Antibiotic resistance genes (ARGs) are commonly detected in the atmosphere, but questions remain regarding their sources and relative contributions, bacterial hosts, and corresponding human health risks. Here we conducted a qPCR- and metagenomics-based investigation of inhalable fine particulate matter (PM_{2.5}) at a large wastewater treatment plant (WWTP) and in ambient air of Hong Kong, together with an in-depth analysis of published data of other potential sources in the area. PM_{2.5} was observed with increasing enrichment of total ARGs along the coastal-urban-WWTP gradient and clinically relevant ARGs commonly identified in urban and WWTP sites, illustrating anthropogenic impacts on the atmospheric accumulation of ARGs. With certain kinds of putative antibiotic-resistant pathogens detected in urban and WWTP PM_{2.5}, a comparable proportion of ARGs co-occurred with MGEs was found between the atmosphere and WWTP matrices. Despite similar emission rates of bacteria and ARGs within each WWTP matrix, about 11–13% of the bacteria and >57% of the relevant ARGs in urban and WWTP PM_{2.5} were attributable to WWTPs. Our study highlights the importance of WWTPs in disseminating bacteria and ARGs to the ambient air from a quantitative perspective, and thus the need to control potential sources of inhalation exposure to protect the health of urban populations.

Antibiotic resistance has become a growing threat to public health. It is estimated that the continued development of antimicrobial resistance will result in 10 million deaths per year and 100 trillion USD in economic losses by 2050 [1]. Some ARGs are intrinsic to some bacteria; however, other ARGs are mobile and can be horizontally transferred to a broad range of host bacteria, a phenomenon that appears to be exacerbated by anthropogenic activities [2]. Inputs of antimicrobials and antibiotic resistance genes (ARGs) to terrestrial and aquatic compartments from various human, agricultural, and industrial sources have now been widely documented [3-10], but only recently is the atmosphere beginning to be recognized as a potential key reservoir of ARGs [11-14]. Notably, ARGs have been found to be associated with airborne particles. In particular, ARGs associated with fine particulate matter (PM_{2.5}) pollution present a concern because PM_{2.5} can penetrate deep into the human lung. While other studies have begun to consider the implications of ARG exposure via water/food ingestion and skin contact, there is a need to better characterize the range of inhalation exposures to ARGs [14-16]. Such exposures are of particular concern when it can be confirmed that ARGs are carried within pathogens suspended in the atmosphere, as has been suggested by prior studies [13,17-19].

69

70

74

75

76

Recent studies are painting a picture of differential ARG distribution in the atmosphere at global and regional scales [11,16], implying that spatial heterogeneity of ARG sources is likely, including in the numbers and types of ARGs emitted. This is in addition to varying atmospheric conditions (e.g., smog) that can influence the transport of resistant strains and potentially also impose selective pressure on their survival. Various potential sources of airborne ARGs have been recognized, including typical anthropogenic ARG hotspots, such as livestock farms, wastewater treatment plants (WWTPs), hospitals, and solid waste treatment systems [20-22].

Diminishing concentrations of source-indicative bacterial and ARG species in the atmosphere with increasing distance from putative source sites, along with close resemblance of ARG profiles between putative sources and nearby aerosols provide strong evidence of key anthropogenic sources [22,23]. However, there is a need to move towards quantifying ARG contributions from various putative sources to the ambient air. Recently, some quantitative source-predictive models, such as SourceTracker [24], have been applied towards source apportionment of ARGs found in sediment and urban stream samples [25,26]. They could potentially be extended to airborne ARGs.

Among putative airborne sources, WWTPs are prime candidates for consideration. They are fundamental to urban infrastructure and are known to receive high concentrations of antimicrobials, antibiotic-resistant bacteria (ARB), pathogens, and ARGs. Recent studies indicate that the treatment processes (e.g., aeration) of WWTPs tend to produce bioaerosols of less than 1–2 µm in size, which is within the respirable range [27,28]. Some studies have correspondingly noted the frequent occurrence of bioaerosol-inducing respiratory symptoms among WWTP operators [29]. In contrast to bacteria, few studies have touched on the field of ARG emissions from wastewater and sludge, especially through metagenomics-based approaches. One recent study provided qualitative comparisons of antibiotic resistome (i.e., total ARGs carried across a sample) profiles between activated/dewatered sludge and bioaerosols, but did not provide a quantitative assessment, such as emission rates [30]. Moreover, antibiotic-resistant pathogens are known to exist in WWTP bioaerosols, as confirmed by culture-dependent methods [31]. The systematic screening of metagenomic data to identify linkages of ARGs with potential pathogenic host bacteria in WWTP aerosols of inhalable range could help to better define the range and extent of associated inhalation exposure and risks, in particular with considerations of World Health Organization (WHO) priority pathogens and clinically-relevant ARGs [32,33]. Further examining the co-occurrence of ARGs with mobile genetic elements (MGEs) could provide additional insight into the extent to which horizontal gene transfer (HGT) occurs among airborne bacteria.

Given the hypothesis that WWTPs are a major source contributor to urban airborne bacteria and ARGs, we conducted a qPCR- and metagenomics-based study of the bacterial and ARG profiles of various compartments and surrounding PM_{2.5} at a large WWTP in Hong Kong, with urban and coastal PM_{2.5} included as well. Based on assembled contigs, we assessed the mobility of ARGs and potential carriage by pathogenic bacteria, i.e., the "resistome risk" [34] of airborne ARGs across urban land-use types. Metagenomes of samples in the current study were further congregated with publicly available sequencing data of other putative emission sources to predict the source profiles of airborne bacteria and ARGs in WWTP and urban areas. A simple one-box model was then applied to estimate the airborne emission potential of bacteria and ARGs in WWTP-relevant matrices to surrounding environments. Overall, we aimed to quantify the contribution of WWTPs to airborne bacteria and ARGs in urban environments, which can help to advance understanding of the potential exposure risks of airborne antibiotic resistance posed to large urban populations.

