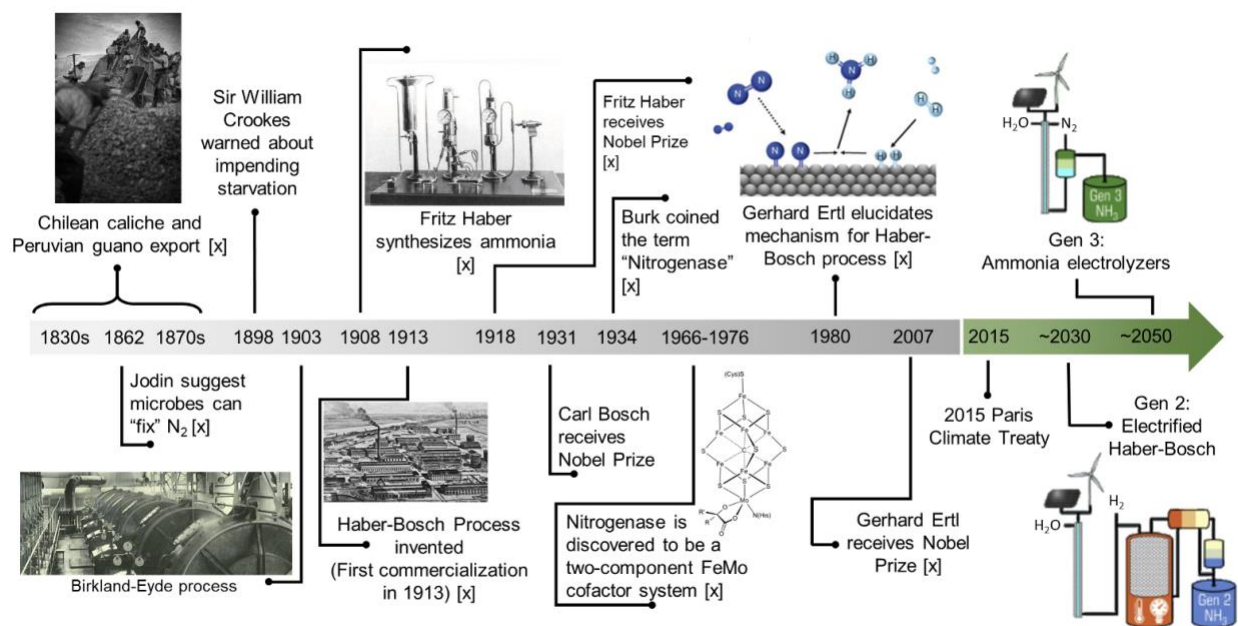

Sources of Contamination	Nitrogen form	Method of Elimination
Feed gas <sup>96</sup>	NO <sub>x</sub> , N <sub>2</sub> O and NH <sub>3</sub>	Use of home-made reduced Cu catalyst and a freeze trap, or commercial gas purifier
Impurities in the catalyst <sup>90,176,177</sup>	NO <sub>x</sub> <sup>-</sup> and NH <sub>4</sub> <sup>+</sup>	Complete removal via pre-reduction of the catalyst before NRR testing
Uptake/release from the membrane <sup>76,105,106</sup>	NH <sub>3</sub>	Replace with contamination-free membrane (such as Celgard)
Electrolyte	NH <sub>4</sub> <sup>+</sup> , NO <sub>2</sub> <sup>-</sup> and NO <sub>3</sub> <sup>-</sup>	Removal via annealing of electrolyte salt or other cleaning methods
Glassware, tubes, laboratory air, etc. <sup>195</sup>	NH <sub>3</sub>	Ensure the entire system is properly cleaned between uses, e.g. by boiling in ultra-pure water and drying in oven

**Table 2.** Required reporting standards across the different catalyst system types used for nitrogen reduction and oxidation.

Data type	Definition	System type
<b>Reporting of catalyst performance</b>		
Yield rate	Amount of product formed in a given time interval	All systems
Area-normalized activity	Yield rate normalized to either geometric or electrochemically active surface area	Electrochemical
Mass-normalized activity	Yield rate normalized by the mass of catalyst	All systems
Turnover frequency	Rate of chemical conversion normalized to number of actives per unit of time.	All systems
Faradaic efficiency	Ratio of charges employed for the synthesis of a given product relative to the total amount of charge passed through the circuit.	(Photo)electrochemical
Stability	Capability of a catalyst to perform in prolonged time intervals without detriment in its intrinsic activity	All systems
Energy efficiency	Ratio of converted energy relative to the initial energy input.	All systems
Average Quantum yield	Ratio of electrons transferred towards product relative to the incident photons reaching the sample at a given wavelength	Photo(electro)chemical
Incident photon-to-current efficiency	Ratio of produced photocurrent versus the incident photon flux at a given wavelength.	Photo(electro)chemical
Reaction orders	The power dependence of the reaction rate on the concentration of each reactant.	All systems
Activation energy	The minimum amount of energy required to activate atoms or molecules to a state in which they can undergo a chemical reaction.	All systems
<b>Reporting of experimental conditions</b>		

