Expanding the synthetic toolbox to access pristine and rare-earth-doped BaFBr nanocrystals†

B. Dulani Dhanapala,[a] Hashini N. Munasinghe,[a] K. Tauni Dissanayake,[a] Leopoldo Suescun [b] and Federico A. Rabuffetti [*a]

A new synthetic route to access pristine and rare-earth-doped BaFBr nanocrystals is described. Central to this route is an organic–inorganic hybrid precursor of formula $Ba_5(CF_2BrCOO)_{10}(H_2O)_7$ that serves as a dual-halogen source. Thermolysis of this precursor in a mixture of high-boiling point organic solvents yields spherical BaFBr nanocrystals ($\approx$20 nm in diameter). Yb:Er:BaFBr nanocuboids ($\approx$26 nm in length) are obtained following the same route. Rare-earth-doped nanocrystals display NIR-to-visible photon upconversion under 980 nm excitation. The temperature-dependence of the green emission from Er^{3+} may be exploited for optical temperature sensing between 150 and 450 K, achieving a sensitivity of 1.1×10^{-2} K^{-1} and a mean calculated temperature of 300.9 ± 1.5 K at 300 K. The synthetic route presented herein not only enables access to unexplored upconverting materials but also, and more importantly, creates the opportunity to develop solution-processable photostimulable phosphors based on BaFBr.

Introduction

Rare-earth-doped BaFX (X = Cl, Br, I) constitute technologically relevant materials in the field of photostimulable phosphors used in medical X-ray imaging.[1–3] BaFBr in particular is the archetypical platform in which iso- and aliovalent substitutions with alkaline-earth metals,[4–6] halogens,[3,6,7] and rare-earths[6,8] are performed to tune the luminescence response. Polycrystalline rare-earth-doped BaFBr bulk phosphors may be synthesized using high-temperature solid-state reaction.[4,5,7,9,10] This route relies on barium and ammonium halides as fluorine and bromine sources. Over the past ten years, however, alternative synthetic approaches have been developed with the aim of achieving control over the morphology of phosphor grains. These developments have been motivated by the realization that the phosphor morphology directly impacts optical data storage performance (*e.g.*, image quality and spatial resolution).[11] As a result, a variety of routes to access nano- and submicron-sized rare-earth-doped BaFBr crystals have been described in the literature.

These routes include oil-in-water microemulsion,[12,13] coprecipitation,[14,15] mechanochemical,[6,16] and ionic liquid-assisted syntheses.[17] Colloidal synthesis in high-boiling point organic solvents is a remarkable absence in this toolbox, despite its potential to afford size- and shape-controlled nano- and submicrocrystals that can be solution-processed into functional form factors (*i.e.*, imaging plates).

Recently, our group reported metal heterohaloacetates as a new family of precursors for the solid-state and solution-phase synthesis of mixed halides.[18] These precursors are synthesized starting from a metal salt and commercially available heterohaloacetic acids and provide a convenient method to prepare pristine and doped fluorohalide nanocrystals *via* colloidal routes. In this article, we further develop this chemistry to expand the synthetic toolkit enabling access to rare-earth-doped BaFBr nanocrystals. $Ba_5(CF_2BrCOO)_{10}(H_2O)_7$ is used as a precursor to pristine and doped BaFBr nanocrystals. Its synthesis and crystal structure are described and its reactivity is investigated in the solid-state and in solution. BaFBr and Yb: Er:BaFBr nanocrystals are obtained upon hot injection of $Ba_5(CF_2BrCOO)_{10}(H_2O)_7$ into a mixture of oleic acid, 1-octadecene, and trioctylphosphine. The resulting nanocrystals are characterized with regard to their phase purity, morphology, doping levels, and luminescence. A new ytterbium-sensitized NIR-to-visible upconverting material suitable for optical temperature sensing is thus realized. Findings presented herein further highlight the utility of metal heterohaloacetates as dual-halogen precursors for the colloidal synthesis of mixed-halide optical materials.

