consistent with the gray-shaded area in Fig. 5; (II) a relatively wide area of $0.35 < \eta < 0.55$, occurring at low to intermediate strain rates for all temperatures. Further microstructural verification is summarized in the next section.

3.4 Microstructure Observation

As depicted in Fig. 5, application of the DMM flow instability criteria ($\xi < 0$) results in two distinct regions with unstable/stable processing window for the hot deformation of the Ti55531 alloy. The flow stability region for this alloy was found at 0.001–0.1 s^{-1} and 1003–1153 K as well as the unstable flow regions are both shown as the gray-shaded areas in Fig. 5.

Figure 6 shows representative micrographs of the Ti55531 alloy under different deformation conditions. From Fig. 6a, it appears the serial growth of α grains along the direction of flow and somewhere a series with more than five grains. This phenomenon may be associated with persistent grain growth and annexation of α grains in the hot deformation process that is the typical dynamic recrystallization

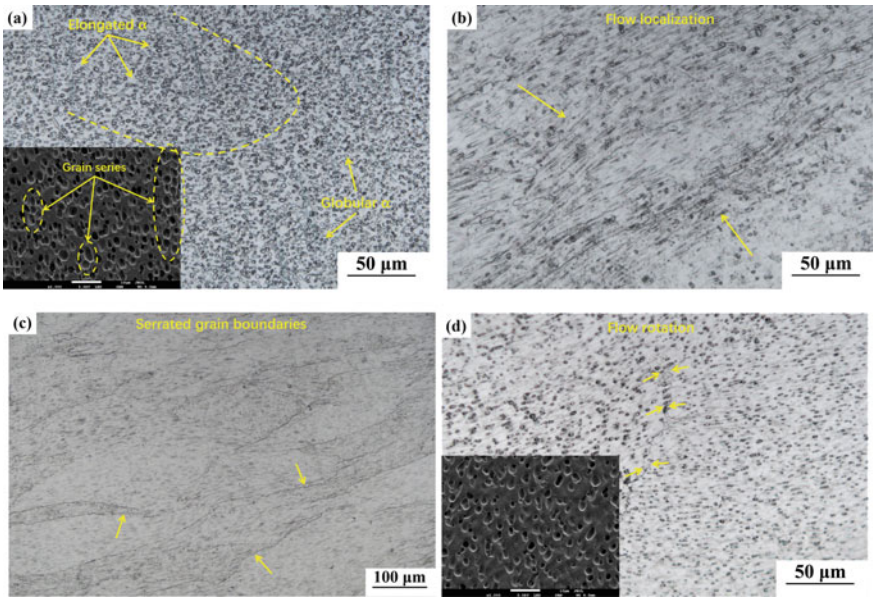

Fig. 6 The typical microstructures of the Ti55531 alloy in the flow instability region for **a** 1003 K, 1 s^{-1}; **b** 1123 K, 1 s^{-1}; **c** 1153 K, 1 s^{-1}; **d** 1093 K, 1 s^{-1}. (Color figure online)

feature. Moreover, it is noted from Fig. 6c that β grains are elongated and deformation bands are formed vertically to the compression direction. β grain boundaries become serrated as some small recrystallized β grains formed in the vicinity of grain boundaries. Generally, all of these processes are beneficial steps in producing the desired fine equiaxed grains for stable plastic flow [18, 23].

The efficiency of power dissipation under the flow instability region is relatively small (η <0.35). Catastrophic flow localization is observed at the temperature of 1123 K and the strain rate of 1 s^{-1} (Fig. 6b). From Fig. 6a, inhomogeneous distribution of α grains is observed, where elongated prior α grains are surrounded by globular α, which indicates slightly localized flow under this condition (1003 K, 0.1 s^{-1}). When the working temperature reached 1153 K (Fig. 6c), there are significantly flow localization zones in the samples, only elongated β with serrated grain boundaries are observed. In general, the flow localization occurs at relatively low temperatures or/and high strain rates due to a combination of microstructure changes and adiabatic heating below T_β. Flow localization is mainly caused by the lack of restoration processes as observed from the instability parameter φ values, which reached values between 5 and 35 [15, 24]. In addition, the other type of flow instability is also found in the microstructure. As shown in Fig. 6d, the sample deformed at 1093 K and 1 s^{-1} developed an evident change in the misorientation toward the grain boundaries during deformation, which represents the typical flow rotation feature. Obviously, these microstructure characteristics observed are consistent with that predicted from the processing maps (Fig. 5) and flow curves (Fig. 2). The flow instability caused by

flow localization or flow rotation is not beneficial for the workability and mechanical properties of materials. It needs to be avoided in the processing of the Ti55531 alloy.

4 Conclusions

The hot deformation behavior of the Ti55531 alloy in the $\alpha + \beta$ and single-β phase field was investigated to optimize the processing window and microstructure characterization. The following conclusions can be drawn:

(1) The flow stress of the Ti55531 alloy decreases with increase in temperature and a decrease in strain rate. Discontinuous yielding phenomenon is observed in the stress–strain curves when the material was deformed at strain rates of 0.1 and 1 s^{-1}. The amplitude of yield drop increases with an increase in temperature.

(2) Arrhenius equations were used to depict the constitutive relationship among flow stress, temperature, and strain rate during hot deformation of the Ti55531 alloy and were proved a good predictive ability.

(3) The DMM processing maps were constructed by superimposing the instability map over the power dissipation map for strains of 0.05, 0.4, 0.6, and 0.9. The efficiency of power dissipation (η) changes slightly with strain rates.

(4) The instability region according to DMM processing map appears at high strain rates ($\dot{\varepsilon}$ >0.1 s^{-1}) but for all test temperatures (1003–1153 K). The efficiency of power dissipation under these deformation conditions is relatively small (η <0.35), which represents the typical instability of flow localization and flow rotation. The optimum conditions for hot deformation were found to 0.001–0.1 s^{-1} and 1003–1153 K.

Establishment of Sheet Plastic Wrinkling Instability WLD and Study on Strain Distribution Characteristics in Instability Region

Bing Du, Han Li, Jun Xie, Pengfei Song, and Changcai Zhao

Abstract In the field of thin-plate plastic forming, the efficient and accurate prediction and control of wrinkles are the basis for product and mold design and process flow formulation. In this paper, a diagonal tensile test of a square plate is taken as an example, and a numerical simulation model for plastic wrinkle analysis of a thin plate is established by using ABAQUS. On this basis, the morphology and characteristics of the critical wrinkle main strain diagram (WLD) under the condition of nonuniform tension are investigated. The distribution position relationship between the strain value at different positions in the deformation region of the specimen and the critical wrinkle main strain curve (WLD) is discussed. The research content of this paper provides ideas for determining the wrinkle instability and establishing the wrinkle critical line under other various bearing conditions.

Keywords Sheet forming · Wrinkle instability · Square plate diagonal stretching · Numerical simulation · Wrinkle instability threshold

1 Introduction

For the design of products and molds, the establishment of technological processes, improving the forming quality and production efficiency of parts, it is very important to how to efficiently and accurately predict and control the wrinkle instability and clarify the relationship between wrinkling instability and forming process parameters. The extensive use of the forming limit diagram (FLD) for the determination of fracture instability has provided ideas for the study of the wrinkle limit diagram (WLD) and stimulated the academic community to study the critical wrinkling curve of sheet forming. Jasion et al. [1] performed analytical, numerical, and experimental studies of the global and local buckling/wrinkling of the face sheets of sandwich beams and sandwich circular plates and developed a mathematical model for displacements that included a shear effect. Jasion's work also derived governing

differential equations for sandwich plates and solved these equations analytically to obtain critical loads. Liewald et al. [2] obtained wrinkle limit curves experimentally using the improved YBT as well as the cone cup drawing test and found some differences between the results. Wang et al. [3] used Hill's general theory of uniqueness and bifurcation to model local wrinkling phenomena and proposed wrinkling criteria for plastic anisotropic shells with compound curvatures. Triantafyllidis [4] developed a suitable bifurcation criterion and a phenomenological corner theory to investigate wrinkling instability during the cup convex test. Based on this bifurcation theory, Kim et al. [5] generated WLDs for anisotropic sheet metals subjected to plane stress and determined the effects of the strain hardening coefficient, yield stress, anisotropy coefficient, and sample thickness on critical wrinkling stress in two-dimensional stress space. Similar to an FLD, the main use of a WLD is to predict wrinkling instability through analyzing the in-plane critical principal strain index of a thin shell and to establish a curve that defines the safety, critical, and instability intervals. This conversion of the internal mechanism of thin shell material wrinkling into the apparent numerical relationship of principal strains is more convenient for engineering applications.

In the present work, the YBT (Yoshida Buckling Test) was used during comparative verification experiments to establish a dynamic explicit numerical analysis model for shell elements incorporating initial defects. Based on the above, real-time visual monitoring of the deformation of test specimens was employed to investigate the morphology and characteristics of critical wrinkle principal strain curves (that is, WLDs) generated during the application of nonuniform tension. The simulated WLD is compared with the experimental WLD. The WLD obtained by the two methods is basically the same. This shows that WLD has very good reliability. Moreover, the wrinkle on the test piece can be determined by the strain distribution, and the strain located below the WLD is considered to be the wrinkled zone. The innovation of this method is that it is inspired by FLD, and analogizes the problem of wrinkling instability to the problem of rupture instability, and establishes WLD (i.e. critical wrinkle main strain curve). The determination method of wrinkle instability was explored, that is, the state at different times in the forming process was judged according to the principal strain value curve.

2 Research Process and Methods

In this work, we used the buckling mode in conjunction with eigenvalue buckling analysis as the disturbance source, to perturb a so-called ideal calculation model in the Explicit algorithm. A nonlinear buckling analysis was then employed to investigate the reliability of the buckling analysis results obtained using this method. Figure 1 summarizes the specific analysis process. In this section, we will use the wrinkling instability numerical analysis model established in reference [6] to explore the existence of WLD under uneven tensile load properties, the morphology, and the relative

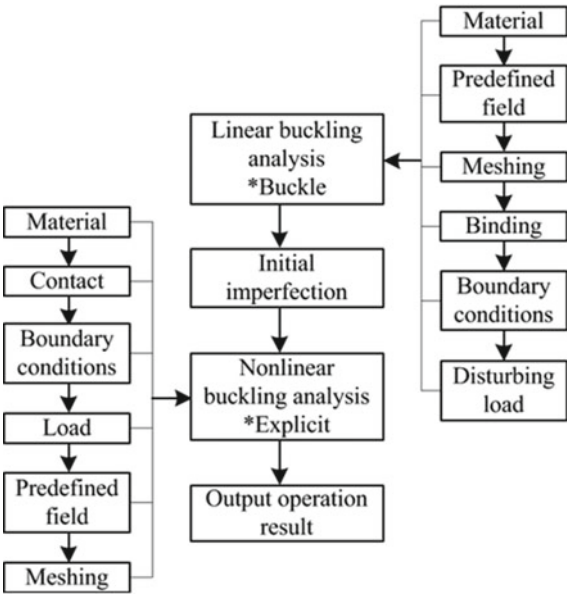

Fig. 1 A flow chart summarizing the nonlinear buckling analysis of sheet metal forming

relationship between the strain value at different locations of wrinkle and WLD And other issues.

WLD is similar to an FLD, a WLD is a curve composed of critical wrinkling strains at the initial positions of wrinkling instability for various stress paths. However, unlike an FLD, the combination of in-plane principal stress states leading to wrinkling instability must include at least one principal compressive stress. Therefore, the critical instability strains will only be distributed in the second principal strain space quadrant. Five models, with plate thicknesses t of 1 mm and side lengths l of 95, 100, 105, 110, and 115 mm, were created, as shown in Fig. 2, and the wrinkling simulation was performed using dynamic numerical simulations of buckling.

On the definition of critical instability in numerical simulation, this paper uniformly defines the vertical distance between the highest point of the wrinkle center and the lowest point of the plate boundary as the wrinkle height. In addition,

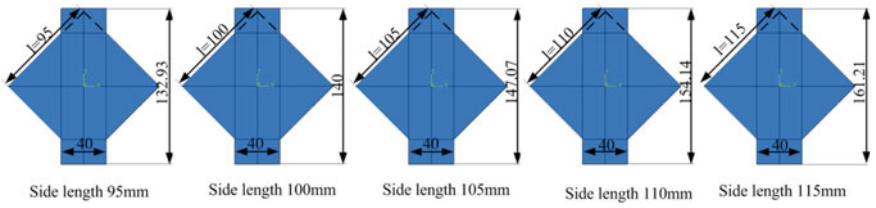

Fig. 2 Buckle-explicit simulation analysis model under different geometric sizes. (Color figure online)

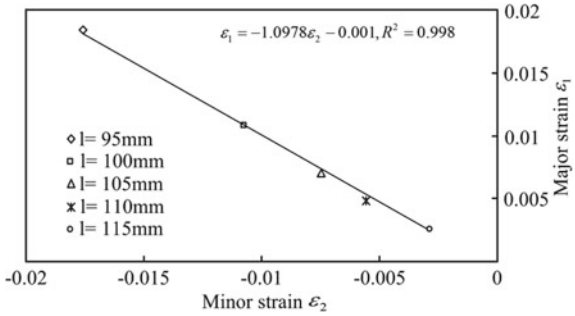

Fig. 3 The WLD generated for 304 stainless steel

the moment at which the wrinkle height equals 10% of the sheet thickness (having a value of 0.1 mm) is considered to indicate the critical wrinkling moment for the specimen. The in-plane critical wrinkle strain of the five model specimens in Fig. 2 at this moment was extracted and plotted in the main strain space for curve fitting, as shown in Fig. 3.

Figure 3 confirms that a critical strain curve for the wrinkling instability of the sheet under uneven tension conditions can be constructed. It is also evident from the equation of the curve that this plot describes a straight line located in the second quadrant and approximately passing through the origin (0, 0), with a slope of approximately −1.

3 Results and Discussion

In order to verify the validity of the WLD obtained by the numerical analysis above, the true plastic wrinkling and instability mechanism of the sheet was obtained through the test strain data of the test piece. The VIC-3D non-contact full-field strain measurement system is used to measure and process the strain data of the 304 stainless steel test specimens of typical size and thickness during the tensile process, as shown in Fig. 4a–c. The strain development trajectories at instability point A for each specimen under the three different combinations of side lengths and thicknesses were extracted during the tensile testing of the square plates (as shown in Fig. 4d). It should be noted that, when the test piece entered the post-buckling stage, the strain trajectory at point A on the upper and lower surfaces of the specimen is bifurcated. This occurred because buckling caused the surface on the side associated with the warping direction of the test piece to be compressed in the horizontal direction at point A, while the tension at the same point on the opposite side was gradually increased. Therefore, the strain trajectories on the upper and lower surfaces at point A gradually deviated. Consequently, the bifurcation point of the strain trajectories at point A on the upper and lower surfaces corresponded to the critical wrinkling strain point for the specimen. Based on the order of the three sets of strain trajectory bifurcation points, the critical buckling order for the three operating conditions can be

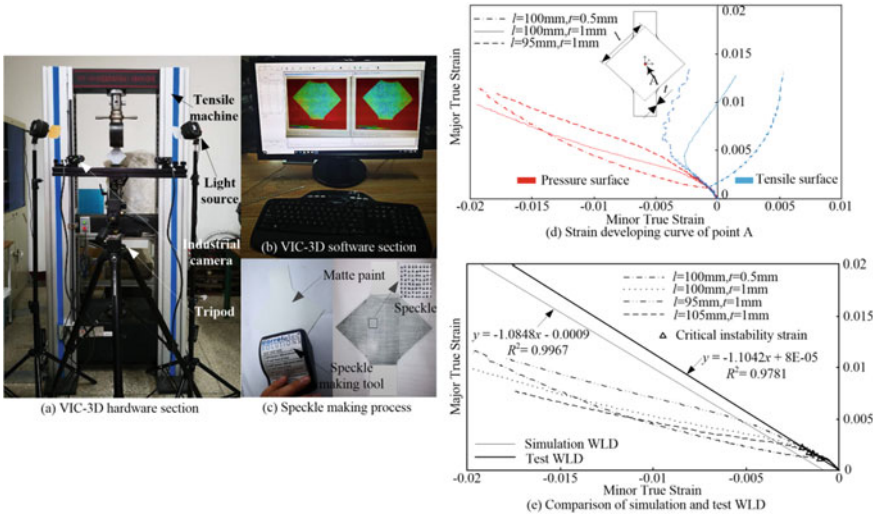

Fig. 4 Test methods and data extraction. (Color figure online)

determined. It can be seen that a smaller side length and greater thickness postpones the onset of instability, which is in complete agreement with the numerical analysis results.

The strain trajectories of point A on the compression surface and their bifurcation points with the tension surface trajectory were extracted under four geometric conditions, and these bifurcation points were used to fit the test WLD, after which the simulated and experimental WLD plots were compared (The results are shown in Fig. 4e). This comparison established that the discrepancy between the simulated and experimental WLDs was only approximately 0.58%, indicating that the WLD obtained by numerical simulations was sufficiently reliable.

When the wrinkle height of the square plate specimen with a side length of 100 mm and a thickness of 0.5 mm reached 9.5 mm, 10 typical positions of the wrinkle area were selected to examine the strain distribution characteristics, as shown in Fig. 5. The 10 observation points on the compressive surface were labeled 1–10 while the relative positions on the tensile surface were identified as 1′ to 10′. The primary and secondary strains at the observation points at the unbuckling and buckling moments (shown in Fig. 5a, b) were all extracted and drawn in the principal strain space, after which they were compared with the simulated WLD (see Fig. 5c). This figure confirms that the strains in the wrinkling areas on the upper and lower surfaces of the specimen overlapped when the test piece was not buckling, and were located near the zero point above the WLD. With the development of buckling, the strain values at different locations were gradually dispersed and exhibited highly regular distributions. The strains on the compressive surface were located below the WLD and along the longitudinal section of the wrinkle, while the absolute values of the

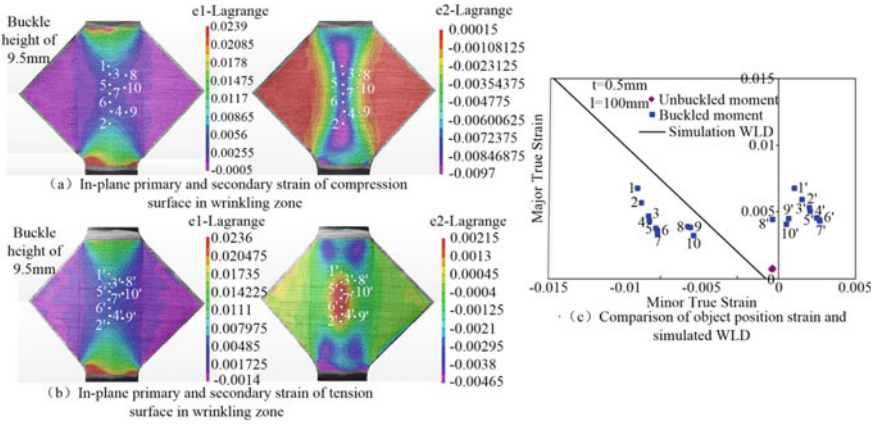

Fig. 5 Strain characteristics of sheet wrinkled zone. (Color figure online)

direction 2 strains at both ends of the wrinkling area were higher than in the central zone.

These results are attributed to differences in cross-sectional areas at the monitoring points. A smaller cross-sectional area at the monitoring point will increase the longitudinal tensile stress. Consequently, the lateral shrinkage of the material will be greater and the corresponding horizontal compressive stress will increase so that the absolute values of the direction 2 strains will also be larger. In contrast, the strains on the tensile surface of the specimen were distributed over the WLD but primarily located in the first quadrant of the double tensile strain space. The numerical distribution trend, in this case, was the same as on the pressure surface. It is also noteworthy that the above rule appears to be less consistent in the case of the transverse compressive strains for the three points 8′, 9′, and 10′ located in the longitudinal wrinkle edge region. This may have resulted from blockage of the transmission of in-plane compressive stress by the wrinkle.

The above figure demonstrates that the strains in the wrinkling area on the compressive surface of the specimen were located below the WLD after buckling, which may be significant with regard to predicting the wrinkling state of the piece. To clarify the meaning of this finding, it is necessary to further analyze the distribution characteristics of strains in the remaining areas on the compressive surface in the principal strain space. As well, to ensure the universality of the analysis results, the strain data on the compressive surface of the specimen under four geometric conditions were extracted for analysis. The test strain cloud map was divided into three zones according to color: the buckled, critical, and unbuckled zones. Some points distributed across the three regions were randomly chosen and the primary and secondary strains associated with these points were output in principal strain space and then compared with the simulated WLD, as shown in Fig. 6.

It can be seen from Fig. 6 that the strain distribution characteristics of the specimen under different geometric conditions after entering the buckling state were the same.

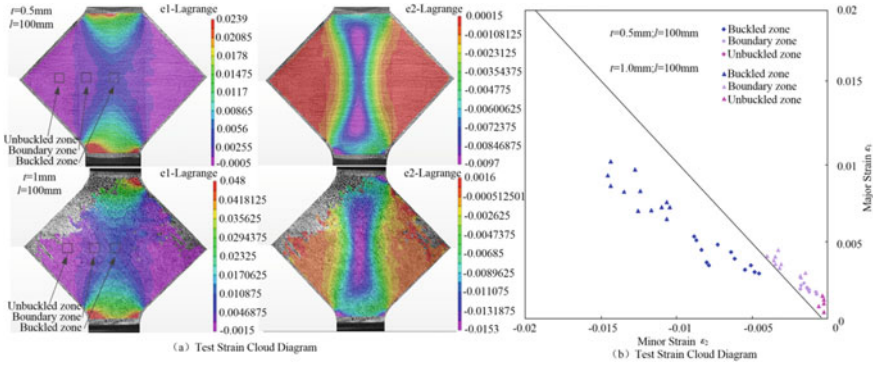

Fig. 6 Strain cloud diagrams for the buckling compression surfaces and the strain of varying zone distributions in principal strain space for specimens. (Color figure online)

The strains in the buckled zone were all below the WLD, while the strains in the critical zone were greater than the strains in the unbuckled zone and both were above the WLD. Increasing the wall thickness gradually moved the strains in the buckled zone away from the ordinate origin such that they spread out. This outcome indicates that changes in the geometrical conditions enhance the uniform deformation of the specimen, such that the occurrence of wrinkling instability is delayed. A change in the shape of the central purple region representing the buckled zone can be clearly observed by comparing the secondary strain clouds. The data show that decreasing the side length and increasing the wall thickness gradually moves the wrinkle away from the clamping end of the specimen in the longitudinal direction. The cross-sectional shape of the wrinkle also became more uniform in the lateral direction.

It is determined from the above analysis that the strain distribution on the buckling compression surface of the test piece can be used to ascertain the wrinkle position on the test piece. Specifically, the region over which the strain is located below the WLD corresponds to the wrinkling instability zone.

4 Conclusions

1. A comparison of simulated and experimental WLDs shows that the disagreement between the two is approximately 2%, indicating that the WLD obtained by the numerical simulation method is sufficiently reliable.
2. The position at which wrinkles appear on a specimen can be determined from the strain distribution on the buckling compression surface of the test piece. The corresponding area where the strains are located below the WLD represents the wrinkling instability zone.

Plasticity and Fracture Characterization of Advanced High-Strength Steel: Experiments and Modeling

Fei Han, Changwei Lian, Jichao Zhang, and Haomin Jiang

Abstract As one of the means of lightweight, more and more ultra-high-strength steel (UHSS) has been applied to the car body. Plasticity and fracture behavior of UHSS under a complex stress state is the key to accurate simulation of forming process and crash. In order to describe the various hardening exponent that lies with the advanced high strength steels, a new hardening law of Modified Power Law (MPL) was proposed and validated for the newly developed high elongation quench & partition steel (QP1180-EL) by Baosteel. Different loading conditions, including shear, uniaxial tension, plane strain tension, and biaxial tension were conducted with the help of digital image correlation technology to test the fracture limit of QP1180-EL under various stress states. Based on testing results and numerical simulation, Modified Mohr–Coulomb (MMC) fracture model and Generalized Incremental Stress State Dependent Model (GISSMO) were calibrated and validated. The research results will provide guidance for parts design and structural performance evaluation in the application of ultra-high-strength steel.

Keywords Ultra-High-Strength Steel · Hardening · Fracture · Damage · Digital Image Correlation

1 Introduction

Advanced high-strength steel materials have been widely used in the automotive industry in recent years due to the advantage of improved crash energy absorption. With the increase in strength, ductility of traditional high-strength steel materials decreases, posing challenges to the forming process and the crash safety of the vehicle. In order to accurately predict the failure behavior of advanced high-strength

steel materials, an accurate hardening, failure criteria and damage accumulation model need to be established.

The hardening model is the most important factor for accurate simulation of forming and crash process. Uniaxial tensile test is widely used to generate experimental stress–strain data due to its convenience. Because of the edge effect, strain data from uniaxial tensile tests are limited to a certain level, which is much lower than the maximum equivalent plastic strain appearing in metal forming and under crash testing. There are two kinds of hardening models widely used for steel. One is power law like Hollomon [1] and Swift [2]. The other is saturation models like Voce and Hockett–Sherby [3]. There is a significant difference by extrapolating the experimentally stress–strain curve to larger strain values with assuming constitutive equations [4]. To overcome the limitation of uniaxial tensile test, other test methods used to obtain stress–strain curve under larger strain were proposed, including hydraulic bulge test [5, 6] and in-plan torsion test [7]. Combinations of models such as the Swift–Voce or Swift/Hockett–Sherby models were used to yield better fitting result [5], but more parameters need to be calibrated.

Fracture criteria can be divided into two types: one is the micro-cavity development theory based on the continuum mechanics, and the other is the semi-empirical failure criterion based on the fracture strain. The second failure criterion is widely embedded in general commercial software since its failure parameters can be more easily determined through tests [8]. Johnson and Cook fracture proposed the Johnson–Cook fracture criteria where fracture strain is function of triaxiality [9]. Recently, modified Mohr–Coulomb model was proposed by Bai and Wierzbicki [10]. Dependence of triaxiality and lode angle for the fracture strain is considered and good fracture prediction results have been achieved for various metal materials. The Generalized Incremental Stress State Dependent Model (GISSMO) was developed by Neukamm et al. [11, 12], which takes into account the damage evolution and fracture dependence on triaxiality and Lode parameter. GISSMO damage model is implemented in the LS-DYNA solver and widely used in the automotive industry to predict material failure in crash simulation.

In this paper, the hardening behavior of QP1180-EL steel was studied and a new modified power law hardening model was proposed to improve extrapolation accuracy. DIC method was used to measure fracture strain under different stress state and MMC fracture criteria as well as GISSMO damage model were calibrated based on experiment results. Three-point bending test was conducted to validate MPL hardening model and GISSMO damage model.

2 Hardening Behavior Under Large Strain

2.1 Modified Power Law Hardening Model

Table 1 lists common hardening model equations with true stress σ, true plastic strain ε, and corresponding parameters. The strain hardening exponent n, which represents material's hardening rate, was used in different models.

There is often a large deviation between experimental hardening data and predicted results. One of the key reasons is the difference in the hardening characteristics of the material. DC56D+ZF (mild steel), HC220B (bake-hardening steel), QP1180-EL (quench & partition steel) were chosen to calculate n value within uniform deformation range respectively using Hollomon respectively. As shown in Fig. 1, instantaneous n value varies with plastic strain developing, especially for high strength steels, indicating that it cannot be well described when extrapolating to larger strain using constant n value.

To improve the modeling accuracy of high strength steels with non-constant n value, modified power law model with adjustable parameter is provided based on power law, where λ_H is a new parameter, expressed as follows:

$$\sigma = k(\varepsilon_0 + \lambda_H \varepsilon)^n. \tag{1}$$

Table 1 Equations of different hardening models

Model	Equation	No. of Parameters
Hollomon	$\sigma = k_H(\varepsilon)^{n_H}$	2 (k_H, n_H)
Swift	$\sigma_{\text{Swift}} = k_s(\varepsilon_0 + \varepsilon)^{n_s}$	3 $(k_s, \varepsilon_0, n_s)$
Hockett–Sherby	$\sigma_{H-S} = \sigma_{\text{sat}} - (\sigma_{\text{sat}} - \sigma_0)\exp(-m\varepsilon^n)$	4 $(\sigma_{\text{sat}}, \sigma_0, m, n)$
Combine Swift/H–S	$\sigma = (1-\alpha)\sigma_{\text{Swift}} - \alpha\sigma_{H-S}$	8 $(\alpha, k_s, \varepsilon_0, n_s, \sigma_{\text{sat}}, \sigma_0, m, n)$

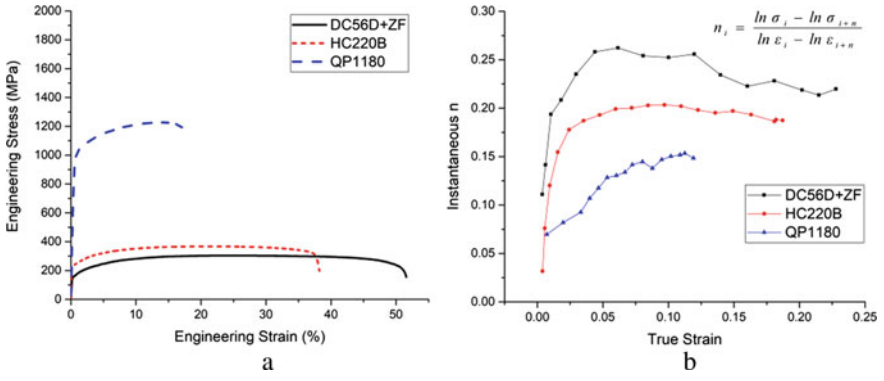

Fig. 1 Engineering stress–strain curve (left) and instantaneous n versus true strain (right). (Color figure online)

Considering the strain hardening trend of high-strength steels, λ_H is defined as Eq. (2). When $\alpha = 0$, it is equivalent to the Swift equation. When $\alpha > 0$, it can well correct the decrease of instantaneous n value at larger plastic strains by varying a value.

$$\lambda_H = \frac{1}{1 + \alpha\varepsilon}. \tag{2}$$

2.2 Test and Calibration of QP1180-EL

QP steel is a typical third-generation advanced high-strength steel. With both high strength and high plasticity, it can meet the needs of automotive users for high-performance ultra-high-strength steel and provide support for the lightweight development of the automotive industry. Baosteel has become the first steel company in the world capable of producing first, second, and third generation advanced high-strength steels in batches. Table 2 shows the tensile properties of QP1180-EL steel at the thickness of 1.2 mm. The valid range of stress–strain curve obtained from uniaxial tensile test is up to the uniform elongation 0.11 (true strain), while the rest need to be extrapolated.

Based on the uniaxial tensile test data, Swift, Hockett–Sherby, and MPL models were used to fit and extrapolate the stress–strain curve. All three models give a relative good fit result but have large differences under large strain, which are shown in Fig. 2.

Table 2 Tensile properties of QP1180-EL steel

Steel grade	Yield strength (MPa)	Tensile strength (MPa)	Uniform elongation (%)	Total elongation (%)
QP1180-EL	896	1179	11.5	16.3

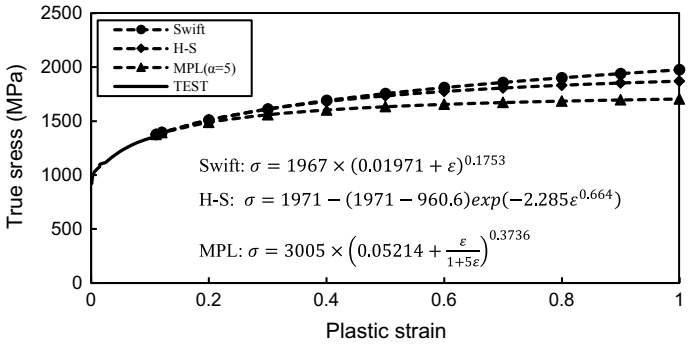

Fig. 2 Extrapolation result of different hardening models

According to the experimental conditions, uniaxial tensile simulation model is established, using the three hardening curve stated above. The results of the experimental and simulated force–displacement curves are shown in Fig. 3. The results show that the MPL model can improve the prediction results of the hardening behavior under large strain.

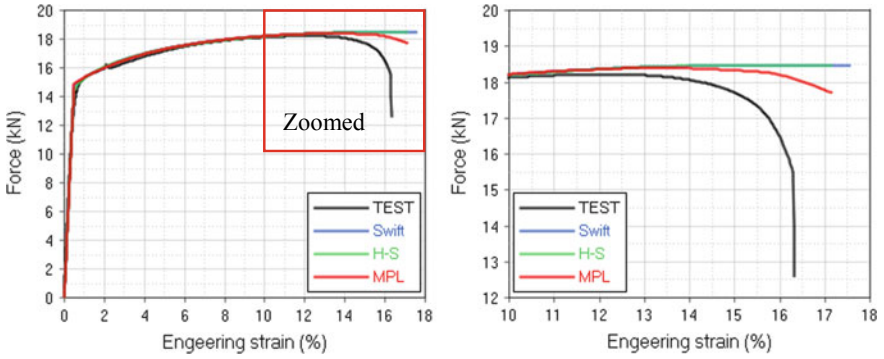

Fig. 3 Force–displacement simulation result of different hardening models. (Color figure online)

3 Damage Behavior Under Complex Stress States

3.1 Damage Accumulation and Fracture Limit Characterization

Most of the ductile fracture models are based on the idea of damage. According to whether the accumulation of damage during the deformation process affects the mechanical response of the material, common ductile fracture models can be divided into two types: coupled damage models and uncoupled fracture models. These two types of ductile fracture models have been widely used in academia and industry [8]. Uncoupled ductile fracture models usually use failure strain as a weight function to integrate equivalent plastic strain and define it as a damage factor:

$$D = \int_0^{\overline{\varepsilon}_f} \frac{d\varepsilon_p}{\overline{\varepsilon}_f(\sigma, \varepsilon, \dot{\varepsilon}, \ldots)} \tag{3}$$

where $d\varepsilon_{\mathrm{p}}$ is equivalent plastic strain increment, and ε_f is the equivalent plastic strain at fracture, which is function of stress tensor σ, strain tensor ε, and strain rate tensor $\dot{\varepsilon}$.

In recent years, research on the fracture behavior of ductile materials shows that stress triaxiality and lode angle are considered to be the key parameters affecting ductile fracture limit. The most influential research work comes from Wierzbicki T (Modified Mohr–Coulomb model). Bai Y. and Wierzbicki T. converted the Mohr–Coulomb model from stress space to equivalent plastic strain, stress triaxiality, and lode angle parameters $\{\varepsilon_f, \eta, \theta\}$, and established a Modified Mohr–Coulomb (MMC) model [10]. The basic formula is as follows:

$$\overline{\varepsilon}_f = \left\{ \frac{A}{c_2}\left[c_3 + \frac{\sqrt{3}}{2-\sqrt{3}}(1-c_3)\left(\sec\frac{\pi\overline{\theta}}{6} - 1\right)\right] \times \left[\sqrt{\frac{1+c_1^2}{3}}\cos\frac{\pi\overline{\theta}}{6} + c_1\left(\eta + \frac{1}{3}\sin\frac{\pi\overline{\theta}}{6}\right)\right]\right\}^{-\frac{1}{n}} \tag{4}$$

where η is stress triaxiality and $\overline{\theta}$ is normalized Lode angle, A, n are parameters related to material hardening rule and c_1, c_2, c_3 are parameters that need to be determined from fracture test.

The Generalized Incremental Stress State Dependent Model (GISSMO) was and developed by Neukamm et al. [11] and later formally presented in more detail by Andrade et al. [13]. Damage accumulation ΔD is calculated at every time step, given by:

$$\Delta D = \frac{DMGEXP}{\mathrm{reg}(L_e, \eta) \times \overline{\varepsilon}_f(\eta, \theta)} D^{\left(\frac{DMGEXP-1}{DMGEXP}\right)} \Delta\varepsilon_p \tag{5}$$

where *DMGEXP* is the damage accumulation exponent. In crash simulation application, element size is usually limited to 2–5 mm in order to reach a balance between reasonable prediction results and overall calculation time. To deal with the influence of mesh size on fracture behavior, a regularization function reg(L_e, η) is introduced, which defines the fracture limit reduction coefficient between element size L_e and stress triaxiality η. Another index instability, which describes the onset of diffuse necking, is also considered in GISSMO model and is calculated similar to the damage accumulation:

$$\Delta F = \frac{DMGEXP}{\overline{\varepsilon}_{\text{ins}}(\eta, \theta)} F^{\left(\frac{DMGEXP-1}{DMGEXP}\right)} \Delta\varepsilon_p. \tag{6}$$

As soon as the instability F reaches unity, the current value of damage D_{crit} in the respective element is stored and damage will from this point on be coupled to the flow stress using the following relation:

$$\sigma = \tilde{\sigma}\left(1 - \left(\frac{D - D_{\text{crit}}}{1 - D_{\text{crit}}}\right)^{FADEXP}\right). \tag{7}$$

The GISSMO damage/failure model is implemented in LS-DYNA solver and can be activated by setting IDAM = 1 and DMGTYP = 1 in keyword *MAT_ADD_EROSION [14]. The modular nature of *MAT_ADD_EROSION allows GISSMO to be combined with any other plasticity model and fracture limit model.

3.2 Fracture Limit Test and Calibration

In order to achieve fracture limit of QP1180-EL under different stress states and calibrate parameters of MMC fracture model, fuve different loading cases and testing coupon were designed. These tests covered the stress state of shear, uniaxial tension, stretching, plane strain, and equi-biaxial stretching. Schematic of these five individual tests is shown in Fig. 4.

Digital Image Correlation (DIC) was used for strain measurement in the five calibration test. Load speed of each test was limit to 0.6 mm/min and DIC image acquisition rate was set to 2 frame per second to get the critical fracture moment as close as possible. DIC strain fields were recorded at both 1 and 2 mm virtual gauge length (VGL) to determine the mesh size regularization curve directly. Figure 5 shows DIC and CAE model strain results at different VGL of the plane strain state.