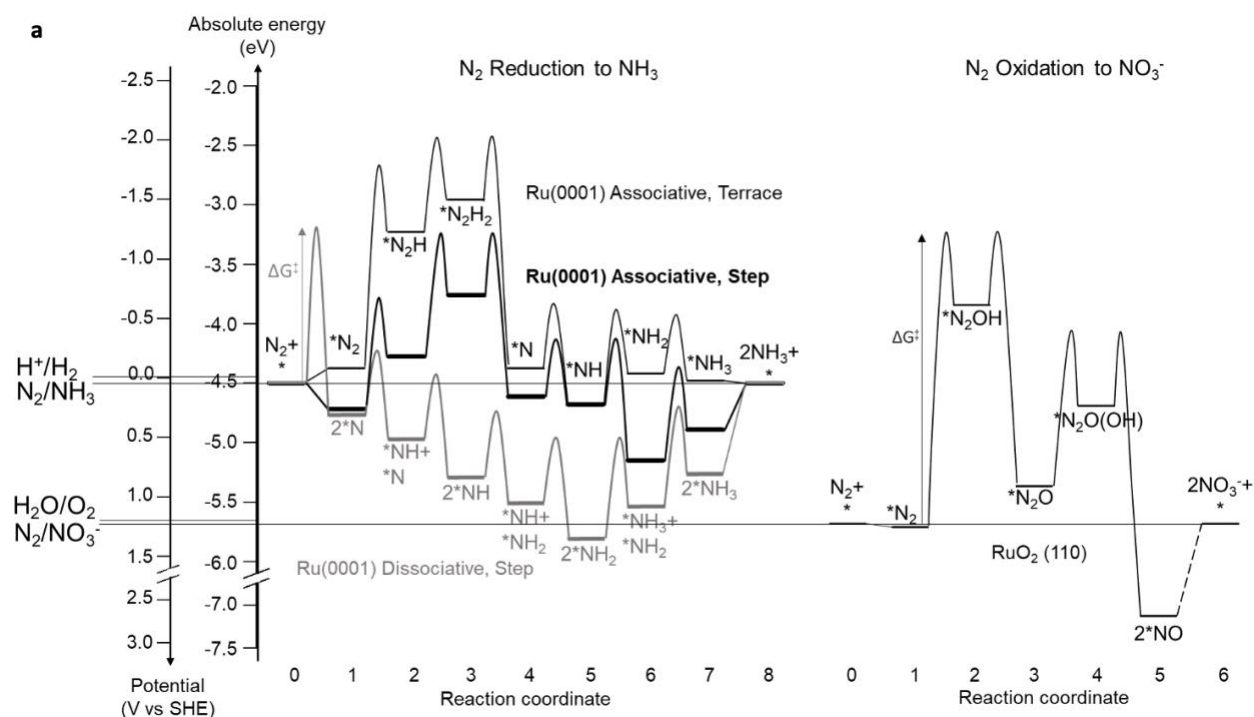

Catalyst loading	Mass of catalyst employed in a single experiment	All systems
Gas Purity	Purity of the $^{14/15}\text{N}_2$ , $\text{H}_2$ and Ar gases used in the experiments.	All systems
Time	Length of time of the experiment	All systems
Potential	The operating potential of working electrode during reaction	Electrochemical
Electrolyte volume	The volume of electrolyte used in the catalytic measurements	(Photo)electrochemical
Temperature and pressure	The temperature of the catalyst bed and the total pressure of the reaction gases.	All systems
Photon intensity	Photon flux reaching the sample per second and illumination area	Photo(electro)chemical
Illumination area/distribution	Available surface for the incident photon flux to reach the sample	Photo(electro)chemical
Weight hourly space velocity	Flow rate of the reaction gas fed to the reactor, divided by the mass of catalyst	Thermochemical (most relevant)
<b>Other Information</b>		
Gas cleaning procedure	A detailed account of how impurities are removed in the gas streams	All systems
Catalyst characterization	Structural or chemical information pre- and post- catalytic measurement to inform changes to the catalyst	All systems

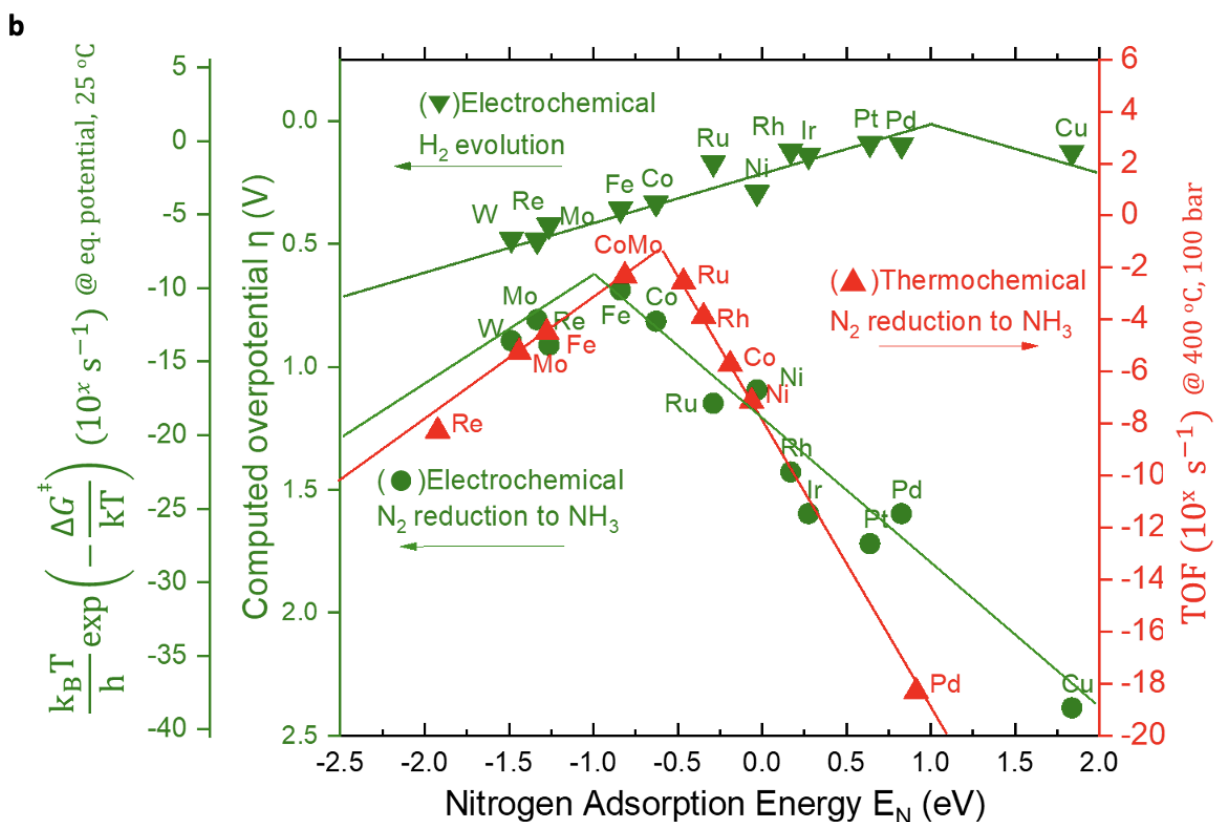

## Figures

**Figure 1. Historical development of  $\text{N}_2$  activation.** Nature mainly produces activated  $\text{N}$ -species via the nitrogenase enzyme<sup>6</sup>. The source of  $\text{N}$ -containing fertilizer first originated from caliche deposits and guano, both predicted to be unsustainable<sup>8</sup>. Two commercial  $\text{N}_2$  reduction processes emerged in early 20<sup>th</sup> century: the Birkland-Eyde and Haber-Bosch process, and the latter has since dominated the  $\text{N}_2$