2. Materials and Methods

2.1 Site description and sampling strategy

A PM_{2.5} sampling campaign was performed at the Stonecutters Island Sewage Treatment Works (SCISTW), the campus of The Hong Kong Polytechnic University (PU), and the Hok Tsui Regional Air Monitoring Station (HT) in Hong Kong, representing WWTP, urban, and coastal background environments, respectively (Fig. 1A; Table S1). SCISTW is the largest sewage treatment plant in Hong Kong, serving almost half the city's population, with a

designed daily capacity for treating 2.45 million m³ of sewage. It applies the process of chemically enhanced primary treatment (CEPT) without secondary biological treatment before discharging the dinsinfected effluent. The sampling period lasted from 24 to 30 October 2016 at SCISTW and HT, and from 28 October to 4 November 2016 at PU. 24-hour PM_{2.5} samples were collected daily on pre-baked (500°C for 5 h) quartz filters (8 × 10 in.², PALL) using highvolume air samplers (TH-1000C II, Wuhan Tianhong Instruments Co., Ltd., China) at a flow rate of 1 m³ min⁻¹. Single samplers were set up to collect PM_{2.5} samples at PU and HT, while four sites were selected for simultaneous sampling at SCISTW, namely the flocculation tank (FT), sedimentation tank (ST), primary sludge storage tank (SST), and barge facility for primary sludge transportation (BF) (Figs. 1B and S1). One sampler was placed beside each of the abovementioned sites, except the BF site equipped with two samplers in 2 m intervals as duplicates. A blank filter was placed in a non-operating sampler at the flocculation tank, PU, and HT for quality control. Correspondingly, aqueous sewage samples, including screened influent, flocculation tank sewage, sedimentation tank effluent, and final effluent after dechlorination, as well as CEPT sludge (primary) before centrifugation and sludge cake (primary) ready for transport to be incinerated at a sludge treatment facility (T·PARK), were collected daily from 24 to 28 October 2016 in SCISTW (Fig. 1B). Samples were kept at 4°C and transported immediately to the laboratory for analysis. More detailed information on SCISTW, the meteorological parameters, and the collected samples (sampling period and sample size) is provided in Section S1, Figs. S2 and S3, and Tables S2 and S3 in the Supporting Information.

2.2 Sample pretreatment and DNA extraction

Since quartz filter is not suitable for direct DNA extraction due to its hygroscopicity, each $PM_{2.5}$ sample was cut into segments and repeatedly sonicated with sterilized 1× phosphate-buffered saline (PBS) for three times (20 min each time) in an ice-water bath to get particles

off from quartz filters. PBS extracts from the same sample were combined and filtered through a 0.2-μm polyethersulfone (PES) membrane disc filter (47 mm, PALL). Blank filters were treated simultaneously using the same operation procedure. Influent, flocculation tank sewage, and sedimentation tank sludge collected from the sludge storage tank (~100 mL) were centrifuged at 9840 g and 4°C for 10 min upon arrival at the laboratory; the supernatant was carefully discarded, and the pellets were kept. With regard to the sedimentation tank effluent and de-chlorinated discharge, 250 mL solutions were filtered through 0.2-μm PES membranes (PALL). All samples were preserved at −80°C before DNA extraction. All the tools and consumables used were sterilized.

DNA extraction was conducted using the FastDNA SPIN Kit for Soil (MP Biomedicals) according to the manufacturer's instructions, except for a modified purification step involving the use of Agencourt AMPure XP beads (Beckman Coulter) for PM_{2.5} samples [17,35]. The 0.2-μm membrane disc filters of effluent and PM_{2.5} were first cut into pieces, while the pellets from sewage and sludge (around 150 mg) were directly used as inputs for the DNA kit. DNA extraction efficiency of the current method for air samples has been estimated in our prior study [36] and listed in Table S4. For each sewage/sludge/effluent sample, DNA extracted in triplicate were pooled together to reduce heterogeneity and then purified using the DNeasy PowerClean CleanUp Kit (QIAGEN). DNA extracts of PM_{2.5} from every three or four consecutive days in each site were combined to ensure sufficient material for a downstream analysis; DNA extracts of other samples from the same sites were combined in a manner corresponding to the time divisions of the PM_{2.5} samples and based on the daily flow of influent (Table S2). Finally, 13 PM_{2.5} DNA samples covering the entire sampling period, 3 DNA samples of the field blanks, and 3 sewage, 2 effluent, and 2 sludge DNA samples covering around half of the sampling period were used for downstream experiments (Table S3).

2.3 qPCR quantification of 16S rRNA genes and shotgun metagenomic sequencing

DNA extracts of PM_{2.5} and sewage/sludge/effluent samples were diluted 10 and 100 times, respectively, to minimize PCR inhibition before quantification of the 16S rRNA gene on a StepOnePlus Real-Time PCR System (Applied Biosystems). The dilution factor was determined by testing a number of randomly selected samples (for details of qPCR, please refer to Section S2 of the Supporting Information). Subsequently, around 25-100 ng undiluted DNA of each sample was used for low-input library construction and shotgun metagenomic sequencing on an Illumina Hiseq X Ten platform with the PE150 strategy. In total, 444 GB of clean data from 20 samples (excluding field blanks that failed in library construction) were obtained after trimming sequencing adaptors and filtering low-quality reads using fastp (v0.21.0 with default parameters) [37]. The sequencing data were uploaded to the NCBI BioProject database (https://www.ncbi.nlm.nih.gov/bioproject/) with the accession number of PRJNA693982.