During calibration of MMC model parameters, in order to represent deformation and damage accumulation history, average triaxiality should be used instead of the triaxiality at fracture moment [15]. Average triaxiality of each loading case is first calculated by following equation, assuming damage accumulation exponent

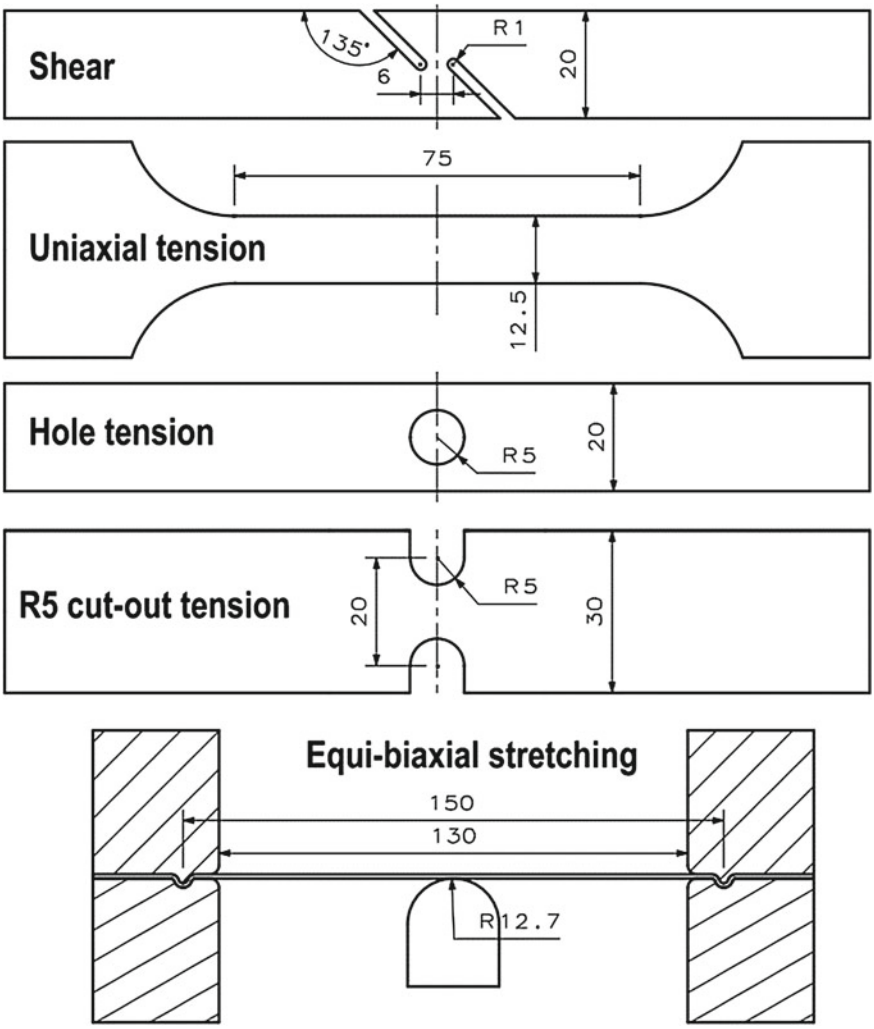

Fig. 4 Fracture limit test specimen. **a** Shear tensile, **b** uniaxial tensile, **c** hole tensile, **d** R5 cut-out tensile, **e** equibiaxial stretching

DMGEXP equals to 2. Fracture strain and average triaxiality of each loading case are shown in Table 3. The final calibrated MMC model and loading path result of the five different tests are shown in Fig. 6, this was used in the following GISSM model calibration.

$$\eta_{\text{avg}} = \frac{1}{D}\int \frac{2}{\varepsilon_f(\eta)} D^{\frac{1}{2}} \eta d\varepsilon_p. \tag{8}$$

Table 3 Fracture limit stain test result

Load case	Average triaxiality	Fracture strain
Shear	0.06	0.476
Uniaxial	0.46	0.440
Hole	0.48	0.553
R5	0.57	0.390
Equi-biaxial	0.66	0.810

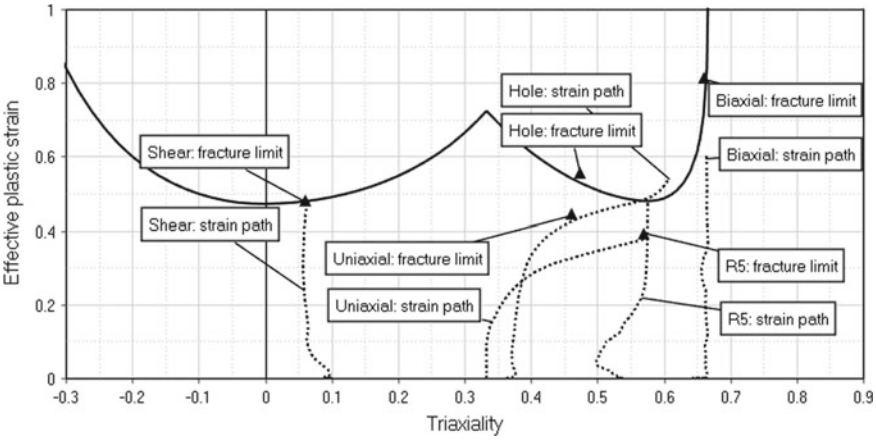

Fig. 6 Calibrated MMC fracture limit and loading path result of different tests

3.3 GISSMO Damage Model Calibration and Validation

As stated above, calibration of GISSMO damage model requires identification of several key parameters besides fracture limit, including instability limit, damage

accumulation exponent, stress fadeout exponent as well as regularization curve that depends on element mesh size and stress state.

Instability limit curve is first set with reference to uniform elongation value tested from uniaxial tension and iteratively identified until a good agreement between simulation and experiment Force–displacement curve was achieved for all five loading conditions. *DMGEXP* and *FADEXP* were set to 2 and 2.5 respectively. *MAT_024 material formulation is used in the calibration process. Finite element mesh size was set between 1, 2, and 4 mm allowed by the specimen geometry, in accordance with the mesh size requirement in vehicle crash simulation.

The experimental as well as simulation results for the force versus gauge point displacement curve in the five loading conditions are shown in Fig. 7. All force and displacement results were regularized to 1 by the maximum force and fracture displacement from the corresponding test. The result shows that GISSMO damage simulation model delivers good agreement with experiments for uniaxial tensile, hole tensile, R5 cut-out tensile, and biaxial stretching, while force simulation result is higher than in experiment, indicating that hardening behavior of QP1180-EL is not correctly described using *MAT_024 material formulation. This should be improved later on by implementing more comprehensive material model that can describe material's yield behavior more precisely. A relatively good convergence between different mesh sizes is also achieved.

Three-point quasi-static bending test was performed in order to validate the calibrated GISSMO damage model. The hat profile used in the bending test was produced using roll-forming process, which can minimize the effects of work hardening and corresponding damage. Figure 8 shows the predicted fracture location and test result. Figure 9 compares the force–displacement result between tests and simulation. In order to obtain relatively accurate simulation results, average mesh size needs to be refined to 2 mm. The simulation results with the calibrated GISSMO fracture model match the test results well.

4 Summary

- A new Modified Power Law (MPL) hardening law was proposed to better describe the phenomenon that hardening index of advanced high-strength steel materials changes with an increase in strain. Simple tensile test shows that MPL model gives better prediction result for QP1180-EL steel.
- MMC fracture model and GISSMO damage model were calibrated to describe the ductile fracture behavior of QP1180-EL and show a good correlation between simulation and experiment. Advance material constitutive model needs to be used to describe yield behavior more precisely.

Design of a New Cruciform-Like Specimen for Combined Tension and Shear of Metal Sheets

Minki Kim, Jinjin Ha, Samantha Bonica, and Yannis P. Korkolis

Abstract This paper is concerned with the design of a new cruciform-like specimen to measure plastic flow under combined tension and shear loading conditions. An AA6013-T4 aluminum sheet is used as example material. The specimen design borrows from the "smiley" shear specimen, which is commonly used for the simple shear experiment, but has four arms, as a cruciform specimen: two arms are used to induce shearing, while the other two induce tension. The details of the geometry are determined by FEA to promote stress uniformity in the gage-section under combined loading conditions with the force ratio of 1 to 1. Parametric studies are conducted to determine the final design in terms of notch shape, gage-length, gage-width and offset of the notch. The dimensions of the final design are suggested with good uniformity in stress distribution along the gage-length.

Keywords Cruciform specimen · Biaxial test · Combined tension–shear · Multi-axial property · Specimen design

1 Introduction

As the design of structures is becoming complicated, material properties in complex stress states are becoming of interest in the automotive industry. Characterization of multi-axial properties must be established with various stress states to predict the deformation of a complicated structure accurately by finite element (FE) simulation. Combined loading conditions, such as tension–torsion or tension–shear, have been

implemented to identify the effect of complex stress state on material properties in terms of flow and fracture behavior [1–5]. Especially for metal sheets, biaxial testing machines are utilized to apply the combined loading to butterfly [2, 3], notch [4], and cruciform-like specimens [5]. A conventional biaxial tension machine [6] is useful to realize various combined loading conditions by control of force ratios, so that the multi-axial flow behavior can be measured in a straightforward way. In this paper, a new cruciform-like specimen is suggested to obtain multi-axial flow behavior under combined tension and shear, including cyclic effects and multiple path changes. The dimensions of the final design are determined by parametric studies with FE simulations.

2 A New Cruciform-Like Specimen

The main idea of the new cruciform-like specimen is the combination of commonly used cruciform specimen [6–8] and the smiley shear specimen [9] for biaxial tension and simple shear tests, respectively. The new design has four arms: two arms for inducing tension while the other two arms for inducing shear in the gage-section as shown in Fig. 1a. The symmetric design with respect to the 22-axis allows the study to be performed on the half model depicted in Fig. 1b. The design parameters are the gage-length L, the gage-width W, and the parallel length G, which are determined by FEA in the next section. Not shown in Fig. 1b is an additional parameter, i.e., the offset along the 11-axis between the two notches is shown.

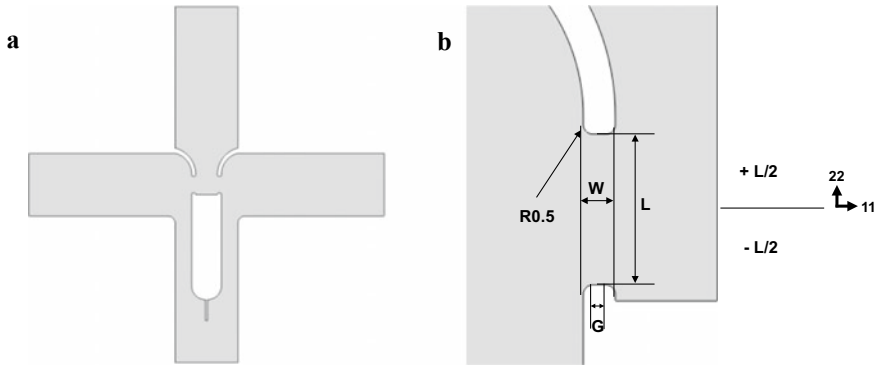

Fig. 1 Schematics of: **a** new cruciform-like specimen, **b** design parameters in gage-section

3 Determination of Specimen Dimensions

To determine the details of the new cruciform-like specimen, specimen geometries are examined by FEA with various notch shapes, gage-lengths, gage-widths, and offsets of notch. The main purpose of the FEA is to find out a proper dimension set with good uniformity of stress distribution in the gage-section under combined tension and shear. Furthermore, it is intended to establish the viability of using the forces measured at the four arms using load cells, to determine the stresses in the gage-sections [8]. For the parametric studies, all FEAs are conducted with the ABAQUS 2019 implicit and reduced integration, quadratic, plane-stress elements (CPS8R). Figure 2 shows the FEA conditions including applied material property and boundary conditions. The stress–strain curve of AA6013-T4 was obtained from uniaxial tension test along the RD [10] as shown in Fig. 2a and the material behavior is assumed to be isotropic hardening. Figure 2b, c represents boundary conditions for the half model of the cruciform-like specimen so the force ratio for the full model is set as 1 to 1.

For the determination of the design parameters, parametric study on the notch shape is performed with various geometries as shown in Fig. 3. All candidates with various notch shapes have a gage-length (L) of 8 mm and a gage-width (W) of 1.7 mm. The radius of the circular notch is 0.85 mm and the parallel length (G) of the flat notch is 0.7 mm to match the gage-width of 1.7 mm. The PST (Plane Strain

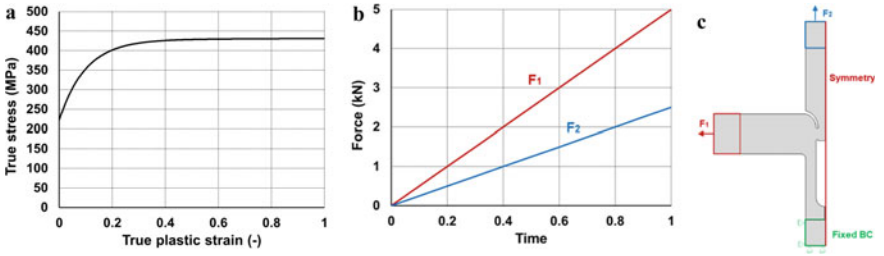

Fig. 2 FEA condition: **a** applied material property, **b** applied load, **c** schematics of boundary conditions. (Color figure online)

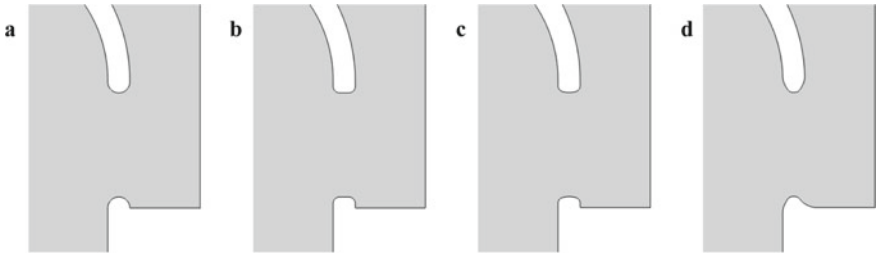

Fig. 3 Notch shapes: **a** circular notch, **b** flat notch, **c** PST notch, **d** groove notch

Tension) [11, 12] notch has two radii of 0.45 and 1.8 mm while the groove notch has the radius of 0.5 mm and the parallel length of 0.1 mm.

In order to evaluate the performance of each geometry, the uniformity of the axial and the shear stresses are investigated along the gage-length at the center of the gage-section. Figure 4 shows the distribution of axial and shear stresses along the gage-length with respect to the displacement in 22-direction, U2 (shear loading direction). The dashed line corresponding to each U2 is the average engineering stress, calculated by the force in each direction divided by the initial area of the gage-section. In the case of the flat notch, the axial stress along 11-direction (tensile direction) and the shear stress are quite uniform compared with other candidates when the deformation amount is high. The axial stress along 22-direction (shear

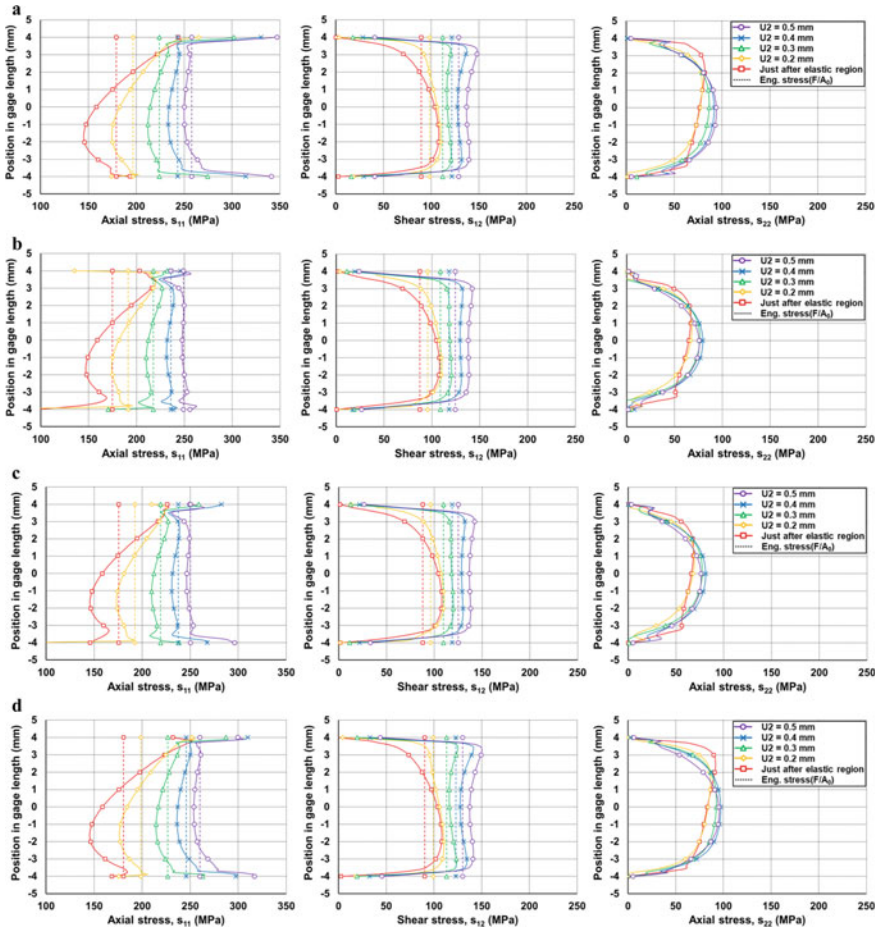

Fig. 4 Axial and shear stress distribution in deformation: **a** circular notch, **b** flat notch, **c** PST notch, **d** groove notch. (Color figure online)

direction) is smaller for the flat notch. This means that most of the shear loading contributes to shear deformation rather than the elongation in 22-direction. The flat notch shape is, therefore, selected for the parametric studies to determine specimen dimensions.

For parametric studies to decide the design parameters, specimen geometries with different gage-length, gage-width, and offset of notch are prepared as illustrated in Fig. 5, Fig. 6, and Fig. 7, respectively. The performance of each geometry is examined with the same method in the case study on the notch shape. As the gage-length becomes smaller, the amount of axial stress along 22-direction becomes smaller while the distribution becomes irregular. For other stress components, the uniformity of the distribution is not sensitive to change of the length from 8 to 6 mm. In case of the gage-width, the distribution of all stress components becomes more uniform when the gage-width increases from 1.5 to 1.9 mm. The offset of upper notch in the gage-section can affect the stress uniformity during the deformation in general [13]. The geometries with ±0.35 mm offset of the upper notch along 11-direction are evaluated to identify the effect of offset on the stress uniformity under combined tension and shear. When the (+) offset exists, the shear stress becomes uniform. The

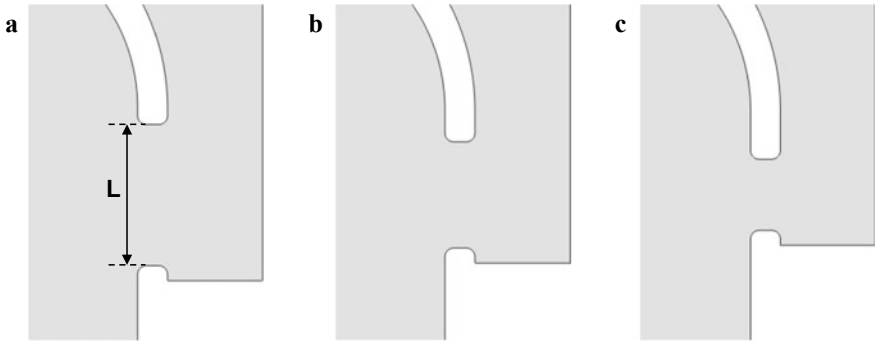

Fig. 5 Geometries of gage-section with the length (L) of: **a** 8 mm, **b** 6 mm, **c** 4 mm

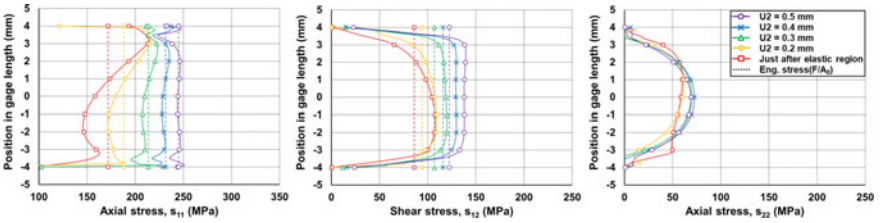

Fig. 8 Stress distributions of the final design. (Color figure online)

tensile stress, however, becomes non-uniform. For the (–) offset case, both tensile and shear stress distributions become irregular. It is noted from the results that the (+) offset is good for the design of a simple shear specimen while the case of without offset is proper to specimen design under combined tension and shear.

According to the parametric studies, the dimensions of the gage-section are determined with the gage-length of 8 mm and the gage-width of 1.9 mm. Figure 8 depicts the axial and shear stress distribution of the final design of the cruciform-like specimen during the deformation. The stress distributions are uniform except early part of the deformation so that the material property could be measured from the gage-section under the combined tension and shear.

4 Conclusion and Future Works

In this work, a new cruciform-like specimen with four arms and two gage-sections is proposed, to obtain multi-axial flow behavior of metal sheets under combined tension and shear, including cyclic loading. Based on the stress uniformity along the gage-length, the dimensions of the final design are determined by parametric studies with FEA. For future works, the final design will be examined for various force ratios. Experiments will be then performed using an in-plane biaxial testing machine, with

different force ratios between tension and shear, so that combined stress states in (σ_{11}, σ_{22}, σ_{12}) 3D-stress space are probed. An anisotropic yield function, such as Yld2000-2D, will be calibrated with multi-axial data, and the influence of shear stress on the yield function parameter calibration will be evaluated by comparing yield surfaces identified by different calibration approaches. Similarly, material models suitable for load-reversals will be examined based on cyclic data obtained with these specimens.

A Study of Anisotropic Yield Function Based on J_2 and J_3 Invariants

YoungSuk Kim, PhuVan Nguyen, and JinJae Kim

Abstract In this paper a new anisotropic yield function that describes the elasto-plastic behavior of sheet metals depends not only on the second stress invariant J2 for the yield, but also on the third stress invariant J3, both may affect the shape of the yield surface. The new anisotropic yield function is general and applicable to three-dimensional stress states. The proposed model is identified by calibration parameters from experimental data of material including uniaxial and biaxial tests. In this study, the predictive capabilities of the new anisotropic yield function are demonstrated by comparison between the predictions and experimental data for yield locus, normalized yield stress, and r-value. The result indicates that the new anisotropic model is reasonable to predict not only the symmetric shape but also the asymmetric shape of yield surface of the sheet metals.

Keywords Invariant J_2 · Invariant J_3 · Stress deviator · Isotropic yield function · Anisotropic yield function and asymmetric yield function

1 Introduction

In industry, sheet metal forming is one of the most important technologies, the metal forming process is an irreversible plastic deformation to form a product. These mechanisms of plastic deformation are slip, twin, creep, diffusion, etc. From the continuum mechanics, the plastic deformation is described mainly by yield condition, plastic flow rule, and hardening behavior. Among these components, the yield condition is one of the important things because it describes the elastoplastic behavior of sheet metals.

Many yield criteria have been proposed in previous studies, for anisotropic material, the yield function ought to be invariant with respect to any orthogonal transformation and it depends on the stress deviator s only through its invariants J_2 and J_3 [1], defined as

$$\begin{aligned} &\mathrm{J}_2 = \frac{1}{2}\left(\mathrm{s}_1^2 + \mathrm{s}_2^2 + \mathrm{s}_3^2\right);\ \mathrm{J}_3 = \mathrm{s}_1\mathrm{s}_2\mathrm{s}_3 \\ &\mathrm{s}_1 = \frac{2}{3}\sigma_1 - \frac{1}{3}(\sigma_2 + \sigma_3);\ \mathrm{s}_2 = \frac{2}{3}\sigma_2 - \frac{1}{3}(\sigma_1 + \sigma_3);\ \mathrm{s}_3 = \frac{2}{3}\sigma_3 - \frac{1}{3}(\sigma_1 + \sigma_2) \end{aligned} \tag{1}$$

where s_k and σ_k, $k = 1.0.3$ denote the principal values of s and σ.

The first isotropic yield function for sheet metals was proposed by Tresca (1864). In Tresca's yield function, the maximum shear stress must have a constant value. Von Mises (1913) proposed the isotropic yield function as below [1]:

$$\mathrm{J}_2 = \mathrm{k}^2 \tag{2}$$

where k is the yield stress in pure shear, which has a relationship of $k = \sigma_\mathrm{T}/\sqrt{3}$, σ_T is the yield stress in uniaxial tension.

Another yield function that involves both invariants J_2 and J_3 was proposed by Drucker. The results indicated Drucker's yield function predicted more accurate than either Tresca or von Mises's yield function on aluminum sheets. To account for anisotropic sheet metals, many anisotropic yield functions have been proposed [2, 3], for example, Hill-48 (1948), Hill-79 (1979), Hosford (1979), Yld2000-2d (2000), Cazacu and Barlat (2001), Yld2004-18p (2004), Banabic (2010), etc.

For the Hexagonal Closed Pack (HCP) metals such as titanium and magnesium alloys, the deformation phenomenon of twinning ultimately leads to distinct strengths in tension and compression loading conditions, which is referred to as the strength differential (SD) effect. In these kinds of material, texture evolution and twinning are important factors that affect specific flow behavior. However, uniaxial tension and compression are utilized for deformation modes in most studies. One of the challenges for these kinds of material that is mechanical behavior in biaxial compressive stress conditions is limited due to experimental difficulties. In the previous study, biaxial compressions were carried out using a unique device developed by Shimizu and Tada [4]. For the prediction of yield surface of these kinds of material, Cazacu and Barlat [5] proposed anisotropic yield criterion that is capable of describing the SD effect with the employment of an odd function of the second and third invariants of the stress deviator is shown as below:

$$f = J_2^{3/2} - \mathrm{c}J_3 \tag{3}$$

Cazacu et al. [6] also developed another yield function by using a fourth-order linear transformation on the stress deviator, referred to as CPB'06, to take into account both anisotropy and tension/compression asymmetry for pressure-insensitive metals.

Gao [7] developed a yield function coupling effect of all three stress invariants as below:

$$f = a(bI_1^6 + 27J_2^3 + \mathrm{c}J_3^2)^{1/6};\ I_1 = \sigma_1 + \sigma_2 + \sigma_3 \tag{4}$$

Another approach, Khan et al. [8] developed a criterion considering the effects of temperature and strain rate based on the experimental investigation of Ti-6Al-4 V alloy in both tension and compression considering the anisotropic effect. In their approach, the normalized third stress invariant was employed to describe the SD effect. Yoon [9] proposed a yield function with three invariants as below:

$$f = a\left[bI_1 + (J_2^{3/2} - \mathrm{c}J_3)^{1/3}\right] \tag{5}$$

In this paper, a new isotropic yield function is proposed. Using the generalized invariants approach, an anisotropic yield function of this criterion is developed. The theoretical prediction of anisotropy in tensile properties for uniaxial tension for arbitrary orientation of the loading axis is presented. In particular, the comparison between the predictions and experimental data for yield locus, the normalized yield stresses and r-values on AA6016-T4 is discussed. Besides that, in this study, the strength differential (SD) effect for hcp crystal structure materials such as titanium, magnesium are also considered in the proposed yield function.

2 New Proposed Model

2.1 New Yield Function

From early discussions, we propose a new isotropic yield function named as Kim-Van 6 (KV6) yield function as expressed below:

$$f \equiv J_2^3 + \alpha J_3^2 + \beta(J_2^{\frac{3}{2}} \times J_3) = \mathrm{k}^6 \tag{6}$$

where J_2 and J_3 are expressed as the above section, k denotes the yield stress in pure shear, α and β are material constants.

If $\beta = 0$, the proposed yield function becomes the Cazacu–Barlat (2001) which is applied for symmetric materials such as aluminum and steel and the proposed yield function as expressed below:

$$\mathrm{f} \equiv J_2^3 + \alpha J_3^2 = \mathrm{k}^6 \tag{7}$$

If $\beta \neq 0$, the proposed yield function represents for asymmetric yield function which is applied for hcp crystal structure materials such as titanium and magnesium

and the proposed yield function as expressed below:

$$f \equiv J_2^3 + \alpha J_3^2 + \beta(J_2^{\frac{3}{2}} \times J_3) = \mathrm{k}^6 \tag{8}$$

In the above expressions a_i (i = 1…6) and b_k (k = 1…11) are coefficients that describe anisotropic property. If $a_i = b_k = 1$, the below Eqs. (12) and (13) return to isotropic yield function.

Using these anisotropic invariants, the anisotropic yield function for asymmetry is developed as below:

$$f\left(J_2^0, J_3^0\right) \equiv \left(J_2^0\right)^3 + \alpha\left(J_3^0\right)^2 + \beta\left(J_2^0\right)^{3/2} \times J_3^0 = \mathrm{k}^6 \tag{9}$$

The anisotropic generalizations of the second and third invariant of the stress deviator should be expressed as follows [10, 11]:

$$J_2^0 = \frac{a_1}{6}(\sigma_{xx} - \sigma_{yy})^2 + \frac{a_2}{6}(\sigma_{yy} - \sigma_{zz})^2 + \frac{a_3}{6}(\sigma_{xx} - \sigma_{zz})^2 + a_4\sigma_{xy}^2 + a_5\sigma_{xz}^2 + a_6\sigma_{yz}^2$$

$$\begin{aligned} J_3^0 = {} & \frac{1}{27}(b_1 + b_2)\sigma_{xx}^3 + \frac{1}{27}(b_3 + b_4)\sigma_{yy}^3 + \frac{1}{27}[2(b_1 + b_4) - b_2 - b_3]\sigma_{zz}^3 \\ & - \frac{1}{9}\left(b_1\sigma_{yy} + b_2\sigma_{zz}\right)\sigma_{xx}^2 - \frac{1}{9}(b_3\sigma_{zz} + b_4\sigma_{xx})\sigma_{yy}^2 \\ & - \frac{1}{9}\left[(b_1 - b_2 + b_4)\sigma_{xx} + (b_1 - b_3 + b_4)\sigma_{yy}\right]\sigma_{zz}^2 + \frac{2}{9}(b_1 + b_4)\sigma_{xx}\sigma_{yy}\sigma_{zz} \\ & - \frac{\sigma_{xz}^2}{3}\left[2b_9\sigma_{yy} - b_8\sigma_{zz} - (2b_9 - b_8)\sigma_{xx}\right] \\ & - \frac{\sigma_{xy}^2}{3}\left[2b_{10}\sigma_{zz} - b_5\sigma_{yy} - (2b_{10} - b_5)\sigma_{xx}\right] \\ & - \frac{\sigma_{yz}^2}{3}\left[2b_7\sigma_{xx} - b_6\sigma_{yy} - (2b_7 - b_6)\sigma_{zz}\right] + 2b_{11}\sigma_{xy}\sigma_{xz}\sigma_{yz} \end{aligned} \tag{10}$$

The effective stress, $\tilde{\sigma}$ is expressed as below:

$$\tilde{\sigma} = V\left[\left(J_2^0\right)^3 + \alpha\left(J_3^0\right)^2 + \beta\left(J_2^0\right)^{3/2} \times J_3^0\right]^{1/6} \tag{11}$$

In the above expressions, V is a constant value which defined for uniaxial tension in one of the orthotropic axes (e.g., for a sheet, in the rolling direction (RD)) the effective stress reduces to the yield stress,

$$V = \frac{1}{\left[\left(\frac{a_1+a_3}{6}\right)^3 + \alpha\left(\frac{b_1+b_2}{27}\right)^2 + \beta\left(\frac{a_1+a_3}{6}\right)^{\frac{3}{2}}\left(\frac{b_1+b_2}{27}\right)\right]^{1/6}} \tag{12}$$

In plane stress $\sigma_3 = 0$, the yielding under equi-biaxial tension in the plane (x–y) occurs when $\sigma_{xx} = \sigma_{yy} = \sigma_b$ with:

$$\sigma_b/\sigma_0 = \frac{1}{\sqrt{3}}\left\{\left(\frac{a_2+a_3}{6}\right)^3 + \alpha\left(\frac{2b_1-b_2-b_3+2b_4}{27}\right)^2 + \beta\left(\frac{a_2+a_3}{6}\right)^{3/2} \times \left(\frac{2b_1-b_2-b_3+2b_4}{27}\right)\right\}^{-1/6} \tag{13}$$

The biaxial coefficient r_b is calculated in the form [12]:

$$r_b = \frac{\frac{\partial f}{\partial \sigma_{yy}}}{\frac{\partial f}{\partial \sigma_{xx}}} \tag{14}$$

The Lankford coefficients r_θ are calculated based on the formula:

$$r_\theta = -\frac{\frac{\partial f}{\partial \sigma_{xx}}\left(\sin^2\theta\right) - (\sin 2\theta)\frac{\partial f}{\partial \sigma_{xy}} + \frac{\partial f}{\partial \sigma_{yy}}\left(\cos^2\theta\right)}{\frac{\partial f}{\partial \sigma_{xx}} + \frac{\partial f}{\partial \sigma_{yy}}} \tag{15}$$

The new anisotropic yield function predicts the following dependence of the normalized uniaxial yield stress σ_θ/σ_0 on the angle θ between the direction of loading and the rolling direction by using the relationship of $\sigma_x = \sigma_\theta cos\theta$, $\sigma_y = \sigma_\theta sin\theta$, $\sigma_{xy} = \sigma_\theta sin\theta\ cos\theta$:

$$\begin{aligned}
&\sigma_\theta/\sigma_0 = \\
&\frac{1}{\sqrt{3}}\left\{\left[\left(\frac{a_1}{6}+\frac{a_3}{6}\right)\cos^4\theta + \left(a_4 - \frac{a_1}{3}\right)\cos^2\theta\sin^2\theta + \left(\frac{a_1}{6}+\frac{a_2}{6}\right)\sin^4\theta\right]^3\right. \\
&+\alpha\left[\cos^6\theta\frac{b_1+b_2}{27} + \sin^6\theta\frac{b_3+b_4}{27} - \cos^4\theta\sin^2\theta\frac{b_1+3b_5-6b_{10}}{9} - \cos^2\theta\sin^4\theta\frac{b_4-3b_5}{9}\right]^2 \\
&+\beta\left[\left(\frac{a_1}{6}+\frac{a_3}{6}\right)\cos^4\theta + \left(a_4 - \frac{a_1}{3}\right)\cos^2\theta\sin^2\theta + \left(\frac{a_1}{6}+\frac{a_2}{6}\right)\sin^4\theta\right]^{3/2} \\
&\left.\times\left[\cos^6\theta\frac{b_1+b_2}{27} + \sin^6\theta\frac{b_3+b_4}{27} - \cos^4\theta\sin^2\theta\frac{b_1+3b_5-6b_{10}}{9} - \cos^2\theta\sin^4\theta\frac{b_4-3b_5}{9}\right]\right\}^{-1/6}
\end{aligned} \tag{16}$$

2.2 *Convexity Condition of Yield Function*

The proposed yield function is convex if $f(\sigma_{xx}, \sigma_{yy})$, $f(\sigma_{xx}, \sigma_{xy})$, and $f(\sigma_{yy}, \sigma_{xy})$ are convex. In order to each $f(\sigma_i, \sigma_j)$ is convex, its Hessian matrix H defined as below is positive semi-definite [13–15]:

$$H_1(\sigma_{xx}, \sigma_{yy}) = \frac{\partial^2 f}{\partial \sigma_i \partial \sigma_j} = \begin{bmatrix} \frac{\partial^2 f}{\partial \sigma_{xx}^2} & \frac{\partial^2 f}{\partial \sigma_{yy}\partial \sigma_{xx}} \\ \frac{\partial^2 f}{\partial \sigma_{xx}\partial \sigma_{yy}} & \frac{\partial^2 f}{\partial \sigma_{yy}^2} \end{bmatrix}; H_2(\sigma_{xx}, \sigma_{xy}) = \frac{\partial^2 f}{\partial \sigma_i \partial \sigma_j} = \begin{bmatrix} \frac{\partial^2 f}{\partial \sigma_{xx}^2} & \frac{\partial^2 f}{\partial \sigma_{xy}\partial \sigma_{xx}} \\ \frac{\partial^2 f}{\partial \sigma_{xx}\partial \sigma_{xy}} & \frac{\partial^2 f}{\partial \sigma_{xy}^2} \end{bmatrix}$$

$$H_3(\sigma_{yy}, \sigma_{xy}) = \frac{\partial^2 f}{\partial \sigma_i \partial \sigma_j} = \begin{bmatrix} \frac{\partial^2 f}{\partial \sigma_{yy}^2} & \frac{\partial^2 f}{\partial \sigma_{xy} \partial \sigma_{yy}} \\ \frac{\partial^2 f}{\partial \sigma_{yy} \partial \sigma_{xy}} & \frac{\partial^2 f}{\partial \sigma_{xy}^2} \end{bmatrix} \tag{17}$$

The property of the positive semi-definite can be proved by showing that the eigenvalues of the Hessian matrix H are non-negative. Based on this analysis, it is easy to check the convexity condition of the proposed yield function. In this study, the results indicated that the proposed yield function satisfies the convexity condition.

2.3 *Effect of A and B on Yield Surface for the Case of Plane Stress*

From the results are shown in Fig. 1, this new isotropic yield function involves the parameters α and β, which affect on the shape of the yield surface. If the parameter β is zero, the yield locus shapes become the symmetric yield locus. If parameter β is positive, the yield locus shapes become the asymmetric yield locus. In this case, the compression region is larger than the tension region as shown in Fig. 1a. If parameter β is negative, the yield locus shapes are also changed to asymmetric yield locus. However, the tension region is larger than the compression region as shown in Fig. 1b. The results indicated that the arbitrary coefficients α and β give a greater degree of flexibility to these shapes of the yield locus.