Experimental

Synthesis

All syntheses were conducted under a nitrogen atmosphere using standard Schlenk techniques. Yb_2O_3 (99.9%), Er_2O_3 (99.99%), $BaCO_3$ (99.98%), anhydrous CF_3COOH (99%), oleic acid (90%), 1-octadecene (90%), and trioctylphosphine (97%) were purchased from Sigma-Aldrich and used as received. $CF_2BrCOOH$ was purchased from SynQuest Laboratories and stored in a nitrogen-filled glovebox (oxygen and water levels below 1 ppm).

Synthesis of $Ba_5(CF_2BrCOO)_{10}(H_2O)_7$

$Ba_5(CF_2BrCOO)_{10}(H_2O)_7$ was synthesized *via* solvent evaporation.[18] First, 2 mmol of $CF_2BrCOOH$ were weighed inside a glovebox and transferred to a 50 mL two-neck round-bottom flask containing 6 mL of double-distilled water. Next, 1 mmol of $BaCO_3$ was added to this solution. The flask was immersed in a sand bath and heated at 60 °C for 12 h until a colorless, transparent solution was obtained; magnetic stirring was employed to aid in the dissolution of $BaCO_3$. Finally, solvent evaporation was conducted at 65 °C for 48 h under a constant flow of nitrogen (200 mL min^{-1}). The resulting poly-crystalline solid, from which single crystals were recovered for structural analysis, was stored under a static nitrogen atmosphere.

Synthesis of BaFBr nanocrystals

Nanocrystals were synthesized *via* a modified hot injection method.[18] First, 1 mL of oleic acid and 1 mL of 1-octadecene were added to a 50 mL two-neck round-bottom flask containing 1 mmol of $Ba_5(CF_2BrCOO)_{10}(H_2O)_7$ (flask A). Next, 3 mL of oleic acid and 3 mL of 1-octadecene were added to a 100 mL flask (flask B). Both flasks were immersed in sand baths and heated to 115 °C under vacuum and vigorous magnetic stirring. After 45 min at 115 °C, the atmosphere of flask B was switched to nitrogen, a needle thermocouple was placed inside the flask in direct contact with the solution, and 4 mL of trioctylphosphine were quickly injected. Next, the temperature of flask B was increased to 300 °C and then the solution in flask A was swiftly injected. The reaction proceeded for 90 min at 300 °C. The flask was then removed from the sand bath and quenched to room temperature using a stream of air, yielding a turbid solution. BaFBr nanocrystals were recovered using a work-up procedure described elsewhere.[18]

Synthesis of Yb:Er:BaFBr nanocrystals

Five Yb:Er:BaFBr samples were prepared, each with a total metal content of 1 mmol. Nominal total rare-earth concentrations (Yb : Er : Ba molar ratios) of 0.50 mol% (0.0045 : 0.0005 : 0.9950), 1.5 mol% (0.0135 : 0.0015 : 0.9850), 3.0 mol% (0.0270 : 0.0030 : 0.9700), 4.5 mol% (0.0405 : 0.0045 : 0.9550), and 6.0 mol% (0.0540 : 0.0060 : 0.9400) were targeted. The nominal erbium concentration was fixed at 10.0% of the total rare-earth content (Yb : Er molar ratio equal to 9). Polycrystalline precur-

sors of Yb:Er:BaFBr nanocrystals were synthesized by dissolving stoichiometric amounts of Yb_2O_3, Er_2O_3, and $BaCO_3$ in a solution of 1 mL of CF_3COOH and 5 mL of H_2O. A colorless, transparent solution was obtained after heating at 65 °C for 12 h. Then, 2 mmol of $CF_2BrCOOH$ were weighed inside a glovebox and quickly added to this solution; magnetic stirring aided in the dissolution of $CF_2BrCOOH$. Upon complete dissolution, solvent evaporation was conducted under the same conditions described above to yield polycrystalline solids. Once obtained, these precursors were decomposed to Yb:Er:BaFBr nanocrystals using a hot injection approach similar to that outlined for BaFBr. The only differences were that (1) the precursors were dissolved in a mixture of 1 mL of oleic acid and 1 mL of 1-octadecene and injected into a flask containing a mixture of oleic acid (1 mL), 1-octadecene (1 mL) and trioctylphosphine (8 mL), and (2) the reaction proceeded for 20 min at 300 °C.