2.4 Bioinformatic and statistical analysis

Taxonomy classification was conducted in Kraken 2 (v2.0.8-beta) [38] and Bracken (v2.5.0) [39] using the standard Kraken 2 database. ARGs were predicted using the DeepARG (v1.0.2) pipeline [40] (--deeparg_identity 70 --gene_coverage 5 --deeparg_probability 0.8) and doubled checked by manual inspection. Alpha diversity (Shannon index) was calculated ("vegan" package [41] in R) after a rarefaction of all sequencing data to 17,754,687 reads per sample, the minimum read number in all of the samples (Table S5), using the seqkit tool [42]. Venn diagrams and Upset plots revealing the intersections of bacterial communities and ARG profiles among different sample types were drawn using the "UpSetR" package [43] in R. Afterwards, a non-metric multidimensional scaling (NMDS) analysis was conducted to

differentiate the bacterial and ARG profiles among different samples based on Bray–Curtis dissimilarity, which was followed by a further identification of the determined biomarkers with a linear discriminant analysis (LDA) effect size (LEfSe) method [44]. Procrustes analysis was then used to check the similarity of bacterial and ARG distribution. Permutational Multivariate Analysis of Variance (PERMANOVA) and Dunn's test for a post-hoc Kruskal-Wallis comparison were conducted using a "vegan" package [41] in R.

To evaluate the co-occurrence patterns of ARGs, MGEs, and bacteria, clean sequencing data were assembled on the MetaStorm platform [45] using the built-in iterative de Bruijn graph de novo assembler for short reads sequencing data with highly uneven sequencing depth (IDBA-UD) [46]. The output contigs (summary statistics in Table S5) were then deposited in the NanoARG platform [47] for annotation of ARGs, MGEs, and putative bacterial hosts. Briefly, ARGs were predicted against DeepARG database using DeepARG-LS model (--iden 70 --prob 0.5 --cov 40) [40]; MGEs were aligned to a combined NCBI non-redundant database and integron-integrase (I-VIP) database using DIAMOND (--id 70 --evalue 1e-5 --query-cover 40) [48]. Taxonomy annotation was conducted using Centrifuge with default parameters [49]. Samples with less than 10 ARG-carrying contigs assembled were excluded from downstream contig-based analyses. Human pathogens, including those known to commonly manifest in resistant infections, such as ESKAPE (Enterococcus faecium, Staphylococcus aureus, Klebsiella pneumoniae, Acinetobacter baumannii, Pseudomonas aeruginosa, Enterobacter spp.) and other WHO priority pathogens in urgent need of novel antibiotics for treatment (Table S6), were identified according to the pathogen list (species level) summarized in a previous study [50] with minor updates (Table S7). The genetic location (chromosome or plasmid) of the identified ARGs was analyzed using PlasFlow (v1.1 with default parameters) [51]. ARGs co-localized with integrase/transposase/recombinase-encoding genes were

considered potentially mobile. Assembled data were uploaded to the online MetaCompare platform to evaluate the potential horizontal dissemination risks of ARGs [34], which was based on the co-occurrence patterns of ARGs, MGEs, and pathogen-like sequences on assembled contigs. In addition, although constrained by the total sequencing depth, metagenome-assembled genomes (MAGs) were constructed using metaWRAP (v1.2.1) [52] and annotated for ARGs, MGEs, and bacterial hosts (detailed information in Section S3 in the Supporting Information).

2.5 Source tracking and estimation of bacterial and ARG emissions from WWTPs

SourceTracker (v1.0.1) [24] was adopted in R with default parameters to explore the contributions of diverse putative sources (e.g., soil, freshwater, seawater, sediment, landfill leachate, human skin, oral cavity, human airway, and WWTP sewage/sludge/effluent) to the airborne bacteria and ARGs. About 345 shotgun metagenomic sequencing data in total, including 338 downloaded from the NCBI and MG-RAST databases (listed in Table S8) and 7 from this study (sewage/effluent/primary sludge), were used as source samples in source tracking, while the remaining 13 PM_{2.5} samples were treated as sink samples. To focus on the local situation, most of the downloaded samples were from Hong Kong and South China, except those without suitable metagenomic data from Hong Kong. Considering that WWTPs with secondary treatment systems could also be an important source, sequencing data of activated sludge from the largest secondary WWTP in Hong Kong, namely the Sha Tin Sewage Treatment Work, were also retrieved from the NCBI database and included in source tracking. All data were subjected to the same bioinformatic analysis pipeline in fastp, Kraken 2, Bracken, and DeepARG. Bacterial profiles at the species level and ARG profiles at the ARG subtype level, after removing those presented in less than half of the samples in each source, were used as the input for SourceTracker. The prediction performance of SourceTracker based on the 252 current source data was evaluated using leave-on-out cross-validation strategy as proposed by

253 Li et al. [25]

To further estimate the emission of bacteria and ARGs from different WWTP media to the ambient air (PM_{2.5}-based), a simple one-box model was applied for calculation (Fig. 1C) with the following assumptions: 1) the flux of PM_{2.5}-associated bacteria and ARGs in and out of the box was from top to bottom; 2) there was no deposition inside the box; and 3) PM_{2.5}-associated bacteria and ARGs were well mixed within the box and under a steady state during the sampling period. In sum, SCISTW was regarded as a cubical box of length *L*, width *W*, and height *H*. The emission potential of bacteria (using the 16S rRNA gene as an indicator) and ARGs from different WWTP matrices within the box was calculated based on the law of conservation of mass following Equations 1–4.

$$\frac{d(LWHC)}{dt} = E_{total} + (C_{in} - C)v_LWH + (C_{in} - C)v_wLH; \text{ for a steady state, } \frac{dC}{dt} = 0$$

Equation 1

266
$$E_i = E_{total}p_i, \sum_i p_i = 1 \text{ and } i = \text{sewage, sludge, and effluent}$$

Equation 2

268
$$E_i = Q_i \alpha_i, i = \text{sewage, sludge, and effluent}$$

Equation 3

270
$$Emission \ rate_i = \frac{\alpha_i}{conc_i}, i = \text{sewage, sludge, and effluent}$$