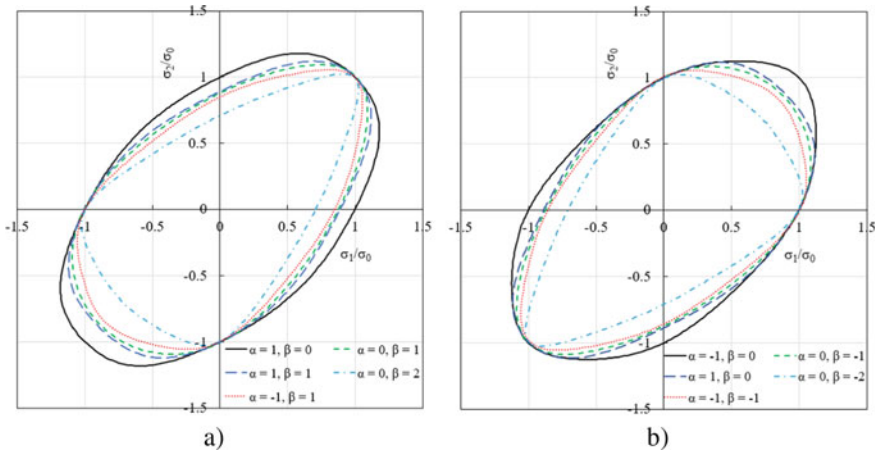

Fig. 1 The yield locus according to the proposed isotropic yield function for different values of the parameters α and β: **a** β is positive **b** β is negative. (Color figure online)

3 Applications of the Proposed Model

3.1 Application of the Proposed Yield Function to AA6016-T4 Sheet

Uniaxial tension and bulge data for the AA6016-T4 sheet were reported in Cazacu-Barlat et al. [10, 16, 17]. To identify the coefficients by fitting the experimental data with predicted ones, we adopt the following error function to be minimized:

$$F = \sum_{i}^{n} \eta_i \left(1 - \frac{(\sigma_\theta)_i^{\text{th}}}{(\sigma_\theta)_i^{\text{data}}}\right)^2 + \sum_{j}^{m} \gamma_j \left(1 - \frac{(r_\theta)_i^{\text{th}}}{(r_\theta)_i^{\text{data}}}\right)^2 + \delta\left(1 - \frac{(\sigma_b)_i^{\text{th}}}{(\sigma_b)_i^{\text{data}}}\right)^2 + \upsilon\left(1 - \frac{(r_b)_i^{\text{th}}}{(r_b)_i^{\text{data}}}\right)^2 + \sum_{k}^{t} \chi_k \left(1 - \frac{(r')_k^{\text{th}}}{(r)_k^{\text{data}}}\right)^2 \tag{18}$$

In the above equation, n and m represent the number of experimental yield stresses and r-values, respectively, for uniaxial tensile tests, corresponding to different orientations θ are available, σ_b and r_b are equi-biaxial tensile yield stress and biaxial coefficient, respectively, t represents the number of experimental biaxial tension and compression at different load ratios, the superscript indicates whether the respective value is experimental or calculated data while η_i, γ_j, δ, υ, and χ_k are weight factors, φ_k is the loading angle of the i^{th} stress point from the x-axis in the principal stress space, r is the distance between the origin of the principal stress space and the ith measured stress point and r' is the distance between the origin of the principal stress space and the calculated yield locus along the loading direction φ_k as shown in Fig. 2 [18].

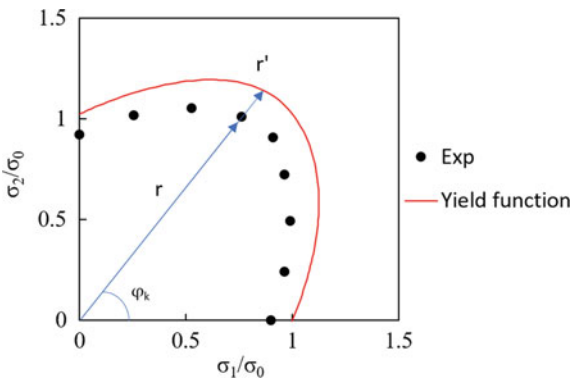

Fig. 2 Schematics for the calculation of the error distance of a calculated yield locus from the measured work contour. (Color figure online)

The yield locus and the predicted variation of the normalized uniaxial yield stress σ_θ/σ_0, r-values r_θ according to the KV6 yield function are shown in Fig. 3a, c, d, respectively, in comparison with the measured yield locus, yield stresses, and r-values for AA6016-T4 sheet [16]. The AA6016-T4 material is one of the FCC crystal structure materials. In previous studies, the yield locus shape of the AA6016-T4 was symmetric shape. Therefore, the parameter $\beta = 0$ is taken in this case. The numerical values of the coefficients involved in the KV6 yield function in plane stress $\sigma_3 = 0$ were determined by minimizing the error function (18) from the experimental yield stresses and r-values for $\theta = 0°$, 15°, 45°, 75°, 90°, the equi-biaxial tensile yield stress $\sigma_b/\sigma_o = 1.0$. These coefficients are shown in Table 1. Figure 3b shows 3D yield surface of the KV6 yield function considering the influence of the shear stress.

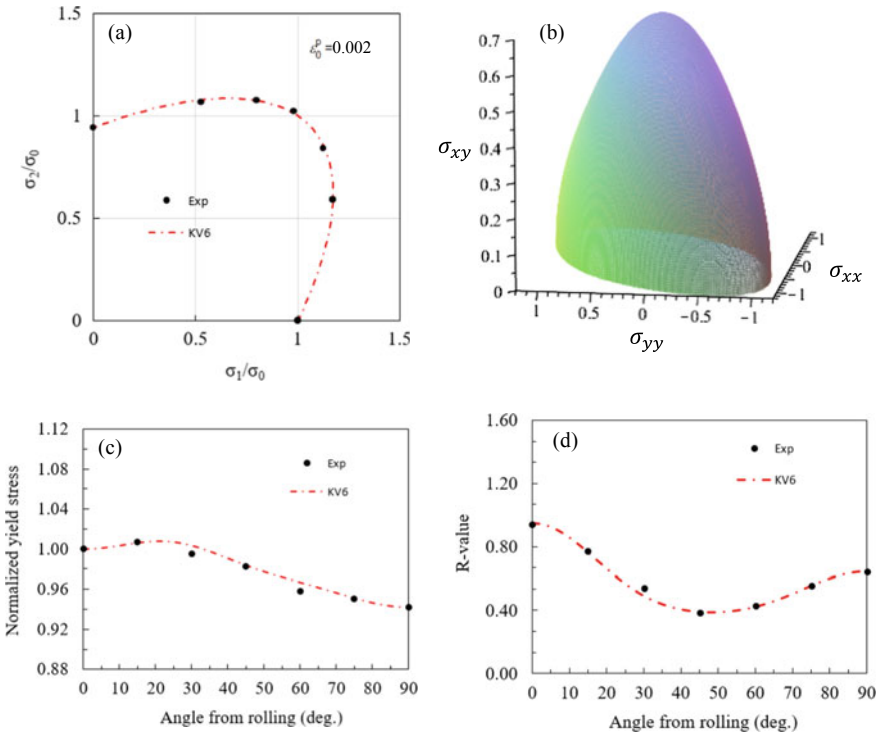

Fig. 3 Predicted anisotropy according to the KV6 yield function for AA6016-T4 sheet: **a** Yield locus, **b** 3D yield surface **c** Uniaxial yield stresses, **d** R-values. (Color figure online)

Table 1 Anisotropic coefficients of the KV6 yield function

Parameters	a_1	a_2	a_3	a_4	b_1	b_2	b_3	b_4	b_5	b_{10}	α	β
KV6	1.085	0.846	0.696	0.697	0.384	1.616	2.408	0.271	1.315	1.257	1.986	0

From the results are shown in Fig. 3, the yield locus shape and the following dependence of the predicted r-values on the angle θ between the direction of loading and the rolling direction in the KV6 model are in good agreement with experimental data.

3.2 *Application of the Proposed Yield Function to the Magnesium Sheet*

The yield locus for the magnesium sheet is shown in Fig. 4. The numerical values of the coefficients involved in the KV6 yield function were determined by minimizing the error function (18) from the experimental biaxial stresses including 7 load ratios of biaxial tensions data (1:0; 4:1; 2:1; 4:3; 1:1; 1:2; 0:1) and 2 load ratios of biaxial compressions data (1:0; 0:1) are shown in Fig. 4 [19]. These coefficients are shown in Table 2.

The yield locus shape in the KV6 model is in good agreement with experimental data [19] as shown in Fig. 4. The comparison between the KV6 yield function and

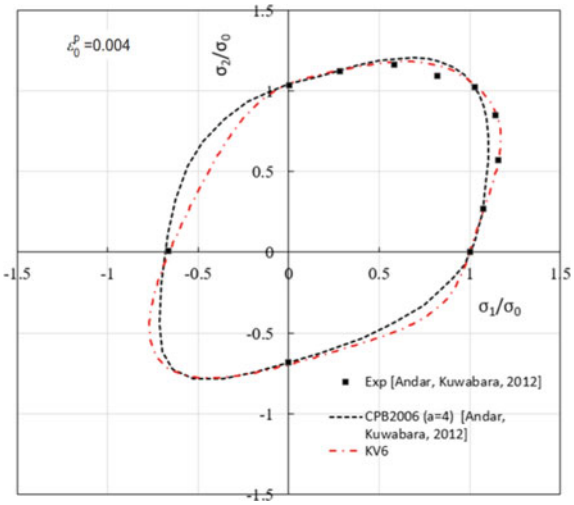

Fig. 4 Predicted yield locus according to the KV6 yield function and CPB2006's yield function for magnesium sheet. (Color figure online)

CPB2006's yield function shows that both predicted yield loci are fitted well with experimental data.

3.3 *Application of the Proposed Yield Function to the Pure Titanium Sheet*

The yield locus for the pure titanium sheet is shown in Fig. 5. The numerical values of the coefficients involved in the KV6 yield function were determined by minimizing the error function (18) from the experimental biaxial stresses including 6 load ratios of biaxial tensions data (1:0; 2:1; 1:1; 3:4; 1:2; 0:1) and 3 load ratios of biaxial compressions data (1:0; 1:1; 0:1) are shown in Fig. 5 [20]. These coefficients are shown in Table 3.

The yield locus shape in the KV6 model is in good agreement with experimental data [20] as shown in Fig. 5. The comparison between the KV6 yield function and Yoon2014' yield function of Eq. (5) shows that both predicted yield loci are fitted well with experimental data. It is clear that the proposed yield function can predict with accuracy for the asymmetric materials as hcp crystal structure materials.

4 Conclusions

In this paper, a new isotropic yield function expressed in terms of both invariants J_2 and J_3 was proposed. This new isotropic yield function involves the parameters α and β, which affect on the shape of the yield surface. If both parameters are zero, the von Mises yield function is recovered. The extension of the new isotropic yield function to anisotropic yield function has been developed. In this study, the result indicates that the proposed anisotropic model is reasonable to predict the yield locus, the normalized yield stresses and r-values of the sheet metals with the strong anisotropy. It was emphasized that the combination of two terms including α and β parameters in the KV6 yield function generates a new yield function that is able to describe the strong anisotropic material with high flexibility. In further work, the application of the new proposed yield function to predict the forming limit curve should be considered and discussed in more detail.

Experimental Implementation of SS 316L Cruciform Testing to Achieve Various Deformation Paths

Elizabeth M. Mamros, Sarah M. Mayer, Jinjin Ha, and Brad L. Kinsey

Abstract By following varying deformation paths, e.g., a linear path to equibiaxial loading versus a bilinear path of uniaxial loading followed by biaxial loading, the same final strain state can be achieved. However, the stress state that the material is subjected to is considerably different due to the varying deformation. This is of interest in a growing field of stress superposition to improve formability and manipulate final part properties in metal forming applications. One potential application is forming patient-specific, trauma fixation hardware with differing strength and weight reduction requirements in various regions. In this paper, experiments were performed on a custom fabricated cruciform machine with the goal of subjecting stainless steel 316L to various deformation paths. A novel cruciform specimen geometry was designed in collaboration with the US National Institute of Standards and Technology to achieve large strain values in the gauge region. Digital Image Correlation was utilized to measure surface strain fields in real time.

1 Introduction

Due to both work hardening and possible phase transformations during forming, the initial material properties are not necessarily representative of the properties in the processed part. Conventional experiments for the material characterization, including uniaxial tension, and basic constitutive laws do not capture the material behavior correctly under complex and varying loading paths that are often intrinsic to forming processes [1].

In order to capture such complex loading experimentally, Shiratori and Ikegami proposed the cruciform biaxial tension experimental procedure in 1967 [2]. In contrast to hemispherical dome tests (another technique for biaxial loading experimentation), cruciform tests do not involve a pressurization effect, allow the same specimen geometry to be used for all experiments, and enable the deformation path to be varied during a test [3]. In recent decades, several biaxial cruciform machines have been developed, some of which are summarized in [3], but, thus far, an ASTM standard for the cruciform specimen geometry does not exist. Common problems that arise when designing cruciform specimens include early failure in the arms, low strain values at failure, and a non-homogeneous strain distribution in the gauge area.

Austenitic stainless steels (SS) undergo stress-induced phase transformation to martensite during forming, particularly at low temperatures and high strains [4]. Hecker et al. found that for the case of balanced biaxial tension of SS 304L, the degree of martensitic transformation is more than twice the amount observed, per maximum principal strain value, during uniaxial tension [5]. Thus, characterization of the transformation kinetics at various proportional loading paths is required to determine the deformation path most beneficial in terms of stress superposition.

In this paper, SS 316L specimens were loaded on a custom cruciform frame [7] designed to implement non-linear deformation paths. A custom cruciform specimen able to achieve large strain values in the gauge area was created in collaboration with the US National Institute of Standards and Technology (NIST) via a previously used methodology [1, 6]. The three loading paths investigated, 4:4 (equibiaxial), 4:2, and 4:0, were applied as constant displacement ratios between the perpendicular axes ($\Delta Y : \Delta X$). The area of interest on the specimen, i.e., the flat surface within the pocket in the gauge area, was chosen to capture a region containing relatively uniform deformation. Digital Image Correlation (DIC) was used to measure the strains *in-situ.* The martensitic transformations of SS 316L will be measured using electron backscatter diffraction (EBSD) with the scanning electron microscope, but this is outside of the scope of this paper.

2 Experimental Setup and Methods

2.1 Material and Specimen Preparation

SS 316L, a biocompatible material, with a thickness of 1.2 mm was used in this study. In collaboration with NIST, a cruciform specimen geometry was designed based on past research [1, 6]. The slightly modified design objectives were to create a specimen that could be manufactured in-house, i.e., with waterjet cutting and milling operations, and achieve both a high equivalent plastic strain and a homogeneous strain distribution in the gauge area. The high equivalent plastic strain threshold was targeted to enhance the amount of martensitic phase transformations, a microstructural change that is common in austenitic stainless steels, including 316L, with large

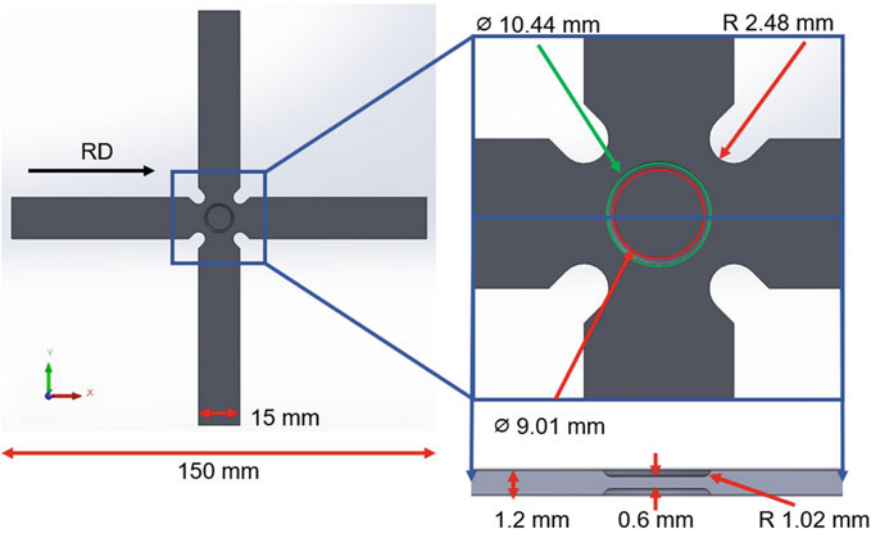

Fig. 1 Overall cruciform specimen geometry obtained from 1.2 mm thick SS 316L [8]. (Color figure online)

deformations. The homogeneous strain distribution in the gauge area will be critical for accurate martensitic transformation measurements. The specimens were oriented with arms parallel to the rolling and transverse directions, and the profile was waterjet cut (see Fig. 1). The edges were sanded prior to testing. A 4 mm diameter end mill was used on each side of the specimen to machine the pocket in the gauge section. The fabricated specimen dimensions were measured using a confocal microscope (Olympus OLS5000-SAF) to confirm that all desired tolerances were achieved.

NIST has investigated this specimen geometry during previous research [1, 6], but in order to use this geometry in conjunction with the cruciform machine at UNH, modifications were required. Two key factors necessitating this geometry study were accounting for the size difference between the testing equipment and meeting the desired minimum equivalent plastic strain threshold of 30% in the center pocket. Table 1 lists the dimensions used to fabricate the specimens at UNH. Figure 2 shows a schematic of the cruciform specimen geometry with dimensions that correspond to the values in Table 1.

2.2 Cruciform Machine

A cruciform machine capable of applying biaxial tension along perpendicular axes was constructed at UNH in collaboration with Prof. Kuwabara at the Tokyo University of Agriculture and Technology [9] (see Fig. 3). The loading is applied via four Parker 3LX Series hydraulic cylinders (see Table 2 for key specifications).

Table 1 Cruciform geometry dimensions

Dimension	Value (mm)
Gauge thickness, T_{pocket}	0.60
Sheet thickness, T_{sample}	1.20
Fillet, F_{pocket}	1.02
Flat area radius, R_{gauge}	4.51
Pocket diameter, D_{pocket}	10.44
Arm width, W_{arm}	15.00
Notch radius, R_{notch}	2.48
Notch diameter, D_{notch}	4.96
Diagonal	21.21

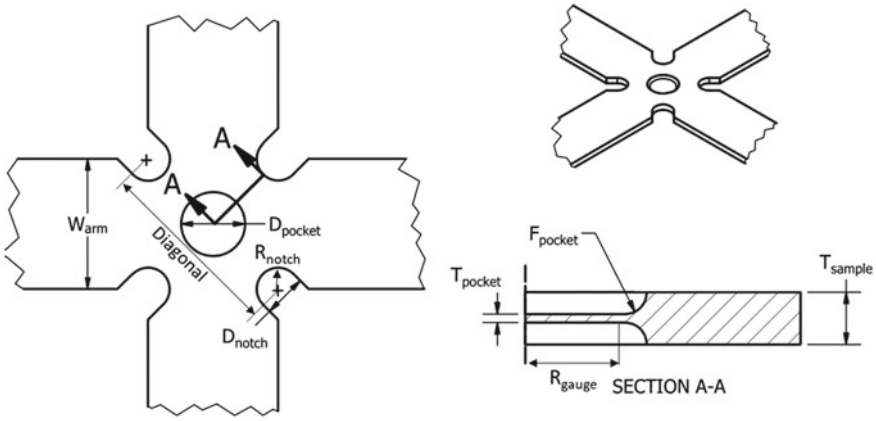

Fig. 2 Schematic of final cruciform specimen geometry (modified from [6])

Greenerd Press and Machine Co. designed and built the hydraulic system and control circuitry. The machine can displace the opposing cylinders equally within 0.1 mm of the programmed value at a maximum velocity of 80 mm/min. A human–machine interface was programmed in LabVIEW software to control the machine.

2.3 Digital Image Correlation

To capture strain measurements in-situ, two FLIR 8.9 megapixel cameras with 50 mm Schneider Xenoplan compact lens were used (see Fig. 3) for 3D DIC analyses. The specimens were prepared with a white background and overlaid black speckle pattern using spray paint. The images were post-processed in VIC-3D from Correlated Solutions, Inc. with subset, step, and filter sizes of 21, 5, and 5 pixels, respectively. The area of interest selected was the ~ 9 mm diameter flat region in the gauge section.

Maximum tensile force	25.8 kN
Maximum compressive force	30.7 kN

The temperature increase during these experiments, captured by the FLIR SC-645 infrared camera, was < 15 °C, and thus, further temperature data is not presented in this work.

2.4 Biaxial Experiments

The biaxial experiments were conducted on the cruciform machine by programming displacements and pulling speeds in each axis. A removable fixture to ensure consistent specimen placement and proper alignment in the grips was designed and 3D-printed (see Fig. 4). For consistency, the arms oriented along the rolling direction (RD) were positioned parallel to the x-axis for each experiment. For equibiaxial conditions, a total displacement of 10 mm, i.e., 5 mm along each arm, and pulling speed of 0.1 mm/s were prescribed to each axis. For the other loading conditions,

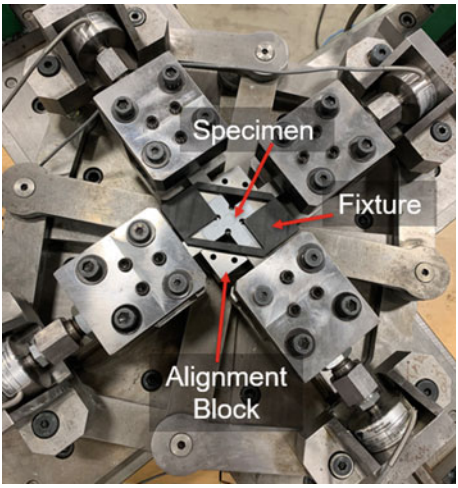

Fig. 4 Specimen alignment fixture on cruciform machine. (Color figure online)

the pulling speed of the x-axis was decreased according to the desired displacement to ensure that the displacement ramps would terminate at the same time. The strain rate along each axis for all experiments was approximately 10^{-3} – 10^{-4} s^{-1}. Three experiments were completed for each displacement case of interest to verify repeatability.

3 Results and Discussion

3.1 Force Versus Displacement Results

During each experiment, the biaxial cruciform machine recorded force and displacement data for each axis from the load cells and embedded linear variable displacement transducers, respectively. The displacement values presented represent the displacement along the positive axes, i.e., the total displacement for each axis is twice the stated value. Figure 5 summarizes these results for all displacement paths. Comparing the maximum displacements along the y-axis (TD), the 4:0 path had the largest value, followed by the 4:2 path, and the 4:4 path had the smallest value as expected. With respect to the y-axis (TD), the maximum force values follow the same trend for the three displacement paths presented.

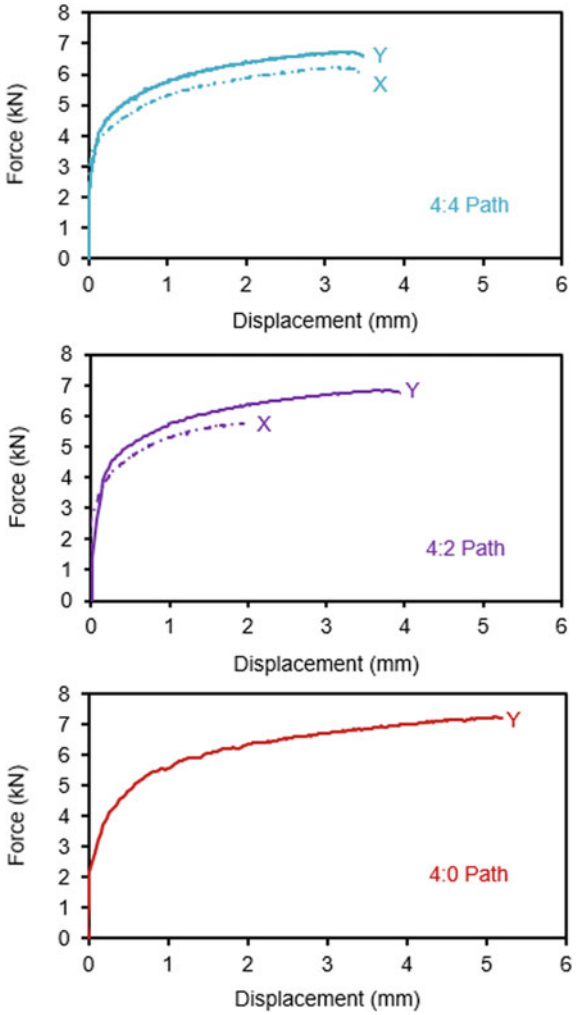

Fig. 5 Force–displacement curves for all 4:4, 4:2, and 4:0 displacement paths. (Color figure online)

Table 3 DIC true strain results from the image prior to fracture for 4:4, 4:2, and 4:0 displacement paths

	Value at center point (mm/mm)		
True strain	4:4 path	4:2 path	4:0 path
ε_{xx}	0.188	0.127	−0.136
ε_{yy}	0.185	0.249	0.233
ε_{VM}	0.189	0.218	0.323

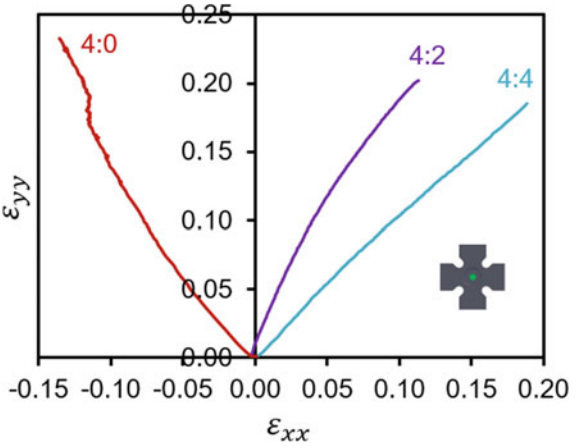

Fig. 6 True strain paths extracted from DIC analyses at the center of the specimen for 4:0, 4:2, and 4:0 displacement paths. (Color figure online)

3.2 Strain Results

Table 3 shows the true strain values onset of fracture at the center point of the specimen geometry. The corresponding strain paths, ε_{yy} versus ε_{xx}, are shown in Fig. 6. The strain contours and values at the center point for the x-direction and y-direction are nearly equivalent as expected for the equibiaxial case, with variations being due to the anisotropy of the material. The 4:2 path had a slightly larger true strain along the y-direction than the 4:0 path, but the 4:0 path exhibited a much larger equivalent von Mises strain than the 4:2 path.

The strain distributions in the gauge area are shown in Fig. 7. The strain contours show that the equivalent von Mises strain is >30% within the gauge region, not necessarily at the center point, for all displacement paths. This indicates that significant martensitic transformation is expected in the corresponding locations.

4 Conclusion and Future Work

Initial experimental results from SS 316L cruciform specimens deformed with 4:4, 4:2, and 4:0 displacement paths have been presented. The resulting strain values were determined with 3D DIC and indicate the propensity for martensitic transformation. Future experiments will be conducted to investigate varying deformation paths and to determine the relationship between a specific non-linear deformation path and the induced martensitic transformations measured by EBSD. An analytical model will also be developed to determine multiple non-linear deformation paths that will result in the same final strain state but hypothesized differing martensite volume fractions.

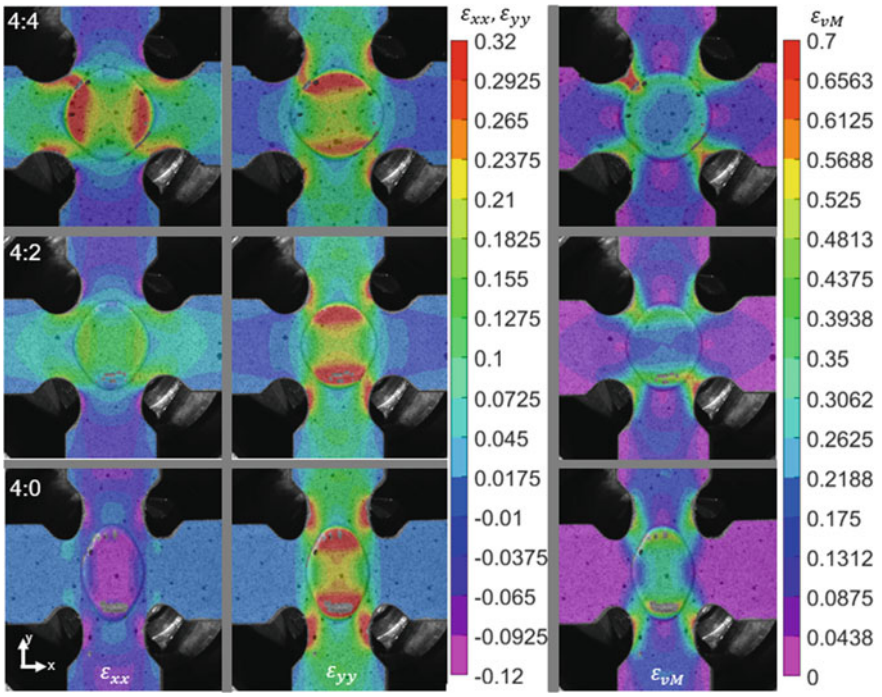

Fig. 7 True strain distribution immediately prior to fracture: x-direction, y-direction, and von Mises for 4:4, 4:2, and 4:0 displacement paths. (Color figure online)

Acknowledgments The authors would like to thank Mark Iadicola and Dilip Banerjee from NIST for their assistance in designing this cruciform specimen. The Olympus confocal microscope used is managed by the University Instrumentation Center (UIC) at the University of New Hampshire (UNH). Support for the NH BioMade Project is provided by the US National Science Foundation EPSCoR award (#1757371).

An Application of Homogeneous Anisotropic Hardening Model to the Prestrained Hole-Expansion Experiment

Jinjin Ha and Yannis P. Korkolis

Abstract In this work, the plastic anisotropy of AA6022-T4 in hole-expansion is investigated focusing on prestraining effect, and its numerical solution is predicted by Homogeneous Anisotropic Hardening (HAH) model combined with an anisotropic yield function. For the prestraining, the material is subjected to a prestrain of 8% in uniaxial tension in the RD. Then, hole-expansion is conducted in a fully instrumented hydraulic press with a flat-headed punch. In both experiments, Digital Image Correlation (DIC) is used, to confirm the prevalence of uniaxial loading in the prestraining step and to measure thickness strain in the hole-expansion. The results show that the plastic anisotropy is manifested as a non-axisymmetric strain distribution around the hole. The prestraining, leading to non-proportional loading, changes the location of failure from ~45° to RD. The simulation shows the current version of HAH model is limited in capturing the thickness contours and the failure location.

Keywords Non-proportional loading · Anisotropy · Hole-expansion · Aluminum alloy

1 Introduction

Stretch flange formability is a particular interest in sheet metal forming, where holes can be an initiator of edge cracking during a subsequent forming operation, such as wheels and suspensions of automotive parts [1]. The edge is deformed under uniaxial tension because of the free surface, but the forming limit is often much higher than that of standard uniaxial tension due to the delayed geometrical instability. In this regard, the flange formability has been evaluated using other kinds of experiments like hole-expansion instead of the standard uniaxial tension. As an approximated solution for the hole-expansion, Parmar and Mellor [2] derived an analytical solution to predict

stress and strain variations in the hole periphery and showed that the prediction highly depended on the yield function used for the analytical model and r-value of the material. More recently, numerous studies used the hole-expansion experiment to validate the ability of the yield function to capture the plastic anisotropy manifested as strain variation around the hole using finite element simulation [3–5].

In this regard, the current study also adopts the hole-expansion experiment but with the accent on the evaluation of the prestraining effect on the evolution of plastic anisotropy [6–9]. Because it is a very simple example of a non-linear strain path, which are prevalent in stamping of complex components. The experiment is performed in 2 steps: (1) uniaxial prestraining in the rolling direction (RD) and 2) hole-expansion with a flat-headed round-punch. Test material is AA6022-T4 sheet of 1 mm thickness [10] which is one of the common automotive aluminum materials. The process is simulated using the Yld2000-2d yield function [11] combined with the Homogeneous Anisotropic Hardening (HAH) model [12–14]. The yield function chosen has been widely used to capture the plastic anisotropy of various aluminum sheets; the strain hardening model, i.e., HAH, is a recent proposal with improved performance in predicting non-linear path behavior, such as the Bauschinger effect, albeit its full potential is not yet known.

2 Material Characterization and Parameter Identification of Constitutive Models

The plastic anisotropy and strain hardening behavior of the material are characterized by uniaxial tension and tension–compression experiments. Uniaxial tension is conducted in every 15° from the RD, from which the plastic anisotropy is presented by normalized flow stress and r-value ($d\varepsilon_w/d\varepsilon_t$) as seen in Fig. 1a. The result represents

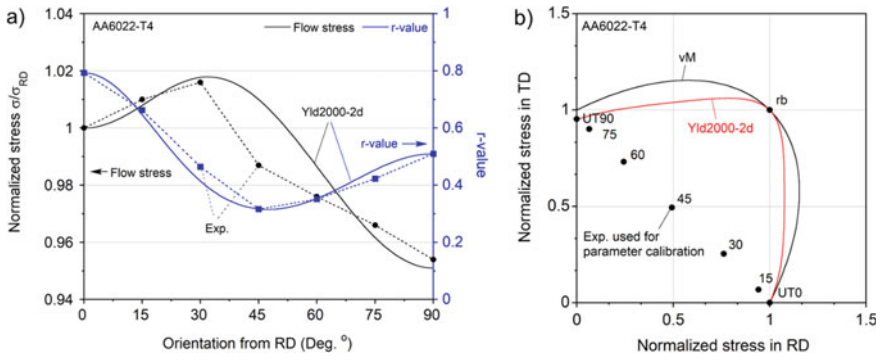

Fig. 1 The experiment of uniaxial tension in every 15° from the RD and the calibration of Yld2000-2d: **a** plastic anisotropy for normalized flow stress and r-value and **b** yield loci of Yld2000-2d and von-Mises (vM). (Color figure online)

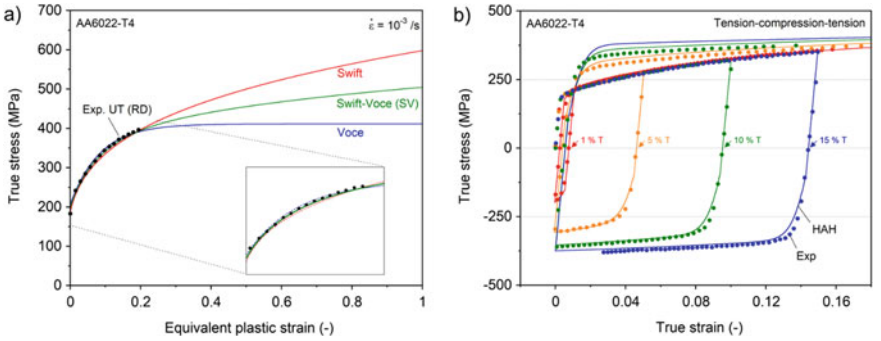

Fig. 2 Hardening parameter identification for **a** Swift-Voce combined model for the uniaxial tension in the RD and **b** HAH model for tension–compression in the RD. (Color figure online)

that higher anisotropy in the strain field is expected than that in the stress field, especially at 45°, which has the lowest resistance to thinning. The data is used to calibrate a non-quadratic anisotropic yield function, i.e., Yld2000-2d (Fig. 1a) using Newton–Raphson method, and the corresponding yield locus in the 1st quadrant is described in Fig. 1b with a quadratic isotropic yield function, i.e., von-Mises, as a reference. Isotropic strain hardening behavior is also identified by the stress–strain curve from uniaxial tension in the RD (Fig. 2a), which is extrapolated by Swift-Voce combined model. In addition, anisotropic strain hardening behavior under a non-proportional loading path is characterized by a tension–compression experiment with different amounts of prestraining in tension (symbol in Fig. 2b), from which HAH model is calibrated (solid line) like in Fig. 2b. The model captures anisotropic strain hardening behavior very well such as Bauschinger effect, i.e., early re-yielding on load reversal, and following transient behavior, i.e., subsequent high strain hardening rate region. The calibrated model parameters are summarized in Tables 1, 2, and 3.

3 Hole-Expansion Experiment with Prestraining

In order to impose the prestraining effect on the hole-expansion, the material is first subjected to 8% true uniaxial tension in the RD using a large specimen (Step 1 in Fig. 3), and then the hole-expansion experiment (Step 2 in Fig. 3) is conducted using a specimen extracted from step 1. The prestraining specimen is designed to induce uniform strain only in the major deformation region for the hole-expansion experiment, i.e., from the hole to the punch radius. The uniform true strain, approximately 8% of uniaxial tension, in this area is confirmed by the digital image correlation (2D-DIC) system. After the prestraining, the large specimen is unloaded from the testing machine, and the hole-expansion specimen is prepared by end-milling for a fine surface quality, to prevent early failure. The hole-expansion experiment is conducted in a double action hydraulic press of 260 kN load capacity, and the real-time strain field during the experiment is acquired by the 3D-DIC system.

In Fig. 4, thickness strain spatial distributions at the onset of fracture are presented for the as-received hole-expansion (HE) and uniaxial tension followed by hole-expansion (UT-HE) in the RD. The profiles measured at 40 mm dia. hoop are compared in the graph as well. As expected from the r-value evaluation, the highest thickness reduction is observed near at 45° from the RD in the HE, while it changes to the RD in the UT-HE. All locations of highest thickness reduction lead to the first rupture that ends the HE experiment. This comparison reveals that the current non-proportional loading path has a strong influence on the evolution of plastic anisotropy, which alters the failure behavior in HE and even reduces the overall formability, i.e., lower level of thickness strain in average for UT-HE (solid line in red) compared to that for HE (dashed line in blank).