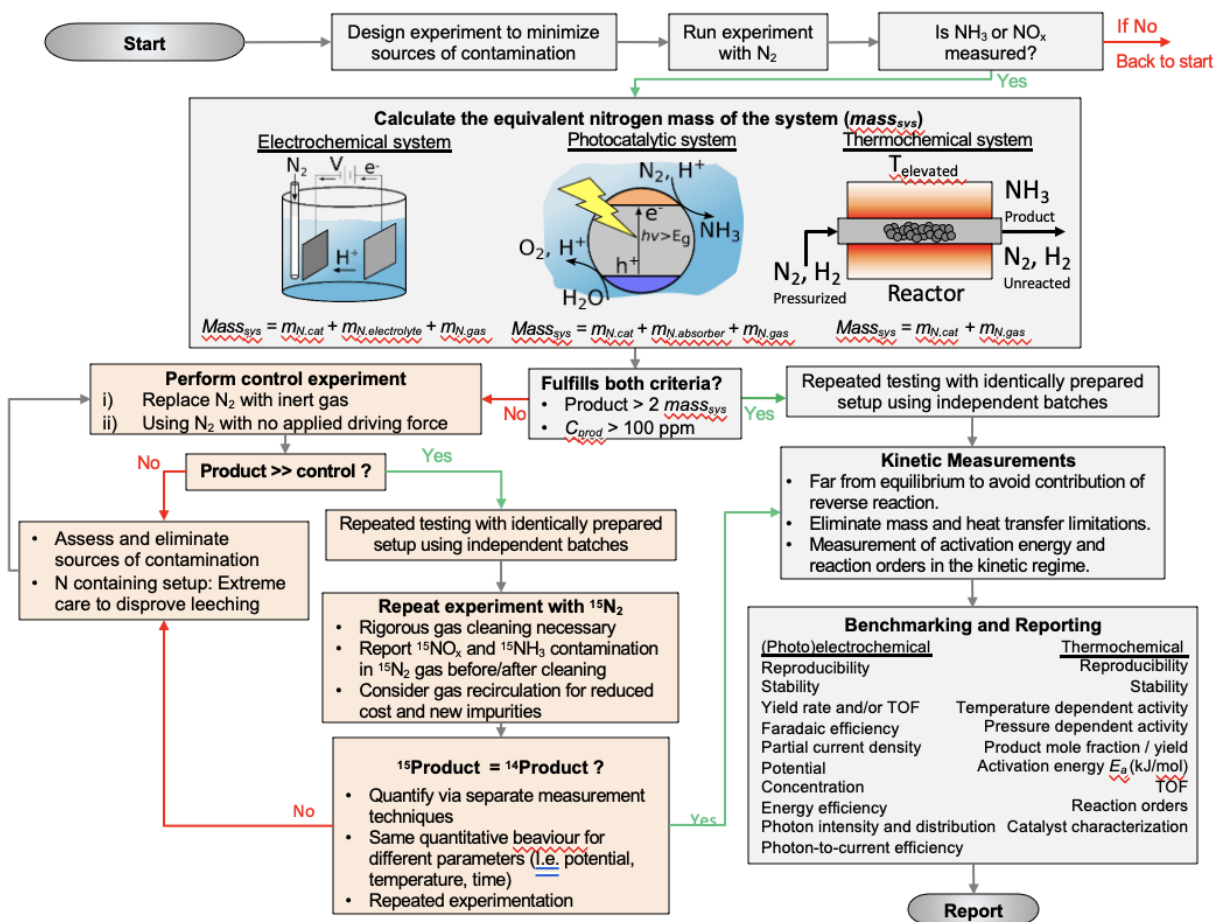

activation industry<sup>7</sup>, with 3 Nobel prizes given for its discovery<sup>14</sup>. With the global commitment to tackle climate change, the decarbonization of nitrogen fixation is envisioned to involve two technology generations: Coupling of Haber-Bosch with renewable  $H_2$  (Gen 2) and electrochemical  $NH_3$  synthesis (Gen 3)<sup>28</sup>.