Equation 4

In Equation 1–4, C_{in} and C represent the concentration of target genes (PM_{2.5}-associated 16S rRNA gene or ARGs [copy m⁻³]) in the inflow air and air within the box, respectively. t refers to time (s). v_L and v_w are the decomposed wind speeds (m s⁻¹) parallel to the length and width direction of the box, respectively, while E is the emission of target genes per unit of time (copy s⁻¹) from the whole SCISTW (*total*) or different matrices (i) inside. p_i refers to the contribution

of the individual matrix (i) to PM_{2.5}-associated bacteria or ARGs within SCISTW, which can be converted from the result of SourceTracker. Q_i is the daily flow of sewage/effluent (m³ d⁻¹) or CEPT sludge (kg d⁻¹). α_i is the emission of target genes (respirable size) per unit volume of sewage/effluent (copy m⁻³) or per unit weight of sludge cake (copy kg⁻¹) to the atmosphere. Conc_i refers to the concentration of target genes in sewage/effluent (copy m⁻³) or sludge (copy kg⁻¹). In this study, 350 m in length, 285 m in width, and 12 m in height were adopted according to the occupied area of SCISTW and the height of flocculation/sedimentation tanks plus the height of the air sampler. The concentration of PM_{2.5}-associated 16S rRNA genes (or ARGs) in HT with the contribution from WWTP deducted, and that in SCISTW were used as C_{in} and C, respectively. The amount of 16S rRNA genes (PM_{2.5}, sewage, sludge, and effluent) was quantified by qPCR, while the total amount of ARGs was the product of the amount of 16S rRNA genes and the relative abundance of ARGs (normalized to the 16S rRNA genes) predicted by DeepARG. v_L and v_w were calculated from the wind speed and wind direction during the sampling period recorded by our weather station (Fig. S2). The daily inflow of influent (Table S2) was used as Q_{sewage} and $Q_{effluent}$, while Q_{sludge} was estimated to be 600,000 kg d⁻¹ during the sampling period.

3. Results and discussion

3.1 Differences in bacterial community composition in PM_{2.5} compared with aqueous and

solid WWTP samples

Overall, more than 99% of the annotated bacterial reads could be assigned to the species level (rarefaction curves presented in Fig S4). A high number of shared bacterial species between sewage/primary sludge/effluent and PM_{2.5} (97% of all bacterial species identified) was observed (Fig. S5A). This suggests that PM_{2.5} could be substantially influenced by WWTPs as a source, even significantly downwind. However, the PM_{2.5} bacterial community structure at

the species level was significantly different from that in sewage/primary sludge/effluent samples in SCISTW (p < 0.001) (Figs. 2A and S6), even though the bacterial species they contained were similar. As revealed by a LefSe analysis, Actinobacteria, which play an important role in decomposing organic materials [53], could be indicative taxa in the atmosphere, in contrast to sewage, primary sludge, and effluent in SCISTW rich in *Pseudomonas* (LDA score > 4.5, p < 0.05) (Fig. 2B). When making comparisons along the land-use transect, the bacterial community structure in urban and SCISTW PM_{2.5} was more stable than the coastal background PM_{2.5}, as reflected by the higher Shannon index scores (Fig. 2C) and was well-separated from them (Fig. 2A). This pattern is consistent with different dominant sources of airborne bacteria across local geographical locations under different levels of disturbance from human activities. Compared with coastal areas, an increase of over one order of magnitude in the concentration of PM_{2.5}-associated 16S rRNA gene (indicating bacterial loads) was noted in urban/SCISTW sites (Fig. 2D), which also suggests higher absolute contributions of potential sources and a more bacteria-favorable atmospheric condition in human-impacted areas.

3.2 Broad spectrum of ARGs found in WWTP and urban PM_{2.5}

More than eight dominant types of ARGs (their relative abundance normalized to the 16S rRNA gene > 0.05) were identified in most of the samples (Fig. S7). The total relative abundance (Fig. 3A) and richness (subtype number) (Fig. S5B) of ARGs in PM_{2.5} were elevated across the coastal–urban–SCISTW transect, finally becoming comparable to the sewage/primary sludge/effluent samples in SCISTW. This remarkable pattern highlights a highly diverse airborne resistome under potential impacts by human activities, especially from WWTPs. This pattern also mirrors the ranking of major ARG types by relative abundance across the different samples. In general, the descending order of relative abundance was:

multidrug resistance (0.62–1.66 copies/16S rRNA gene) > peptide, macrolide-lincosamide-streptogramin (MLS), and aminoglycoside resistance (0.08–0.48 copies/16S rRNA gene) > tetracycline and beta-lactam resistance (0.04–0.26 copy/16S rRNA gene) > rifamycin and glycopeptide resistance (0.01–0.14 copy/16S rRNA gene) (Fig. S7). This pattern is qualitatively consistent with the view that WWTPs are an important source of ARGs in urban air environments, although we may not confirm the extent to which the proportion of the observed similarity between PM_{2.5} and WWTP matrices was attributed to the inherent baseline of ARGs across environment.

Even though the dominant drug resistance categories appeared to be those shared between PM_{2.5} and other samples, as aforementioned (Fig. S7), PM_{2.5} ARG profiles with a broad composition at the subtype level were clearly separated from those of sewage/primary sludge/effluent samples (Fig. S8). Since the ARG richness in human impacted PM_{2.5} is comparable to that in sewage/primary sludge/effluent (Fig. S5B), the lower Shannon Index scores of the ARG profiles in PM_{2.5} samples (Fig. 3B) indicated a markedly lower evenness of airborne ARGs in urban/WWTP sites compared to the aqueous and solid WWTP samples, especially for sewage (p < 0.01). The LEfSe analysis further served to identify a series of indicator ARGs that effectively discriminated between the ARG profiles of airborne particles versus other sample types. These discriminatory ARGs were distributed across various drug resistance types and included: tetA (48), conferring resistance to tetracycline; bacA and rosB, conferring resistance to peptide antibiotics; and mtrA, mexF, and cpxR, conferring resistance to multiple antibiotics (LDA score > 3.5, p < 0.05) (Figs. 3C and S9).