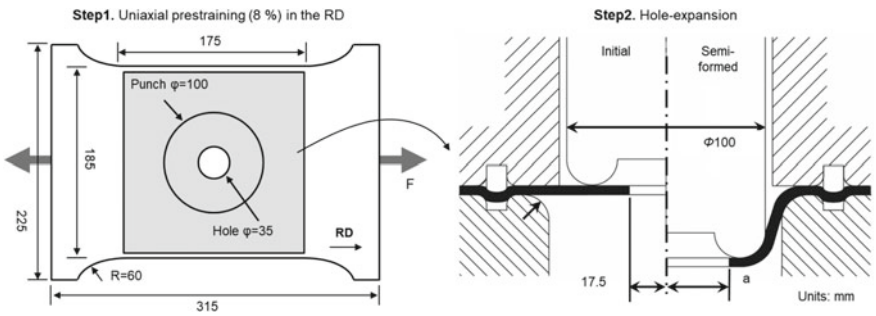

Fig. 3 Illustration of 2-step experiment: the uniaxial prestraining followed by hole-expansion experiment

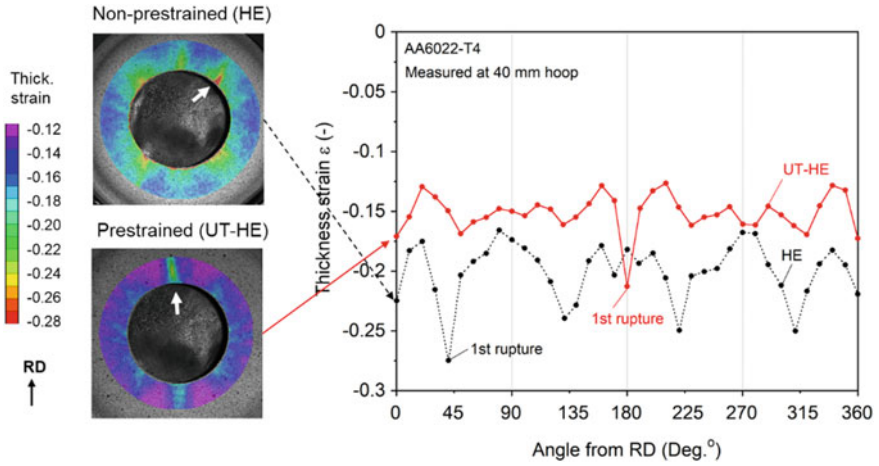

Fig. 4 Thickness strain distribution on the surface and the profiles along 40 mm dia. hoop for the hole-expansion (HE) and the 8% uniaxial tension followed by the hole-expansion (UT-HE). (Color figure online)

4 FE Simulation

The experiment is used to evaluate the adopted constitutive models through the FE simulation using the Abaqus 2019 implicit solver. The constitutive models, i.e., Yld2000-2d and HAH are implemented in a user subroutine. As with the experiment, the simulation is carried out in 2 steps: the uniaxial prestraining around 8% in the RD and the subsequent hole-expansion (Fig. 5). The specimen is modeled in a quarter size considering plane-symmetry and composed of shell elements with reduced thickness (S4R). The necessary initial conditions for Step 2 such as stress, strain, state variables,

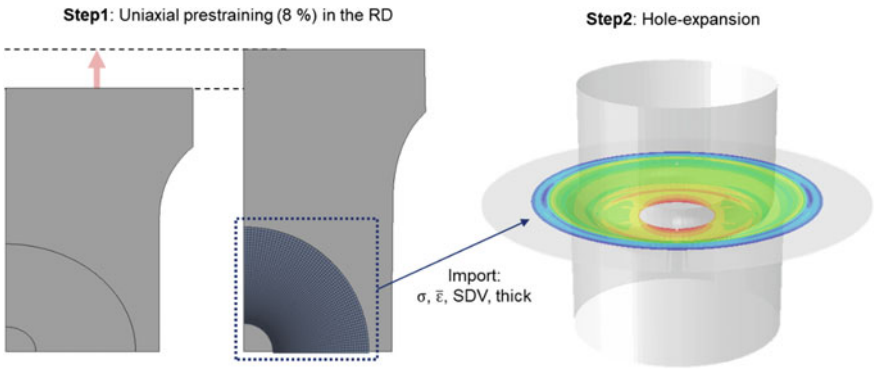

Fig. 5 Schematic of FE simulation for the uniaxial prestraining followed by the hole-expansion. (Color figure online)

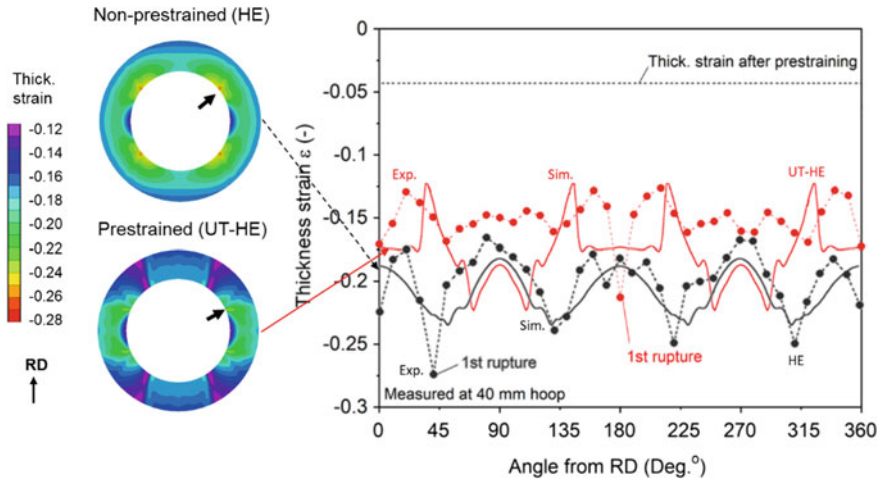

Fig. 6 Prediction of thickness strain variation along the circumference for the hole-expansion (HE) and 8% uniaxial tension followed by hole-expansion (UT-HE). (Color figure online)

thickness, and the geometry are imported from Step 1. Coulomb friction law is assumed with a constant friction coefficient $\mu = 0.17$. This was determined by optimal matching of the punch force–displacement curve by the FE model.

Figure 6 shows the prediction result with the experiment. The same colors correspond to the same experiment and simulation, i.e., blank for HE and red for UT-HE, in which the experiment is in the dashed line with symbol and the simulation in the solid line. Overall, the average strain variation in HE is well captured by the models and, in an average sense, in a good agreement with the experiments. In the as-received HE, the point-to-point, circumferential distribution is also very close between experiments and predictions. However, in the prestraining one, i.e., UT-HE, the predicted distribution is quite off from the experiments, with extreme values appearing at 40° and 70° from the RD.

The prediction difference in HE and UT-HE is caused by the amplitude of non-proportionality of loading path: throughout the hole-expansion deformation, each material point is exposed to light non-proportionality in HE while it is more significant in UT-HE. Especially, the irregular strain variation at 34.6° from the RD, in which the stress state is uniaxial tension in 55.6° from the RD, coincides with the discontinuity in the fluctuation component F, i.e., $F = (\phi_h/\tilde{\sigma})^q$, where $\phi_h = f_1^q \left|\widehat{\mathbf{h}} : \mathbf{s} - \left|\widehat{\mathbf{h}} : \mathbf{s}\right|\right| + f_2^q \left|\widehat{\mathbf{h}} : \mathbf{s} + \left|\widehat{\mathbf{h}} : \mathbf{s}\right|\right|$ with state variables $f_{i,i=1,2}^q$, deviatoric stress $\mathbf{s}$, and normalized microstructure deviator tensor $\widehat{\mathbf{h}}$, which controls the distortional shape of the yield locus as seen in Fig. 7. It should be noted that a solid line presents the yield locus predicted by HAH model with a distortion while a dashed line is a reference yield locus with an isotropic hardening assumption. Dots indicate uniaxial tension in every 15° from the RD, and empty dots represent projected states

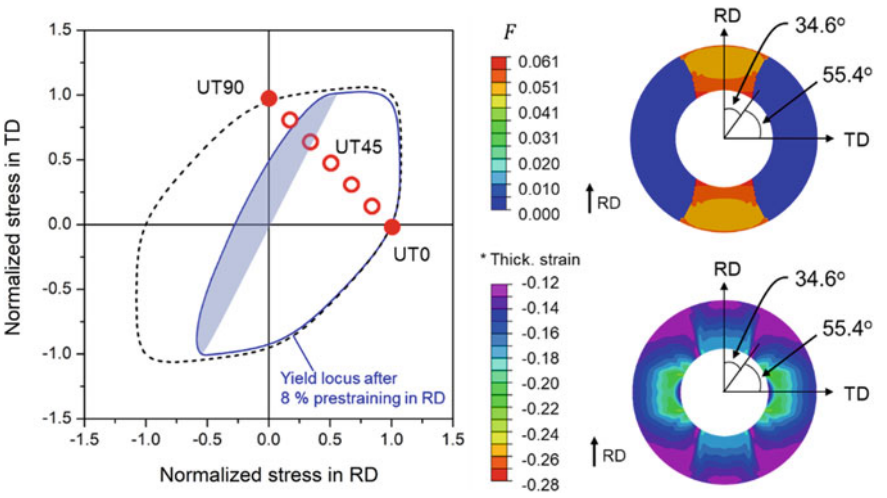

Fig. 7 Discontinuity near distortion affected area. (Color figure online)

on x–y plane, i.e., $\sigma_{12} = 0$. Further analysis for the limited prediction of HAH model related to this discontinuity is necessary in the future to improve the model.

5 Conclusion

The effect of the non-proportional loading path on the evolution of plastic anisotropy is clearly demonstrated through the hole-expansion experiment with uniaxial prestraining, for AA6022-T4. The experiment exhibits that the plastic anisotropy is interrupted by the prior deformation and the overall material formability can be reduced for the particular non-proportional loading paths. The constitutive models adopted for the FE simulation show prediction limitations for the strain variation in the non-proportional loading path case. Thus, further analysis will be necessary with a focus on the observed discontinuity of the fluctuating component and distortional shape in the future.

Work Hardening and Fracture Strain Evaluation of Hardened SKD11 Steel Using Shear Punching Test

Takashi Matsuno, Kouta Nakagiri, Hiroto Shoji, and Mitsuru Ohata

Abstract This study identified the work-hardening parameters and fracture strain of a hardened die-steel (SKD11). Herein, a shear punching test was used as the low stress-triaxiality suppresses material fracture due to the brittle behavior of SKD11 in tensile tests. Furthermore, a minute punch-die clearance was used to increase the compression stress due to the material deformation. SKD11 steel sheets of 1.0 mm thickness were successfully deformed, and the punching force as well as stroke were recorded for inverse analysis using the finite element analysis (FEA). Subsequently, FEA of the shear punching test was repeated to optimize the parameters of Swift's work-hardening law. Consequently, the Swift parameters were derived to ensure that the measured values of the punching force and stroke correspond with the numerically simulated curve. The fracture strain was identified as the maximum equivalent plastic strain at the punch stroke of specimen rupture.

Keywords Tool material · Shear punching test · Ductile fracture · Inverse analysis

1 Introduction

In recent years, ultra-high strength steel sheets have been used in automobiles. Thin ultra-high strength steel sheets can be substituted for thick and mild steel sheets in order to reduce the weight of automobiles without adversely affecting their crash-worthiness. Recent ultra-high strength steels exhibit both high elongation and good tensile strength [1–3] and consequently, a high crash absorption energy.

However, the strengthening of steels for automobiles has introduced difficulties in press-forming. Spring-back and material fracture are well-known phenomena, which are associated with the use of ultra-high strength steel sheets. Further, die failures

during press-forming have particularly become a problem in the shearing process, in addition to conventional die wear. As reported by Yasutomi et al. [4], the edges of the shearing punch are plastically deformed in the piercing process for the 1180 MPa class cold-rolled steel sheets with 1.4 mm thickness. After such an edge deformation, the punch edges are chipped; however, shearing of the 590 MPa class cold-rolled steel sheets did not exhibit punch edge deformation and chipping. Tool materials for shearing punch are extremely hard and brittle, but these undergo ductile fracture in the shearing process of ultra-high strength steel sheets.

To solve this problem, some studies proposed improving the shape of the punch edge, e.g., punch edge chamfer [5, 6] and obtuse punch edge [7]. Finite element (FE) analysis accelerates the design process of the punch edge shapes when the punch edge deformation and fracture are simulated precisely. However, the analysis requires input parameters, work-hardening, and a fracture criterion.

The objective of this study is to identify these parameters for the fabrication of a tool material by using a shear punching test [8–10]. Herein, hardened die steel, SKD11, which was standardized by Japanese Industrial Standards (JIS) G 4404:2015, was studied. In this method, punching force and stroke were measured when the SKD11 plate with 1.0 mm thickness was pierced; further, FE analyses were recursively performed with different work-hardening parameters. These were to ensure that the punching force–stroke simulation corresponded with the measurement. A compression state around the punch edge suppressed the material fracture, which caused even the brittle SKD11 to plastically deform. The fracture strain was evaluated as the equivalent plastic strain numerically simulated at the punch displacement when the abrupt force release was measured.

The following sections present the method and result of this parameter identification for hardened SKD11.

2 Method

2.1 Material

A commercial hardened SKD 11 die steel, produced by Hitachi Metals Ltd. under the trade name of SLD, was used for this study. Table 1 presents the chemical composition of this steel. The steel was quenched from 1000 °C by air cooling and tempered at 150 °C for 60 min, which resulted in a hardness of 62.6 HRC on the Rockwell scale. The steel was shaped by wire cutting it into thin sheets with thicknesses of 1.0 mm for the shear punching test. The surfaces of the sheets were polished by emery paper.

Table 1 Chemical composition of SKD11 (mass %)

C	Si	Mn	P	S	Cr	Mo	V
1.47	0.25	0.41	0.021	< 0.001	11.82	0.83	0.24

Table 2 Mechanical property of 590 MPa steel with 1.2 mm thickness. The steel was used in validating punching force and stroke simulation through FE analysis

Tensile strength	Yield stress	Uniform elongation	Total elongation
621 MPa	493 MPa	13%	23%

For validation of FE analysis, 590 MPa class of cold-rolled steel sheets with 1.2 mm thickness was evaluated through the shear punching test. The mechanical properties were already measured for this steel, and they are shown in Table 2. The measurement and simulation of the punching force and stroke curves was compared to estimate the validity of FE analysis.

2.2 Shear Punching Test

The shear punching test consisted of fabricating holes with 10.0 mm diameter through the specimens. An image of the experimental setup is shown in Fig. 1. The piercing punch and die were composed of cemented carbide coated with TiCN. They are harder than SKD11 steels. The specimen was clamped using a cylindrical holder to avoid the inflection accompanying punch penetration. The holder was bolt-locked to the base for the specimen. A hydraulic tension/compression testing machine, whose maximum force is 294.2 kN, pressed the punch with a measured punching force and ram displacement until the punch passed through the sheet thickness.

The punching speed was set to 0.1 mm/s.

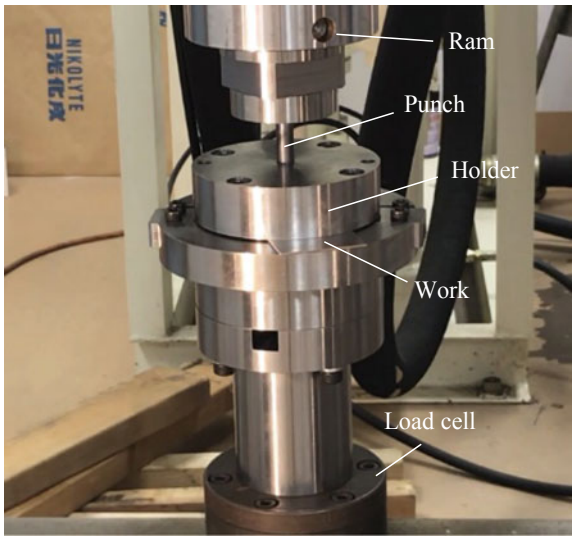

Fig. 1 Experimental set up of the shear punch test. (Color figure online)

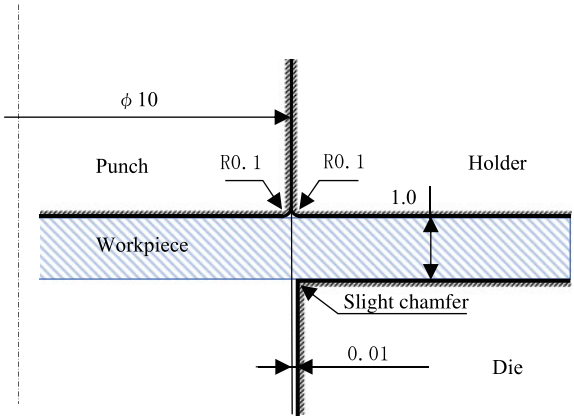

Fig. 2 Schematic figure of tool setting for the shear punching test. (Color figure online)

The condition for the shear punching tools is schematically presented in Fig. 2. As shown in Fig. 2, the tests were done with 0.01 mm clearance between punch and die edges. Such a minute clearance is for imposing compression state around the tool edges, where the brittle material plastically deforms under a compression state. A large clearance would generate a state of tension and result in an earlier material fracture during shear punching. Indeed, the SKD 11 sheets were irregularly fractured at separate sites from the contact zone with punch and die edges; this was observed when the clearance was 0.05 mm, which is conventionally used in the actual shearing processes.

Additionally, a punch edge was rounded with a 0.1 mm radius. This was to achieve the suppression of edge chipping, and such a dull edge induces more plastic deformation than a sharp edge. Furthermore, the edge roundness avoids the contact problem in FE analysis. The sharp edge frequently causes a singularity problem, which can adversely affect the corner contact with the specimen surface.

As mentioned above, the punching stroke was measured as the ram displacement of the tension/compression machine. For accurate evaluation of the punching stroke, we had to remove the tool deformation factors caused by the low stiffness of the assembled tools. The ram displacement is much larger than the actual punching stroke. For this correction from the ram displacement to the punching stroke, we referred to the FE-simulated punching force and stroke curves. Assuming that the linear parts of the curves were accurately simulated when the material was elastically deformed, we concluded that the difference between the ram displacement measurement and the punching stroke simulation at the same punching force was caused by tool deformation. The relationship between the punching force and this difference was the tool stiffness; further, the ram displacement was corrected to the punching stroke by subtracting the tool deformation calculated from the punching force.

2.3 *Finite Element Simulation*

The conditions of the shear punching test are schematically presented in Fig. 2; these parameters were numerically simulated by the commercial FE solver TP-Mform. Axisymmetric two-dimensional solid elements were used for this simulation. Figure 3 shows the simulation.

The mechanical behaviors of the materials were characterized based on their isotropic elasticity, von Mises plasticity, associated flow rule, and isotropic hardening as governed by the Swift law shown in the following equation:

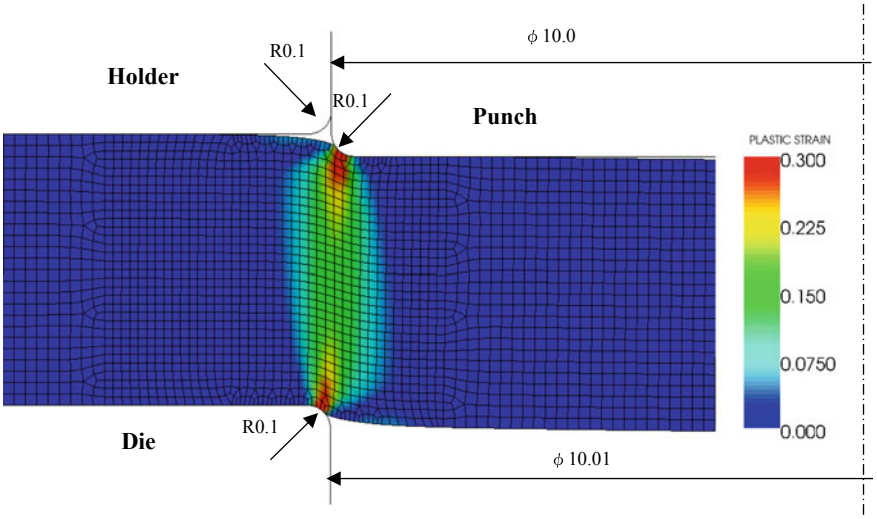

Fig. 3 Finite element simulation of shear punching test under axisymmetric two-dimensional condition. The figure exemplifies contour map of equivalent plastic strain for the shear punching of JSC590R. The punch stroke is approximately 0.1 mm. (Color figure online)

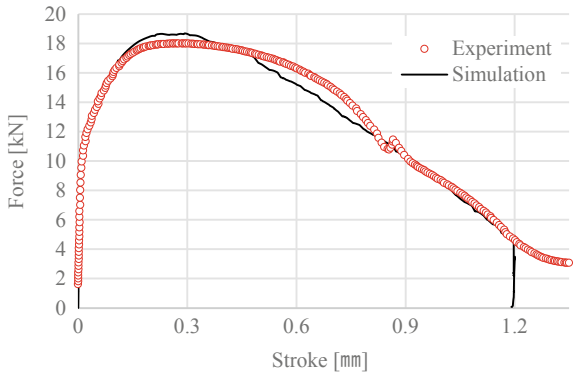

Fig. 4 Measurement and simulation of punching force–stroke curves for JSC590R. (Color figure online)

$$Y = F\left(\varepsilon_0 + \bar{\varepsilon}_p\right)^n, \tag{1}$$

where Y is yield stress, $\bar{\varepsilon}_p$ is equivalent plastic strain, and F, ε_0, n are material parameters.

The fracture was not included in this FE simulation. Fracture strain was evaluated as the equivalent plastic strain around the punch edge at the point of the material fracture in the experiments.

2.4 Fitting Scheme for the Swift Law's Parameters

The Swift law parameters F, ε_0, n for the SKD 11 steel were identified so that the punching force–stroke curve measured in the shear punching test corresponds to the numerically simulated curve.

The scheme for this identification is as follows: Firstly, the temporal values of F and n were set as F_t and n_t. The remaining ε_0 was derived from the initial yield stress, which is expressed as $F_t\varepsilon_0^{n_t}$ from Eq. (1), where the elasticity limit in the punching force–stroke curve provided the actual initial yield stress for the SKD11 steel. The FE simulation was done with the parameters F_t and n_t, and error sum of squares between measurement and simulation was evaluated. Then, the simulated punching force was scaled by r so that the error sum of squares is minimized. Because the punching force is proportional to the parameter F, the scaled punching force is in the case with $F = rF_t$. This sequence was repeated with a slight increase (or decrease) in n to find the parameter sets that minimize the error sum of squares. In this study, the initial n was 0.01 and it increased by 0.01 for each sequence.

3 Results and Discussion

3.1 Validation of FE Simulation

Figure 3 presents the measurement and simulation of the punching force–stroke curves for JSC590R with the mechanical properties shown in Table 2. The simulation agrees with the measurement up to the punching stroke of 0.15 mm.

Taking the large strain in shear punching into account, which exceeds 200% at the punching stroke of 40% of material thickness [11], the simulation is valid. The mechanical properties were measured through the tensile test. The tensile test can measure stress–strain curves in the region of uniform elongation, where uniform elongation of the JSC590R is 13%. Thus, the measurement and simulation have to be compared in the short punching stroke, where the strain is not so large. As shown in Fig. 3, the plastic strain around the punch and die edge definitely exceeded the 13% at the punching stroke of 0.1 mm.

3.2 *Flow Stress and Fracture Strain of SKD11*

The parameter identification of the Swift law for the SKD11 steel resulted in $F = 3203, n = 0.04, \varepsilon_0 = 7.68 \times 10^{-6}$. The measurement and simulation of the punching force–stroke curves are shown in Fig. 5 and the two curves are shown be in accordance, except for the load range between 10 and 18 kN. In the load range from 10 to 18 kN, mechanical slipping of the ram was observed, which probably caused the disagreement between the measurement and the FE simulation.

These parameters correspond to values of 2706 MPa for tensile strength and 2000 MPa for initial yield stress. The validity of these values has to be proven using other mechanical tests, which we will conduct as future work.

The contour map of equivalent plastic strain at the punch stroke of approximately 0.05 mm is shown in Fig. 6. The load measurement presented a sudden decrease

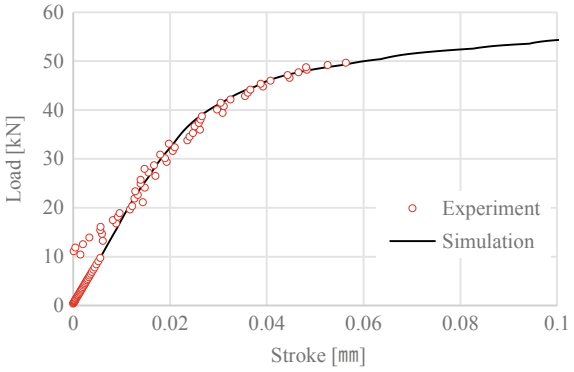

Fig. 5 Measurement and simulation of punching force–stroke curves for SKD11 steel. (Color figure online)

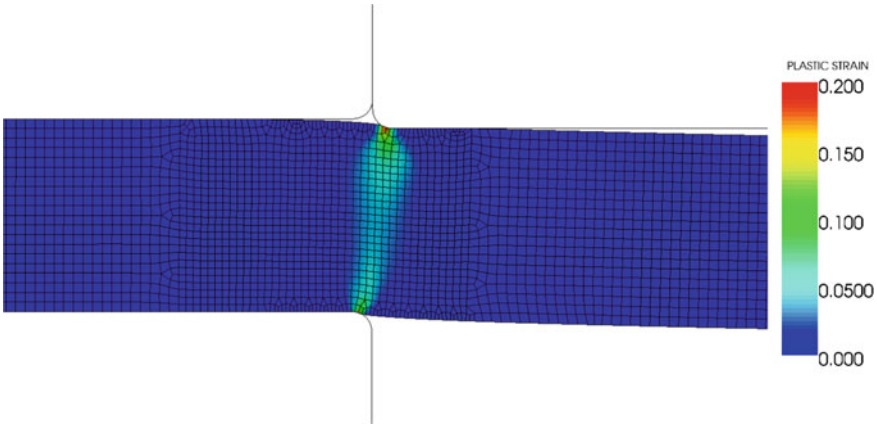

Fig. 6 Contour map of the equivalent plastic strain for SKD11 steel. (Color figure online)

at this punch stroke by material fracture. From this figure, the fracture strain was evaluated approximately 20%.

4 Summary

The study identified the stress–strain curve for the hardened JIS SKD11 steel. Shear punching test was used for this identification, wherein the Swift law's parameters were optimized; this was aimed at minimizing the error sum of squares between the measurement and the FE simulation of the punching force–stroke curves. Further, fracture strain was evaluated as the equivalent plastic strain at the punch penetration, when the material fracture had occurred. For preliminary validation of the FE simulation, the shear punching test was performed using the 590 MPa class steel(JSC590R), whose mechanical properties were measured using the tensile test. The results were as follows:

(1) The FE simulation was validated in the case of the shear punching test for JSC 590R. The simulation resulted in a good agreement with the measurement of the punching force–stroke curve.
(2) The parameters of the Swift law for the SKD11 steel were identified as $F = 3203, n = 0.04, \varepsilon_0 = 7.68 \times 10^{-6}$ in $Y = F\left(\varepsilon_0 + \overline{\varepsilon}_p\right)^n$, where Y and $\overline{\varepsilon}_p$ denote flow stress and equivalent plastic strain, respectively. These parameters produced the values of 2706 MPa and 2000 MPa for tensile strength and initial yield stress, respectively.
(3) The fracture strain was evaluated as approximately 20% for the SKD11 steel.

Deformation of Metals Under Complex Loading

R. A. Abirov

Abstract The purpose of the issue is to present the approaches of complex loading for the possible reduction of energy consumption at metal processing. When forces are applied to isotropic material, there is always an active process of complex loading at which the work of external forces is less than the one under simple loading upon reaching the same strained state. Experiments on complex loading and approaches of the mathematical theory of plasticity are used in this article. Empirical results on complex loading were mathematically explained based on the Il'yushin's theory of elastic–plastic processes.

Keywords Stress · Strain · Plasticity · Complex loading

1 Introduction

At some complex loading processes at a constant strain rate, the value of equivalent stress drops [1]. These experimental data provide a base for assuming that the effect of complex loading on the amount of work under plastic strain can be substantially lower than that at simple loading.

In processing metals by pressure like cold-drawing reduction, face broaching, extrusion forging, cold rolling, etc., it is observed that the work of external forces at various ways of complex strain is less than at simple loading. These effects were established in experimental studies. This can be clearly traced on the strain process with breakpoint. This effect can be explained on the basis of Il'yushin's theory of elastoplastic processes and the so-called "damping memory" principle or the principle of delay of vector and scalar properties of the material (confirmed in numerous experiments). On the basis of this, the following lemma is proposed, which will be useful in what follows. Here, we will specify the positions and hypotheses on which we will base:

https://doi.org/10.1007/978-3-030-75381-8_169

– we assume that the total strain consists of the sum of elastic and plastic parts, independent of each other;
– the work of forces on elastic strains is conservative;
– the principle of delay is a clearly manifested property of material.

Lemma The minimum work of external forces to achieve a given form under plastic strain of the body is achieved only with the implementation of strain processes with breakpoint.

Proof Based on the generalized Clapeyron theorem, which states that the work of external forces on the corresponding displacements is equal to the accumulated potential energy of the deformable body, we have:

$$A = \int_V \int_0^s \sigma_{ij} d\varepsilon_{ij} \mathrm{d}V = \int_V 3 \int_0^s \sigma_0 \mathrm{d}\varepsilon_0 \mathrm{d}V + \int_V \int_0^s s_{ij} de_{ij} \mathrm{d}V,$$

here s—is a magnitude of strain path, de_{ij}—are the components of strain deviation increment, σ_{ij}—are components of stresses, s_{ij}—are components of stress deviator, σ_0—is the modulus of spherical stress tensor, and $\mathrm{d}\varepsilon_0$—is the increment in mean tensile strain, V—is the volume of considered continua.

Follow Il'yushin, let us consider vector space in stress and strain representation. Relations between vector components and tensors ones in our case as:

$$\sigma_1 = \sqrt{\frac{2}{3}}\sigma_{11}, \quad \sigma_3 = \sqrt{2}\sigma_{12}, \quad \vartheta_1 = \sqrt{\frac{3}{2}}\varepsilon_{11}, \quad \vartheta_3 = \sqrt{2}\varepsilon_{12}.$$

Since the work of forces on elastic strains does not depend on the loading path, the created field of stress vector on strains prior to the onset of flow is conservative. The work of hydrostatic pressure on strains of volume compression is also conservative. This is based on the fact that material is taken as plastically incompressible.

Further, we have:

$$\int_0^s s_{ij} \mathrm{d}e_{ij} = \int_0^s \bar{\sigma} \mathrm{d}\bar{\vartheta} = \int_0^s \sigma \cos\vartheta \mathrm{d}s = \int_0^{e_s} \sigma \mathrm{d}s + \int_{e_s}^s \sigma \cos\vartheta \mathrm{d}s$$

where ϑ—is an angle of approach of stress vector and the increment of vector of strain.

Under active loading process, a minimum of the functional of work is achieved when the approach angle is $\pm\ \pi/2$. This is possible only if the stress vector σ is normal to the Frenet basis vector $\overline{p}_1$ (tangent to strain path), i.e. at path breakpoint. ⊗

Maintaining the angle of approach at that value is not possible over the whole process of strain, according to the principle of delay. This means that when loading up to the exhaustion of delay trace of vector properties of material, it is necessary to produce a bend point of strain path. Such breakpoint in strain path, generally speaking, realizes multi-link strain processes. In [2], the problem of optimal control of strain path under complex loading of metals is posed and solved. The solution to the optimization problem is obtained using dynamic programming method. Strain process of a homogeneous cylindrical sample is considered. It is shown that the Il'yushin theory of elastic–plastic processes describes the effect of reducing the work of plastic forming of metals under complex loading.

This effect finds application in the optimization of technological processes of metal working with pressure [3]**.** The disadvantage is that the problem of optimal control is not solved with a fixed right end, i.e. the given point in strain space is not reached.

In manufacturing steel hollow cylinder by the method of reverse extrusion (pressing-out), the application of zigzag strain paths leads to a significant decrease in extrusion force.

Conclusion: To attach a certain shape to material in metal working with pressure, by punching, etc., the possibility of optimal control of loading process is important. Thus, to achieve the goal, it is necessary to put as a term the optimal number of links of the path. With this term, it is possible to determine at what stage to produce a breakpoint. Here, in addition to classical physical parameters of material, one should also know its delay trace $\overline{\lambda}$.

Note: When implementing loading processes with breakpoint (stress space), a situation arises when the scalar product of the stress vector $\overline{\sigma}$ and the vector of strain increments $\overline{p}_1$ is at a minimum. But the difference in the breakpoint in strain space and in stress space is that, in addition to the change in vector properties of material, the stress "leaps" occur in the former case, which gives the minimum work precisely under the strain processes with a breakpoint.

The possibility of using the effect of reducing the external force in the development of new technologies for plastic processing of metals and controlling the strain paths of these processes is considered in [2]. Strain processes of a specified length are also studied in the paper with minimization of the energy expended. Thus, the consideration of complex loading and identification of the effects arising in this case, besides revealing the reserves of bearing capacity of materials, allows to minimize the work of external forces (to reduce energy costs) in technological processes.

For further discussion, we need to accept the following statements: the Il'yushin isotropy postulate, the delay principle, universality of the loading diagram $\sigma = \sigma(s)$.

The universality of the function ϑ for material at the same angles at breakpoint was observed experimentally. Based on this, empirical formulas (1–2) for the approximations of function ϑ were proposed. The delay trace of vector material properties is assumed as equal to $\overline{\lambda} = 5\varepsilon_s$.

$$\vartheta = \theta / \exp\left(k\left(1 + \frac{1}{\bar{\lambda}}\right)\Delta s\right), \text{ here} k = \ln 16/(1 + \bar{\lambda}) \tag{1}$$

$$\vartheta = Carcctg\left(\frac{r}{\bar{\lambda}}\Delta s\right), \text{ here } C = \frac{2\theta}{\pi}, \quad r = ctg\left(\frac{\pi}{32}\right) \tag{2}$$

Δs is a magnitude of strain path after break point, ε_s is yield strain.

2 To Optimal Control of Metal Forming Under Complex Loading

Consider the following optimal control problem: to find the minimum of functional:

$$J = \min \int_{S_{in}}^{S_{ult}} \sigma \cos\vartheta \, ds \tag{3}$$

subject to restrictions: $S_{in} \le s \le S_{ult}$, $\vartheta \le \pm\frac{\pi}{2}$.

Since, according to the lemma, we have chosen a multi-link broken line as an optimal one, the strain path can be represented as a piecewise continuous curve and the initial problem can be represented as a quadrature sum

$$J = \min \sum_{k=1}^{n} \int_{s_k}^{s_{k+1}} \sigma \cos\vartheta \, ds \tag{4}$$

with initial conditions $\gamma_{(1)} = 0$, $\beta^{(1)} = 0$ with a control function β and restrictions in the form $\vartheta_1^l = \vartheta_1^{l-1} + \Delta s^{(l)} \cos\alpha^{(l)}$, $\vartheta_2^l = \vartheta_2^{l-1} + \Delta s^{(l)} \sin\alpha^{(l)}$, $s_l = s_{l-1} + \Delta s^{(l)}$.

Functional $B_w = \inf \sum_{k=w}^{n} \int_{s_k}^{s_{k+1}} \sigma \cos\vartheta \, ds$ at k = 1, n is the Bellman function of the basic problem (3), which satisfies the recurrence relations (5)**.**

$$B_w = \inf \int_{s_w}^{s_{w+1}} \sigma \cos\vartheta \, ds + B_{w+1}. \tag{5}$$

When choosing the approach angle in the form (2), the minimum of the Bellman function is achieved at:

$$\vartheta = \left\{\left[\gamma_{(l-2)} + \beta^{(l-1)}\right]\frac{2}{\pi} arcctg\left(\frac{r}{\bar{\lambda}}\Delta s^{(l-1)}\right) + \beta^{(l)}\right\}\frac{2}{\pi} arcctg\left(\frac{r}{\bar{\lambda}}(y - s_l)\right). \tag{6}$$

The recurrence relation for the control function β, in this case, has the form:

$$\beta^{(l)} = \pm\frac{\pi^2}{4} - \left\{\beta^{(l-1)} + \gamma_{(l-2)}\right\}\frac{2}{\pi} arcctg\left(\frac{r}{=}\Delta s^{(l-1)}\right). \tag{7}$$

The general solution to problem (4) for the control function β at equal lengths Δs of path links is:

$$\beta^{(l)} = \pm\frac{\pi}{2}\left(\frac{\pi}{2} - arcctg\left(\frac{r}{=}\Delta s\right)\right). \tag{8}$$

When choosing an approximation for the approach angle in the form (1), we get:

$$\vartheta = \left\{\left[\gamma_{(l-2)} + \beta^{(l-1)}\right]/\exp(k(1+\frac{1}{=})\Delta s^{(l-1)}) + \beta^{(l)}\right\}/\exp(k(1+\frac{1}{=})(y - s_l)).$$

The recurrence relation for the control function β and the general solution to problem (3) are, respectively:

$$\beta^{(l)} = \pm\frac{\pi}{2} - \left\{\beta^{(l-1)} + \gamma_{(l-2)}\right\}/\exp(k(1+\frac{1}{=})\Delta s^{(l-1)})$$

$$\beta^{(l)} = \pm\frac{\pi}{2}\left(1 - 1/\exp(k(1+\frac{1}{=})\Delta s)\right). \tag{9}$$

As can be seen, the minimum of functional (3) is achieved for a multi-link strain path at kink angles depending on the link length of the broken line. At a link length $\Delta s = \overline{\lambda}$, the breakpoint angle is ± π/2, at a link length $\Delta s = \overline{\lambda}/2$, the breakpoint angle is β = 3π/8, provided that the loading (strain) process activity is maintained.

Introducing additional restrictions into the main problem (4) in the form of $\left(\vartheta_1^l\right) + \left(\vartheta_2^l\right) \geq \left(\vartheta_2^{l-1}\right)^2 + \left(\vartheta_1^{l-1}\right)^2$, instead of (8) and (9), we get the solutions:

$$\beta^{(l)} = (-1)^{l-1}\frac{\pi}{2}\left(1 - 1/\exp\left(k\left(1+\frac{1}{=}\right)\right)\Delta s)\right),$$

$$\beta^{(l)} = (-1)^{l-1}\frac{\pi}{2}\left(\frac{\pi}{2} - arcctg\left(\frac{r}{=}\Delta s\right)\right).$$

Under other initial conditions, it is possible to obtain similar conditions for the minimum of functional (3).

According to the isotropy postulate, the loading process image does not depend on the rotation and reflection procedures. Any deformed state in the five-dimensional vector space of strains can be achieved in the form of a plane multi-link trajectory. All plane trajectories out of their entire set are isomorphic ones.

Based on this, we make the following statements:

When a force is applied to an isotropic material, there will always be an active process of complex loading in which the work of external forces is less than under simple loading in the same deformed state.

Note: It should be noted that there is no universal function for the approach angle ϑ under spatial loading processes. This does not give us the right to state that the minimum of functional of work in the general case of the spatial process of strain is achieved precisely under plane processes of complex loading. We also note that the behaviour σ is assumed to be strengthening under complex loading (without local softening – "drops").

3 The Effect of Work Reducing Under Complex Loading in Technological Problems.

Let consider the technological problems where it is possible to apply the effect of work reducing plastic forming under complex loading. Various studies are being carried out in this field and proposed in some issues [4–6].

Consider the cold-drawing process of brass pipe through a conical matrix where dimensions are: $y = C - ax$, here: C = 113.75, a = 5.67, the angle at the top of the matrix is 100, 0.2 m ≤ x ≤ 0.25 m. The narrowing is 0.8, which meets the condition of the maximum possible narrowing of the pipe. Pipe's wall thickness is h = 0.002 m, at an external axial force $P_0 = 26948$ Pa. The friction coefficient is taken equal to f = 0.3. The pipe pressure on the walls of the matrix depends on the friction forces with the parameter k = 0.15.

The stress and strain diagram in vector space is taken in the form:

$$\bar{\sigma} = Ath(\beta\ \ni), \quad \bar{\ni} = {}^{1}\!/_{\beta} arth\left({}^{\bar{\sigma}}\!/_{A}\right), \quad A = \sigma_\infty, \quad \beta = 2G/\sigma_\infty, \quad \sigma_\infty = {}^{5}\!/_{3}\bar{\sigma}_s$$

$$\sigma_s = 117MPa, \quad E = 113796MPa, \quad \mu = 0.348.$$

We have here the equilibrium equations as:

$$(T_1 \sin\theta - Q\cos\theta) \cdot 2\pi r = F(s)$$

$$F(s) = P_0 + \int_{s_0}^{s} (q_n \cos\theta - q_1 \sin\theta) 2\pi r ds.$$

At axisymmetric deformation of shell of revolution, we have:

$$-\frac{T_1}{R_1} - \frac{T_2}{R_2} + q_n = 0, T_1 = \frac{F}{2\pi r \sin\theta}$$

here T_1, T_2—tension forces in normal cross section, θ—angel between perpendicular to shell surface and + OY axis, R_i—curvature radiuses, P_0—tensile force.