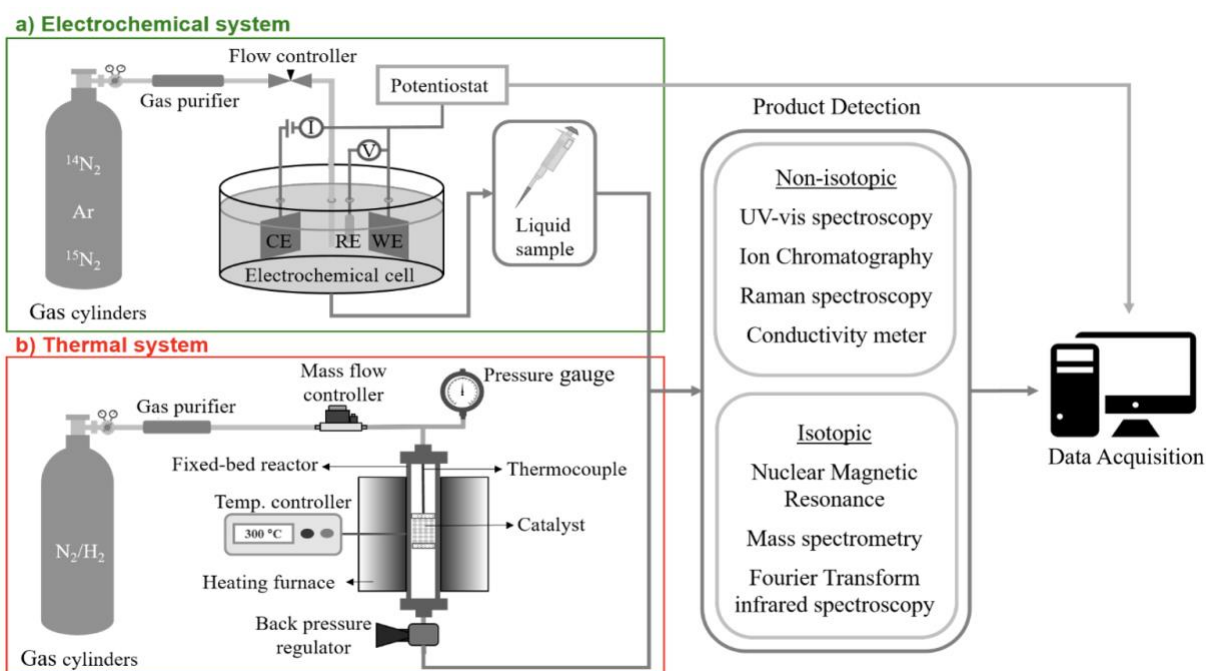

**Figure 2. The fundamental challenges of N<sub>2</sub> activation** **a)** Standard equilibrium potentials for N<sub>2</sub> and H<sub>2</sub>O redox are aligned with the electron energy (0 V<sub>SHE</sub> equals -4.44 eV on the absolute scale where electron in vacuum is 0 eV<sup>43</sup>). The free energy diagrams for N<sub>2</sub> reduction<sup>74</sup> and oxidation<sup>56</sup> on selected surfaces are plotted at the equilibrium potential referenced to standard conditions, 1 bar NH<sub>3(g)</sub> and 1M H<sup>+</sup>NO<sub>3</sub><sup>-</sup>(aq). \*X refers to surface adsorbed intermediates. The energy difference between two states (e.g. step 1-2 of associative N<sub>2</sub> reduction) corresponds to the thermodynamic barrier and can be lowered by potential if the step involves an electron transfer. An additional activation barrier may be present, shown as bumps between steps, whereby the value 0.7 eV is chosen for all coupled proton-electron transfer steps (consistent with Singh et al<sup>66</sup>). The N-N dissociation barrier is chosen as per ref<sup>196</sup>. The overall reaction barrier can be approximated by the step with the highest barrier (ΔG<sup>‡</sup>), which is much slower than other elementary steps thus governing the rate. **b)** Limiting potential analysis<sup>66</sup> for electrochemical N<sub>2</sub> reduction (overpotential referenced to N<sub>2(g)</sub>/NH<sub>3(g)</sub>) and H<sub>2</sub> evolution (overpotential referenced to H<sup>+</sup>(aq)/H<sub>2(g)</sub>) as a function of N binding energy on transition metal terraces. For electrochemical N<sub>2</sub> reduction, N<sub>2</sub>+\*+H<sup>+</sup>+e<sup>-</sup> → \*NNH (Step 1-2 in a) and \*NH+H<sup>+</sup>+e<sup>-</sup> → \*NH<sub>2</sub> (Step 5-6) define the right and left legs respectively. For H<sub>2</sub> evolution, \*+H<sup>+</sup>+e<sup>-</sup> → \*H and \*H+H<sup>+</sup>+e<sup>-</sup> → H<sub>2</sub> define the right and left legs respectively. The rate constants are shown in the second green axis, where kT/h equals 10<sup>13</sup> at 25 °C. The red points correspond to the calculated turnover frequencies (TOF) on transition metal FCC/HCP (211), computed using a micro-kinetic model by considering the dissociative mechanism as described in ref<sup>69</sup>. The synthesis condition is 400 °C, 100 bar, gas composition H<sub>2</sub>:N<sub>2</sub>=3:1 containing 5% NH<sub>3</sub>.