Yang et al. [20] observed similar airborne ARG patterns: resistances to multiple drugs and bacitracin (a kind of polypeptide) were dominant in nearby WWTPs and urban areas.

Remarkably, some multidrug resistance genes, such as mexF, were prevalent and enriched in airborne particles in poultry farms and WWTPs at a higher relative abundance than that observed in animal feces and activated sludge, respectively [20]. Observations in the present study and Yang et al. [20]'s suggest the possibility to identify ARGs that are indicative of contaminants from different sources. Interestingly, there was a lack of correlation between the airborne antibiotic resistome and the taxonomic composition of the bacterial community (Fig. 3D); thus, such indicators would likely be associated with a limited number of bacterial hosts [16]. In addition, it was of concern to discover a number of clinically-relevant ARGs, which encode resistance to certain kinds of antibiotics in the "watch" and "reserve" groups proposed by the WHO [54]. Such ARGs are prominent airborne biomarkers in human-impacted areas. For example, bla_{SHV} , which confers resistance to beta-lactam, and vanR and vanA, which encode resistance to vancomycin, were enriched in urban PM_{2.5}. Additionally, mcr-5, which encodes resistance to colistin (peptide), was more abundant in SCISTW air in comparison with urban and coastal air (Fig. 3C and Table S10; LDA score > 2.5, p < 0.05).

3.3 Co-occurrence patterns of ARGs, MGEs, and potential hosts to indicate the environmental resistome risks

3.3.1 Potential mobility of airborne ARGs across sampling sites

An analysis of the assembled contigs generally indicated that ARGs were widely distributed on both chromosomes and plasmids in bacterial genomes. Notably, plasmids were found to be the dominant genetic location for ARGs detected in PM_{2.5} samples, in contrast to the comparable roles between plasmid and chromosome in other more compact media in SCISTW (Fig. 4A). However, when considering the potential mobility of ARGs, only a small minority of the identified ARGs (at the subtype level) co-occurred with MGEs (i.e., integrons/transposons) on the same contig: <2% in sewage/primary sludge/effluent, around 3%

in urban PM_{2.5}, and none in coastal and SCISTW PM_{2.5} (Table S11 and Fig. S10A). The potentially mobile ARGs (PM-ARGs) in urban PM_{2.5} were less associated with humans, such as *sul1* (sulfonamide-resistant) and *aadA* (aminoglycoside-resistant), which are commonly found in the environment [32]. A low proportion of ARGs co-occurred with MGEs at contig/genome level have also been observed previously: in the metagenomic investigation only a small portion of ARGs were found to have been carried physically on MGEs (<20% ARGs on plasmid or integron), despite the fact that ARGs and MGEs were widely detected and frequently found to be correlated in varying kinds of environmental samples, including human and animal feces, influent/effluent and activated/digested sludge from WWTPs, soil, sediment, permafrost, and natural water [55,56]. Moreover, in stark contrast to the diverse range of ARGs encountered across the samples (Fig. S7), the potentially mobile ARGs (PM-ARGs) identified in urban PM_{2.5} mainly appeared to only confer resistance to aminoglycoside and sulfonamide (Figs. S10B and S12). The differences between the total ARG and PM-ARG profiles suggest that dissemination rates will vary across drug resistance types.

3.3.2 Conserved bacterial hosts of airborne antibiotic resistance, including human

pathogens

Proteobacteria and Firmicutes were found to be the phyla most highly associated with airborne ARGs encountered in this study, regardless of sampling location, carrying 30%–83% and 13%–46% of the total identified ARGs in the airborne bacterial community, respectively. In SCISTW and urban sites, a substantial portion of airborne ARGs were associated with Actinobacteria (24% and 17%, respectively) (Fig. S10A). This observation also corresponded to the MAG-based result on ARB profile (Fig. S11). At the species level, ARGs in PM_{2.5} near aqueous sources (in coastal areas and sites near flocculation/sedimentation tanks in SCISTW) tended to be associated with potential pathogens, including *Ralstonia picketti* and *Ralstonia*

insidiosa, which prefer moist environments. In contrast, in the urban sampling location and near SCISTW sludge sites, ARGs were associated with a broader distribution of both pathogenic and ostensibly benign species (Fig. 4B and Table S12).

DNA markers pertaining to putative ESKAPE and priority pathogens identified by the WHO (Table S6) were found to be associated with ARGs on assembled contigs from WWTP and urban PM_{2.5} samples. A lower total relative abundance of these putative antibiotic-resistant pathogens (normalized to the total contig number) was estimated in PM_{2.5} (14.4 \pm 18.6 ppm in the urban site and 7.3 ± 3.3 ppm in SCISTW) compared with other potential source matrices in SCISTW (98.0 ± 26.3 ppm); however, different species were dominant in airborne communities (Fig. S13). In contrast to K. pneumoniae as the predominant species in sewage/primary sludge/effluent, A. baumannii and S. aureus were found to be the predominant antibiotic-resistant priority pathogens in SCISTW and urban PM_{2.5}, respectively. Antibioticresistant A. baumannii existed in considerable abundance both in SCISTW air and in sewage, primary sludge, and effluent, but was not detected in urban air in the present study. This observation suggests that antibiotic-resistant A. baumannii might possibly be disseminated from aqueous and solid matrices in SCISTW to the nearby air, but that it might not be easy for this species to survive airborne transport to downwind areas. It was also worth noting that there has been a remarkable increase in hospital-associated cases of methicillin-resistant S. aureus in Hong Kong over the past few years, as well as a noticeable rate of detection of carbapenemand multidrug-resistant Acinetobacter, extended-spectrum β-lactamase (ESBL)-producing and cephalosporin-resistant E. coli and Klebsiella, and erythromycin- and penicillin-resistant S. pneumoniae [57]. While certain kinds of the abovementioned resistant species were identified in SCISTW air, including multidrug-resistant A. baumannii, vancomycin-resistant E. faecium, and macrolide-resistant S. pneumoniae, the ARGs co-occurring with these putative priority pathogens in urban PM_{2.5} in this study were different from the drug resistance types associated with the clinical cases in Hong Kong (Table S13). This suggests that these particular ARGs with clinical relevance are less likely to directly migrate from a clinical environment to urban areas via airborne communication or fail to persist long in air after transmission. However, this result could have been too limited by the current sequencing depth to have allowed for a comprehensive screening of antibiotic-resistant pathogens, and there was a lack of verification of resistance by culture-based methods.