Taking in the relations: $R_1 = \infty$; $\cos\theta = \frac{1}{\sqrt{1+a^2}}$; $\sin\theta = \frac{a}{\sqrt{1+a^2}}$; $R_2 = -\frac{r}{\sin\theta}$; $F(x) = \pi q_n\left(x^2 - x_0^2\right) - \pi q_1 a\left(x^2 - x_0^2\right)$.

So, external forces are:

$$q_1 = \frac{F}{f\,\pi L(r_0 + r_n)}, q_n = -q_1 k.$$

At simple loading, we apply forces at the same time, at complex loading apply forces sequentially.

Calculate the work of forming $\int_{s_0}^{s} \overline{\sigma} d$, since precisely this part of the work gives us the opportunity to reduce the costs of the forming process. When calculating the work, the strains in equidistant layer were taken equal to the middle surface strains. To analyse the qualitative pattern, this can be taken as a first approximation. As can be seen (Fig. 1), work under complex loading is less than under simple loading.

Figure 2 shows the work process depending on the degree of loading. At the initial stage, under complex loading, work is greater. This can be explained by the very process of complex loading. First, the internal pressure was set, and then surface friction. The effect of internal pressure on work (as this is the main load) dominates compared with other loads.

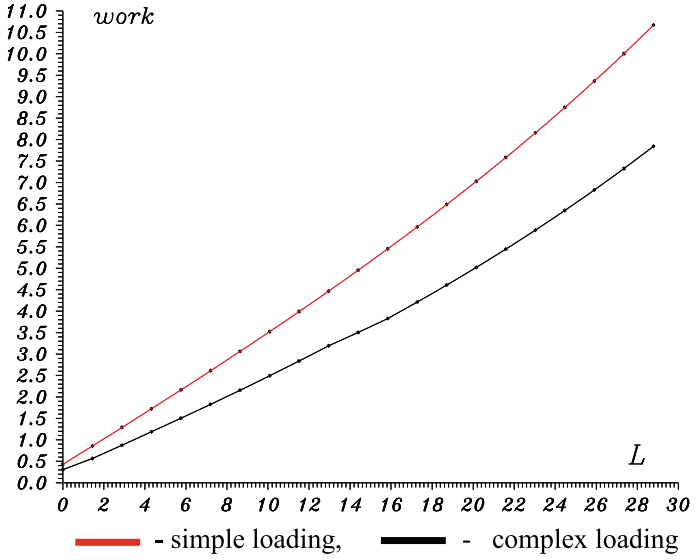

Fig. 1 Work on forming. (Color figure online)

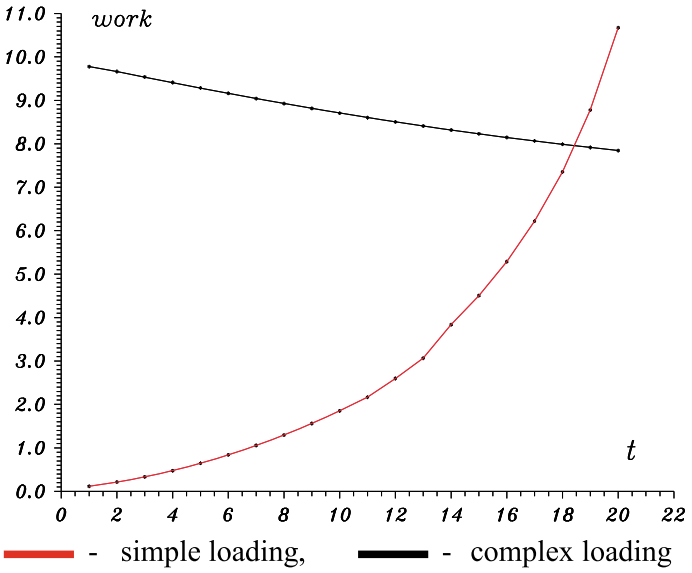

Fig. 2 Work vs loading process. (Color figure online)

4 Conclusion

The minimum of work of external forces at metal processing is achieving only at strain processes with breakpoint. This statement was used during analytical derivation of conditions for minimization of work of external forces.

On the picture, we can see the conditions for work of plastic deformation at complex loading comparing with simple loading. These data can be used in metal processing in different stages of manufacturing.

Novel Processes

Numerical Simulation of Tube Bending Supported by Hydraulic Pressure for Manufacturing Butt-Welding Fittings

Josef Domitner, Peter Auer, and Christof Sommitsch

Abstract An innovative tube bending process supported by hydraulic pressure was patented in 1995. This process was designed for producing butt-welding fittings which particularly fulfil the dimensional specifications of the ASME B16.9, MSS SP-75, and MSS SP-43 standards. Since the patent has meanwhile expired, the bending process is now available for common use. This work presents a novel finite element (FE) model build using the software package LS-DYNA, which enables determining the process window for bending defect-free butt-welding fittings. This model was exemplarily applied for investigating the bending process of a 90° stainless steel elbow based on a straight tube of nominal pipe size (NPS) 6. Comparing the calculated geometry of the elbow with the actual geometry of an industrially produced elbow revealed very good dimensional agreement. This confirms that the presented model can be utilized for determining suitable process conditions, which allow for producing defect-free components.

1 Introduction

1.1 Butt-Welding Fittings

Butt-welding fittings are important components of industrial piping systems. They join straight pipe sections, connect pipes of different sizes or shapes, change the flow direction, branch off or join the flow, integrate equipment such as measuring or regulating devices, etc. [1]. The size of fittings is classified based on the nominal pipe size (NPS). The dimensions and tolerances are defined in the ASME B16.9 standard

"*Factory-Made Wrought Buttwelding Fittings*" (NPS ½-48) [2] and in the MSS SP-75 standard practice "*High-Strength, Wrought, Butt-Welding Fittings*" (NPS 16–60) [3] for carbon steel, and in the MSS SP-43 standard practice "*Wrought and Fabricated Butt-Welding Fittings for Low Pressure, Corrosion Resistant Applications*" [4] for stainless steel.

Large quantities of pipe fittings are produced using rotary-draw bending (mainly 45° and 90° elbows) or compression bending (mainly 180° returns) [5]. These processes are fast and efficient, however, in particular bending of materials possessing marked springback tendency, e.g. high-strength stainless steels or aluminium alloys [6, 7], and bending of components possessing strong wrinkling tendency, e.g. elbows of large diameter, low wall thickness, and small bending radius [8–10], is challenging. In order to improve the dimensional accuracy of the bends, mechanical [11] or usually hydraulic [12] pressure is often applied to stabilize the inner surface of the tube during the bending process. In addition to the pressure support, axial forces can be applied in rotary-draw bending [12, 13] or double-layer support tubes can be used in ram bending [14, 15]. In push bending, deformable polyurethane rods [16, 17] or granular media [18] are used instead of hydraulic fluids for stabilizing the inner surface of the tube. Though these measures may generally improve the bendability, the active control of the material flow during the bending processes and, therefore, the influence on the final shape of the bends are limited.

1.2 Tube Bending Process

An innovative cold push bending process patented in 1995 [19] was designed with the aim to fulfil, in particular, the dimensional specifications of the fore-mentioned butt-welding fitting standards by active adjustment of the internal hydraulic pressure. Since the patent has meanwhile expired, this process is now available for common use. As the bending process is applicable to materials that are basically difficult to bend, its two major advantages are: (i) elbows or returns can be produced from the same material as the straight sections in the piping system and (ii) both outer diameter as well as shape of the tube stay constant during bending, i.e. the diameter of the final elbow or return is de facto identical with the original diameter of the straight tube. The industrial practice has shown that these two features—same material and same outer diameter—are highly favourable for butt-welding of fittings and pipes.

The tube bending process investigated in this study works as follows [19]: A massive steel die is used for guiding the tube at its outer surface and for determining the movement directions of the mandrel and of both punches. The die is divided horizontally into the lower half and the upper half, which separate after bending has completed. Before inserting the straight tube into the die, it must be well lubricated for reducing friction. The tube endings are sealed with two hemispherical caps for obtaining the closed internal volume, which is mandatory for supporting the inner surface of the tube by high hydraulic pressure. The pressure prevents buckling of the tube during the bending process. For adapting the internal pressure, a valve controls

filling and releasing the hydraulic fluid through a hole inside the working punch. In order to ensure sealing, the working punch presses one sealing cap against the front-ending of the tube, and the counterpunch presses the other sealing cap via flexible mandrel against the rear-ending of the tube. The working punch pushes the tube into the die while the counterpunch controls the position of the multi-segment mandrel. The mandrel consists of five hemispherical segments, which can tilt and rotate relative to each other.

Due to the complex interactions between the working punch force, F_W, the counterpunch force, F_C, the die closing force, F_D, and the internal hydraulic pressure, p, controlling the bending process is the key challenge. Therefore, this work presents a novel three-dimensional finite element (FE) model build using the software package LS-DYNA [20] for determining the suitable process window.

2 Numerical Model

2.1 Geometry and Mesh

The three-dimensional model of the 90° bending process is shown in Fig. 1. The model includes the tube of ND 6 (Ø 168.3 mm × 11 mm × 520 mm); both tube endings are tapered with 15°. The working punch is only able to move axially in y-direction and the counterpunch is only able to move axially in x-direction, but the five segments enable the mandrel to follow the 90° bend of the die. The die and the punches are modelled as rigid and meshed with triangular shell (2D) elements. Elastic deformation of the sealing caps and of the mandrel segments, as well as elastoplastic deformation of the tube are considered. The mandrel segments and the caps are meshed with tetrahedral solid (3D) elements. The tube is meshed with five layers of

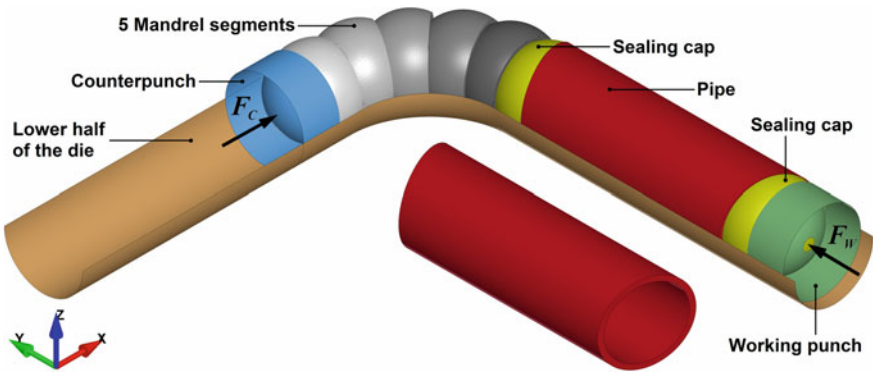

Fig. 1 Initial tube geometry and model of the bending process (for visualization reasons, the upper half of the die is hidden). (Color figure online)

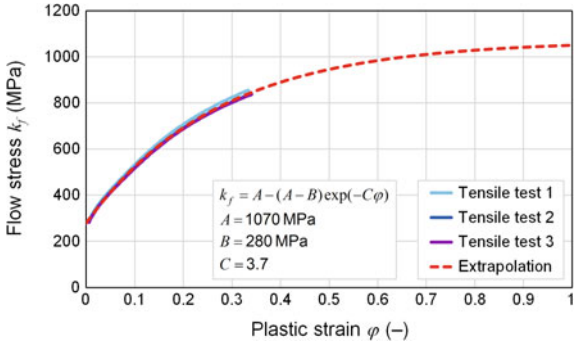

Fig. 2 Extrapolated flow curve of steel TP316/316L (the curves of tensile tests 1, 2, and 3 overlap). (Color figure online)

hexahedral solid (3D) elements arranged along the wall thickness direction. In total, the model consists of approximately 127,000 shell elements and of approximately 562,000 solid elements.

2.2 Material Properties

The 90° elbow was produced using a straight tube of stainless steel TP316/316L. The elastoplastic properties of this steel were determined using a Zwick/Roell Z100 uniaxial testing machine, which was combined with a GOM ARAMIS camera system for optical strain measurement. The testing speed was 5 mm/min. Three cylindrical tensile samples (type A 8 × 40 according to DIN 50,125) were extracted from different sections of the straight tube. Based on the results of the tensile tests, the flow curve shown in Fig. 2 was extrapolated using the Voce model [21]. For the elastic components, the Young's modulus was 207 GPa, the Poisson's number was 0.28, and the density was 7,850 kg/m^3.

2.3 Process Conditions

The main conditions of the investigated bending process are summarized in Table 1. In order to reduce the required calculation time, the actual velocity of the working punch, v_W, was scaled up by the factor of 100 in the present model. This scaling method is feasible, because the kinetic energy is significantly smaller than the internal energy of the system. Both, kinetic and internal energy of the modelled system, were directly calculated using the LS-DYNA software. Note that the force applied by the counterpunch, F_C, must be sufficient to ensure sealing at both endings of the tube when applying the internal hydraulic pressure, p. Insufficient counterpunch force would cause leakage between the sealing caps and the tube. Graphite is used for lubricating the tube surface, which is in contact with the die during the bending

Table 1 Process conditions

Velocity of the working punch, v_W (unscaled)	25 mm/s
Force at the counterpunch, F_C	1.55 MN
Internal hydraulic pressure, p	800 bar
Total time of the process, t_t (unscaled)	20 s
Coefficient of friction between die and components, μ_1	0.08
Coefficient of friction between tube endings and sealing caps, μ_2	0.20

process. To consider the effect of lubrication in the model, a comparatively low and uniform coefficient of friction, μ_1, was defined at the contact faces between the die and the components contacting the die. Since the tube is bent in the as-cut condition with rough faces at both endings and in order to model the interlocking effect of the sealing cap edges, the coefficient of friction, at the tube endings μ_2, was comparatively high. In addition, a rigid plane was introduced at each of these two contact faces for preventing local distortion of the mesh and, therefore, for improving the numerical stability of the model.

The total time of the bending process, t_t, was 20 s. The time increment predefined to run the explicit LS-DYNA solver was 0.275×10^{-6} s. In order to avoid the actual time increment to decrease below this value, automated global mass scaling was enabled for all components of the model.

3 Results and Discussion

3.1 Design of the Process

Figure 3 illustrates the geometry of the elbow calculated using the numerical model. Since neither buckling nor severe local thinning occurred, the bending process can obviously be considered as stable under the conditions listed in Table 1.

The numerical model provides important information, which is mandatory for designing the basic equipment of the bending process. In this context, the minimum die closing force, F_D, which acts against the internal pressure and which is perpendicular to the partition plane of the die, is of central interest. F_D is the minimum force required to keep the die closed during the process, i.e. to prevent both halves of the die to separate from each other. As shown in Fig. 4, F_D varies with process time t. From the practical point of view, the closing force required for producing the particular elbow geometry should be about 10 MN, which includes a safety margin of 15–20%. Figure 4 also illustrates that for bending the tube, the force applied by the working punch, F_W, should be about 5 MN. Note that the force of the counterpunch, F_C, was almost constant over time in the industrial bending process and, therefore, the force was also predefined as constant in the numerical model.

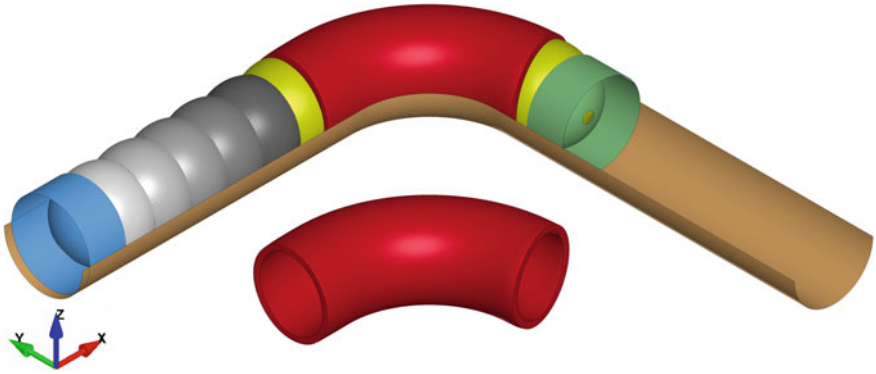

Fig. 3 Elbow geometry calculated with the numerical model (the upper die half was opened after completing the bending process). (Color figure online)

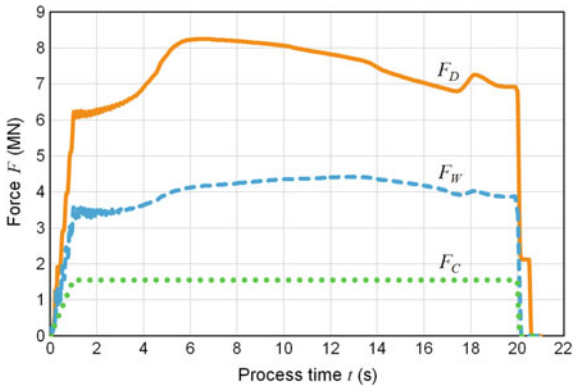

Fig. 4 Minimum die closing force, F_D, working punch force, F_W, and counterpunch force, F_C. (Color figure online)

As shown in Fig. 3, a defect-free elbow is obtained when using the counterpunch force of $F_C = 1.55$ MN and the internal pressure of $p = 800$ bar. Figure 5 illustrates typical problems that may occur in the bending process, if either F_C or p, or even both, are chosen inappropriately. As example, Fig. 5a shows the leakage between the sealing cap and the elbow, whereas Fig. 5b shows buckling at the inner bending radius of the elbow. Leakage would be initiated at $t = 16.8$ s, if F_C decreases just slightly from 1.55 MN to 1.40 MN, but p remains 800 bar. Buckling would start at $t = 13.4$ s, if F_C remains 1.55 MN, but no internal pressure is applied.

3.2 Geometry of the Elbow

As shown in Fig. 6, comparatively high effective plastic strain of about 0.5 resulting in unfavourable plastic deformation was observed only at the ending of the elbow

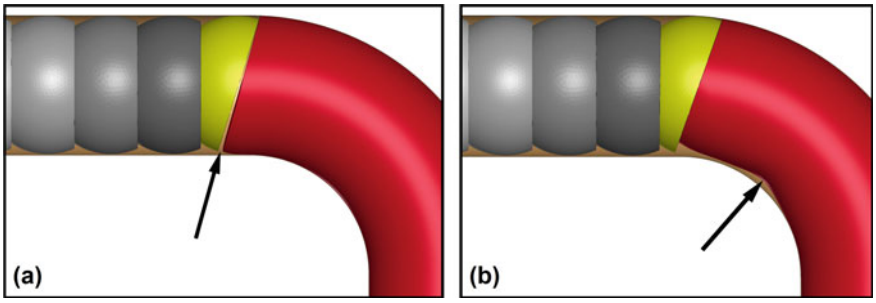

Fig. 5 Typical problems due to inappropriate process conditions: **a** leakage between sealing cap and elbow and **b** buckling of the elbow. (Color figure online)

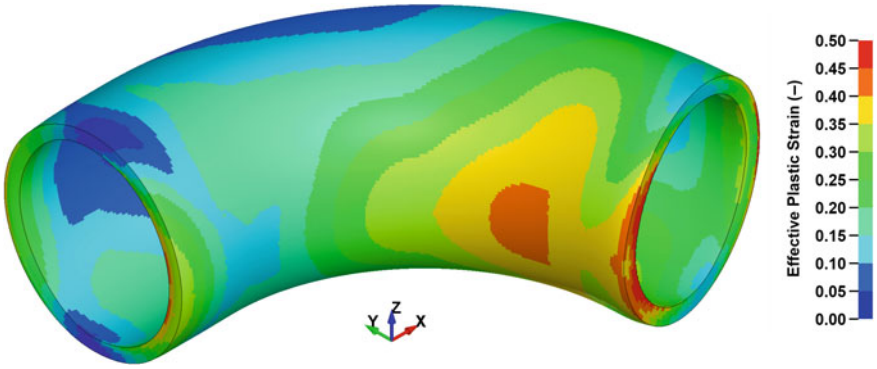

Fig. 6 Effective plastic strain at the elbow. (Color figure online)

where the working punch had pushed the sealing cap against the tube. However, from the practical point of view, this local deformation is negligible, because after bending both endings are usually machined for obtaining the final geometry of the 90° elbow.

The results illustrated in Figs. 3 and 6 demonstrate that the presented numerical model can be applied successfully for predicting the outcome of the bending process. In order to validate the prediction quality of the model, the calculated geometry was compared with the geometry of the elbow shown in Fig. 7, which was produced in the industrial bending process. The full 3D geometry of this elbow was captured using the GOM ATOS III Triple Scan measuring system. Measured and calculated elbow geometries were then superimposed using the GOM Inspect 2019 [22] software for quantifying dimensional differences. Note that the geometries and nominal process parameters of both, industrial bending process and numerical model, were de facto identical. Due to lack of monitoring in the industrial process, however, the time-dependent variation of the parameters is actually unknown.

Fig. 7 Elbow produced in the industrial bending process and machined to obtain final dimensions (the circular black/white reference markers on the surface are required to capture the 3D geometry; the measuring tape is scaled in cm). (Color figure online)

As illustrated in Fig. 8, good dimensional agreement is generally achieved between the calculated geometry and the actual geometry of the industrially produced elbow. The colour scale represents the dimensional difference between both geometries. It is obvious that the biggest difference of more than −1 mm occurs near the front-ending of the elbow, as marked with the dark blue area. This area is located where the most serious die wear occurred in the industrial bending process which, however, is not considered in the numerical process model. Note that the circumferential dark blue

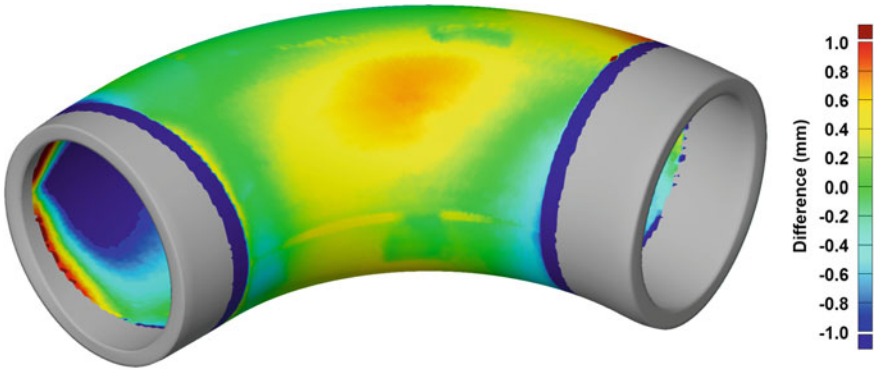

Fig. 8 Comparison between calculated geometry of the elbow and geometry of the industrially produced elbow. (Color figure online)

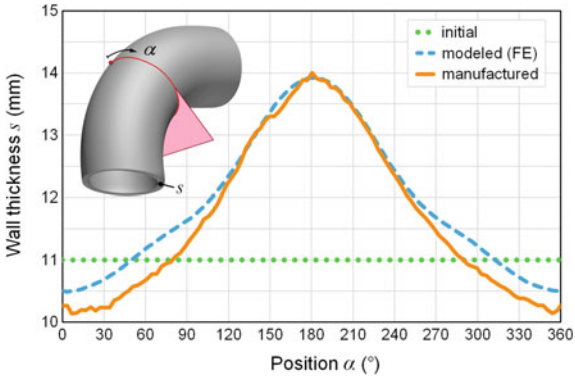

Fig. 9 Variation of the local wall thickness, s, of the elbow. (Color figure online)

bands shown in Fig. 8 origin from the chamfers, which are machined after removing the grey endings of the elbow. These chamfers are also shown in Fig. 7.

Figure 9 illustrates the variation of the wall thickness along the circumference of both the modelled elbow and the manufactured elbow. The thickness of the manufactured elbow was calculated from the 3D data captured at the central cross-section. It is obvious that the wall thicknesses of both elbows was de facto identical at the inner bending radius ($\alpha = 180°$), whereas the maximum difference of approximately 0.4–0.5 mm was observed close to the outer bending radius ($\alpha = 0°/360°$). This difference could be due to local variations of the friction conditions during the bending process, which were not included in the present model. However, from the practical point of view, this comparatively small difference is negligible, since the initial wall thickness of the straight pipe was 11 mm.

4 Summary and Conclusions

In this work, a novel three-dimensional finite element model of a tube bending process supported by hydraulic pressure for manufacturing butt-welding fittings according to ASME B16.9, MSS SP-75, and MSS SP-43 standards was presented. The model build in LS-DYNA was exemplarily applied for investigating the bending of a 90° stainless steel elbow from a straight tube of NPS 6. The results of the simulations were compared with an elbow produced in the industrial bending process. Based on the results, the following conclusions are drawn:

- The numerical model can be used for predicting the required pushing force of the working punch and the closing force of the die. In order to manufacture the elbow geometry presented exemplarily, the force of the working punch is about 5 MN and the closing force of the die is about 10 MN.
- The relationship between the force of the counterpunch and the internal pressure was identified as critical process parameter influencing the stability of the

bending process and, therefore, influencing the geometry of the elbow. In order to avoid leakage during the bending process, the counterpunch force must match the hydraulic pressure acting on the internal surface of the pipe.

- Comparing the calculated geometry with the actual geometry of the elbow revealed very good dimensional agreement. Therefore, (i) the experimentally validated model enables predicting the geometry of the elbow for a given set of process conditions or (ii) the particular process window for bending defect-free butt-welding fittings in accordance with the specifications of the standards can be determined for a given nominal pipe size.

Fluidity of Wood Composite Combined with Natural Binder on Injection Molding

Shohei Kajikawa, Masaya Horikoshi, Takashi Kuboki, Soichi Tanaka, Kenji Umemura, and Kozo Kanayama

Abstract This paper describes injection molding of a new wood composite with a natural binder composed of sucrose and citric acid. The wood composite was plasticized to be deformable when heated, making molding possible. In this study, the effects of the natural binder content and mixture ratio of the sucrose and the citric acid on the fluidity of the wood composite on injection molding were investigated. At first, the appropriate molding temperature for plasticizing the wood composite was determined to be 180 °C by thermal analysis. In the injection molding test, products were obtained successfully when the fluidity of the wood composite was high. The fluidity was improved by increasing the binder content, and the optimum mixture ratio of the sucrose and the citric acid was 75:25.

1 Introduction

Research and development for processing technology for naturally derived materials are needed for preventing mass disposal of petroleum-derived plastics. In particular, wood is an appropriate alternative to plastics because it has high strength and is sustainable and biodegradable. However, mass production techniques have not been established for processing wood into various shapes, because the deformability of wood is low. Therefore, wood products are manufactured mainly by cutting, which makes their cost higher than that of plastics.

Wood material development studies have been conducted. For example, wood-plastic composites (WPC), composed of wood powder and plastics, are used for automotive components, architectural materials, and household electronics [1]. The production of WPC is easier than that of wood, because mass production techniques, which include press molding, extrusion, and injection molding, are available for the production of WPC. However, petroleum-derived plastics, which act as the binder, must be combined with wood, and the binder content is generally at least 40–50% to maintain good moldability and product properties [2–4]. Therefore, problems related to the disposal of petroleum-derived plastics remain.

The use of a natural binder for wood is proposed. In a previous study, sucrose was used as a natural binder, which allowed fabrication of the product by injection molding of wood powder with the sucrose [5]. In this method, the binder plasticizes upon heating at first. When the wood powder is pressed with the binder, the wood powder flows with the binder during the deformation of the binder. The fluidity of the binder is important, and the moldability of the wood composite is improved by using a highly flowable binder.

In this study, the use of a mixture of sucrose and citric acid, called SC (sucrose:citric acid) binder here, is proposed. The sucrose is hydrolyzed by citric acid to low-molecular-weight sugars [6]. Therefore, the fluidity of SC binder should be higher than that of sucrose alone. To verify the effectiveness of the SC binder, the fluidity of the wood composite with SC binder in injection molding was investigated, and appropriate molding conditions, binder content B and binder mixture ratio of the sucrose and the citric acid S:C, were clarified. At first, thermal analysis of sucrose, citric acid, and SC binder was carried out to understand the thermal properties of the SC binder and determine the appropriate molding temperature. After that, an injection molding test of the wood composite with SC binder was conducted, and the effects of the molding conditions on fluidity were investigated.

2 Material and Methods

2.1 Material Preparation

Japanese cedar powder, after passing through a 500 μm sieve, was used as a wood filler, and sucrose and citric acid (anhydrous), produced by Nacalai Tesque, Inc. (Kyoto, Japan), were used as the materials for the SC binder. The wood powder, sucrose, and citric acid were dehydrated in a drying oven at 80 °C for 24 h to equalize the moisture conditions of the materials before mixing the wood powder with the binder.

Figure 1 shows a schematic diagram of the material preparation for the experiment. First, the sucrose powder was mixed with the citric acid powder at a prescribed *S*:*C* mixture ratio (Fig. 1i), and the mixture was dissolved in distilled water (Fig. 1ii). For preparing a sample for thermal analysis, the aqueous solution of the binder was dehydrated in a drying oven at 80 °C for 48 h, and the dried binder, composed of the sucrose and citric acid, was the sample used for thermal analysis. For preparing a sample for the molding test, the wood powder was added to the aqueous solution of the binder and mixed (Fig. 1iii). The aqueous solution with the wood powder was dehydrated in a drying oven, and the dried composite powder was used in the molding test. The moisture content of the dried composite powder was less than 3%. The binder content *B* in the composite powder was fixed at 20, 30, 40, and 50 wt%

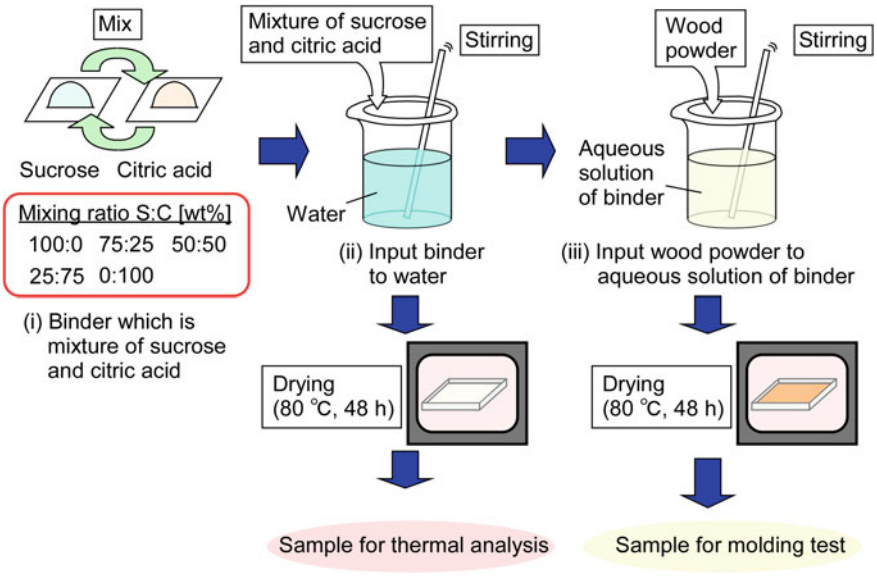

Fig. 1 Schematic diagram of material preparation. (Color figure online)

by controlling the concentration of the aqueous binder solution during the process of Fig. 1ii.

2.2 Differential Thermal Analysis and Thermogravimetry

Differential thermal analysis (DTA) and thermogravimetry (TG) analysis of the binder of various *S*:*C* mixture ratios were carried out to determine the appropriate molding temperature by clarifying the thermal properties of the binder. A differential thermogravimetric analyzer (TG8120), produced by Rigaku Corporation, was used for DTA and TG. The binder was placed in an aluminum pan, and aluminum oxide was used as a reference. For the analysis, the temperature was increased at a constant rate of 10 °C/min with purging nitrogen gas.

2.3 Injection Molding Test

Figure 2 and Table 1 show a schematic diagram and conditions for the injection molding test, respectively. Various composite powders with different binder content *B* and mixture ratios *S*:*C* were used in this test. The equipment included the container, nozzle, and cavity, and the container and the nozzle had axial symmetry. The composite powder flowed from the container to the cavity via the nozzle in

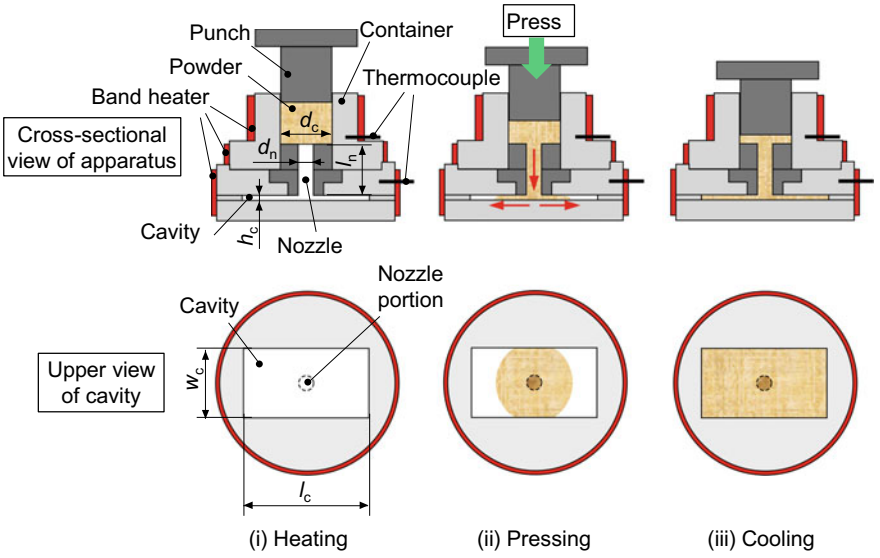

Fig. 2 Schematic diagram of injection molding test. (Color figure online)

Table 1 Molding Conditions

Container inner diameter d_c [mm]	30
Nozzle diameter d_n [mm]	10
Nozzle length l_n [mm]	25

Binder content B [wt%]	20, 30, 40, 50

the molding. The band heaters heated the equipment from the outer periphery for preventing temperature variation in the equipment. The temperatures at two positions on the outer surface were measured by two thermocouples as shown in Fig. 2i, and these temperatures were kept constant by controlling the power of the band heaters during the experiment. The temperature inside the equipment was the same as that of the outer surface before inputting the powder. The target temperature T_m was set to 180 °C based on the thermal analysis results. First, the composite powder was added to the heated container and heated in the container for 5 min (heating time, t_h) as shown in Fig. 2i. After heating, the composite powder was pressed at a constant velocity of 0.1 mm/s (press velocity, v_p) in the container, and then the composite flowed into the cavity via the nozzle (Fig. 2ii). When the punch surface pressure P reached 200 MPa (pressure limit, P_{lim}), the punch movement was stopped. The equipment was cooled to 80 °C (Fig. 2iii), and the molded product was removed from the cavity. If the composite completely filled the cavity, a plate with dimensions of 90 × 50 × 4 mm was obtained. Fluidity was evaluated by observing the appearance of the plate and the punch surface pressure P variation during the molding.

3 Results and Discussion

3.1 Thermal Reaction of Binder During Heating-Up

Figure 3 shows the thermal analysis results. The DTA results (Fig. 3a) show two endothermic peaks for each S:C mixture ratio. For sucrose (S:C = 100:0) and citric acid (S:C = 0:100), the first endothermic peak indicates melting, because the melting temperatures of sucrose and citric acid are 185–192 °C and 153 °C, respectively [7].

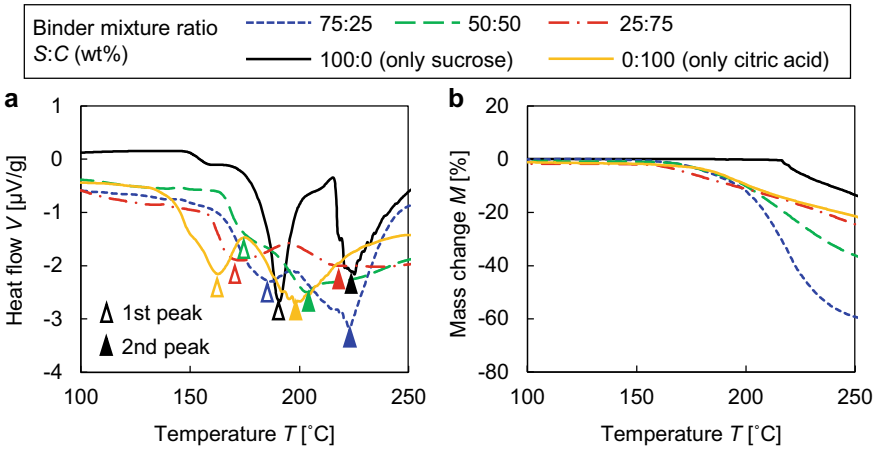

Fig. 3 Thermal analysis results: **a** Differential thermal analysis, **b** Thermogravimetry. (Color figure online)

The first peak of the SC binder for each *S*:*C* (75:25, 50:50, and 25:75) also was to be considered due to melting. The first peak of the SC binder occurred between that of citric acid and sucrose, and the first peak temperature increased with sucrose amount in the SC binder ratio. Results of TG (Fig. 3b) indicated that mass decreased with an increase in temperature *T*. The mass reduction occurred because some components in the binder volatilized due to thermal decomposition. In particular, the mass reduction rate of *S*:*C* = 75:25 increased dramatically above 200 C compared with that of other *S*:*C*, and the mass reduction increased with sucrose ratio in the SC binder when *T* reached 250 °C. Sucrose is hydrolyzed to low-molecular-weight components with acid at high temperatures [6]. Therefore, the large mass reduction was thought to occur due to thermal decomposition of the low-molecular-weight sugars, glucose and fructose.

Thus, the appropriate heating temperature for injection molding, T_m, should be near or above the melting temperature of the binder to provide good fluidity of the composite powder. However, large gas generation from the binder adversely affects molding, which can cause gas blowout from the mold. In addition, high temperatures, such as those over 200 °C, could decrease the strength of the molded product due to the thermal decomposition of the wood component [8]. Therefore, 180 °C was applied as the molding temperature T_m in this study.