Single-crystal X-ray diffraction (SCXRD)

SCXRD analysis was carried out using a Bruker X8 Apex single-crystal diffractometer. $Ba_5(CF_2BrCOO)_{10}(H_2O)_7$ crystals were mixed with Paratone oil under a nitrogen atmosphere prior to mounting. A colourless crystal with approximate dimensions of $0.301 \times 0.444 \times 0.574$ mm was selected for structure determination and mounted on a microloop. X-ray diffraction intensities were measured at 100 K using Mo Kα radiation (λ = 0.71073 Å). Frames were integrated using Bruker's SAINT software. Experimental data were corrected for Lorentz, polarization, and absorption effects; for the latter, the multiscan method was employed using Bruker's SADABS software.[19] The crystal structure was solved using (1) a dual-space approach as implemented in SHELXT,[20] and (2) difference-Fourier (ΔF) maps as embedded in SHELXL-2018/1 [21] running under ShelXle.[22] The structure was visualized using VESTA.[23] Hydrogen atoms belonging to water molecules were not clearly visible in ΔF maps. They were not included in the final structural model because an unambiguous determination of their positions using geometrical restrictions was not possible. Full details on the data collection, structure refinement, and structural data are given in the ESI (Tables S1–S4 and Fig. S1†). Crystal data were deposited in the Cambridge Crystallographic Data Centre with number 1961033.†

Powder X-ray diffraction (PXRD)

PXRD patterns were collected at room temperature using a Bruker D2 Phaser operated at 30 kV and 10 mA. Cu Kα radiation (λ = 1.5418 Å) was employed. A nickel filter was used to remove Cu Kβ. A step size of 0.025° and a step time of 0.5 s were used to collect diffractograms in the 10–60° 2θ range.

Rietveld analysis

Rietveld analysis[24,25] of PXRD patterns was performed using the General Structural System (GSAS) with the graphical user interphase (EXPGUI) software.[26,27] The crystal structures of BaFBr and Yb:Er:BaFBr were refined using the tetragonal $P4/nmm$ space group. The following parameters were refined: (1)

scale factor; (2) background, which was modeled using a shifted Chebyshev polynomial function; (3) peak shape, which was modeled using a modified Thompson-Cox-Hastings pseudo-Voigt function;[28] (4) lattice constants (a and c); (5) fractional atomic coordinates of the metal (zBa) and bromine (zBr) atoms; and (6) an isotropic displacement parameter for all the atoms (U^{iso}). In the case of Yb:Er:BaFBr nanocrystals, the occupancy of the metal site (M) was fixed according to the Yb:Er:Ba ratio obtained from elemental analysis. Visual inspection of the difference curves and R_{wp} residual values were used to assess the quality of the refinements.

Thermal analysis (TGA/DTA)

Thermogravimetric (TGA) and differential thermal analyses (DTA) were conducted using an SDT2960 TGA–DTA analyzer (TA instruments). ≈10 mg of the precursor were placed in an alumina crucible, held at 35 °C for 30 min under a flow of argon (100 mL min^{-1}), and ramped to 600 °C at a rate of 10 °C min^{-1}.

Transmission electron microscopy imaging (TEM)

TEM images were obtained using a Talos F200X G2 S/TEM (Thermo Scientific) or a JEOL JEM2010F (JEOL Ltd). 200 kV was used as the accelerating voltage. A small aliquot of the native solution containing Yb:Er:BaFBr nanocrystals was diluted with toluene and dropcast onto a 200 mesh Cu grid coated with a Lacey carbon film (Ted Pella Inc.). Size distribution histograms were obtained after analyzing 250–300 nanocrystals.