Compared to the host profile of total ARGs in PM_{2.5}, PM-ARGs that were only detected in urban sites were observed to be harbored by fewer taxa, i.e., only Proteobacteria (dominant) and Firmicutes (Fig. S10). PM-ARGs appeared to be similarly constrained taxonomically in sewage/primary sludge/effluent samples as well. Such findings correspond to a previous study on *int11*, showing that ARG-carrying integrons were highly conserved in Proteobacteria [55]. In general, across this study, the associated range of bacterial taxa appeared to diminish from the whole microbial community to ARG hosts, and then to PM-ARG hosts. Given the uncertainty in the accuracy of the assembly of metagenomic data [58], future studies with culture-based approaches to more closely examine the postulated relationships identified here would be beneficial.

3.3.3 Comparable resistome risk score of PM_{2.5} among coastal, urban, and WWTP sites Based on the association of ARGs, MGEs, and putative pathogens annotated on assembled contigs, MetaCompare was employed to rank the resistome risk among samples, with a particular focus on critical human pathogens (Table S6). Compared with sewage/primary sludge/effluent, PM_{2.5} generally exhibited a lower resistome risk score (p < 0.05; Figs. 4C and S14). However, there were no significant differences in score among the PM_{2.5} samples

collected in the different sites (p > 0.05). This finding is consistent with the aforementioned observation that ARGs were rarely associated with MGEs in the air examined in this study. Putative ESKAPE pathogens carrying ARGs were more abundant in potential emission sources, such as sewage and sludge in WWTPs. Still, it is important to consider that any pathogenic bacteria harboring ARGs dwelling in the atmosphere could pose exposure and infection risks, particularly in the PM_{2.5} fraction, since it is amenable to inhalation. Thus, there is a need for human health risk assessments of environmental sources to consider the potential for exposure to airborne ARGs.

3.4 Estimating the contributions of WWTPs to the ambient airborne bacteria and ARGs

About 345 metagenomes representing different sample types collectively formed a database of putative sources of airborne bacteria and ARGs. These samples tended to be clustered by source category, regardless of the composition of the bacterial community or ARG profile (*p* < 0.01, Fig. S16). It should be noted that activated sludge was also included as a potential source since it was found different from CEPT sludge in both ARG relative abundance and composition (Figs. S15 and S16). The prediction performance of the model using the current datasets is described in Supporting Information (Section S4 and Figure S17).

Echoing the comparable bacterial community structure in PM_{2.5} between the urban and SCISTW sites (Fig. 2), their corresponding source profiles of bacteria were relatively consistent (Fig. 5A). Notably, there appeared to be a dominant contribution of bacteria from agricultural soil and plants (26%–29%) among the identified sources. Others have also suggested that terrestrial sources play an important role in shaping the composition of the airborne bacterial community in human-impacted areas [17,59], along with WWTP matrices (11%–13%), including primary sludge (4.5–5.4%), secondary sludge (3.6–4.9%), sewage

(1.9–2.0%), and effluent (0.8%–1.1%) in descending order, and human skin (8%–10%). Although the leading sources of bacteria in coastal areas turned out to be of human origin (55%), the absolute contributions from human airways, human skin, and human oral cavities appeared to be comparable across the three sites (p > 0.05) (Fig. 5B). This finding is reasonable since the coastal site was situated downwind of major urban areas (receiving human-related impacts) and ~60 m above sea level (few apparent marine-indicative signals detected). However, it should be noted that nearly 21% of the PM_{2.5}-associated bacteria in the coastal site and around half in the other two sites could not be apportioned to the current listed sources. This is probably because potential sources are still missing in the current model due to their lack of representation in public databases.

In contrast to the source tracking results of bacteria, the ARG source profile was more comparable among the three sampling sites (Fig. 5A), with less than 12% undetermined. 57%–60% of the PM_{2.5}-associated ARGs were ascribed to WWTPs (26%–27% from primary sludge, 15%–18% from sewage, 6%–10% from secondary sludge, and 6%–9% from effluent), followed by agricultural vegetation (10%–14%) and the remaining sources with comparable contributions (2%–4%). The disparities between the source profiles of PM_{2.5}-associated bacteria and ARGs could be due to the different enrichment levels of ARGs in bacterial communities from different sources. Specifically, WWTP-originated matrices in this study were responsible for up to 13% of the PM_{2.5}-associated bacteria, but for much higher proportions of ARGs at the three sites, as mentioned above. This finding corroborates the view that WWTPs, as an important ARG hotspot in urban areas, could be a major anthropogenic source of ARGs in the atmospheric environment. In addition, the contrasting source profiles could also suggest the dissimilar adaptability to the atmospheric environment among different ARB or between ARB and other general bacteria after their aerosolization from source

environments, e.g., many ARG-carrying bacteria have more similar patterns of survival, growth, and decay than the general bacterial community. Based on the current resolved sources, the PM_{2.5}-associated ARGs in Hong Kong are more likely attributable to anthropogenic activities in agricultural and engineering systems. Moreover, additional comparisons were made with PM_{2.5} collected during a similar period (unpublished data) in urban Guangzhou, a megacity located 120 km northwest of Hong Kong. Not surprisingly, Hong Kong-style WWTPs, characterized by mixed sewage (fresh and saline) and application of either CEPT or secondary treatment, contributed much less to airborne ARGs of urban Guangzhou than its contribution in Hong Kong (Fig. S18). Despite the low proportion in source profile, CEPTrelated ARG signals in Guangzhou still highlight the potential impact of Hong Kong's sewage treatment activities on the airborne resistome in nearby cities. These prediction results accord with the regional pollution pattern via air transportation and reflect the feasibility of using ARG signature in source tracking. However, the current results could be biased by the limited sample size in this study and a certain portion of non-local metagenomic data with potentially geographically dependent microbial features. In consideration of this eventuality, it is important to conduct a metagenomics-based survey in various local putative sources, including those not involved in the current study, such as hospitals and waste transfer stations, to further improve the completeness and accuracy of the results.