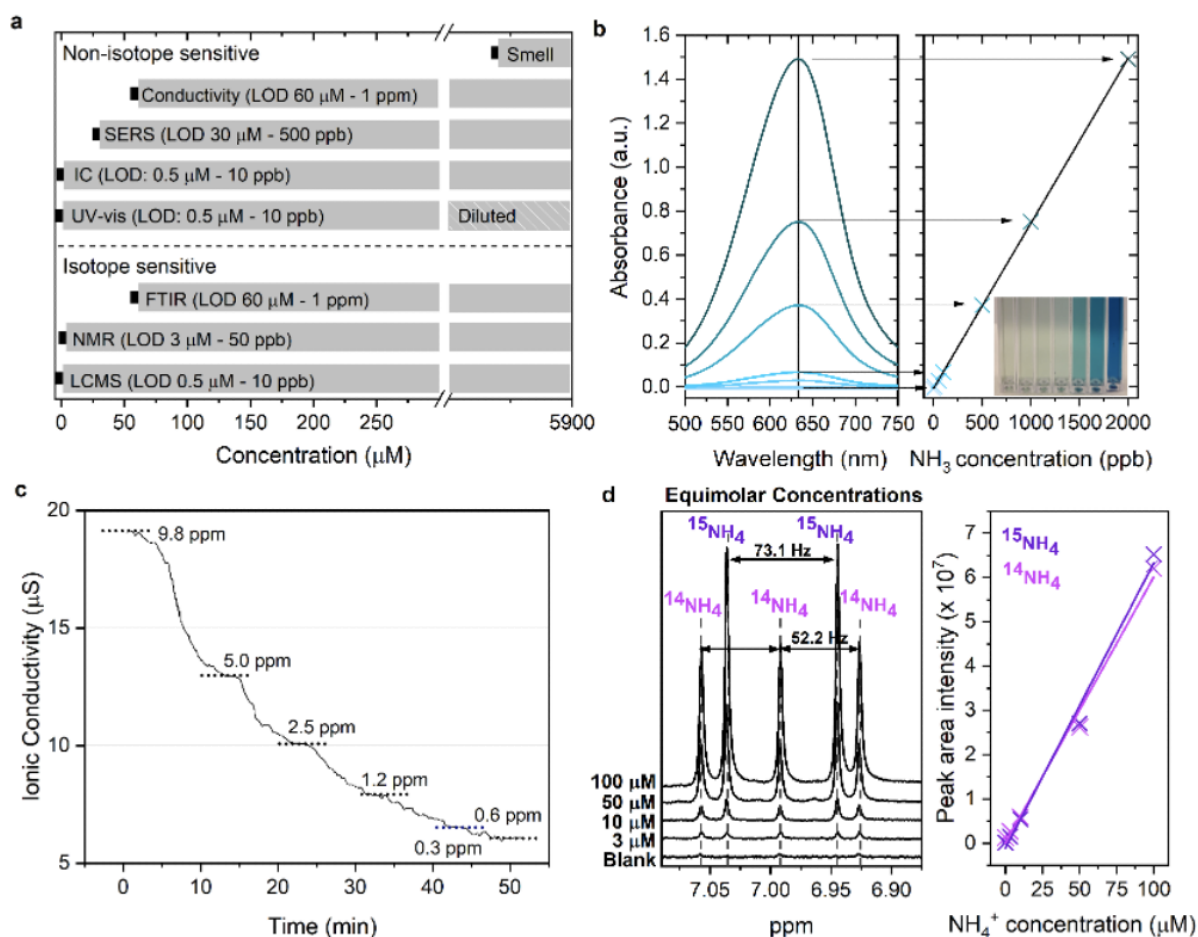

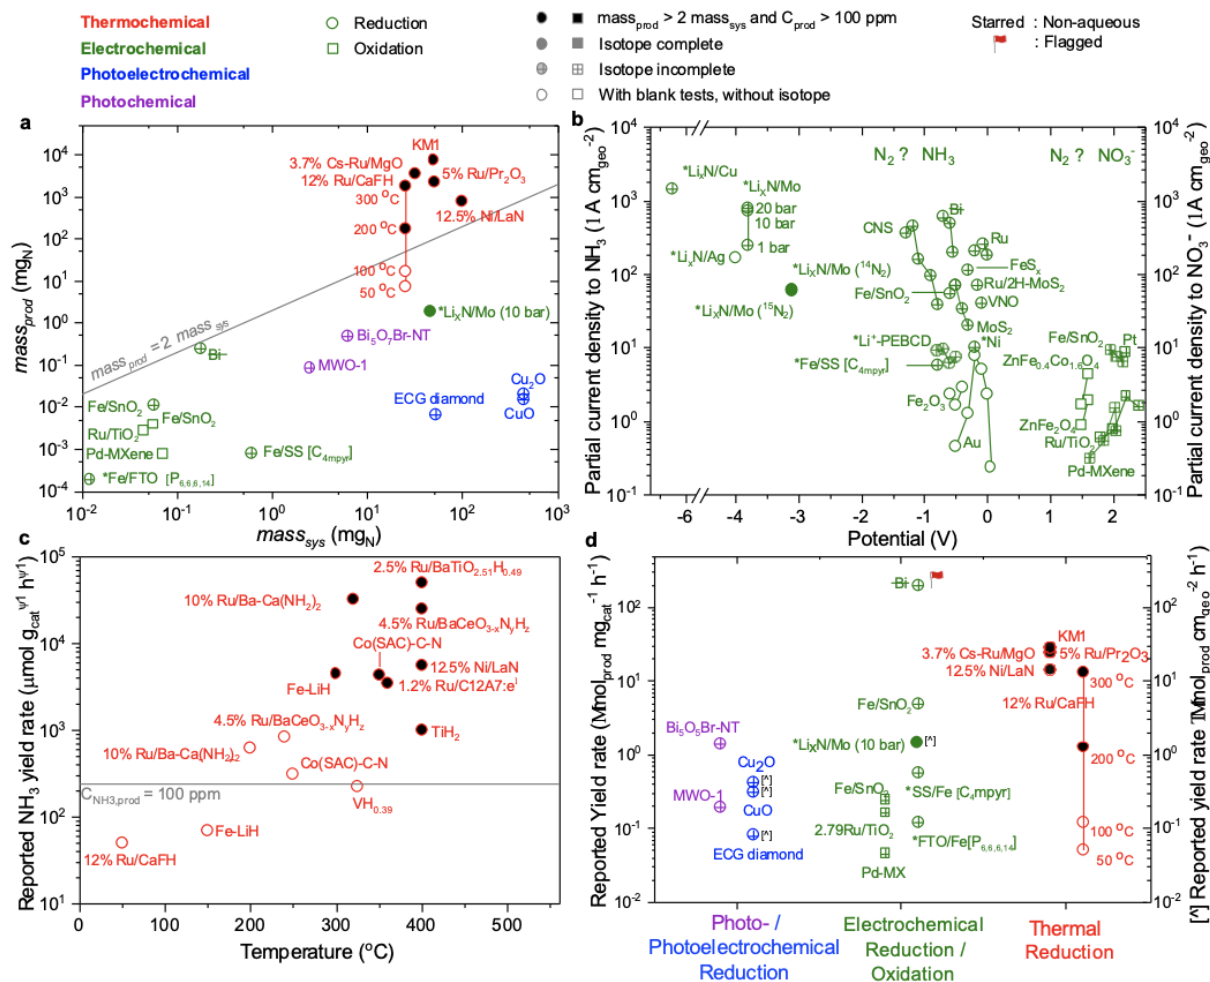

**Figure 3. General flow chart of experimentation.** The total equivalent mass of the system,  $mass_{sys}$ , must be determined, which will be compared with the amount of product (NH<sub>3</sub> or NO<sub>3</sub><sup>-</sup>) measured,  $mass_{prod}$ , in order to determine the need for isotope labelled experiments. The  $mass_{sys}$  is the summation of the relevant N-containing masses, which includes the experimentally measured N in the catalyst ( $m_{N,catalyst}$ ), the mass of N in the electrolyte ( $m_{N,electrolyte}$ ), the mass of the N-containing absorber ( $m_{N,absorber}$ ), and the calculated or measured mass of impurities in the gas stream ( $m_{N,gas}$ ).

**Figure 4. Experimental setup for electrochemical and thermochemical  $\text{N}_2$  activation.** a) Experimental setup for electrochemical  $\text{N}_2$  reduction or oxidation reactions. The gas passes through a gas cleaner (either a reduced metal catalyst and freeze trap, or a commercial purifier), then flows into the electrochemical cell with a defined flow rate. The setup can be adapted for photoelectrochemical systems by using a photoelectrochemical cell with an illumination source. The reaction of interest is undertaken by controlling the potential across the electrodes via a potentiostat. For photochemical systems, the setup does not require a potentiostat, and the cell typically contains a suspension of particles or a surface with the active catalyst, and an illumination source is used to drive the reaction. b) Activity measurement system for thermal  $\text{NH}_3$  synthesis. The setup contains a fixed-bed reactor, a furnace with a temperature controller, a thermocouple placed on the top of catalyst bed, gas purifiers, a flow meter, a pressure gauge and a back-pressure regulator. Then, for any catalytic system, the product of catalysis is detected via either non-isotope or isotope-sensitive techniques if necessary.