Inductively coupled plasma mass spectrometry (ICP-MS)

Elemental analyses of metals in Yb:Er:BaFBr nanocrystals were carried out using a 7700 Series ICP-MS (Agilent Technologies). ≈3–4 mg of sample were dissolved in 20 mL of aqua regia at 65 °C. Ytterbium (1000 μg mL^{-1}, High Purity Standards), erbium (998 μg mL^{-1}, Fluka), and barium (1000 μg mL^{-1}, High Purity Standards) in 2% HNO$_3$ were used as standards.

Spectrofluorometry

Spectrofluorometric analyses were conducted using a Fluorolog 3-222 fluorometer (Horiba Scientific). An MDL-N-980 (Opto Engine, LLC) continuous-wave 980 nm laser and an R928 photomultiplier tube were used as the source and detector, respectively. Room-temperature emission spectra were collected for all Yb:Er:BaFBr samples. Variable-temperature spectra were recorded for nanocrystals with a nominal total rare-earth concentration of 6.0 mol%. In this case, the sample was loaded onto a VPF-800 variable-temperature stage (Lake Shore Cryotronics) and degassed at 450 K for 2 h under vacuum (≈80 mTorr) prior to data collection. Temperature control was provided by a Lake Shore 335-3060 controller. Emission spectra were collected in the 150–450 K temperature range at 25 K intervals. A heating rate of 5 K min^{-1} was employed. The samples were allowed to dwell for ≈10 min at the target temperature prior to spectral collection. All spectra

were recorded using a slit width of 2 nm and an excitation power density of 2.0 W cm^{-2}.