519

Finally, the emission rates of bacteria and ARGs in WWTP, expressed as the proportion of bacteria and ARGs in a certain source to be released to the atmosphere, were estimated. In general, the emission rates of both bacteria and ARGs was significantly higher (by two orders of magnitude) from primary sludge (1E-7 and 6E-8 on average for bacteria and ARG, respectively) than from sewage and effluent (p < 0.01) under the current configuration of SCISTW. The comparable levels of the estimated emission rates between bacteria and ARGs

from each WWTP matrix would seem to indicate a similar aerosolization potential of general bacteria and ARB. However, whether the antibiotic resistance property benefits the survival of these aerosolized ARB in the harsh atmospheric environment with distinct selective pressures (e.g., UV light, desiccation) still requires investigations. Lastly, as another important source, WWTPs incorporating a range of secondary biological treatments should be incorporated into future studies to fully estimate the emission of bacteria and ARGs from WWTPs to the urban environment.

3.5 Environmental Implications

This study highlights the dissemination of ARGs and their bacterial hosts from typical urban sources like WWTPs to the ambient atmosphere based on investigations into PM_{2.5}, which can be inhaled into the human respiratory tract and thus has potential health implications. Nevertheless, there is still a lack of emission standards of airborne bacteria and ARGs from such sources. The high contribution of anthropogenic sources (e.g., WWTPs) to airborne ARGs emphasize the need to regulate and manage relevant urban settings to mitigate the dissemination of ARGs to the atmospheric environment. However, the complex interactions between bacterial taxa and how environmental stress alters the bacterial communities after their aerosolization from putative sources does not seem to have been considered extensively in the algorithm. The current simple box model used to estimate the emission rates of bacteria in WWTP-originated matrices is an initial attempt to address this issue from a macro perspective. Future studies should also address the bacterial aerosolization within microenvironments, such as considering the partitioning of bacteria in at the air-liquid/air-solid interface. Further, a combination of the use of aerodynamic transport models and efforts to monitor the dynamic process of aerosolization (coupled with chamber tests) may help to produce a more accurate picture of the dissemination flux of bacteria and ARGs from various sources to the ambient atmosphere. In this study, although only a small portion of bacterially associated ARGs was linked with MGEs in PM_{2.5}, the HGT potential of ARGs in the atmosphere should not be overlooked. This evaluation should also consider the extracellular fraction of airborne ARGs [36] and the phage-mediated process, an important HGT pathway in highly turbulent environments [60], such as the atmosphere. In addition, culture-dependent techniques are required to confirm the existence and viability of ARB identified in this study and their expression of antibiotic resistance, as well as to verify the *de facto* transmission of ARGs via HGT. Such efforts will help to provide solid evidence beyond inferences derived from metagenomic data and further facilitate understanding of ARG dissemination mechanisms, including the linkage to specific host species.

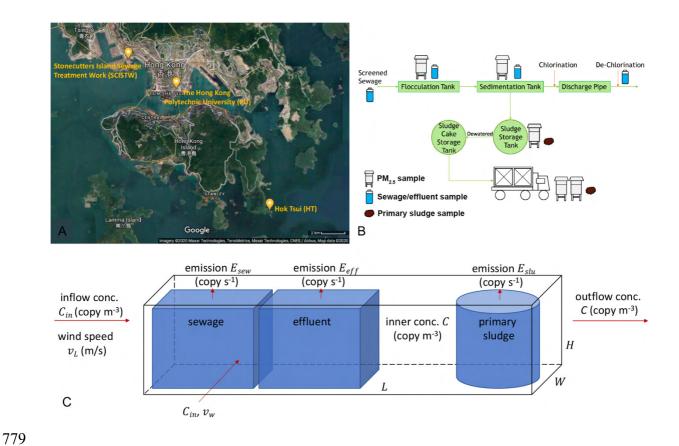

Figure 1. Map of three sampling locations in Hong Kong (A) and the general sewage treatment process in SCISTW, with the specific sampling positions and corresponding sample types marked (B). Panel (C) presents the conceptual simple box model used in the calculation of the emission potential of bacteria and ARGs from different SCISTW matrices to the ambient atmosphere.

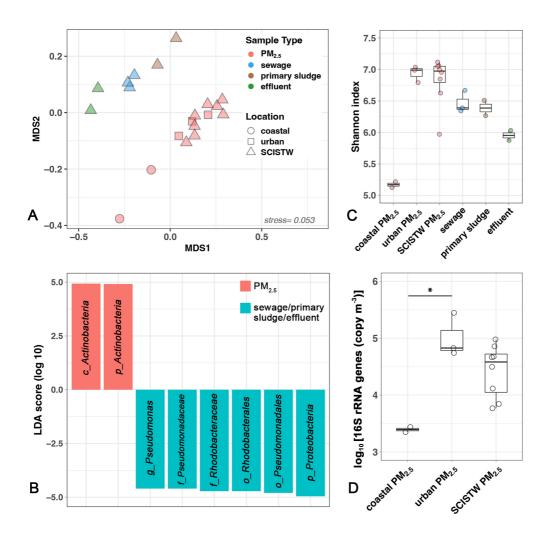

Figure 2. Comparison of bacterial abundance and community composition among sample types and sampling locations. Panel (A) visualizes the NMDS results (Bray–Curtis dissimilarity) of the bacterial community at the species level (PERMANOVA $R^2 = 0.5152$, p < 0.001, permutations = 999), which corresponds to the differentiation of key taxon indicators among different sample types revealed by a LEfSe analysis (LDA score > 4.5, p < 0.05) in Panel (B). Panels (C) and (D) show the alpha diversity (bacterial species-based Shannon index) among different sample types and the absolute abundance of PM_{2.5}-associated bacteria (indicated by the 16S rRNA gene) across the coastal–urban–SCISTW transect, respectively.