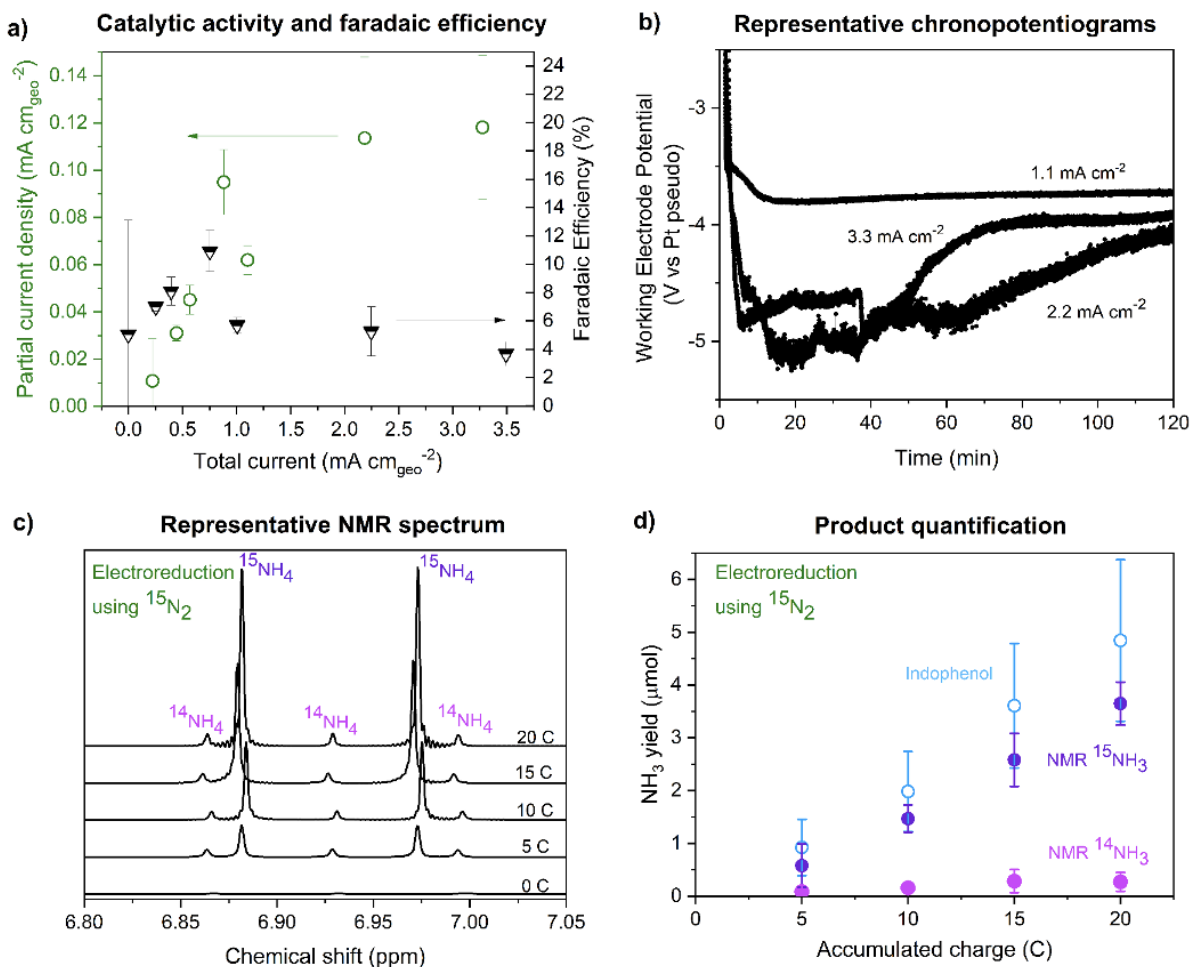

**Figure 5. Isotopic and non-isotopic ammonia detection methods.** a) Detection limits of well-known techniques for  $\text{NH}_3$  quantification. The bar at 5882  $\mu\text{M}$  (100 ppm) corresponds to  $\text{NH}_3$  concentrations in liquid where olfactory detection is possible beyond any doubt<sup>95</sup>. UV-vis<sup>76</sup>, Conductivity meter<sup>119</sup>, and nuclear magnetic resonance (NMR)<sup>76</sup> is discussed in text, Fourier transform infrared spectroscopy (FTIR)<sup>83</sup>, liquid chromatography mass spectroscopy (LCMS)<sup>197</sup>, surface enhanced Raman spectroscopy (SERS)<sup>198</sup> and ion chromatography (IC)<sup>199</sup> is discussed in the SI. b) UV-vis spectra of indophenol blue method, showing quantification via calibrated samples from 10 to 2000 ppb  $\text{NH}_3$  in  $\text{H}_2\text{O}$ . Straight line is fitted based on peak absorbance of each sample, displaying linearity with sample concentration. c) Conductivity measurement curve showing sensitivity of the  $\text{NH}_3$  concentration from 9.8 to 0.3 ppm in purified  $\text{H}_2\text{O}$ <sup>200</sup>. Due to the intensity of the conductivity baseline, it is difficult to detect an  $\text{NH}_3$  concentration below 1 ppm. d) Example of NMR spectra of increasing equimolar  $^{14}\text{NH}_3$  and  $^{15}\text{NH}_3$  concentrations, clearly showing the respectively distinct triplet and doublet peaks. Calibration curve for  $^{14}\text{NH}_3$  and  $^{15}\text{NH}_3$  based on area under respectively the triplet and doublet peaks from the NMR spectra<sup>76</sup>.