Results and discussion

The crystal structure of Ba$_5$(CF$_2$BrCOO)$_{10}$(H$_2$O)$_7$ is shown in Fig. 1a and b. This extended inorganic hybrid[29] crystallizes in the $P2_12_12_1$ orthorhombic space group and is isostructural to its chlorodifluoro counterpart Ba$_5$(CF$_2$ClCOO)$_{10}$(H$_2$O)$_7$ first reported by our group.[18] Barium atoms feature coordination numbers ranging from 8 to 11 and coordinating atoms include oxygen and fluorine from the carboxylate ligand and oxygen from water. Ba(O,F)$_n$ polyhedra share edges and faces to yield a three-dimensional framework displaying microchannels that run parallel to the a axis (Fig. 1a). Alternatively, the structure may be visualized as a result of stacking layers along the b axis. These layers consist of trimers of face-sharing Ba2(O,F)$_9$–Ba3(O,F)$_{11}$–Ba4O$_8$ polyhedra; each trimer is connected to four neighboring trimers belonging to the same layer through Ba1O$_{10}$ and Ba5O$_{10}$ polyhedra (Fig. 1b). Ba1O$_{10}$ and Ba5O$_{10}$ polyhedra also link neighboring layers along the b axis. Thermolysis of Ba$_5$(CF$_2$BrCOO)$_{10}$(H$_2$O)$_7$ in the solid-state was probed using a combination of TGA/DTA and PXRD; results from these analyses are summarized in Fig. 1c and d. Ba$_5$(CF$_2$BrCOO)$_{10}$(H$_2$O)$_7$ decomposes in two stages (Fig. 1c). The first stage corresponds to an endothermic process in which water molecules are removed. The second one corresponds to the thermolysis of the organic moiety and the subsequent crystallization of BaFBr; these processes occur between ≈218 and 226 °C and, as expected, are accompanied by an exotherm peaking at 226 °C. The total weight loss (≈52.7 wt%) is in good agreement with the theoretical value computed by assuming quantitative decomposition to BaFBr (53.7 wt%). Rietveld analysis of the PXRD pattern of the solid obtained after thermal analysis confirms that BaFBr is indeed the only decomposition product (Fig. 1d and Table S5†); all diffraction maxima in the pattern can be indexed to tetragonal BaFBr (PDF No. 00-024-0090, a = 4.5118 (3) Å, c = 7.4456 (5) Å). Motivated by the absence of colloidal routes to access BaFBr nanocrystals, we also investigated the thermal decomposition of Ba$_5$(CF$_2$BrCOO)$_{10}$(H$_2$O)$_7$ in high-boiling point organic solvents; results from these studies are summarized in Fig. 1e and f. A mixture of oleic acid, 1-octadecene, and trioctylphosphine in a 1 : 1 : 1 volume ratio provides good results in terms of phase purity and nanocrystal morphology. Decomposing Ba$_5$(CF$_2$BrCOO)$_{10}$(H$_2$O)$_7$ at 300 °C in this mixture yields phase-pure BaFBr nanocrystals; no diffraction maxima corresponding to secondary crystalline phases are observed in the PXRD pattern (Fig. 1e and Table S5†). Electron microscopy reveals that BaFBr nanocrystals exhibit a spherical shape with an average diameter of ≈21 nm (Fig. 1f). Outcomes from thermal decomposition studies highlight the utility of Ba$_5$(CF$_2$BrCOO)$_{10}$(H$_2$O)$_7$ as a dual-halogen precursor to BaFBr, both in the solid-state and in solution. This result and our previous report on the decomposition of Ba$_5$(CF$_2$ClCOO)$_{10}$(H$_2$O)$_7$
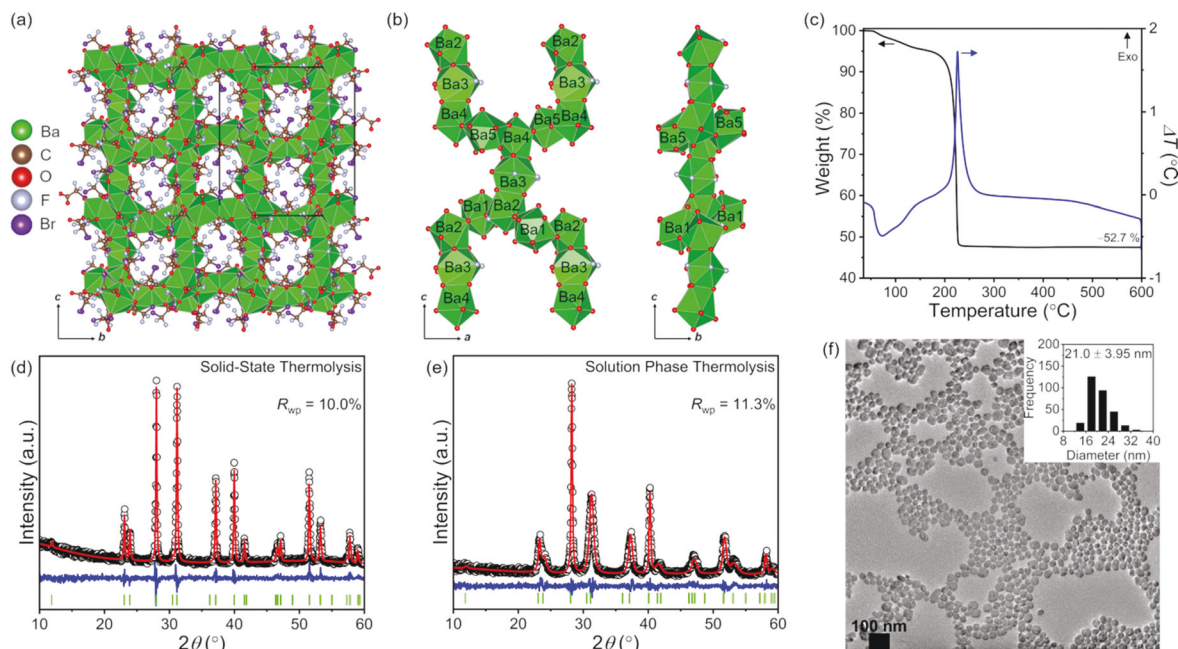