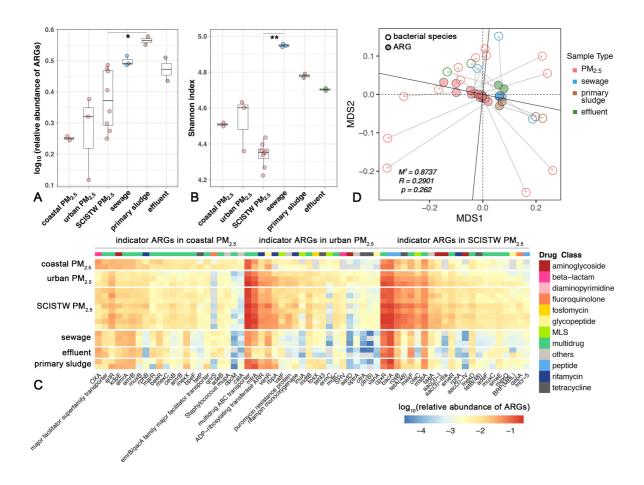

Figure 3. Antibiotic resistome across sample types and sampling locations. Panels (A) and (B) show the relative abundance of total identified ARGs (normalized to the 16S rRNA gene, log scale) and the alpha diversity of ARGs (Shannon index based on ARG subtype), respectively. Panel (C) is the relative abundance profile of indicator ARG subtypes (normalized to the 16S rRNA gene, log10 transformed) in PM_{2.5} across sampling locations determined by a LEfSe analysis (p < 0.05). Panel (D) tests the correlation of community structure between bacteria and ARGs via a Procrustes analysis (NMDS-based).

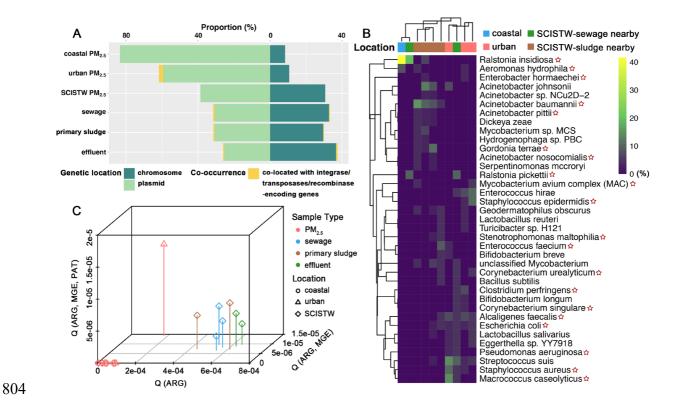

Figure 4. Co-occurrence patterns of ARGs, MGEs, and potential bacterial hosts based on assembled contigs. Panel (A) shows the genetic locations of ARGs in bacterial genomes (unclassified fraction not shown), as well as the proportions of ARGs that are co-localized with integrase/transposase/recombinase-encoding genes. Panel (B) presents the percentage of the identified ARGs in various bacterial species in each PM_{2.5} sample (using package "pheatmap" in R). Here only the antibiotic-resistant species presented in no less than two PM_{2.5} samples are shown. The red stars indicate the (emerging) human pathogens. Panel (C) shows the co-occurrence probability of the targeted components – ARGs, ARGs–MGEs, and ARGs–MGEs–putative pathogens (PAT), respectively – identified in the samples. This information is expressed as the contig number with critical components divided by the total assembled contig number.

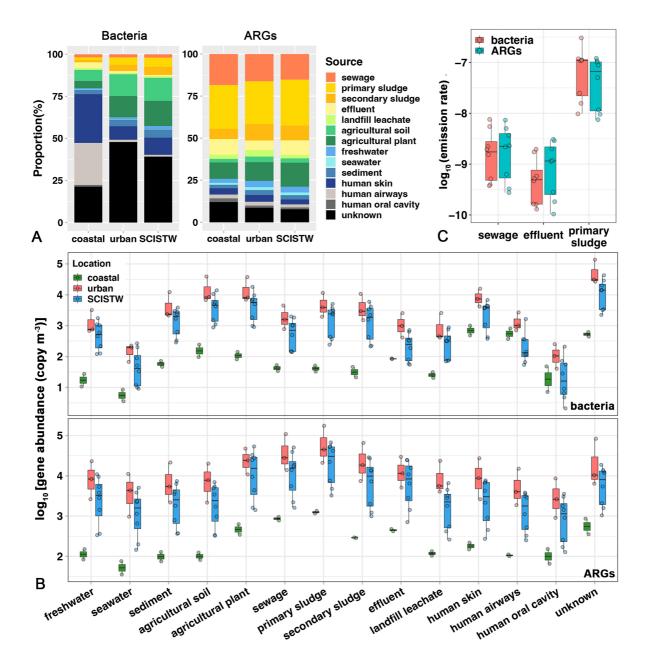

Figure 5. Contributions of various potential sources to PM_{2.5}-associated bacteria and ARGs in coastal, urban, and SCISTW sites. Panel (A) is the source profiles of bacteria and ARGs predicted by SourceTracker. Panel (B) shows the estimated absolute abundance of PM_{2.5}-associated 16S rRNA genes and ARGs contributed by different sources. The absolute abundance of ARGs was assumed to be the product of the absolute abundance of the 16S rRNA genes and the relative abundance of ARGs normalized to the 16S rRNA gene (predicted by DeepARG). The estimated emission rates of bacteria and ARGs in different SCISTW matrices are displayed in Panel (C), and are expressed as the proportion of bacteria or ARGs emitted to the ambient atmosphere.