3.2 Relation Between Moldability and Fluidity

Figure 4 shows the typical appearance of the molded plates, and Table 2 shows the effect of binder content *B* and mixture ratio *S*:*C* on the moldability of the plate. The

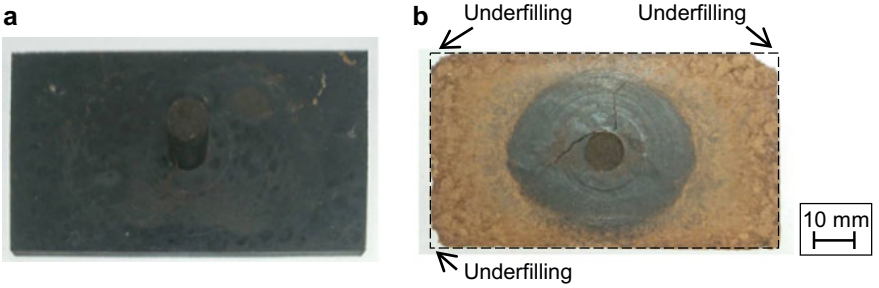

Fig. 4 Typical appearance of plates (binder mixture ratio S:C = 50:50): **a** successfully molded plate (binder content B = 50 wt%), **b** plate molded with defects (binder content B = 30 wt%). (Color figure online)

Table 2 Effect of binder content and mixture ratio on moldability

Mixture ratio S:C [wt%]	Binder content B (wt%)			
	20	30	40	50
75:25	D	D	S	S
50:50	F	D	S	S
25:75	F	F	S	S

S: Success (completely filled)
D: With defects (filled except edge portion)
F: Failure (not molded)

moldability was evaluated by a degree of the composite material filling in the cavity. When B was 40 and 50 wt%, the composite was completely filled in the cavity, and plates with a uniform dark brown color (Fig. 4a) were obtained at all S:C values; this state is defined as "success" in Table 2. However, an underfilling molding defect occurred when B was decreased to 30 wt%. For S:C = 75:25 and 50:50, plates were obtained, but the composite was not filled at the plate edge as shown in Fig. 4(b); this state is defined as "with defects" in Table 2. For S:C = 25:75, plates were not obtained because the composite powder did not flow into the cavity upon pressing the composite powder at 200 MPa, or the molded plate was too brittle for removal from the cavity; this state is defined as "failure" in Table 2. When B was decreased to 20 wt%, S:C for obtaining the plate was only 75:25. To summarize, moldability improved with an increase in B and the sucrose ratio of the SC binder; appropriate B and S:C were 40–50 wt% and 75:25, respectively, in this experiment.

Figure 5 shows the punch surface pressure P-stroke S curve during injection molding. In these graphs, the P–S curve had two bending points for each condition. These bending points generally appear when the material is extruded from a nozzle, or the flow direction changes during wood powder molding [9]. Therefore, the composite powder flow behavior was estimated from the P–S curve, as shown in Fig. 5c. Before the first small bending point, the composite powder was

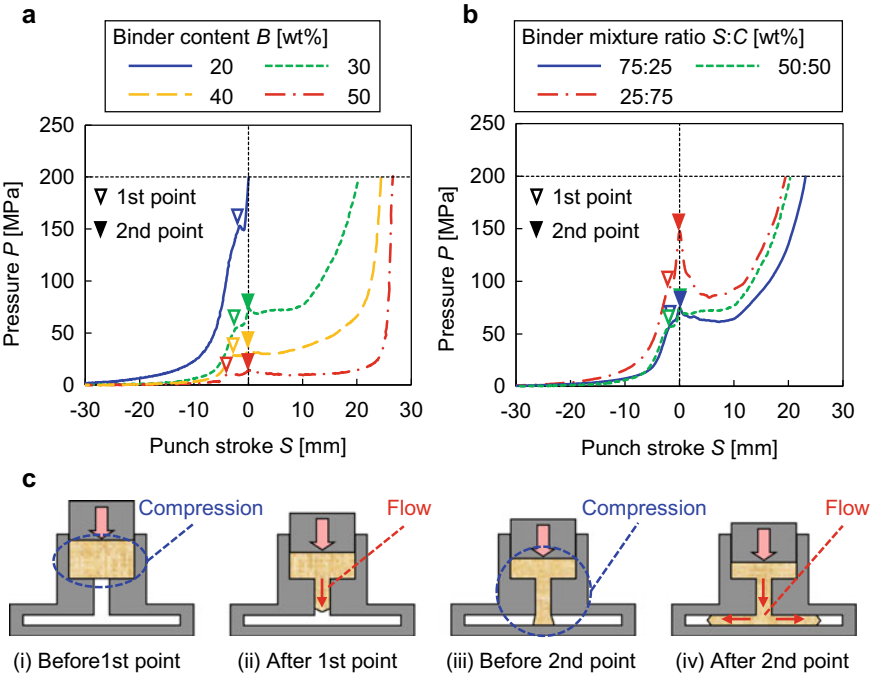

Fig. 5 Punch surface pressure variations during injection molding: **a** Effect of binder content B (binder mixture ratio S:C = 50:50), **b** Effect of binder mixture ratio S:C (binder content B = 30 wt%), **c** Schematic of composite powder flow. (Color figure online)

compressed in the container without flow (Fig. 5c(i)). At the first small bending point, the composite powder started to flow into the nozzle from the container, and the increase in P stopped (Fig. 5c(ii)). When the composite powder reached the bottom of the cavity, P increased again (Fig. 5c(iii)). The composite powder started to flow in a direction perpendicular to the pressing direction at the second bending point (Fig. 5c(iv)). In Fig. 5a, b, P variations are summarized by punch stroke s from the second bending point to consider the fluidity during composite powder flow into the cavity.

Figure 5a shows the effect of the binder content B on the P–S curve. A large binder content B decreased the punch surface pressure P. For B = 20 wt%, P reached the pressure limit of 200 MPa before the second bending point. Therefore, the composite powder did not flow into the cavity. Except for B = 20 wt%, the composite powder flowed into the cavity, and P decreased with an increase in B. Thus, the fluidity of the composite powder improved by increasing B. The maximum punch stroke S became small when P was large, indicating that the composite powder did not completely fill the cavity, as shown in Fig. 4b, due to low fluidity of the powder. Therefore, the moldability, shown in Table 2, improved by increasing B.

Figure 5b shows the effect of the binder mixture ratio *S*:*C* on the *P*–*S* curve. The punch surface pressure *P* decreased with an increase in the sucrose ratio of SC binder, i.e., the fluidity of the composite powder improved by increasing the sucrose ratio of the SC binder. Many low-molecular-weight components, apparently, were generated by hydrolysis of the sucrose by acid in the SC binder with a high sucrose ratio. Many low-molecular-weight components could have had a positive effect on the fluidity of the composite powder. Therefore, the moldability, shown in Table 2, improved by increasing the sucrose ratio in the SC binder.

Based on the above results, the fluidity of the composite powder was correlated with moldability. The fluidity could be activated by low-molecular-weight components generated from the sucrose in the SC binder. The binder content *B*, or the sucrose ratio in the SC binder, should be increased by increasing the low-molecular-weight components. However, too large a value of *B* could have a negative effect on the strength of the molded product, based on a previous study of sugarcane bagasse particleboard that was bonded with sucrose and citric acid [10]. Therefore, the optimum *S*:*C* was 75:25, and *B* should be controlled depending on the cavity shape and size.

4 Conclusions

The use of a natural binder, composed of sucrose and citric acid, was proposed for fabricating a naturally derived wood composite, and the fluidity of the wood composite with the natural binder on injection molding was examined. At first, differential thermal analysis and thermogravimetry of the binder were carried out to clarify the thermal properties of the binder. Endothermic reactions, which indicate melting, appeared between the melting temperature of sucrose and the citric acid. In contrast, some components of the binder volatilized at temperatures over 200 °C due to thermal decomposition, and this volatilization could have negative effects on the molding process. Therefore, molding should be conducted at a temperature between melting and volatilization. In the injection molding test of the composite powder, wood composite plates were successfully molded under appropriate molding conditions of binder content *B* and binder mixture ratio of sucrose and citric acid *S*:*C*. Moldability was improved with fluidity of the composite powder by increasing the binder content *B* and the sucrose ratio in the binder. However, when the fluidity of the composite powder was low, molding defects, such as cracks and chipped edges, occurred because the composite powder could not reach the cavity end. In this experiment, the appropriate binder mixture ratio *S*:*C* was 75:25 for successfully fabricating products.

Accurate Mapping of Thermal Camera Measurements on Planar Deformations

Celalettin Karadogan and Mathias Liewald

Abstract Synchronous measurement of temperature distribution with infrared cameras has been increasingly used in the thermomechanical analysis of sheet material behavior. Measured temperatures are used, however, only qualitatively due to the absence of well-developed coordinate mapping methods applicable to thermographic measurements. The study introduces a primitive, easy to use, yet effective approach for accurate coordinate mapping from real to image coordinates, and inverse, applicable to even highly oblique thermographic and photographic measurements of planar deformations. The method is not limited to any camera model and precisely counteracts inhomogeneous image distortion. It can be used as a standalone optical measurement approach, but at the same time, it allows flawless correlation with available digital image correlation systems by enabling accurate mapping between thermographic and photographic measurements of planar deformation in real and image coordinates.

Keywords Temperature · Sheet metal · Full-field · Optical

1 Introduction

Thermomechanical full-field measurements have a growing and promising potential in thermomechanical analysis of material behavior [1–3]. Deformation measurement by digital image correlation (DIC) is well developed in mechanical testing [4], whereas the accurate integration of infrared thermography (IRT) is still under development [5, 6]. A major necessity addressed in these studies is the mapping of measured temperature fields, i.e. temperature images, in real space defined on the specimen surface. There are two requirements for such a mapping: a mapping function and a calibration plate for the parameter fitting. The features on the calibration plate must be visible to the infrared camera. Some researchers have approached this issue by using geometric shapes [6], infrared visible led-lighted plates [7], paintings

[8], or test fields made of reflective patterns [9]. The control points defined on these calibration plates are then used to determine the parameters of camera models. Due to difficulties in the application, some researchers have ignored the camera models and performed mapping by uniform scaling, relying on the closer and perpendicular positioning of the infrared camera [3, 4]. Simple and invertible polynomials were also used for mapping between IRT and DIC images [6]. Decoupling linear exterior (affine transformation) and interior (combination of focal length factor and pixel ratio) mappings and combining these with a polynomial distortion function considered as a classical camera model parameters of which are usually computed by optimizing the linear least-squares of the error function [10, 11].

The use of a 45°-positioned dichroic mirror [8, 12] allowed the splitting of infrared and visual radiations, which virtually positions both measurement systems to the same location in space. This advantage, along with the introduced difficulties, cannot eliminate the necessity of an accurate coordinate mapping due to the difference in camera and lens structures and resolutions.

The "infrared image correlation" was alternatively proposed [13], where only the infrared image measurements of a speckle pattern clearly distinguished due to the emissivity difference is also used for image correlation and displacement measurement. Temperature measurement is done on a single pixel value. This is, however, not possible for DIC, since the displacement tracking of a single material point requires a bunch of pixels around this point. Hence, the accuracy of the displacement measurement is drastically reduced especially when done by an infrared camera, which usually has low resolution compared with digital cameras.

To gain the state-of-the art accuracy also for the IRT camera, available DIC camera models can also be used as mapping functions for IRT [4, 7]. Image distortion can be corrected by using a calibration grid and the parameterized Bezier patches fitting on the distorted image to compute the new corrected pixel coordinates from the original pixels [14]. Higher order radial lens-distortion functions are proposed to counteract the local image distortion being variably dependent on physical depth [15]. These approaches, however, do not offer a complete solution for real coordinate mapping. It is not always possible or correct to perform DIC and IRT measurements at the opposing faces of the specimen. Therefore, the oblique positioning of cameras pointing at the same side becomes inevitable and the use of higher order lens-distortion models is necessary. In such applications, the correct determination of the temperatures over a speckle painting with varying emissivity has already been studied [8].

Referring to Zhang [16] and covering the recent advancements, MathWorks has recently introduced a comprehensive single-camera calibration application in MATLAB. As explained in [17], this can be used "*to estimate the camera parameters which can be used for removing the effects of lens distortion from an image, measuring planar objects, or reconstructing 3D scenes from multiple cameras.*" However, the number of calibration snapshots and the number of points on the calibration plates increase drastically with complicated camera models. A single-image linear calibration method is introduced recently by using a calibration gadget having two perpendicular faces with checkerboard pattern [18]. These attempts concentrate on finding the best-fitting model parameters of camera models.

The extraction accuracy of the control points from the calibration targets is also influential in the overall accuracy of the measurement. It is reported that the checkerboard pattern, for which the intersection of edges are used as control points, may yield inaccurate results due to blurred edges and low-resolution images [10]. On the other hand, control points corresponding to circular patterns are computed as the center of the approximated ellipse, which yields better accuracy [10].

Authors readdress the problem of constructing an experimental setup with separate IRT and DIC systems positioned at either common or opposing faces of the specimen. Accurate mapping of in-plane measurements even for oblique positioning of cameras is intended. This paper develops and demonstrates the successful application of a nonlinear finite-element interpolation-based mapping function, performed on a single snapshot of the calibration object. Hence, the method is independent of any kind of camera models and applicable to any kind of cameras for either thermographic or digital measurements of planar deformations. The method is proven to bring a better accuracy even for the extremely oblique views of cameras making it possible to measure the thermographic and digital images from the same face of the specimen. The procedural application of the proposed method only to thermographic measurements where the digital deformation measurements are done by the available system is also demonstrated. An easy to manufacture calibration plate with accurately drilled holes and a speckle painting is clearly visible for IRT and DIC systems. Beyond constructing a well-defined common coordinate system attached to the specimen surface, such a holed pattern in N-by-N grid layout initiated the idea of using finite element shape functions to define a mapping from real coordinates to image coordinates for the IRT measurements. This novel mapping approach maps real coordinates directly to image coordinates and provides accurate mapping with more parameters despite its theoretical simplicity and practicality. The necessary inverse mapping from image coordinates to real coordinates is performed by a primitive approach by computing all at once, in a relatively short time, the corresponding real coordinates for all the pixels in the relevant measurement area right after the calibration snapshot. This discrete mapping data still allow sub-pixel calculations if desired.

The paper presents the experimental setup consisting of a calibration plate, calibration snapshot, and the mapping approach. The coordination of many simultaneous IRT and DIC measurements for precisely overlapping measurements is also explained. The methodology is then applied to a photographic and thermographic measurement to demonstrate functionality and accuracy.

2 Experimental Setup

This study focuses on experimental setups consisting of a mechanical testing device, optical deformation measurement camera, and a thermographic infrared camera observing either the same or the opposing faces for planar deformations of a specimen. Figure 1 shows two possible configurations where the infrared camera is positioned either at the same side or at the opposing side of the specimen with respect to

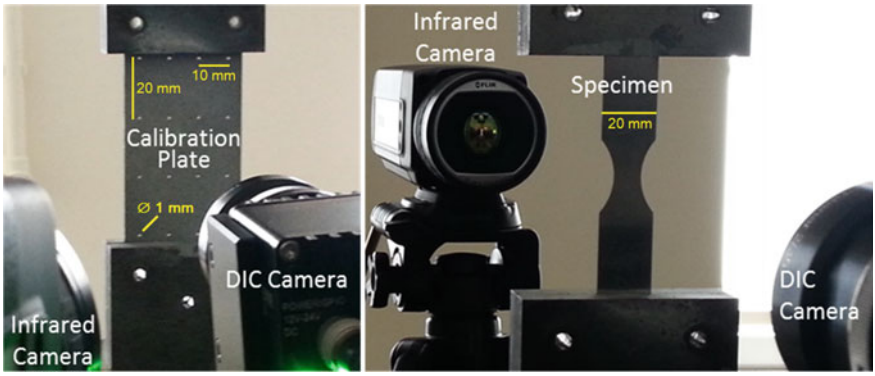

Fig. 1 Possible camera positions for thermomechanical measurements. (Color figure online)

the deformation measurement camera. When both cameras are positioned at the same side at least one of them must be positioned oblique. When cameras are positioned at the opposing sides of the specimen, they can be positioned close and perpendicular to the specimen faces, but camera distortion is still at work even for this configuration. For all cases, precise real-to-image and image-to-real mappings are necessary for accurate evaluation of the measurements. This study develops an accurate and easy to use mapping and matching approach for infrared cameras, and homemade or commercial deformation measurement systems. This is achieved by a new mapping approach, which uses a single calibration snapshot on a simple calibration plate before the experiment begins. These are introduced in the rest of this section.

2.1 Calibration Plate

The recent proposal in [7] for the calibration of thermal cameras using infrared visible light falls short in several aspects. First of all, the light grid cannot be produced with the ordinary milling machine accuracy of 10 microns and the observed edges of the lights are not sharp. Furthermore, the light grid is not a common platform to create a spatial matching between IRT systems and commercial DIC systems. Alternatively, an object with a few geometric features is used in [6] as a means to define easy to invert linear mapping between the DIC and IRT measurements. Such a mapping is unfortunately inaccurate [4].

A planar calibration plate providing a sharp infrared image obtained by accurately drilled 16 holes in the form of a 4×4 Cartesian grid layout is proposed, Fig. 2. This calibration plate defines a common real coordinate system in the plane of the specimen for both IRT and DIC measurements. Grid separation may be different between Cartesian directions but suggested to be common in each direction to create a rectangular measurement region. Such a calibration plate can be manufactured

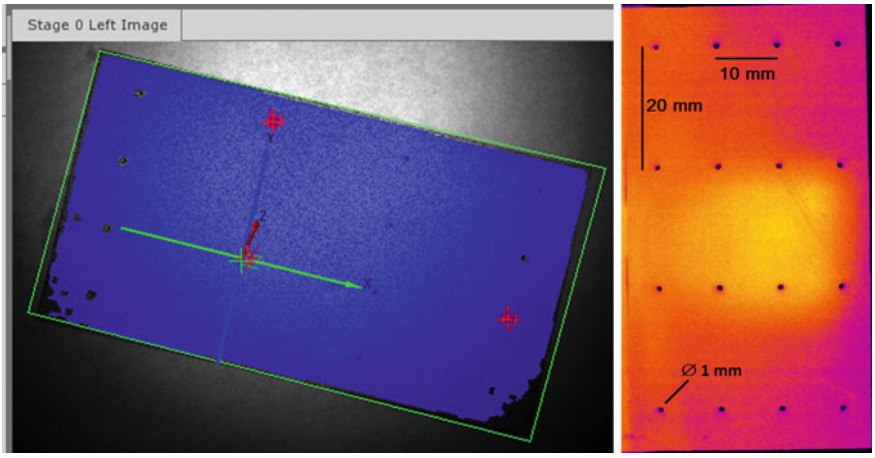

Fig. 2 Calibration snapshot for an IRT measurement (right) and a commercial DIC system (left). (Color figure online)

from a flat sheet material on a milling machine with at worst 10-micron locational accuracy.

2.2 Calibration Snapshot

A calibration snapshot is taken to determine the image (i.e. pixel) coordinates of the calibration plate holes. This is used to build an interpolative mapping function from real coordinates to the corresponding image coordinates. As shown in Fig. 2, a two-dimensional Cartesian coordinate system in real space is centered at any one of the holes and aligned with the grid directions defined by the holes. This is achieved either by using the proposed coordinate mapping strategy for a homemade DIC system or transforming the coordinate system of a commercial system using the holes' locations, e.g. 3-2-1 coordinate system transformation used by GOM-ARAMIS [19]. In this way, all the infrared and digital measurements done during the experiment are set up to use the same real coordinate system defined by the calibration plate. To gain this extensibility, the calibration plate must be painted by a speckle pattern. The visible holes buried in the speckle pattern create a snapshot to be used for the coordinate system transformation in the commercial DIC system as shown in Fig. 2.

Together with the mapping functions constructed for each IRT and DIC measurement device, real-to-image, image-to-real, and image-to-image mappings are then trivial as explained in Sect. 2.3. Furthermore, the holed nature of the calibration plate makes it irrelevant whether different cameras are located to view the same or the opposing faces of the specimen. During the calibration snapshots taken from all measurement devices, the calibration plate must be positioned stationary in the

plane where the deformation of the specimen takes place. Furthermore, the rectangular periphery formed by the holes is defined as the measurement range and must cover the specimen's gauge. After the calibration snapshots from all the devices, the cameras must remain stationary.

The accuracy of the calibration snapshot totally depends on the accurate determination of the holes' pixel locations. Since only 16 locations need to be determined, this could be done precisely by manual work in a short time. The accuracy can be further increased by using sub-pixel location detection approaches as proposed in the literature [20–22]. Calibration snapshot from an infrared camera can always be made further clear and sharp, by placing either hotter or a colder object behind the calibration plate, without changing the temperature of the calibration plate.

2.3 Mapping Algorithm

The common strategy in the available camera models is to compute the extrinsic (position and orientation) and intrinsic (optical and internal geometric characteristics) parameters of the camera model by using calibration snapshots of predefined calibration plates. Since inverse mapping from pixel to real coordinates is necessary, intrinsic and extrinsic characteristics of cameras are expressed preferably by invertible, hence simple, functions of geometry and optics possibly with the least number of parameters. The camera parameters are computed by regression analysis and/or many smaller sub-regions are considered to reduce the possible mapping errors. The proposed approach, however, does not consider the camera as a device with intrinsic and extrinsic characteristics but rather as a mapping function. This approach with an increased number of parameters improves the accuracy of the mapping function and further eliminates the necessity of using excessive number of points on the calibration plates or considering sub-zoning for better accuracy in mapping.

The proposed approach uses the bi-cubic shape functions (1) from the finite element method as the mapping function:

$$\begin{aligned} u &= \alpha_1 + \alpha_2 X + \alpha_3 Y + \alpha_4 XY + \alpha_5 X^2 + \alpha_6 Y^2 + \alpha_7 X^2 Y + \alpha_8 XY^2 + \alpha_9 X^2 Y^2 \\ &\quad + \alpha_{10} X^3 + \alpha_{11} Y^3 + \alpha_{12} XY^3 + \alpha_{13} XY^3 + \alpha_{14} X^3 Y^2 + \alpha_{15} X^2 Y^3 + \alpha_{16} X^3 Y^3 \\ V &= b_1 + b_2 X + b_3 Y + b_4 XY + b_5 X^2 + b_6 Y^2 + b_7 X^2 Y + b_8 XY^2 + b_9 X^2 Y^2 \\ &\quad + b_{10} X^3 + b_{11} Y^3 + b_{12} X^3 Y + b_{13} XY^3 + b_{14} X^3 Y^2 + b_{15} X^2 Y^3 + b_{16} X^3 Y^3 \end{aligned} \tag{1}$$

The mapping function (1) defines the mapping from the real coordinates (X, Y) to image coordinates (u, v). The real coordinates of the 16 holes on the calibration plate are well known as far as a coordinate system is defined on the calibration plate.

As soon as the corresponding image coordinates of holes obtained from the calibration snapshot are determined, (1) can be used to construct two equation systems to determine the coefficients α_i and β_i for which a unique solution always exists.

The major weakness of this extended, nonlinear, and monolithic definition (1) instead of a camera model is the necessity to perform an iterative solution for the inverse (i.e. from image to real) mapping. This is true but practically not a drawback for the proposed approach at all. Knowing the corresponding 16 calibration plate locations in real and image space, inverse mapping from image to real coordinates for these 16 pixels is already known exactly. Starting from these locations and progressing to the neighboring pixels, it takes only a couple of minutes for practical camera resolutions to accurately find the corresponding real coordinates of all the pixels within the measurement range. Newton–Raphson approach applied for this purpose uses the known real coordinates of the neighboring pixels as initial guesses for the iterative solution. This iterative root finding for each pixel generates a correspondence table, which can be stored for later use as a mapping function from image coordinates to real coordinates. Since real-to-image mapping function (1) is more accurate, the inverse mapping from image to real coordinates obtained by its inverse solution is also more accurate as far as sufficiently tight tolerances for the inverse solution are used. Practical examples in Sect. 3 provide the computation times for the inverse mapping, which turns out to be totally reasonable in exchange for improved accuracy. In fact, computation of the corresponding real coordinates and storing them for later use right after the calibration snapshot, once for all, save time in the experimental image analysis phase by eliminating repetitive calculations for the same pixels. For mapping from sub-pixel locations to real coordinates, the computed mapping table still provides an accurate solution by means of interpolation.

The real-to-image mapping function (1) and its inverse for each relevant pixel from image to real coordinates in terms of a stored table provide the complete mapping functionality for a thermographic or a photographic measurement. In case more than one measurement devices are used, real coordinates can be used as an intermediate mapping space, to obtain the image-to-image mapping from one measurement device to another. The discussion above provides the necessary mathematics for the computation of the mapping functions in case all the measurement systems are located to view the same face of the specimen. If infrared and digital cameras are positioned to view the opposing faces of the specimen, the horizontal X-coordinate of one of the systems should be redefined to be $X_{\text{backside}} = -X_{\text{front}}$ to construct a collaborative measurement setup.

3 Results

The proposed mapping strategy between real and image coordinates is applicable to any kind of digital or infrared camera. This section presents the comparative performance of this mapping approach for two camera types with respect to the results computed by the METROVISIONLAB Toolbox [23]. For this purpose, two types

of cameras are considered, namely, an 8 MP digital camera and an infrared camera to investigate the accuracy performance and infrared applicability of the proposed approach, respectively. With a 10 mm spacing, a square grid of 90 mm size was manufactured using a 1 mm thick sheet metal on a CNC milling machine, Fig. 3. This creates a total of 100 grid points. Evenly distributed 16 points, 12 of which are at the corners and edges, are used as the calibration locations for the proposed approach. The comparison is done against the results obtained by the METROVISION Toolbox using all of the 100 grid points for calibration. Locations of the 100 grid points are well defined in real coordinate space. Their pixel locations are precisely determined by applying manual image zooming and ignoring sub-pixel estimation. The precision of reconstruction for the known image and real coordinates is used to evaluate the accuracy of the reconstruction, where image coordinates are expressed using Eq. (1) and real coordinates are reconstructed by inverting and computing the correspondence table from image to real coordinates. Due to convenience, distance and component errors are provided only over mean and maximum values in Tables 1 and 2.

Another measure for the performance of the proposed approach is the time spent on the necessary computations. The bottleneck here is the computation time spent for the construction of the correspondence table from image to real coordinates for all the pixels located within the measurement range. This computation uses the pixel distance residual threshold of 10^{-9} for the iterative Newton–Raphson solution of the Eq. (1). The total number of pixels and the corresponding computation time are also provided below for the studied cases. The platform for the mentioned computations is MathWorks® MATLAB.

3.1 Photographic Performance

The accuracy of the proposed mapping approach is demonstrated on the introduced grid shown in Fig. 3, with a perspective of roughly 20 cm distance, 60° from the vertical and 45° from the *X*-direction using a digital camera with an 8 MP CMOS sensor and F2.6 lens. This perspective can be considered as an extreme situation. The construction of the inverse mapping table from image to real coordinates for all the 2 megapixels lying within the measurement range takes only 397 s on the Intel® i5-3317U@1.7 GHz processor and occupies a storage of 30 MB in MATLAB. The corresponding computation time reduces to 261 s on Intel® Xeon® E5-1620@3.6 GHz.

3.2 Thermographic Performance

The functionality of the proposed approach using a 640 × 480 pixel resolution infrared camera FLIR-A655-sc with F24.6 mm lens is demonstrated next. For this purpose, a perspective of roughly 45 cm distance and 15° from the vertical is used as shown in Fig. 3. This perspective can be considered as a probable orientation for a two-camera measurement on the same specimen face. The construction of the inverse mapping table from image to real coordinates for all the 82,285 pixels lying within the measurement range takes only 9 s on the Intel® i5-3317U@1.7 GHz processor and needs a storage of 1.2 MB.

The reconstruction quality of the proposed approach as shown in Tables 1 and 2 for all the 100 grid locations is significantly better. Despite the fact that the proposed approach uses only 16 points, whereas the compared and similar strategies require all of the 100 points for the calibration.

4 Summary, Discussion, and Outlook

A new real to image mapping approach is introduced for the planar measurements. The approach uses the bi-cubic interpolation functions based only on 4 × 4 grid points identified by a single calibration snapshot. The calibration plate is manufactured by precisely drilling small holes in a 4 × 4 grid pattern on a flat thin rigid sheet. This enables accurate mapping for thermographic measurements. Simultaneous IRT and DIC measurements are also possible by positioning the systems either at the same side or at the opposing sides of the specimen. The gauge of the specimen must be in the same plane and totally covered by the 4 × 4 grid on the calibration plate. The holed calibration plate painted by speckle pattern facilitates a flawless collaboration with commercial DIC systems for deformation measurements. As demonstrated in the paper, the proposed mapping approach is more accurate compared with available digital camera modeling techniques. In this way, highly oblique views are made practicable without losing measurement accuracy. Any available technique used to increase the accuracy by sub-pixel evaluation can also be integrated in the proposed mapping approach. No more than 16 calibration points are required, so that a manual determination of the pixel positions is practically possible and the error-prone automation of control point detection is eliminated. The approach is simple and does not require any expertise in camera modeling approaches.

Having them apparent for both infrared and digital cameras, it is suggested to have the holes' diameters as small as possible to increase the accuracy of mapping. The proposed approach can be extended to use higher order mapping functions with more parameters as a better alternative to (1). Hence, the number of holes on the calibration plate should be increased accordingly. A 5 × 5 grid, for example, will provide a bi-quartic mapping function. The proposed approach is applicable to only planar measurements and provides only a mapping function from real to image

coordinates. Due to its nonlinear nature, the inverse mapping from image to real coordinates is done by inverse numerical solution of the forward mapping functions. Practical time loss due to this drawback, however, is a couple of minutes only once for all of the pixels within the measurement range. This primitive approach of calculating and storing real coordinates corresponding to all relevant pixels once as part of the calibration procedure saves time in the later evaluation phase.

Determination of camera orientation and position, elimination of camera distortion, camera calibration, and modeling are not concerns of this approach and can be considered as a weakness in the perspective of camera modeling. An extension to three-dimensional measurements is possible for photographic measurements with a two-camera system. For this purpose, accurate repositioning of the calibration plate perpendicular to itself to cover the whole volumetric range of measurement is necessary. Hence, a tri-cubic interpolation function, for example, can be obtained using four positions of the calibration plate. A three-dimensional thermographic measurement is only possible over a coupled three-dimensional photographic measurement. A further limitation of the approach could be the change in camera distance due to thickness changes during the testing of the sheet specimen. This is a general concern for all single-camera measurement systems that use a camera model and can be reduced by positioning the cameras as perpendicular as possible to the specimen surface.

The accurate measurement of the thermomechanical full-field opens the way for new characterization methods. Tracking the temperature of a material point during mechanical loading yields a temperature progression as shown in Fig. 4, [24]. This figure shows the measured temperatures at the two marked locations, on a tensile specimen, and on an in-plane shear specimen. The shown measurements start in

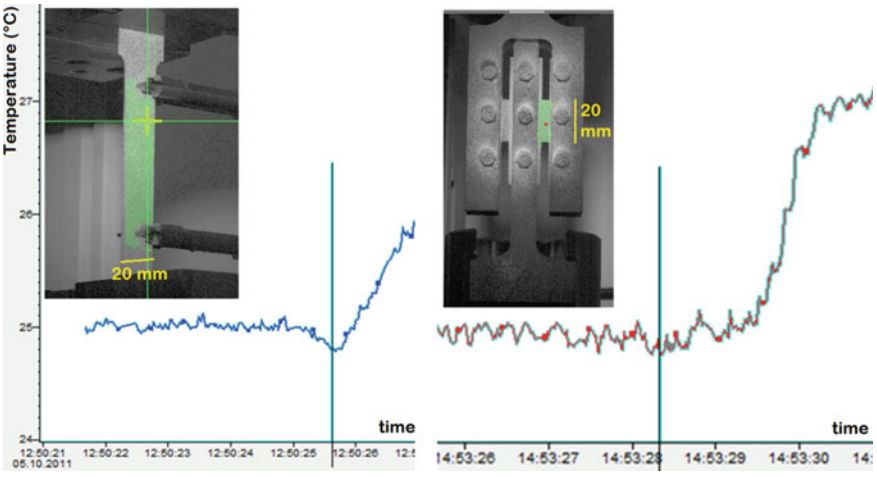

Fig. 4 Temperature development during tensile (left) and in-plane shear test (right) [24]. (Color figure online)

the phase of elastic deformation and go further in the early phase of the plastic deformation. Depending on the stress state causing expansion or contraction of the material, a slight cooling or warming can be observed during elastic deformation. However, the plastic deformation is always associated with a considerable increase in temperature due to generated heat. Using this advantage of thermomechanical full-field observations, stress values on the yield locus of a material can be determined more accurately. For this purpose, specimen geometries that simultaneously exhibit a wider range of practical stress ratios could be useful to reduce the number of experiments required for the characterization of the yield locus [25].

Effect of Bending Intensity on Straightness in Spinner Straightener

Keiichiro Kawasaki, Shohei Kajikawa, Hiromichi Matumura, Tetushi Ono, Hikaru Seimiya, and Takashi Kuboki

Abstract This paper presents the optimum processing condition of spinner straightener. Spinner straightener straightens wire rod using several straightening tools by subjecting the rod to repetitive bending and unbending with rotational movement. This research investigated the effect of bending intensity on the straightness of wire by changing the die positions, which determine the bending intensity. Both the experiment and analysis were carried out for the investigation. One of the unique points of this study is the usage of the actual operation line for the experiment instead of laboratory equipment. Another unique point is the combination of the finite element analysis (FEA) and a purpose-built fundamental analysis. The analysis and experiment were in good agreement and showed the existence of the optimum condition. The straightness was improved with the increase in the bending intensity up to the optimum bending intensity. However, the excessive bending intensity deteriorated the straightness.

Keywords Spinner · Straightener · Straightness · Curvature · FEM

1 Introduction

Straightening is located at the end of the manufacturing process for bars and wire rods. Bars and wire rods are used as materials for precision parts such as automobile and printer shafts. Recently, the requirements for the dimensional precision of bars and wire rods are getting stricter due to the recent trend of requirements to the final products, which use the bars and wire rods. So the role of the straightening process is more and more important. Figure 1 shows the process line of bars. The initial bar is unwound from the coils on the supply stand and drawn before the line of

straitening processes. The straightening line includes spinner, polishing, and two-roll straighteners. These straightening processes would collaboratively determine the quality of the bars, and the spinner is located at the first of the three processes.

There are few research works for the spinner, though there are many for the final process, like two-roll straighter. Yanagihashi et al. [1] and Mutrux et al. [2] tried to apply the FEM to solid-bar straightening by deciding the deformed shape in advance. Kuboki et al. composed a Finite Element Method (FEM) model applying the implicit scheme for three-stand tube straightening [3]. Wu et al. carried out a theoretical approach for analyzing the mechanism of the two-roll straightener [4]. However, all the above works focused upon the final process in the production line without knowing phenomena in the first process, which is spinner straightening. Although Tsurumi et al. conducted a study on a spinner-like machine, the material was a very thin wire and the study is not so general [5].

The present study focuses upon the spinner straightening, which is the first process and may play an important role in the production line. Analysis methods are proposed utilizing the Finite Element Method for clarifying a guideline for optimum conditions. Two types of analysis methods are shown. Model 1, full actual model with explicit scheme [F-Model], considers the rotational movement of dies as the actual process using the explicit scheme. Model 2 is a model carrying out fundamental analysis by approximating the spinner process to three bending processes with bar rotation based on the results of simple bending in FEM, named [B-Model]. B-Model used FEM only for calculation of simple bending without rotation for obtaining the deformed bar shape. A series of experiments were conducted in an actual production line as well as the analyses by Models [F-Model] and [B-Model]. The examination mainly focused upon the effect of straightening intensity by changing the die positions for showing mechanism in spinner straightening and a guideline for the optimum working condition.

2 Condition for Spinner

Figure 2 shows a schematic illustration of the spinner. The die positions h_i(i = 1–5) were defined so that the h_i should be zero when the dies contact with a completely straight bar without any load. The sign (positive/negative) of h_i was defined as shown in the figure. The die positions h_i determine the bending intensity during straightening. The detailed condition on the die positions is shown in Table 1. Condition [A] is intuitively expected to have the strongest straightening effect. Table 2 shows the drawing condition in advance of spinner straightening. Coils of lead-free free-cutting steel were annealed and drawn. Table 3 shows other working conditions.

3 Analytical Models

3.1 Full Explicit Scheme Model [F-Model]

Two analytical models were composed, and the detailed settings are explained in this section. Figure 3 shows the composition of spinner in the Finite Element Analysis (FEA). Guides and rollers were made as well as the bar and the dies. Residual stresses are assumed to be zero in the analyses in this study.

The first model almost fully reproduced the movement of spinner straightening using the explicit scheme. The analysis was carried out by two steps as shown in Fig. 4. The bar was set through Guide 1 to roller 2 via dies #1−#5, and the front tension T was applied. The dies gradually moved to the target position of h_i(i = 1 ~ 5) at Step 1. At Step 2, the rotational movement was given to the dies, while feeding movement was given to the bar end. Although model [F-Model] would not be as

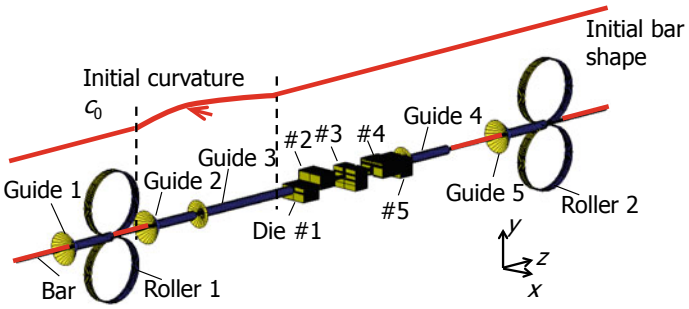

Fig. 3 Analysis steps in [F-Model]. (Color figure online)

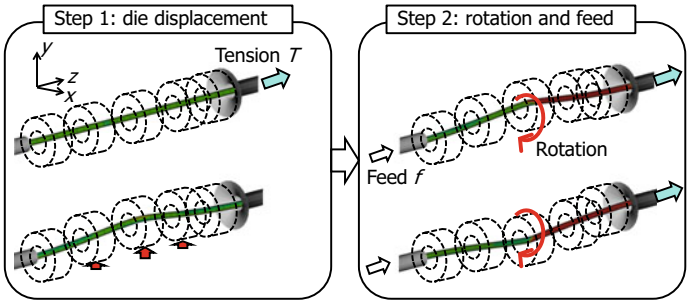

Fig. 4 Analysis steps in the model [F-Model]. (Color figure online)

precise as a model with the implicit scheme, it can consider the centrifugal force and the convergence would be stable. An initial curvature C_0 was given to the bar between the Roller 1 and Die #1, and the curvature was evaluated at the same portion of the bar during and after the spinner straightening.