Fig. 1 (a) Crystal structure of $Ba_5(CF_2BrCOO)_{10}(H_2O)_7$. Microchannels run in the [100] direction and are lined with $-CF_2Br$ groups. Atom splitting in disordered positions has been omitted for clarity; only major occupancy positions are shown. The unit cell is shown with black solid lines. (b) A single layer built of $Ba(O,F)_n$ polyhedra viewed along [010] and [100] directions. (c) Thermogram and differential thermogram of $Ba_5(CF_2BrCOO)_{10}(H_2O)_7$; the total weight loss is indicated. (d and e) Rietveld analyses of the PXRD patterns of solid-state and solution decomposition products. Experimental (hollow black circles) and calculated patterns (solid red lines) are shown along with the difference curve (solid blue line) and tick marks corresponding to BaFBr (vertical green bars). to BaFCl[18] demonstrate that, more generally, heterohalocarboxylates provide synthetic access to mixed-halide materials. This family of precursors streamlines synthetic procedures by eliminating the need for external halogenating agents such as corrosive fluorine sources (e.g., F_2 and HF).

$Ba_5(CF_2BrCOO)_{10}(H_2O)_7$ was decomposed in solution in the presence of Yb^{3+} and Er^{3+} to probe the ability to aliovalently dope BaFBr nanocrystals with rare-earths. This experiment also allowed us to explore the feasibility of realizing BaFBr NIR-to-visible upconverting phosphors operating on the basis

of $Yb^{3+}-Er^{3+}$ sensitizer–activator pairs. Results from these studies are summarized in Fig. 2 and Table S6† for the case of BaFBr featuring a 3.0 mol% nominal total rare-earth concentration; results for other members of the Yb:Er:BaFBr concentration series are given in the ESI (Fig. S2–S5 and Table S7†). Rietveld analysis of PXRD data confirms the phase purity of Yb:Er:BaFBr nanocrystals, as no diffraction maxima belonging to crystalline phases other than tetragonal BaFBr are observed (Fig. 2a). Although nanocrystals appear as ≈26 nm cubes at first (Fig. 2b), closer inspection and quantitative analysis of
Fig. 2 (a) Rietveld analysis of the PXRD pattern of Yb:Er:BaFBr nanocrystals doped with a nominal rare-earth concentration of 3.0 mol%. Experimental (hollow black circles) and calculated patterns (solid red lines) are shown along with the difference curve (solid blue line) and tick marks corresponding to BaFBr (vertical green bars). (b) Corresponding TEM image and size distribution histogram. Nanocrystal size distribution is obtained by estimating edge length as (width × length)$^{\frac{1}{2}}$ (see the text for details). (c) Metal concentration curves for the Yb:Er:BaFBr concentration series. Dotted lines are guides-to-the-eye.

TEM images reveal that they are not isometric, with an average aspect ratio of ≈1:1. Quantification of metal concentrations *via* ICP-MS confirms the presence of Yb^{3+} and Er^{3+} (Fig. 2c). Total rare-earth concentrations increase as a function of their nominal values. Doping efficiencies range between 71 and 87% and experimental ytterbium-to-erbium molar ratios vary between 10 and 18. Attempts to dope BaFBr with a nominal total rare-earth concentration of 7.5% result in the appearance of secondary crystalline phases (see the ESI, Fig. S3†). This observation suggests that the experimental solubility limit for codoping Yb^{3+} and Er^{3+} into BaFBr under the experimental conditions described herein is on the order of 4.5–5.0 mol%. Considering elemental analysis results in the context of our previous studies of rare-earth-doped MFX nanocrystals (M = Ca, Sr, Ba and X = Cl, Br),[18,30,31] we conclude that the solubility of Yb^{3+}–Er^{3+} pairs (Yb : Er molar ratio equal to 9 : 1) in nanocrystalline MFX (1) increases upon going from calcium to strontium to barium, and (2) increases upon going from fluorobromides to fluorochlorides (see the ESI, Fig. S5†). We note that doping of trivalent rare-earths must be accompanied by the formation of charge-compensating defects. Pristine and aliovalently doped single crystal and bulk alkaline-earth fluorohalides have been shown to incorporate oxide anions as defects or as charge-compensating species.[32–35] This may also be the case in Yb:Er:BaFBr nanocrystals, as oxygen traces are certainly present in the reaction medium.