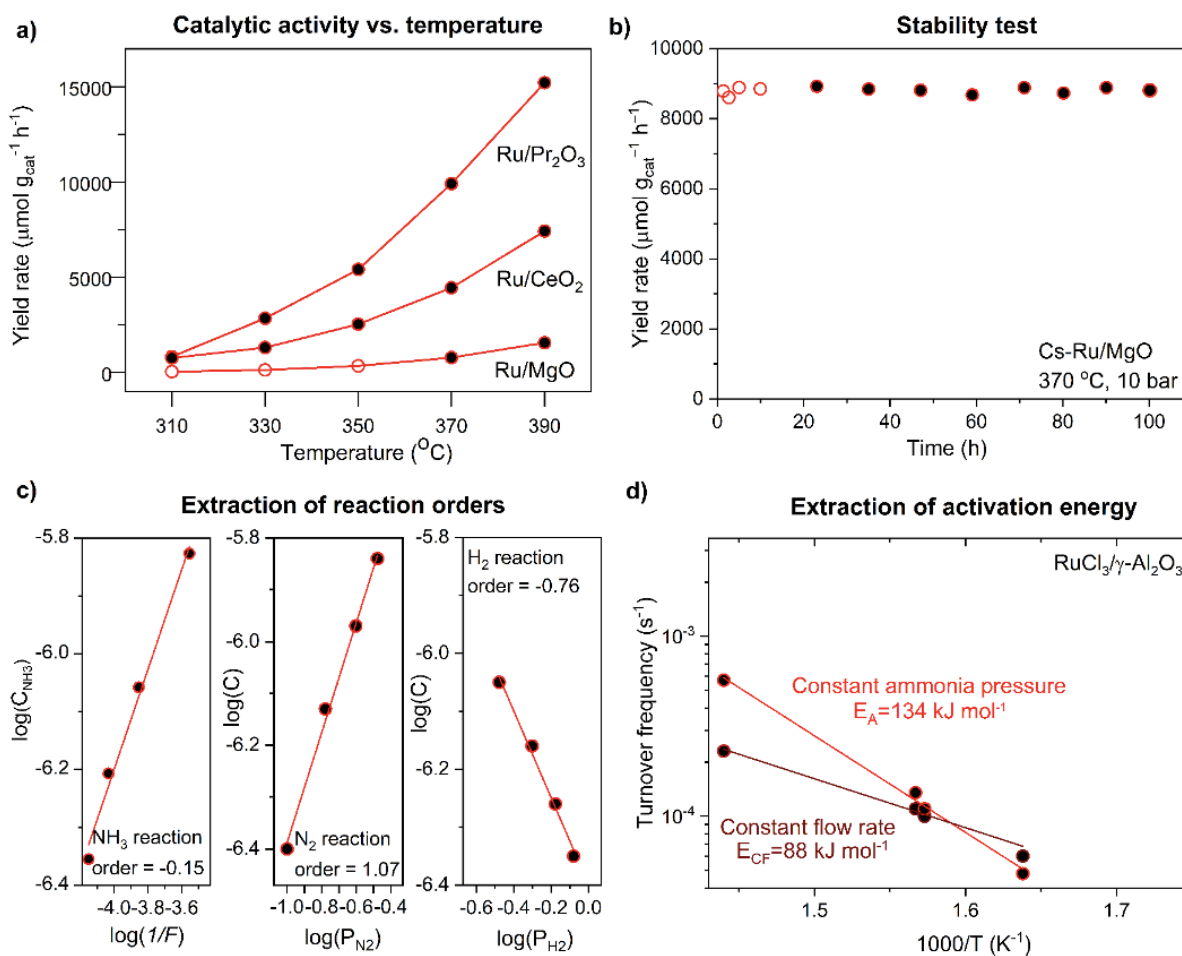

**Figure 6. State-of-the-art literature overview of electrochemical, photo(electro)chemical, and thermochemical N<sub>2</sub> activation** Evaluation of experimental conditions for thermochemical (red), electrochemical (green), photochemical (purple), and photoelectrochemical (blue) N<sub>2</sub> fixation. Experimental details found in Table S1-3. Circle represents reduction, square represents oxidation. Unfilled symbol represents data with simple background tests. Cross represents data with either qualitative or quantitative isotope labelled experiments at a single point, without measuring or cleaning gas contaminants. Filled symbol represents repeated isotope labelled experiments with rigorous gas cleaning. Black-filled data satisfy both mass<sub>prod</sub> > 2mass<sub>sys</sub> and product concentration above 100 ppm. Starred points contain non-aqueous electrolytes. Flagged data raise suspicion. **a)** Comparison of mass<sub>prod</sub> with mass<sub>sys</sub> for different catalytic systems. mass<sub>N,cat</sub> calculated based on 25% catalyst weight for non-N-containing catalysts, and 100% for N-containing catalysts. Thermochemical data at 400 °C and 1 bar unless otherwise specified. **b)** Literature overview of partial current density towards NH<sub>3</sub> (left y-axis) or NO<sub>3</sub><sup>-</sup> (right y-axis) from product detection as a function of potential vs RHE, unless otherwise specified. **c)** Literature overview of thermochemical NH<sub>3</sub> synthesis catalyzed by “reactive” materials whose composition or active phase may change during or after reaction. The line C<sub>NH3-prod</sub> = 100 ppm was calculated with the assumption of WHSV= 60,000 ml g<sub>cat</sub><sup>-1</sup> h<sup>-1</sup>. Data at 10 bar unless otherwise specified. **d)** Comparison of reported mass-specific activity. Yield rates of data points annotated by [^] are expressed in μmol cm<sub>geo</sub><sup>-2</sup> h<sup>-1</sup>. Fe on Stainless Steel (Fe/SS) and Fe/FTO<sup>137</sup> reported vs NHE, Li<sub>x</sub>N/Cu<sup>81</sup> total cell potential with Ohmic correction, Ni<sup>201</sup>

vs Ag wire in 0.1 M LiCl/EDA,  $\text{Li}_x\text{N}/\text{Ag}^{138}$  is vs Ag/AgCl/AgCl (sat), LiCl, LiClO<sub>4</sub>/THF reference, Cs-Ru/MgO<sup>113</sup> at 9 bar, Ru/Pr<sub>2</sub>O<sub>3</sub><sup>202</sup> at 390 °C and 9 bar, Ru/CaFH<sup>85</sup> at 1 bar, KMI<sup>148</sup> at 10 bar, Mn<sub>4</sub>N-LiH<sup>203</sup> at 30 bar, TiH<sub>2</sub><sup>155</sup> at 50 bar, 2.5%Ru/BaTiO<sub>2.51</sub>H<sub>0.49</sub><sup>154</sup> at 50 bar, 4.5%Ru/BaCeO<sub>3-x</sub>N<sub>y</sub>H<sub>z</sub><sup>204</sup> at 9 bar, Ru/Ba-Ca(NH<sub>2</sub>)<sub>2</sub><sup>205</sup> at 9 bar, 12.5%Ni/LaN<sup>153</sup> at 1 bar, VH<sub>0.39</sub><sup>156</sup> at 50 bar.

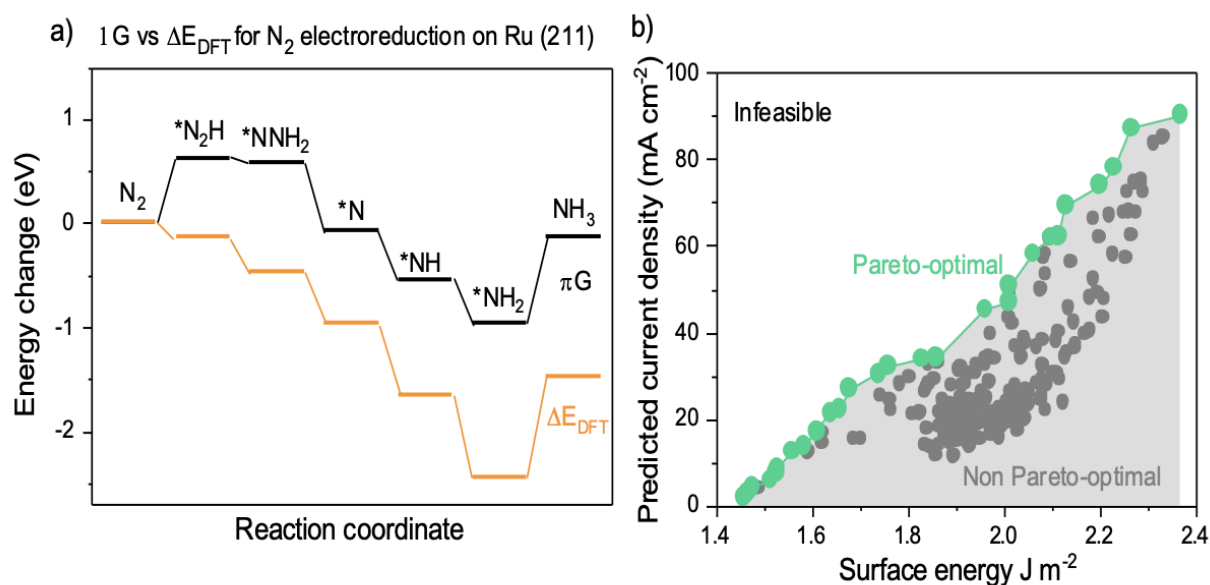

**Figure 7. Example data of Li-mediated NH<sub>3</sub> synthesis in THF with LiClO<sub>4</sub> salt and EtOH as the proton source.** a) Partial current density to NH<sub>3</sub> ( $i_{\text{NH}_3}$ , left y-axis) and Faradaic efficiency ( $FE_{\text{NH}_3}$ , right y-axis) as a function of total applied current. b) Representative CPs for experiments plotted in panel a). c) Representative NMR data from a single measurement, with samples taken every 5 C using cleaned  $^{15}\text{N}_2$  as feed-gas. d) Yield of NH<sub>3</sub> as a function of charge passed, showing quantitative agreement between isotope sensitive results (purple and pink) with non-isotope sensitive result (blue). Error bars signify mean and standard deviation of 3 repeated identical but independently prepared experiments. a-b) replotted from Schwalbe et al.<sup>79</sup>, c-d) replotted from Andersen et al.<sup>76</sup>.