3.2 *Approximation to Three-Point Bending from FE Bending [B-Model]*

B-Model was also composed of two steps as shown in Fig. 5 and the meanings of symbols are shown in Table 4. This model assumed that the bending deformation of the bar by spinner straightener can be approximated to three-point bending with

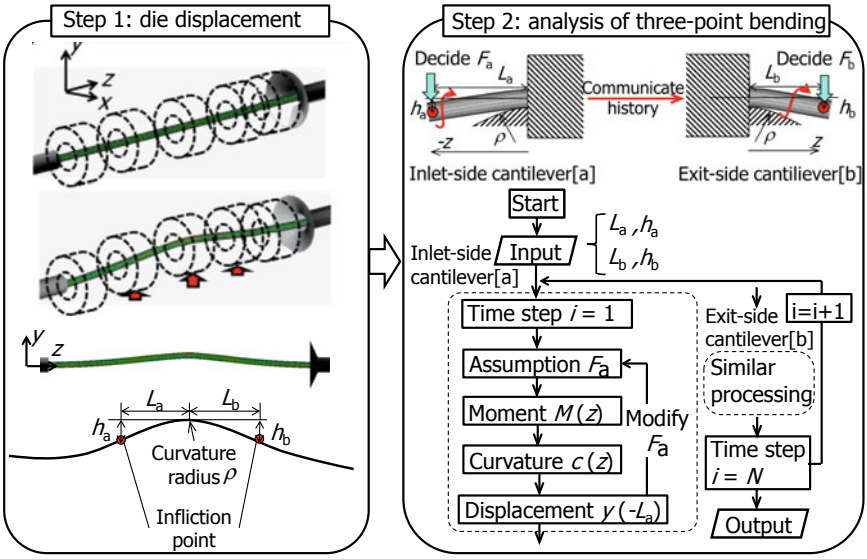

Fig. 5 Analysis steps in model [B-Model]. (Color figure online)

Table 4 Notion

L_a distance between #3 die and inform point in inlet-side cantilever	z axial position
L_b distance between #3 die and inform point in exit-side cantilever	$M_{(z)}$ moment of z
h_a height inflection point in inlet-side cantilever	$C_{(z)}$ curvature of z
h_a height inflection point in exit-side cantilever	$Y_{(z)}$ displacement of z
F_a force in inlet-side cantilever	F_b force in exit-side cantilever

bar rotation. The composition of tools and the work Step 1 is the same as that of model [F-Model]. There is an inflection point for inlet and exit sides. The positions of the inflection points, i.e. L_a, L_b, h_a, and h_b were extracted. The distance between #3 die and inflection point L_a in inlet-side cantilever, the distance between #3 die and inflection point L_b in exit-side cantilever, height of inflection point h_a in inlet-side cantilever, and height of inflection point h_b in exit-side cantilever were extracted and transferred to Step 2. Step 2 calculated moment distribution $M_{(Z)}$, curvature distribution $C_{(Z)}$, displacement distribution $y_{(z)}$ in order. Bauschinger effect was taken into account. The curvature was evaluated at the exit-side inflection point where moment was zero.

3.3 Numerical Representation of the Bauschinger Effect

The Bauschinger effect is a phenomenon in which the yield stress or flow stress decreases during stress reversal. The bar is repeatedly bent by rotating the die and feeding the bar while undergoing repeated plastic deformation in a reciprocating manner. Therefore, it is necessary to consider Bauschinger effect in the analysis of spinner straightening.

Figure 6 shows the numerical representation of the Bauschinger effect, which is proposed in the present paper. The flow stress calculated by isotropic hardening rule is $\sigma_{iso}(\varepsilon_p)$, plastic strain is ε_p, and the coefficient is γ, and γ is assumed as a function of stress σ. The relationship between stress and plastic strain considering the Bauschinger effect is expressed by Eq. (1). The Young's modulus is E, the elastic strain is ε_e, the stress–elastic strain relationship is expressed by Eq. (2). The stress–strain relationship taking the Bauschinger effect is expressed by Eq. (3), As the total strain ε_t is represented by the sum of ε_e and ε_p.

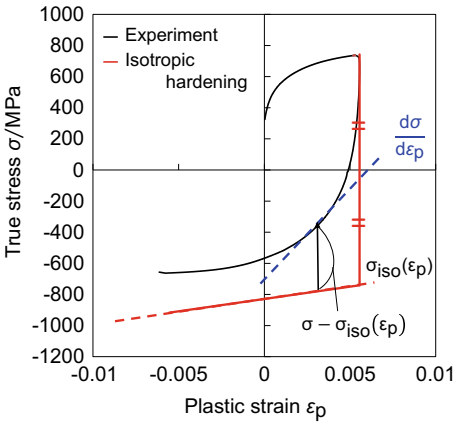

Fig. 6 Numerical representation of Bauschinger effect. (Color figure online)

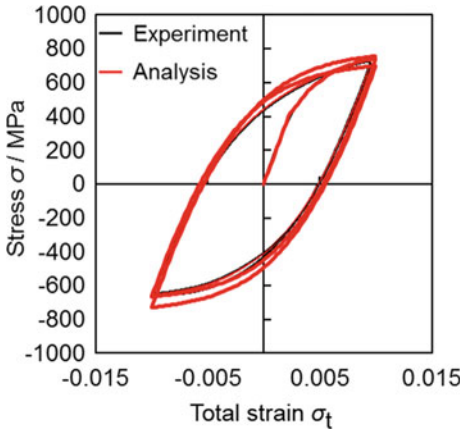

Fig. 7 Comparison stress–strain curve of experiment and analysis. (Color figure online)

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\varepsilon_p} = \gamma\left(\sigma_{iso}\left(\varepsilon_p\right) - \sigma\right) \tag{1}$$

$$\frac{\mathrm{d}\varepsilon_e}{\mathrm{d}\sigma} = \frac{1}{E} \tag{2}$$

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\varepsilon_t} = \frac{1}{\frac{1}{E} + \frac{1}{\gamma\left(\sigma_{iso}\left(\varepsilon_p\right) - \sigma\right)}} \tag{3}$$

The reproducibility of the stress–strain curve of the proposed model was verified. Figure 7 shows the results of a comparison between the experimental and the calculated values of the proposed model at the same strain history. The tension and compression test of the bar was controlled the strain history between −1% and +1%. The proposed model accurately reproduced the Bauschinger effect during compression and the stress during reloading and agreed with the experimental results. [B-Model] analysis adopted the proposed stress–strain relationship and considered the Bauschinger effect.

3.4 Evaluation of Straightness

Curvature was used for the evaluation of straightness and was defined as shown in Fig. 8. Curvature was calculated for each node as shown in Fig. 8a. When the value was positive, the node was placed on the extrados of the bar arc. When it was negative, the node was on the intrados. The chord lengths L_{sp} were set to be 9.52 mm (feed pitch f) and 190.4 mm ($10f$) for the evaluation of short-span curvature C_S and long-span curvature C_L.

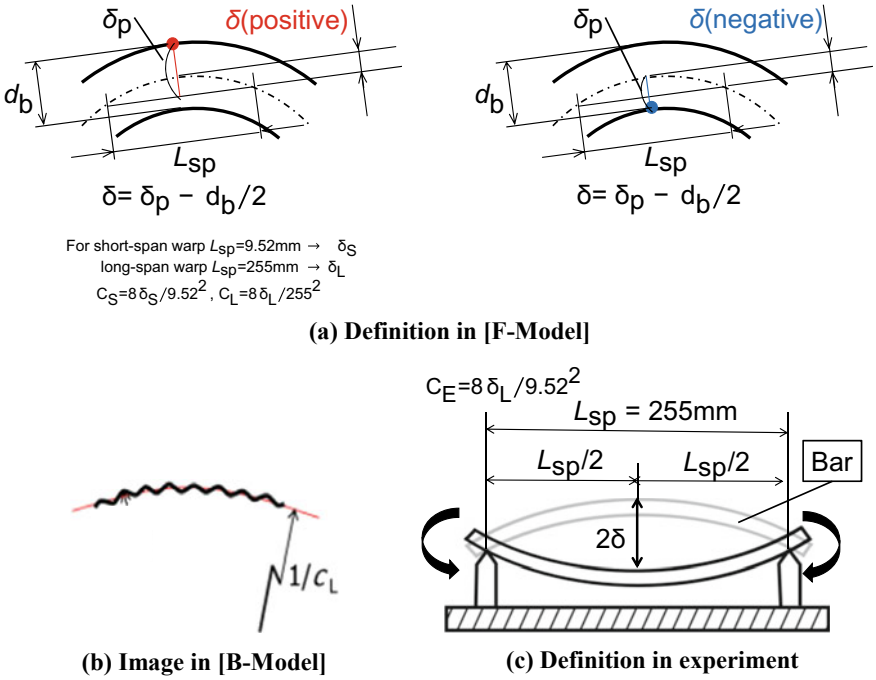

Fig. 8 Curvature. (Color figure online)

In Model [B-Model], the short-span curvatureC_S and long-span curvature C_L were calculated by equations in Fig. 5. The image of C_S and C_L is shown in Fig. 8b. The long span curvature C_E was measured in the experiment as shown in Fig. 8c.

4 Analytical and Experimental Results

4.1 Result in Full Explicit Scheme Model [F-Model]

Figure 9 shows the curvature distribution after spinner straightening under the condition of Table 1[B]. It is noteworthy that the extrados (red part) and the intrados (blue part) are found to be inconsistent before and after spinner straightening by comparing (a) and (c). In other words, the initial curvature was eliminated by spinner straightening. On the other hand, short-span curvatures periodically exist as shown in (b). If these curvatures C_S cancel each other, the long-span curvature C_L should be leveled to zero. However, the C_S did not cancel each other, and then C_L appeared.

Figure 10 shows the effect of Die #3 position h_3 on the curvature after spinner straightening in [F-Model]. 0.1 times of C_L was used for the prediction. The spinner

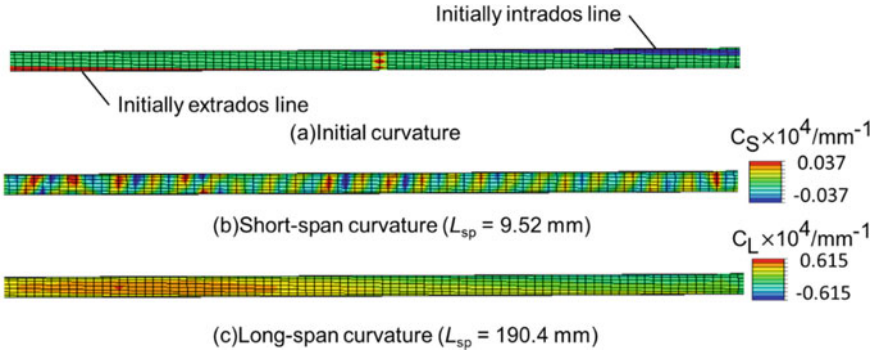

Fig. 9 Spiral and warp after spinner straightening. (Color figure online)

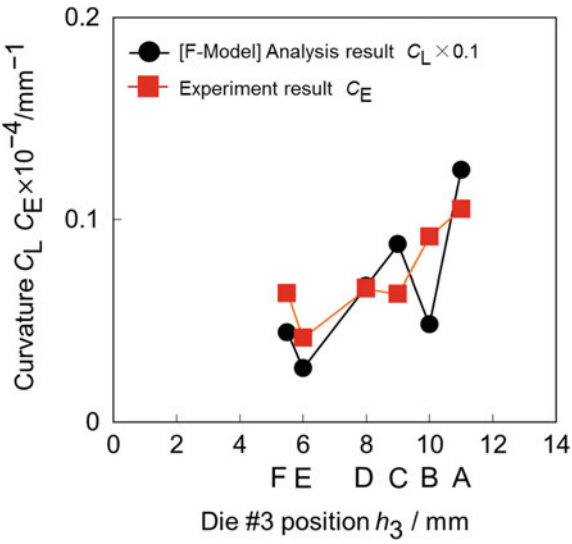

Fig. 10 Effect of die position on curvatures In [F-Model] and experiment. (Color figure online)

conditions in Table 1 might be strong enough for the elimination of the initial curvature. In the conditions [E] –[F] ($h_3 \leq 6$mm), the curvatures C_L and C_E decreased with an increase in h_3. These conditions would be called as "under straightening". The conditions [E]–[A] ($h_3 \geq 6$mm), thecurvatureC_L and C_E increased with an increase in h_3. These conditions would be called "over straightening", which shows optimum condition is [E] ($h_3 = 6$ mm) in this study. The model [F-Model] and experimental results qualitatively show the same tendency. As the result, the large h_3 caused large short-span curvature C_S, resulting in large long-span curvature C_L.

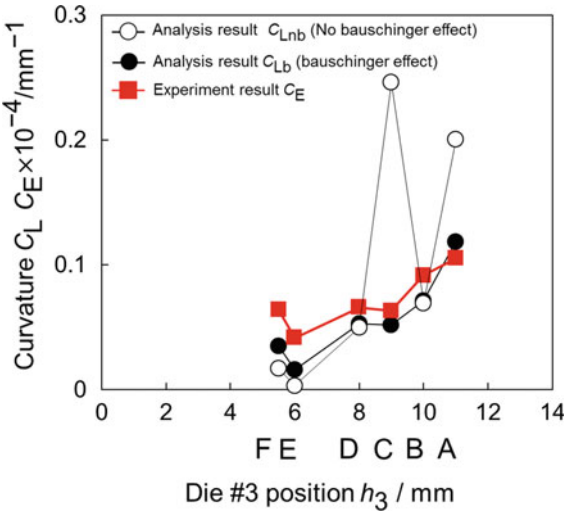

Fig. 11 Effect of die position on curvatures In [B-model] and experiment. (Color figure online)

4.2 Result in Approximation Three-Point Bending from FE Bending [B-Model]

Figure 11 shows the effect of Die #3 position h_3 on the curvature after spinner straightening [B-Model]. The analyses were conducted to obtain the curvatures C_{Lb} with considering Bauschinger effect and C_{Lnb} without Bauschinger effect. The curvatures C_{Lnb} and C_{Lb} were shown the similar tendency to the curvature C_E and C_L in [F-Model]. Curvature C_{Lb} was better agreement with the curvature C_E than curvature C_{Lnb}. Above all, Bauschinger effect needs to be considered in the analysis of spinner straightening. In the spinner conditions in Table 1, the condition for obtaining the most straight bar was [E] ($h_3 = 6$ mm) in both the experimental and analytical results.

5 Conclusion

This paper presents two analytical models. One is model [F-Model] and the other is model [B-Model].

- [F-Model] almost fully reproduced the movement of spinner straightening using the explicit scheme.
- [F-Model] shows the distribution of both short and long-span curvatures in a visual way.
- [F-Model] showed the existence of optimum Die #3 position in this study. Long-span curvature decreased with an increase in the intensity less than 6 mm, and the curvature increased with an increase in the intensity greater than 6 mm. Optimum

intensity is 6 mm in this study. This analytical tendency is qualitatively the same to that in experiment.
- The proposed numerical expression of Baschinger effect could precisely express the same stress–strain relationship as the experimental result.
- [B-Model] was modeled by approximation to three-point bending with bar rotation based on the FEM result of simple bending deformation in straightener without bar rotation.
- [B-Model] showed the effect of die position on curvatures. Analytical result is qualitatively and quantitatively the same to the experimental result. Analysis of spinner straightening needs to consider the Baushinger effect.

Using Local Heat Treatment for Producing Uniform Profile Hollow Components by Radial Rotation Profile-Forming

Robert Laue, Sebastian Härtel, and Birgit Awiszus

Abstract The incremental forming process Radial Rotation Profile-Forming (RRPF) has been developed at the Professorship Virtual Production Engineering of the Technical University of Chemnitz. The aim is to enable the production of profiled hollow parts with low sheet thinning and high geometrical accuracy. Because of low thinning due to the process, a smaller initial sheet thickness can be used, whereby material and weight can be saved. RRPF is a two-step forming process. The two principal steps are the production of the preform by Rotational Swing-Folding and the subsequent radial profile-forming of the hollow part in one clamping position. During the preform production, wrinkles occur and these wrinkles can be directly formed in the indentation of the mandrel. In the second process step, the wrinkles are used to form the finished profile of the component. However, due to the geometrical stiffness and the material behavior, there is no wrinkle formed in every indentation of the mandrel. An indentation without wrinkle lead to a high sheet thinning, wich occurs due to forming of the final profile. The best component with less sheet thinning and uniform properties is created for a preform with uniform wrinkles in each indentation of the mandrel. Therefore, the approach of a local laser heat treatment is carried out to control the wrinkling for the first time. This extends the original two-step forming process by a further process step. Before forming, local heat treatment creates a tailored blank with locally varying strength. Therefore, wrinkling occurs in the area with the lower strength of the basic material. The approach and experimental basic investigations of the laser heat treatment are shown in this paper.

1 Introduction

Tailored Blanks have local adapted properties like material, roughness, or sheet thickness and are used for sheet metal forming processes [1]. Basically, Tailored Blanks are classified according to the production (Fig. 1) in Tailored Rolled Blanks (TRB), Patchwork Blanks (PB), Tailored Welded Blanks (TWB), and Tailor Heat-Treated Blanks (THTB) [2].

Tailored Heat-Treated Blanks have locally adapted material properties due to local heat treatment. The local heat treatment of metallic materials can be carried out by flame hardening, induction hardening, or laser hardening. These processes are often used for surface hardening in order to increase the hardness values on the component surface [4].

Using laser hardening, the surface layer of the workpiece is heated above the austenitizing temperature and then cooled very quickly by the surrounding material (self-quenching). As a result, the metal lattice cannot return to its original shape, and martensite is formed. Typical surface hardening depths are between 0.1 mm and 2.5 mm, for higher surface hardening depths, there must be a corresponding surrounding volume so that the heat can be dissipated quickly enough [5, 6].

The process is mainly used to optimize component properties, such as increasing the surface hardness to reduce wear or increasing the crash stability. Through the targeted introduction of hardening structures by a laser, for example, the deflection of a tube in bending tests could be reduced by 55% [7]. Another possible application is the use of locally adapted material properties in the production process, to extend the procedural limits significantly. Investigations at the Fraunhofer IPT show that laser heat treatment processes can reduce the minimal bending radius without damage by 87%. In addition, the deep drawing depth without damage can be increased by more than 100% [8]. Further investigations show that the influence of anisotropy can be reduced by local heat treatment. In the numerical investigations, the height of lip formation after the deep drawing of a cup from DC04 can be reduced by 85% [9].

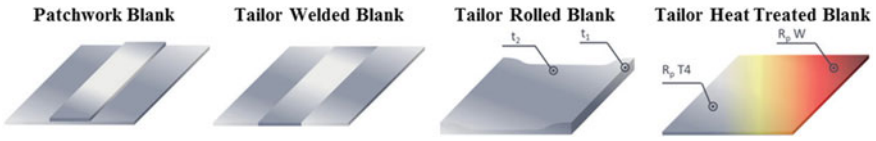

Fig. 1 Different kinds of tailored blanks according to [3]. (Color figure online)

2 Process Analysis of Radial Rotation Profile-Forming

The Radial Rotation Profile-Forming was recently developed based on the idea of reducing the relative movement between the tool and the workpiece [10]. The incremental sheet forming process is used for the production of profiled hollow components, like clutch plate carriers, sensor disks, or synchronous pulleys. The principle of the process is shown in Fig. 2. The two principal tasks are the production of the preform by Rotational Swing-Folding and the afterward profiling of the hollow part. For the preform production, the circular blank is fixed on a rotating profiled mandrel. Due to the swinging of a cylindrical forming tool, the blank is placed on the contour of the mandrel and shaped into the preform. In turn, a minimum relative movement in the axial and radial directions between the tool and the workpiece exists, due to the special position of the swinging axis. As a result, low sheet thinning occurs in the flange of the workpiece In addition, tangential compressive stresses occur because of the reduction of the diameter, which initially leads to a thickening of the edge. Furthermore, wrinkling occurs when the buckling stability is exceeded and the wrinkles are formed in the indentation of the profiled mandrel (Fig. 2: detail Z).

However, in the second process step, the material distribution at the edge and the wrinkles are used to produce a profiled hollow part with low sheet thinning by radial profile-forming. Due to the rotation and continuous radial feed of the forming tool to the profiled mandrel, the axial profiling is formed.

Wrinkle formation during Rotational Swing-Folding depends on the material and geometry. These two parameters influence the buckling stability (stiffness against wrinkling) mainly. Wrinkling occurs when the tangential compressive stress during Rotational Swing-Folding exceeds this stiffness. In previous experimental and numerical investigations, the stress distribution during the forming process was analyzed [11]. The implicit simulation model uses hex-volume elements and experimentally determined elastic/plastic material properties. The tangential stresses during the forming process (Fig. 3) show that the stress distribution is similar to sheet metal spinning and an elastic dent forms under the tool. This disturbs the rotational symmetry of the workpiece and the highest stresses are formed on the underside of

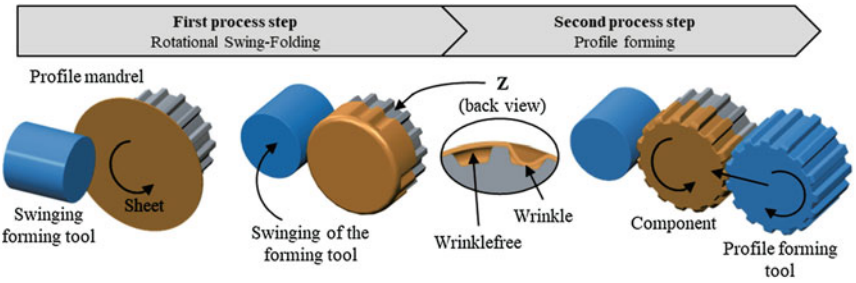

Fig. 2 Process principle of Radial Rotation Profile-Forming. (Color figure online)

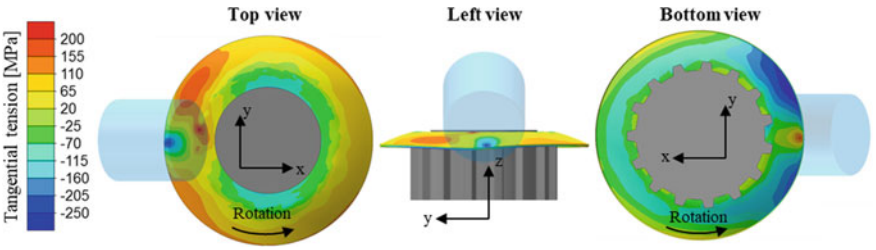

Fig. 3 Tangential stresses during Rotational Swing-Folding. (Color figure online)

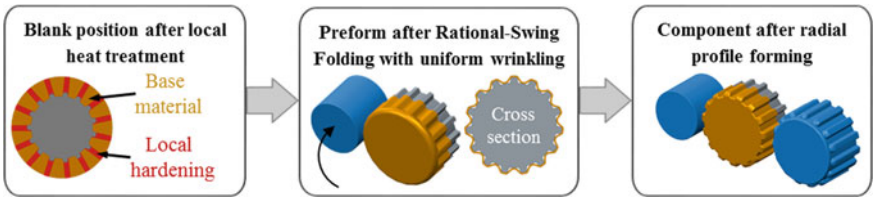

Fig. 4 Solution approach for the production of components with homogeneous properties. (Color figure online)

the blank after contact between tool and workpiece. These tangential compressive stresses are responsible for the formation of wrinkles.

If a wrinkle occurs, depending on the material and sheet geometry, the tangential compressive stresses may be too low for further wrinkling. Therefore, it is possible that a wrinkle will not form in every indentation of the mandrel. Consequently, the formation of wrinkles can only be minimally influenced by process parameters. Investigations show that in this case, a high sheet thinning occurs during the profile forming in the second forming step. The consequences are non-homogeneous component properties or even cracks. However, if a wrinkle forms in the indentation of the mandrel, the profile is formed very well with minimal sheet thinning [12]. Therefore, the aim is to identify an approach that allows controlling the wrinkle formation independent of material and geometry so that forms a wrinkle in each indentation of the mandrel.

3 Local Heat Treatment

3.1 Solution Approach

To control the formation of wrinkles, a local heat treatment with a laser was investigated. This results in the production of a Tailored Blank before the forming steps, which has areas with higher stiffness. These are positioning on the profiled mandrel

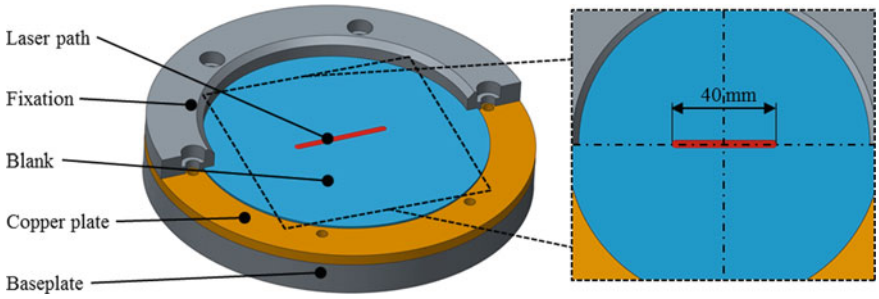

Fig. 5 Clamping device (left) and laser path (right). (Color figure online)

in such a way that the wrinkles do not form in these areas, but in the less hard initial material, as shown in Fig. 5.

Experimental investigations have already shown that wrinkling in deep drawing without a blank holder can be influenced by local heat treatment [13]. Sufficient knowledge about the mechanisms during heat treatment of low-alloy steel has not yet been achieved. Due to the low carbon content, no phase transformation to martensite is assumed. In addition, it is necessary to investigate how the heat treatment must take place in order to bring sufficient heat energy into the circular blank to create a big difference in strength but without melting the material.

The aim of this paper is to obtain a straight uniform track without melting and to investigate the mechanism inside of the blank. First of all, it is to be investigated what happens in the material and how the local heat treatment is deflected. Subsequently, the findings will be used to validate a numerical simulation model, which will be used for the calculation of the Tailored Blank for Radial Rotation Profile-Forming.

3.2 Experimental Setup

For further investigations, a typical cold-forming steel with a very low carbon content is used, as shown in Table 1. Due to the low carbon and manganese content, excessive hardening in the heat-affected zone is not expected. This material was also used for the preceding forming tests since it is well suited for forming and unalloyed steels are usually used for profiled hollow components.

A device as shown in Fig. 5 (left) was manufactured for the experimental investigations. This device can also be used for the local heat treatment of the blanks, which will be used for the afterward forming process steps. The circular blank is

Table 1 Chemical composition DC04 (1.0338) according DIN EN 10130

C	P	S	Mn
0.08%	0.03%	0.03%	0.40%

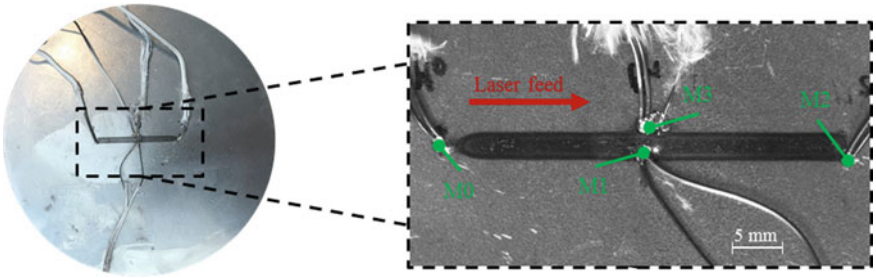

Fig. 6 Laser path after local heat treatment. (Color figure online)

clamped in the middle of a copper plate, which on the one hand leads to a high heat conduction, and on the other hand the position of the blank is exactly defined and the local areas of the heat treatment can be positioned exactly.

For the first investigations, a simple CNC-controlled track with a length of 40 mm is assumed (Fig. 5: right) in the middle of the sheet. Laser parameters are similar to those used in the previous studies were used, in which an influence on wrinkling was experimentally proven. The laser is switched on and off in a ramp of 50 ms and has a power of 1200 W. The constant feed speed of the laser is 2 m/min, resulting in a processing time of 1.2 s. A lens is used for focusing, which should produce a uniform power distribution within the laser beam.

3.3 Experimental Results

Figure 6 (left) shows the round blank after the local heat treatment. The shape of the laser path is very uniform and no melting of the material is visible. This shows that there is enough surrounding material to cool very quickly and that the surface has become hot enough to get tarnish colors. The length of the track is 38.35 mm and the width is 2.65 mm (Fig. 6: right).

For a detailed investigation of the heat input, four thermocouples of type K were mounted on the circular blank, one each at the beginning and end of the laser track and the other two in the middle. The two thermocouples in the middle (M1 and M3) are located behind each other in order to be able to measure the radial heat flow. The measurement frequency was 280 Hz, which is very important because the heat flow is very fast. Figure 7 shows the measured temperatures. At the beginning of the process, the laser power increases evenly, the measuring sensor M0 is located directly next to the starting point of the laser. The temperature increases evenly up to a maximum of about 150 °C and then the uniform cooling begins. The sensor M1 is located nearly to the middle (+0.1 mm) of the laser seam and measures a maximum temperature of 754 °C. However, the temperature in the center of the contact point between the laser and the surface will be much higher. Moreover, the measuring point is at the surface, in deeper areas, the temperature may be higher. The measuring sensor is located in

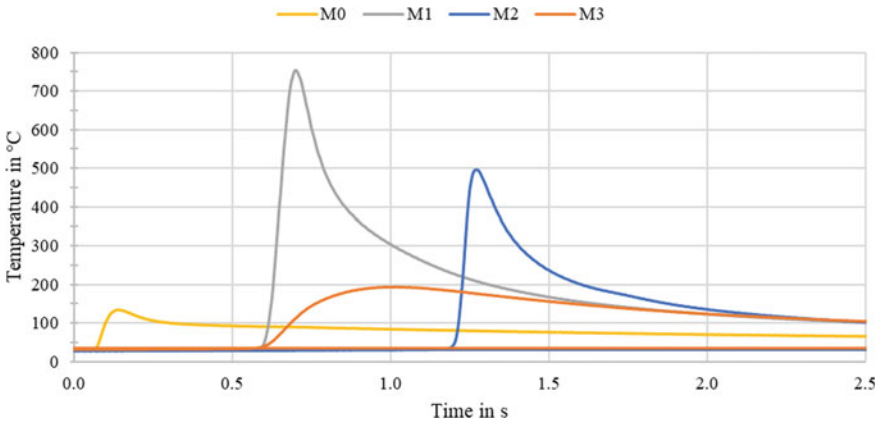

Fig. 7 Temperature during the laser heat treatment. (Color figure online)

the quasi-static area of the heat treatment. A time of 0.146 s is required for heating up to the maximum. Cooling from 750 °C to 450 °C takes about 0.114 s. The sensor M3 is located at a distance of 2.12 mm and has a lower maximum temperature of 550 °C. This makes it clear that a very large temperature gradient occurs. Sensor M2 is located at the end of the laser seam and rises abruptly to 500 °C and then cools down evenly.

To obtain more information about the mechanisms in the blank during the local heat treatment, macro-section samples were prepared. Figure 8 (left) shows a cross-section of the laser feed direction from the middle of the laser path. It can be seen

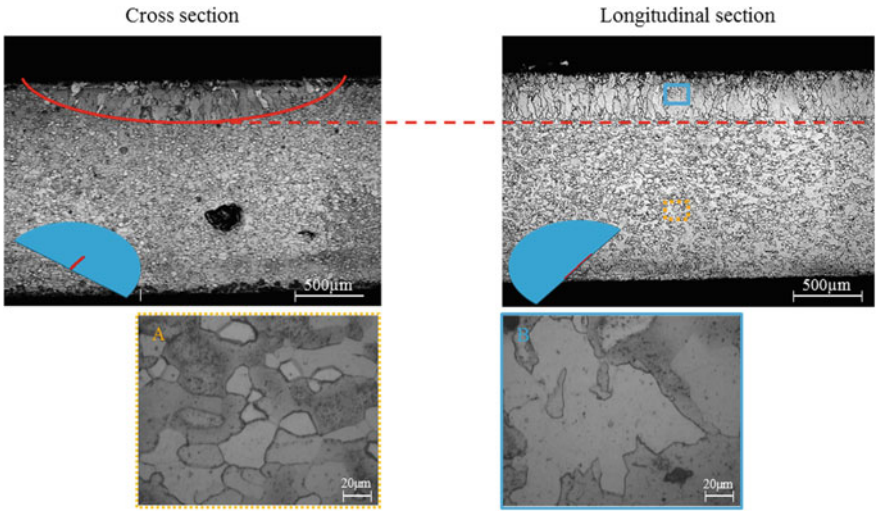

Fig. 8 Grinding pattern. (Color figure online)

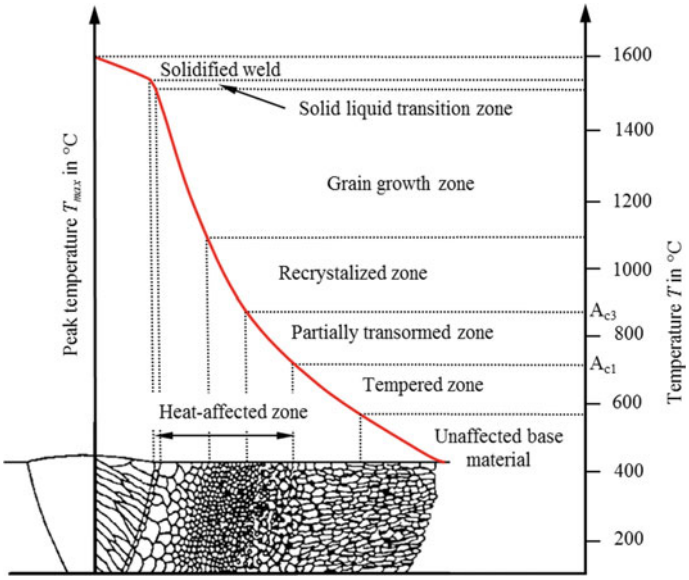

Fig. 9 Heat-affected zone (HAZ) [14]. (Color figure online)

that the heat-affected zone is similar to an ellipse and in a radial direction from the contact between laser and the blank; the grain size is very big and elongated.

Especially, for the comparison from details A (base material) and B (heat-affected zone), the grain growth can be seen. Furthermore, it can be assumed that after the heat treatment, no phase transformation has occurred. The grain growth is also shown in the longitudinal section in Fig. 8 (right). In addition, a uniform depth of the heat influence is achieved and a uniform cross-section can be assumed. The area of influence by heat treatment has a maximum depth of 0.39 mm.

Overall, the grain size distribution is similar to that of the heat-affected zone during welding (Fig. 9). Based on the grain growth, it is indicated that the temperatures in the center of the laser beam were at least above A_3 temperature. However, the measured temperatures are not above the A_3 temperature, which may be due to the fact that the measuring point is not exactly in the center of the laser beam and was on the surface of the sheet. The micrographs clearly show that grain growth has occurred. Afterward, there is a small transition area to the unaffected base material. However, no hot cracks are visible in the middle of the laser beam (temperature under melting temperature), this is very important for afterward forming processes.

To investigate the change in hardness, micro-hardness tests were carried out in accordance with DIN EN ISO 6507–1 (Fig. 10). The results show that the hardness increases about 34% toward compared to the base material. The reason for the different hardness is the different cooling rates in the middle and at the edge of the heat treatment.

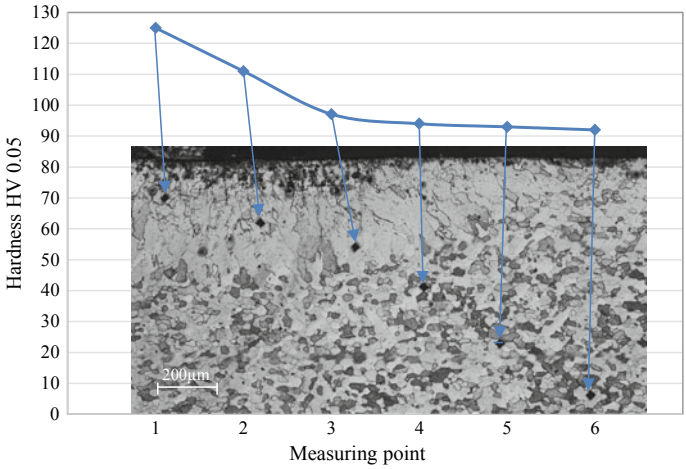

Fig. 10 Measured hardness. (Color figure online)

4 Summary and Outlook

In this paper, the new production technology RRPF is presented, which has the aim to produce profiled hollow components with low sheet thinning and homogeneous component properties. Previous investigations carried out that the wrinkling control is necessary during the preform production to achieve an evenly wrinkled preform. The approach is to change the local material properties by laser heat treatment. This changes the buckling stability and the number, position, and shape of the wrinkle can be influenced. A simplified laser heat treatment is shown and investigations of the laser seam geometry, temperature, microstructure, and hardness were performed. The main findings are:

- There is no material melting with the selected laser parameters.
- Heating and cooling of the material are very fast, about 0.15 s.
- Grain growth occurs radially to the contact point of the laser beam.
- A uniform depth is created in the longitudinal direction.
- The hardness in the heat-affected zone increases up to 34%.

The next step will be to calibrate a simulation model using these data in order to vary numerically individual process parameters. Furthermore, it will be necessary to find out how the laser heat treatment has to be done in order to influence wrinkling during the preform production.

Analysis of Tube Spinning

E. C. Sarıyarlıoğlu, O. Music, and M. Bakkal

Abstract Tube spinning is a bulk deformation process used to produce seamless, cylindrical, conical, and contoured tubes. Over the last six decades, tube spinning process has been applied in a wide range of engineering applications; especially in automotive, aerospace, and nuclear industry. However, the process has seen little change, and despite a large volume of literature investigating the process, understanding of the process mechanics is limited and the key references have been published about 50 years ago. This paper investigates the process mechanics, looking into the mechanism of deformation. The process is investigated using a numerical model using an implicit time integration and Arbitrary Lagrangian–Eulerian scheme (ALE). The numerical model has been developed and validated against physical trials. The maximum difference between tube geometry predicted by the model and measured in the trials is 4%. Model results further show that both equivalent plastic strain and plastic strain rate are concentrated in the region immediately under and ahead of the roller and that the process reaches a steady state early in the process. The stress state is dominated by compressive normal stresses in all three directions.

Keywords Tube spinning · Flow forming · Power spinning

1 Introduction

The term *metal spinning* refers to a group of forming processes used for the production of hollow, axially symmetric sheet, and bulk metal components. The basic spinning technique involves clamping a sheet, plate, or a tube against a mandrel on a spinning plate, and gradually forming this workpiece against a mandrel surface using an idle roller (Fig. 1a). The process can be performed in a single step or a series of steps, depending on the process window for a given material.