The functionality of Yb:Er:BaFBr nanocrystals as NIR-to-visible upconverters and luminescent thermometers was probed using steady-state spectrofluorometry. Results from these studies are summarized in Fig. 3 for nanocrystals doped with a nominal total rare-earth concentration of 6.0 mol%. The room-temperature emission spectrum demonstrates the ability to perform NIR-to-visible light upconversion (Fig. 3a). Bands at 525, 545, and 660 nm are observed upon 980 nm excitation, corresponding to the $^2H_{11/2} \rightarrow {}^4I_{15/2}$, $^4S_{3/2} \rightarrow {}^4I_{15/2}$, and $^4F_{9/2} \rightarrow {}^4I_{15/2}$ transitions of the Er^{3+} activator, respectively. Additionally, a very weak band arising from the $^2H_{9/2} \rightarrow {}^4I_{15/2}$ transition is observed at ≈410 nm. To the best of our knowledge, this is the first report of ytterbium-sensitized upconversion in BaFBr. Since the spectrum is dominated by the band centered at 660 nm, Yb:Er:BaFBr behaves as a red phosphor under NIR excitation. Red and red-orange upconverting phosphors have also been obtained using SrFCl as a host.[30,36] The spectral distribution of the upconverted emission does not change significantly with the rare-earth concentration; integrated intensities, on the other hand, increase with doping (see the ESI, Fig. S6 and S7†). 6.0 mol% Yb:Er:BaFBr nanocrystals were thus used to test their ability to operate as ratiometric luminescent thermometers. To this end, the temperature-dependence of the emissions from the $^2H_{11/2}$ and $^4S_{3/2}$ thermally coupled levels of Er^{3+} was monitored between 150 and 450 K. Inspection of the emission spectra shows that the intensity of the 525 nm band increases with temperature, whereas that of the 545 nm band decreases (Fig. 3b). The luminescence intensity ratio ($R(T)$) between these two bands was fit using eqn (1)
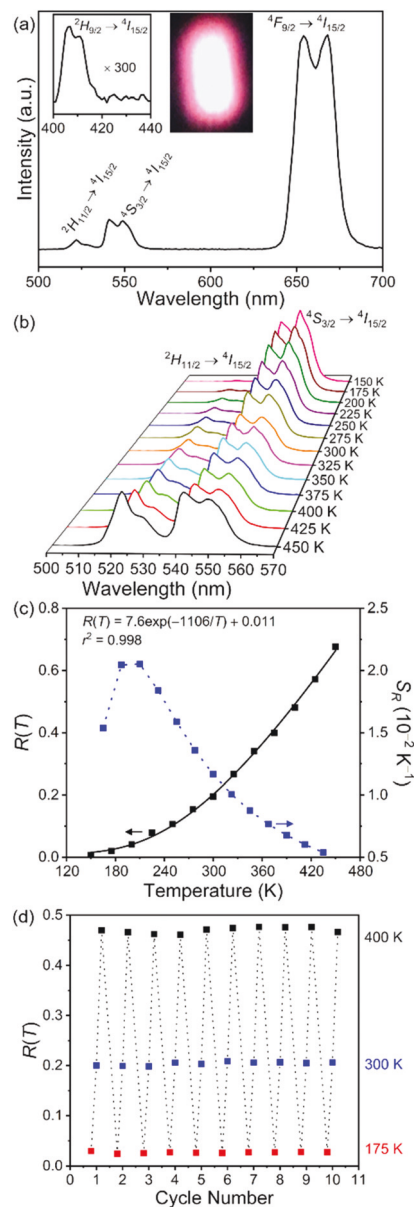

Fig. 3 Room temperature (a) and variable temperature (b) emission spectra of Yb:Er:BaFBr nanocrystals doped with a nominal total rare-earth concentration of 6.0 mol% under 980 nm excitation. Insets in (a) show the room temperature emission spectrum in the blue region and a digital picture of the sample under NIR illumination. (c) Luminescence intensity ratio ($R(T)$) and relative thermometric sensitivity ($S_R(T)$) as a function of temperature. Fit of eqn (1) to experimental ratios is depicted with a solid line. (d) Cyclability plot; dotted lines are guides-to-the-eyes.