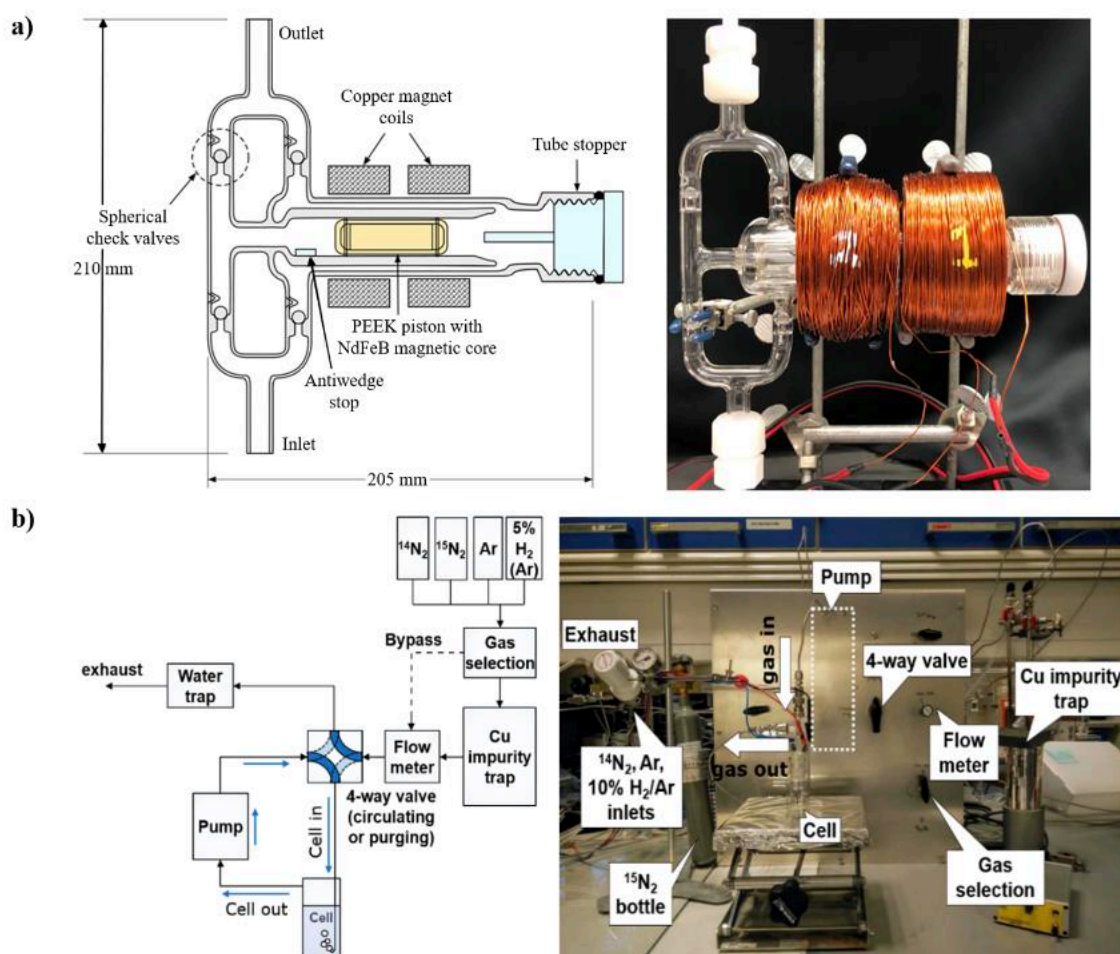

**Figure 8. Recommended reports of catalytic performances for thermal NH<sub>3</sub> synthesis.** (a) NH<sub>3</sub> synthesis rate as a function of temperature<sup>78</sup>; (b) Stability test of NH<sub>3</sub> synthesis rate<sup>113</sup> (c) extraction of reaction orders with respect to NH<sub>3</sub>, N<sub>2</sub>, and H<sub>2</sub><sup>206</sup>. Here, the term of  $\log(r) - a\log(P_{\text{NH}_3})$  is represented by  $\log C$ ; (d). Arrhenius plots at constant NH<sub>3</sub> pressure (red) and at constant flow rate (brown) resulting in a difference in the extracted activation energy. Dark-filled points satisfy the  $\text{mass}_{\text{NH}_3} > 2 \text{ mass}_{\text{sys}}$  criteria.

**Figure 9. Density functional theory results** (a) An energy diagram of  $N_2$  reduction on Ru (211) showing the free energies and DFT energies respectively (black and orange respectively)<sup>65</sup>. (b) The surface energy plotted against the predicted current density for the  $O_2$  reduction reaction on defected Pt (111) surfaces. Green points represent points on the Pareto Frontier, grey points represent non Pareto-optimal surfaces. The grey area represents sub optimal surfaces whereas the white region represents unobtainable surfaces<sup>165</sup>. The current density ( $i$ ) is calculated using the expression  $i = i_c \exp(-\Delta G_{ORR}/kT)$ , where  $i_c$  is an experimental value  $3.68 \times 10^{11}$  kA mol<sup>-1</sup> at cell potential 0.9 V, and  $\Delta G_{ORR}$  is the change in Gibbs energy of the limiting step. The surface energy of each defected surface is calculated by dividing the formation energy by the surface area. The full methodology can be found in Ref<sup>165</sup>.

## Glossary Terms

**Activation barriers:** The minimal amount of energy required for reactants to undergo a chemical reaction.

**Standard potential:** The potential of a reversible electrode at standard state with ions at an effective 1 M concentration at the pressure of 1 atm.

**Electrochemical half-cell reactions:** Either an oxidation reaction on the anode electrode where an electron is lost or a reduction reaction on the cathode electrode where an electron is gained.

**Electric arc-generated hot plasma:** A discharge of electric current across a spatial gap, sustained by the presence of a thermally ionized plasma, which allows for the flow of said current.

**Reaction orders:** the power dependence of the rate on the concentration of each reactant, which is an experimentally determined parameter that can have fraction values.

**Tafel analysis:** is used to determine an electrochemical systems transfer coefficient via voltammograms, thereby providing information about the electrochemical mechanism and catalytic activity.

**Ohmic correction:** Accounting for the Ohmic resistance of the media to accurately determine the potential at the surface of the electrode.

**Quantum yield:** Determining the number of times a specific event occurs per absorbed photon by the system in question.

**Density functional theory:** a computational quantum mechanical modelling method used to investigate the electronic structure of many-body systems.

**Zero point energy:** The lowest possible energy that a quantum mechanical system contains, which includes fluctuations in the lowest energy state from the Heisenberg uncertainty principle.