$$R(T) = \frac{I(^2H_{11/2} \rightarrow {}^4 I_{15/2})}{I(^4S_{3/2} \rightarrow {}^4 I_{15/2})} = A \exp\left(-\frac{B}{T}\right) + C \qquad (1)$$

$$S_R(T) = \frac{1}{R(T)} \frac{dR(T)}{dT} \qquad (2)$$

and the relative thermometric sensitivity ($S_R(T)$) was computed using eqn (2). Intensities were estimated by integrating green

emission bands between 505 and 535 nm ($I(^2H_{11/2} \to {}^4I_{15/2})$)) and between 535 and 570 nm ($I(^4S_{3/2} \to {}^4I_{15/2})$)). $R(T)$ is adequately fit using $A = 7.6$ (6), $B = 1106$ (35) K, and $C = 0.011$ (6) as adjustable parameters (Fig. 3c). Sensitivity reaches a maximum of 2.1×10^{-2} K^{-1} at 200 K and decreases to 1.1×10^{-2} K^{-1} at room temperature. These values are in line with those obtained for upconverting luminescent thermometers based on other alkaline-earth fluoro-halide hosts such as CaFCl (2.2×10^{-2} K^{-1} at 200 K; 1.0×10^{-2} K^{-1} at 300 K),[31] SrFCl (1.7×10^{-2} K^{-1} at 200 K; $\approx 1.0 \times 10^{-2}$ K^{-1} at 300 K),[37] and SrFBr (2.1×10^{-2} K^{-1} at 200 K; 1.2×10^{-2} K^{-1} at 300 K).[37] Their similarity simply reflects the rather restricted range of sensitivities that may be achieved in single-activator ratiometric thermometers based on thermally coupled emissions. Finally, the thermometric performance of Yb:Er:BaFBr nanocrystals was further evaluated by computing repeatability, mean calculated temperature ($\langle T_{\text{calculated}} \rangle$), and temperature resolution (ΔT) at 175, 300, and 400 K. Nanocrystals were subjected to 10 heating–cooling cycles (Fig. 3d). Repeatability was calculated using eqn (3), where $R_i(T)$ is the value of the intensity ratio in the ith cycle and $R(T)$ is the average value computed over 10 cycles.

$$\text{Repeatability } (T) = 100 \times \left[1 - \frac{\max |R_i(T) - \langle R(T) \rangle|}{\langle R(T) \rangle} \right] \quad (3)$$

For each cycle, temperatures were backcalculated using eqn (1) and the average and standard deviation of these distributions were used to estimate temperature accuracy and resolution (see the ESI, Table S8†). Repeatabilities equal to 89, 99, and 99% are thus estimated at 175, 300, and 400 K, respectively. Likewise, mean calculated temperatures equal to 180.2 (2.6), 300.9 (1.5), and 393.5 (1.8) K are obtained.

Conclusions

The utility of $Ba_5(CF_2BrCOO)_{10}(H_2O)_7$ as a precursor to BaFBr was demonstrated. Thermolysis of this organic–inorganic hybrid in the solid-state and in solution yielded crystalline, phase-pure BaFBr at 300 °C. The organic moiety CF_2BrCOO^- acted as an *in situ* fluorinating and brominating agent. Pristine and doped BaFBr nanocrystals were obtained upon decomposition of the precursor in a mixture of high-boiling point organic solvents. Yb:Er:BaFBr nanocrystals were shown to serve as upconverting phosphors whose temperature-dependent green emission makes them ratiometric thermometers between 150 and 450 K. Results presented in this article further support heterohalogenated monocarboxylates as a family of hybrid precursors broadly applicable to the synthesis of mixed-halide materials. From the perspective of realizing solution-processable photostimulable phosphors, future synthetic efforts should seek to (1) develop the chemistry presented herein to dope divalent lanthanides such as Eu^{2+} into BaFBr nanocrystals, and (2) functionalize the nanocrystals' surface.