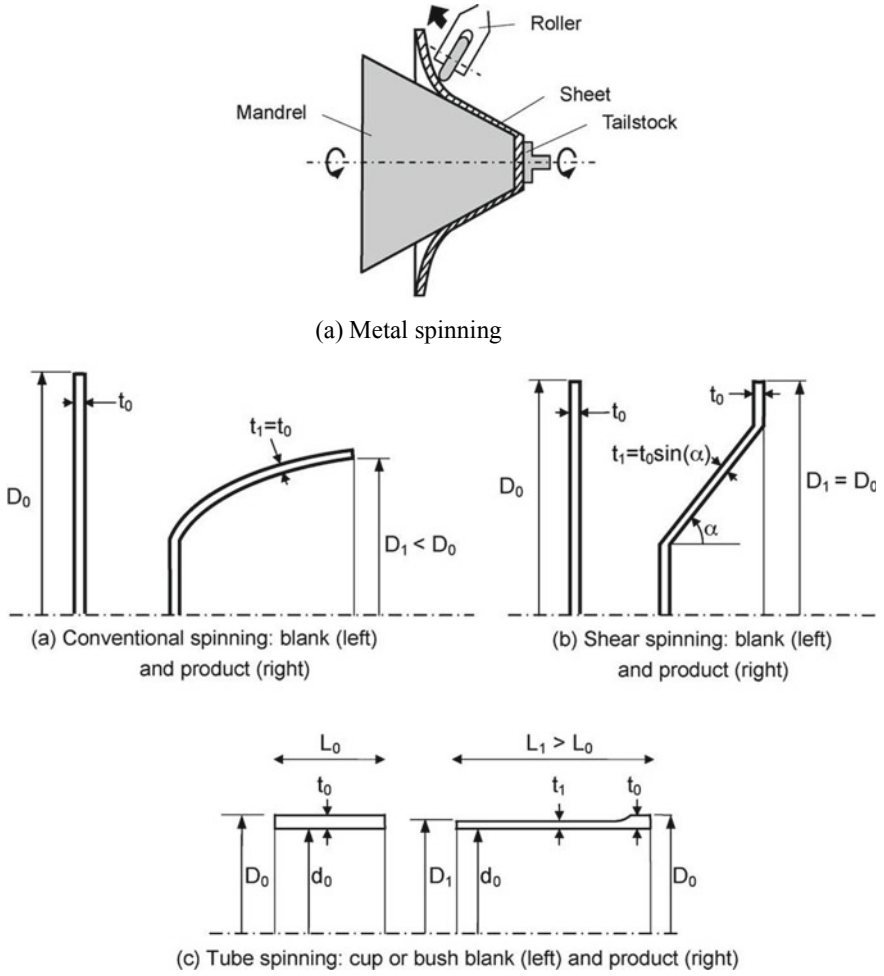

Fig. 1 Metal spinning processes

Three processes that the term metal spinning refers to are conventional spinning, shear spinning, and tube spinning (Fig. 1b). Conventional spinning is used to form a sheet metal blank into a target shape by gradually pushing it onto a mandrel in a single step or multiple steps while largely preserving the sheet thickness. Shear spinning, on the other hand, reduces the blank thickness, and the thickness is determined by the wall angle; the angle between the wall of the component and the axis of rotation. Both processes are classified by [6] as sheet metal forming processes, together with bending, stretching, and drawing [5]. While conventional spinning

involves bending, stretching, and compressive stresses, shear spinning, as the name implies is dominated by shear stresses with some bending.

In tube spinning, a roller pushes the outer wall of the tube against a rotating mandrel while moving along its length. As the roller pushes against the tube and moves forward, wall thickness is reduced, and the tube elongates. The material flows mainly axially (along the mandrel length) and any increase in the internal diameter of the tube is undesirable. Tube spinning process is used in the production of seamless, cylindrical, conical, and contoured tubes (Fig. 3).

There are two approaches to spinning tubes; forward and backward tube spinnings (Fig. 2). In forward tube spinning, the tube elongates in the same direction as the roller movement (Fig. 2a). This method requires a closed-end tube with a base or an internal flange (cup) to allow the tube to be clamped against the mandrel (tailstock). This method is preferred for the production of high-precision tubes but requires a mandrel covering the complete length of the tube. In backward tube spinning, the tube is clamped between the serrated driven part and the rollers in order to transmit the torque (Fig. 2b). The tube elongates in the opposite direction as the roller movement towards the unsupported end of the mandrel. There is no length limit of the final tube. Therefore, this method is preferred for the production of long tubes. Achievable geometries in tube spinning are shown in Fig. 3.

As mentioned before, the mechanics of conventional and shear spinning processes is largely similar. However, the mechanics of tube spinning is different. Reference [2] shows that tube spinning is a combination of extrusion and rolling and treats it as a bulk-forming process in their investigation [2]. This is further supported by Kalpakcioglu [3, 5] who shows that the mode of deformation in tube spinning resembles extrusion [3, 4].

Over the past 60 years, a large volume of research on tube spinning has been published. Reference11 [10] reports on studies on the mechanics of spinning and existing and novel machine configurations [8]. They conclude that the mechanics of the process is complex, and it is clear that it is still largely not understood and as such requires further research.

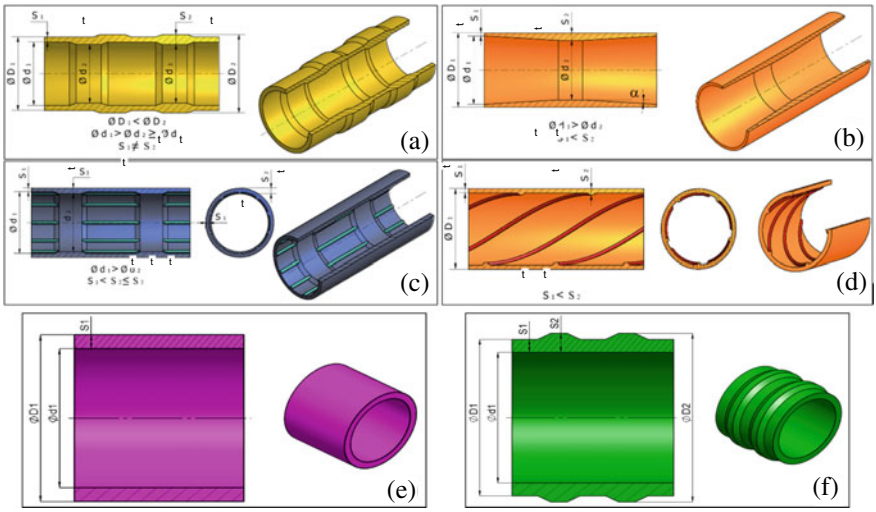

Fig. 3 Feasible geometries in tube spinning: **a**, **b**, **c**, **d** geometries produced by using specialised tube spinning processes and mandrels [9]; **e**, **f** geometries produced using conventional mandrels. (Color figure online)

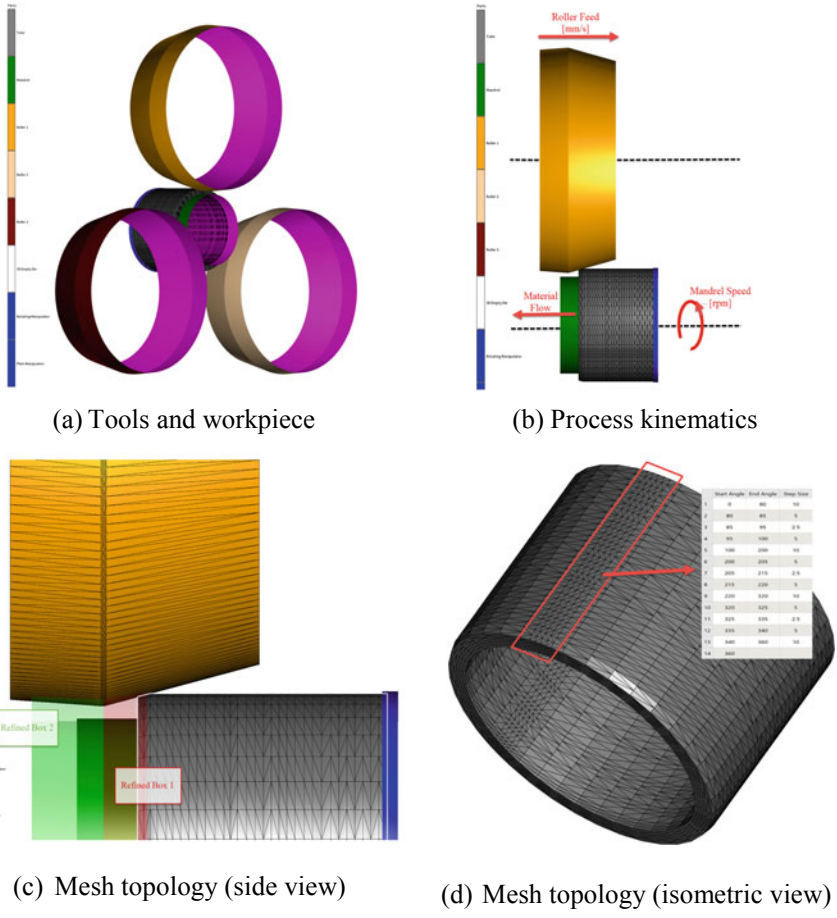
This paper is aimed at developing a model of the backward tube spinning process and investigating its mechanics; mechanism of deformation. The investigation focuses on backward tube spinning; however, the general principles applied here should be applicable to forward tube spinning as well.

2 Modelling Approach



Given the relatively complex nature of deformation in tube spinning, analytical models are limited to estimates of forming forces and power in tube spinning. A detailed analysis of the process mechanics requires the use of numerical models. However, numerical models of tube spinning require long solution times. Two main reasons for this come from the incremental nature of tube spinning: continuously changing contact conditions requiring repetitive iterations between the roller and the tube and the long path traversed by the roller requiring a large number of steps in the numerical solution.

A potential solution to this problem was proposed by Houillon et al. [1] using an Arbitrary Langrangian–Eulerian (ALE) formulation [7]. This formulation allows for a significant reduction in both the number of elements and remeshing attempts. In this study, commercial software package Transvalor Forge is used to model the backward tube spinning process. This software package uses the approach proposed by Houillon et al. [1].

2.1 Numerical Model

Figure 4 shows the main components of the model (Fig. 4a). The model uses an implicit time integration scheme, with an isotropic elastic–plastic material. The tools and mandrel are assumed to be rigid, and the only deformable body is the tube, meshed using tetrahedral elements. To allow the model to accurately capture the behaviour around the high stress and strain gradient areas, elements are concentrated in the region around the nose radius of the roller, both in the radial and axial directions (Fig. 4c) and the circumferential direction. The three rollers forming the tube are located at the same radial and axial position and are idle.

Process parameters, roller, and tube geometry used in the analyses are given in Table 1.

Table 1 Process parameters, tool, and tube geometry

Process parameters	Roller feed ratio (mm/rev)	Mandrel rotational speed (rpm)	Roller feed (mm/s)	Roller axial offset	Number of rollers	Thickness reduction (%)
	0.5	120	0.25−1	0	3	0.25−0.75
Total geometry	Mandrel diameter (mm)	Roller max. diameter (mm)	Attack angle (degrees)	Roller nose radius (mm)	Exit angle (degrees)	
	96.6	225	15	5	4	
Tube geometry	Inner diameter (mm)	Outer diameter (mm)	Thickness (mm)	Length (mm)		
	96.6	112.6	8	100		

Table 2 Flow curve coefficients for Hänsel–spittel equation

Coefficient	A_1	m_1	m_2	m_3	m_4	m_5	m_6	m_7	m_8	m_9
Value	929.8	−0.00064	0.0089	0.0011	−0.008	0	0	0	0	0

Material behaviour was modelled assuming elastic–plastic isotropic behaviours, and the flow curves for 42CrMo4 were described by the Hänsel–Spittel equation, with material coefficients shown in Table 2, using the material library available in the software. The computational time for the final model used was 13 h on a 12-core Xeon processor using parallel processing.

Even using the ALE approach, a typical tube spinning analysis requires a relatively large number of elements and steps, leading to high computational time. To reduce computational time, only the transient and steady-state stages of the process were simulated. This approach is proposed based on the examination of a force–time graph for a roller in tube spinning (Fig. 5). The figure shows that for the specific configuration used in this study, beyond 25 s (30% of the total roller stroke), the process seems to reach a steady state. Therefore, modelling only a fraction of the process, coupled with a short tube length reduces the computational time significantly, allowing for a detailed three-dimensional mesh to be used, and improving the overall accuracy of the model.

Since this approach does not model the process from the beginning to the end, it does have its disadvantages; however, if the purpose is to study the process and its mechanics, it should be sufficient.

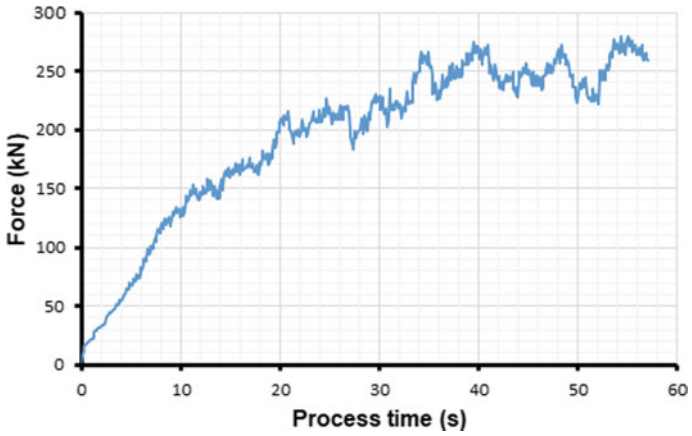

Fig. 5 Roller radial force versus time. (Color figure online)

2.2 Numerical Model Validation

The model is validated by first performing a sensitivity study on numerical parameters, followed by a comparison with physical trials on an industrial high-precision three-roller tube spinning machine.

A sensitivity study was performed on three parameters; element size under the tool, size of the elements through the thickness and along the circumferential direction. For a sensitivity of approximately 5%, element size in the locally refined zone underneath and around the roller should be selected so that there are at least three elements under the roller nose radius in both circumferential and axial direction, and at least six elements through the thickness. The strain distribution was observed to be sensitive to element size, due to its non-linear distribution through the thickness.

Comparison of tube profiles from physical trials and numerical model results shows agreement within ~96% of physical trials. The model captures the geometry and the potential defects well. Both tube geometry and roller radial force were measured, and the comparison is shown in Figs. 6 and 7.

Comparison of tube profiles for physical trials and numerical model results shows that the maximum difference in diameter is just under 2%. The model captures the bulge at the outer diameter and the ridge at the inner diameter accurately. The length of the tube is not predicted as accurately, with the maximum difference of just over 11%. This discrepancy occurs because of the difficulty in accurately adjusting the roller starting axial position in physical trials and the fact that even a small difference in the starting position makes a significant difference in tube length.

Comparison of roller radial force measured in physical trial with numerical model prediction shows a difference of just under 30%. While this is relatively high, both forces show similar trends. This is considered to be acceptable for the purposes of this study. The difference is likely because material property values were extracted

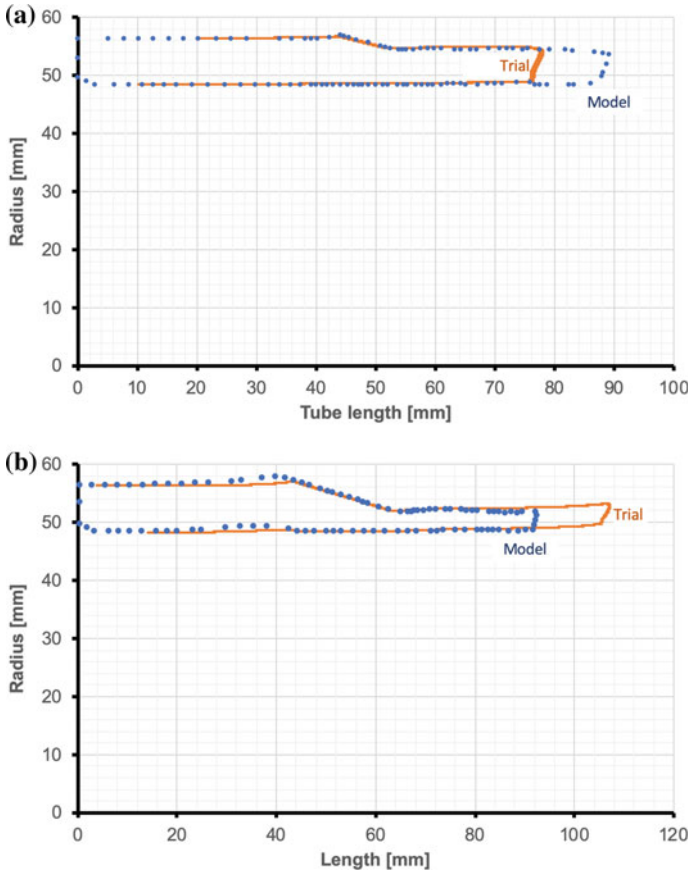

Fig. 6 Tube geometry for **a** 25% thickness reduction and **b** 60% thickness reduction. (Color figure online)

from the literature. A separate set of material tests will be conducted to determine the material properties and re-run the numerical analyses.

3 Process Mechanics

Having described the modelling approach and validated the model, the model can now be used to study the mechanics of the process. There are two main aspects of the mechanics of tube spinning: mechanism of deformation and mechanism of failure, the latter leading to an understanding of the process operating window.

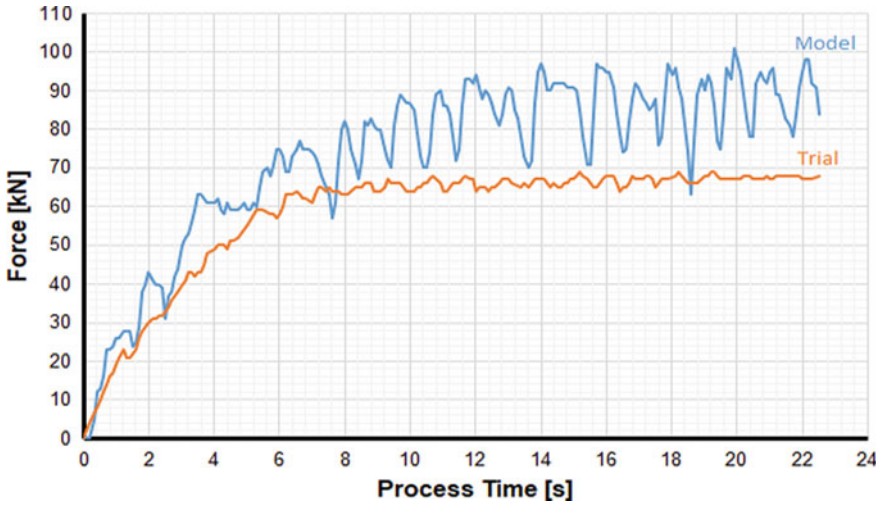

Fig. 7 Roller radial force for 25% thickness reduction. (Color figure online)

3.1 Deformation Mechanism

To examine the effect, the roller has on the tube as it is spun, contour plots of equivalent plastic strain, equivalent plastic strain rate, and stresses generated in the tube are used. All plots show a radial cross-section of the tube along its axis and the distribution of strain, strain rate, or stress in this cross-section.

A plot of equivalent plastic strain and strain rate is shown in Fig. 8. Strain and strain rate are shown for three stages in the process, early-stage, mid-process, and

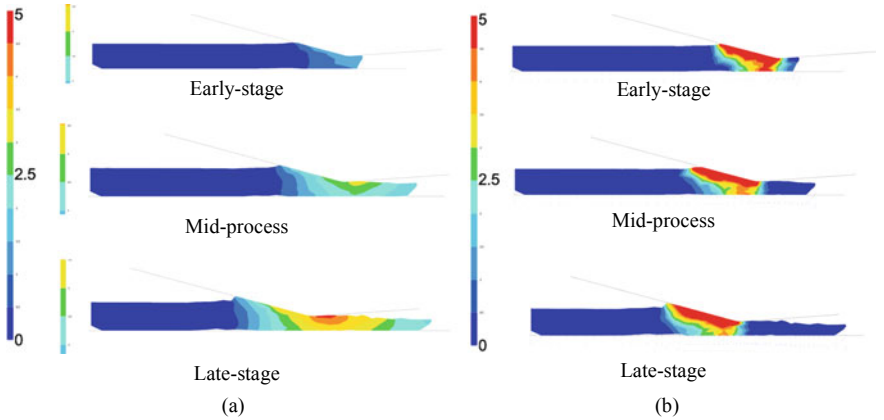

Fig. 8 Equivalent plastic strain **a** and strain rate **b** distribution in tube cross-section at different stages in the process. (Color figure online)

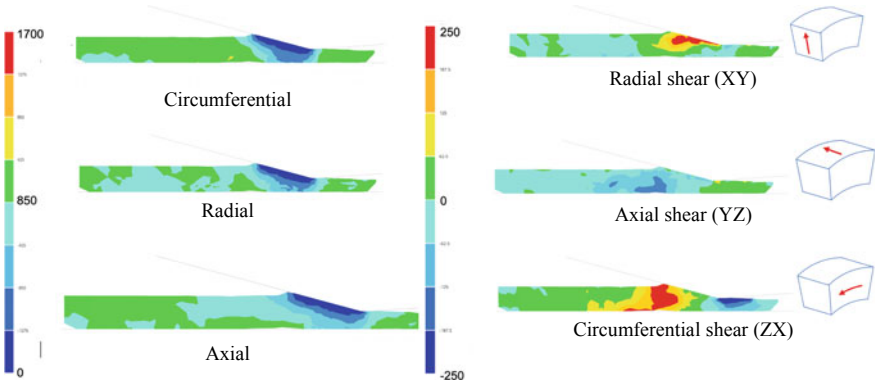

late-stage, corresponding to 30%, 60, and 90% of the roller stroke along the tube. Three main conclusions can be drawn from the results in Fig. 8a, b.

The equivalent plastic strain distribution and therefore deformation through the thickness of the spun section is highly non-uniform, with the strain gradually increasing from the minimum at the inner diameter to the maximum at the outer diameter. This agrees well with measurements and observations by [8, 1]. As the roller moves forward, the strain levels increase, reaching 3.5 at the inner diameter and 5 at the outer diameter.

Equivalent plastic strain rate distribution shows the instantaneous deformation in the tube providing information about the mechanism of deformation. As suggested by the strain results described previously, the tube deformation is concentrated in the region ahead of and immediately under the roller.

Perhaps more importantly, the strain rate distribution does not seem to change as the process progresses from beginning to end. While the plot of roller force vs. time in Fig. 5 shows that the steady state is reached at just over 80% of roller stroke, these strain rate plots suggest that the mechanism of deformation does not change throughout the process; that steady state is reached even at the early stage. The increase in force observed in Fig. 7 is likely caused by an increase in the contact area as the material accumulates in front of the roller, forming a bulge.

Normal and shear stresses in the tube cross-section are shown in Fig. 9 below. Two observations can be made based on these results. All three components of the normal stress are compressive, implying a stress state with high hydrostatic stress reaching up to 1700 MPa. Compared with normal stresses, shear stresses are low, at a maximum value of 250 MPa, suggesting that principal stresses are closely aligned with the tube axes.

(a) Normal stress [MPa] (b) Shear stress [MPa]

Fig. 9 Stresses in tube spinning. (Color figure online)

4 Conclusions

In this paper, to understand the deformation mechanism of the process, a numerical model of tube spinning has been developed using an ALE approach and the results are compared with the physical trials. The comparison shows that the difference between the tube geometry for FE results and physical trials is within 4%. Also, the difference of radial force measurements between FE results and physical trials is just under 30%. However, force shows a similar trend in both the numerical model and the physical trial, which considered to be sufficient for the purposes of this study.

A detailed examination of equivalent plastic strain, equivalent plastic strain rate reveals four key points:

- Equivalent plastic strain increases gradually from the minimum inner diameter to maximum outer diameter. Also, strain levels increase as the roller moves along the tube
- Equivalent plastic strain rate does not change after the process reaches the steady-state conditions. Also, the deformation is concentrated in front of and under the roller.
- In the region under and around the roller, all of three normal stress components are compressive and also, it shows that the stress state is that of high hydrostatic stress. At the maximum value, normal stress it reach values of up to 1700 MPa.
- In comparison with the normal stresses and shear stresses, the normal stresses are higher. At the maximum value, the shear stress reaches up 250 MPa.

Further studies of the process will involve a set of material tests to accurately determine the properties of the material used in physical trials, friction coefficient and most importantly, a set of trials combining the physical trials with the numerical will be done to generate an understanding of the mechanism of failure leading to an estimate of the process operating window.

Transcription of Mirror-Finished Surface onto A5083 Aluminum Alloy Plate by Friction Stir Forming

Takahiro Ohashi, Kento Okuda, Hamed Mofidi Tabatabaei, and Tadashi Nishihara

Abstract In this study, the surface smoothing effect of friction stir forming on a JIS A5083 aluminum alloy plate with a mirror-finished die was investigated. A material plate was placed on a mirror-finished die, and friction stirring was conducted on its back surface. The material deformed because of the high pressure and heat caused by the friction stir process, and the surface profile of the die was transferred to the material. The average arithmetical mean height (Ra) and maximum profile height (Rz) of the material plate surface were improved from 2 to 1 μm and 17 to 9 μm, respectively, by using a die with surface roughness and an Ra of 1 μm and Rz of 8 μm. Details of the finished surface, including its surface profile and microstructure, and the transcription mechanism were investigated using spectrum analysis with the maximum entropy method.

Keywords Friction stir forming · Mirror-finished surface · Burnishing · Spectrum analysis

1 Introduction

Friction stir welding (FSW) was developed as a new joining technology at The Welding Institute (TWI) in the UK [1]. Its applications have been extended to joining, material processing, and forming. For example, the authors have attempted to apply friction stirring to metal forming with a die and termed the process "friction stir forming (FSF)" [2–4], (see Fig. 1). Sasahara et al. [5] proposed friction stir burnishing. They utilized a burnishing tool to stir the surface of a product for metallic grain refinement and martensitic transformation for strengthening. It is well known that the conventional burnishing process is employed for not only product surface strengthening but also smoothing rough surface textures. In this study, the utilization of FSF for product surface smoothing is proposed, which can contribute to improving the surface quality of products joined by FSW.

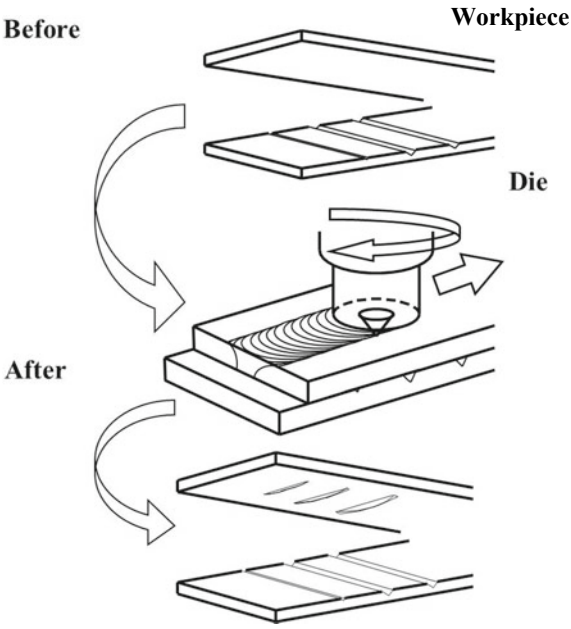

Fig. 1 Schematic of friction-stir forming (FSF) [3]

In the previous study [6], the transcription of the mirror-polished surface of SUS304 stainless steel dies onto the A5083P-O aluminum alloy plate was examined using FSF. In that study, no lubricant was applied to prevent surface deterioration during the plastic deformation of the material. A probe-less tool was utilized in the previous study to control the contact pressure between the material and die, though probe-less tools are not practical options in FSW. The probe-less tool contributed to preventing the excessively high pressure, which causes a reaction between the material and die surface to result in a rough surface of the product. Consequently, the mirror-finished surface was successfully printed on the aluminum alloy plate; however, the experimental results implied that a higher contact pressure may indicate a better surface from view to material deformation.

In the present study, a tool with a probe for higher contact pressure was utilized. Electroformed nickel die was employed to prevent the die from reacting with the material. In addition, details of the finished surface, including its surface profile and microstructure, and the transcript mechanism are discussed using spectrum analysis with the maximum entropy method (MEM).

Spectrum analysis has been utilized to evaluate the characteristics of the surface topographies of metal forming products [7–10]. For example, Kawai et al. [7] investigated the change in wavelength of the spectrum with different strain paths in the bulging process of an aluminum plate with a press. They plotted the primary frequency of the analysis at polar coordinates, revealing that an isotropic structure was created under single and biaxial tensile conditions and observing the array structure at the right angle with the main strain direction under a plane tensile condition.

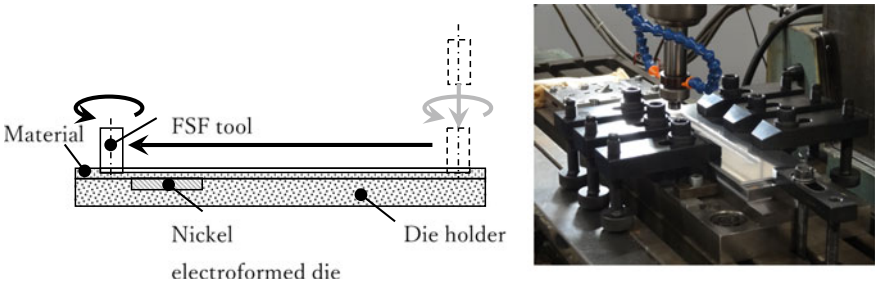

Fig. 2 Experimental setup. (Color figure online)

In addition, they reported that the primary wavelength was 15–20 times the crystal size, which was independent of the strain magnitude. Nagaki et al. [8, 9] conducted tensile and compressive tests to evaluate the surface roughness's wave of their specimens. They reported that there exists a correlation between roughness and strain magnitude; however, the primary wavelength was not found to be correlated to the strain magnitude. Nosho et al. [10] analyzed the plastic deformation behavior on the free surface of copper during plane strain compression using spectrum analysis and found that a microscopically small uneven deformation was averaged over a range longer than 20 times the crystal size. Thus, the spectrum analysis and primary wavelength of a deformed surface can contribute to the understanding of the deformation mechanism through comparison with the lengths of known structures, e.g., grain size. In the transcription of the mirror-finished surface, the surface of the product may contain the roughness's waves owing to the plastic deformation as described above, imprinted structure from the die, and remaining structure from the original material. In this study, spectrum analysis is utilized to classify the causes of the roughness of the product surface.

2 Experiment

2.1 Materials

JIS A5083P-O aluminum plates with thicknesses of 3 mm were utilized as the base metal. The mirror-finished die was fabricated by nickel electroforming. No lubricant was utilized to prevent the surface deterioration of the products.

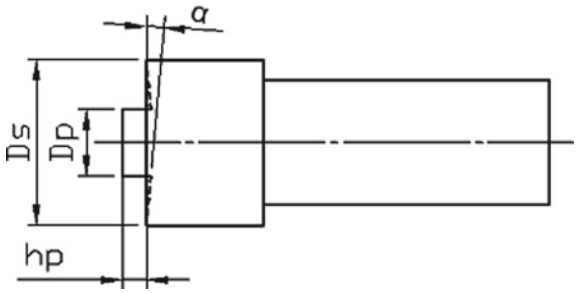

Fig. 3 FSF tool (Ds = 20 mm, Dp = 5 mm, hp = 2.5 mm, α = 5°)

Table 1 Experimental conditions

Lubricant	None
Tilt angle $\boldsymbol{\alpha}$ (°)	3
Tool feed rate $\boldsymbol{v_t}$ mm/min	50
Tool spindle speed $\boldsymbol{n}$ rpm	1,240
Tool plunge depth $\boldsymbol{z_p}$ mm	2.5
Tool rotating direction	Counterclockwise

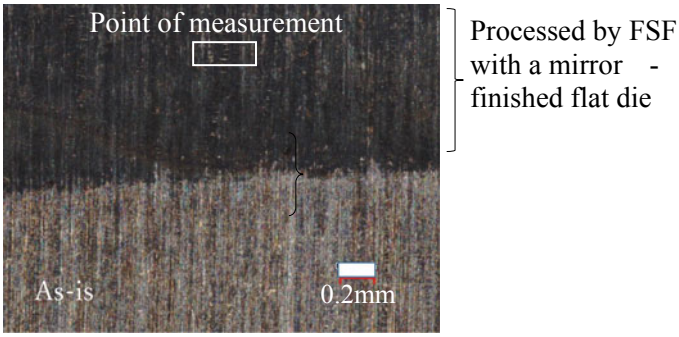
2.2 Methods

Figures 2 and 3 depict the die and the FSF tool used in the experiment. Table 1 lists the experimental conditions. The die was set in a die holder, and an approach run longer than 150 mm was conducted on the die holder to obtain stable results. A probe was prepared on top of the tool for increased contact pressure between the material and die. No adherence was observed between the material and the electroformed nickel die without lubricant. The tool rotated in a counterclockwise direction, the tilt angle was 3°, and the tool plunge depth was 2.5 mm. Additionally, the spindle speed was 1,240 rpm and the feed rate was 50 mm/min. The non-contact three-dimensional (3D) measurement system Keyence VR-3000/3200 (resolution: 0.0001 mm, repeat accuracy: 0.0005 mm, inspection field 1.9 mm × 1.4 mm) was employed for the evaluation of the surface roughness of the product. The sequence of measured surface points was processed by SPCANA (Ver.4.92) for the analysis of the power spectra of the roughness waves on the base metal surfaces, product, and die.

3 Results and Discussion

3.1 Surface Profiles and Textures

Figure 4 illustrates an image of the product surface near the boundary between the processed and raw parts. The raw part appears brighter than the processed part



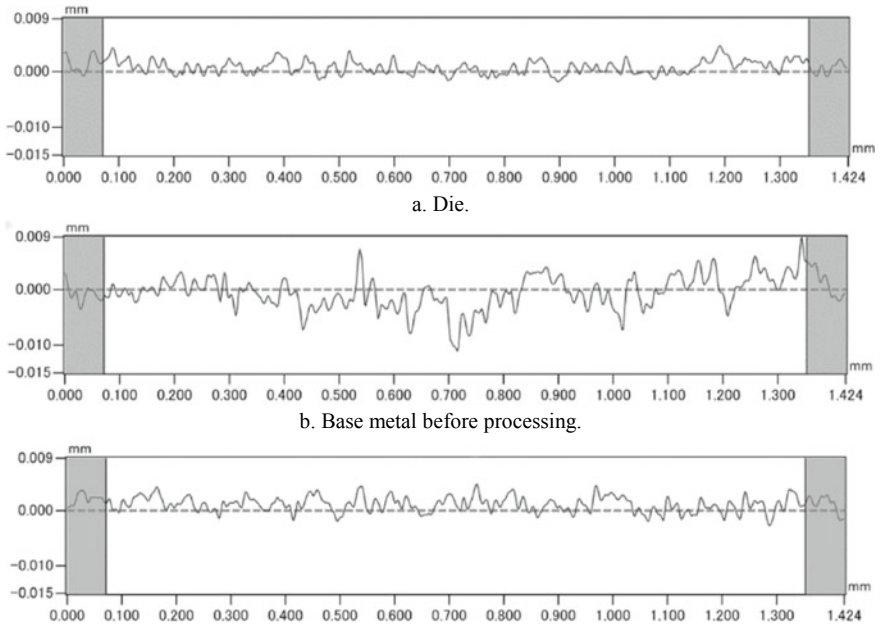


Fig. 4 Surface of product (FSF tool rotating speed: 1,240 rpm; feed rate: 50 mm/min; tool plunge depth 2.7 mm). (Color figure online)

because of its diffused reflection, and the processed part appears mirror-finished to the naked eye.

Figure 5 depicts the primary surface profiles of the die, base metal, and product after processing. The average arithmetical mean height (Ra) and the maximum profile height (Rz) of the surface of the material plate were improved from 2 to 1 μm and 17 to 9 μm, respectively, using a die with surface roughness and an Ra of 1 μm and Rz

a. Die.

b. Base metal before processing.

c. Product after processing.

Fig. 5 Primary surface profile for tool travel direction

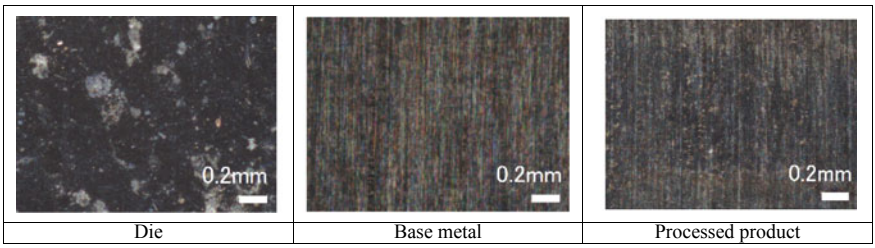

Fig. 6 Texture of the die and product. (Color figure online)

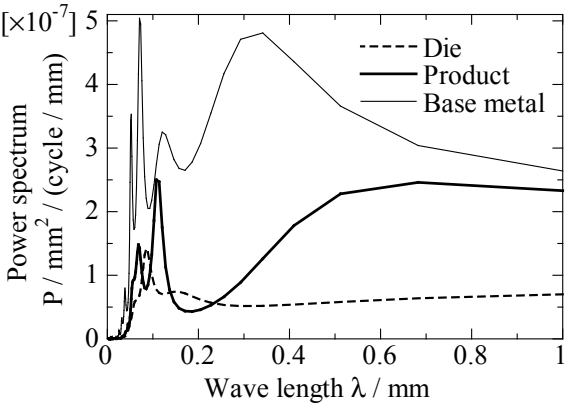

of 8 μm. Figure 6 depicts the textures of the die and product. A faint brushed pattern, which was not observed on the die surface, remained on the surface of the processed product, although the surface appeared mirror-finished to the naked eye. The power spectra of the roughness waves of each surface were evaluated to investigate the causes of this pattern.

3.2 Spectrum Analysis

Figures 7 and 8 illustrate the power spectra of the roughness waves on the surfaces of the die and product compiled using MEM. Only one peak was observed at 0.0853 mm on the die surface; however, no corresponding peak was observed in the processed part. It is thought that this peak corresponded to the surface roughness of the die with an Ra of 1 μm and Rz of 8 μm. Considering the surface roughness of the finished part with an Ra of 1 μm and Rz of 9 μm, the roughness with an Ra of 1 μm and Rz of 8–9 μm was a resolution limit in the pattern transfer of the process.

Multiple peaks were included in the graph of the original base metal, and the peaks at wavelengths longer than 0.2 mm and shorter than 0.06 mm were eliminated after

Fig. 7 Power spectrum

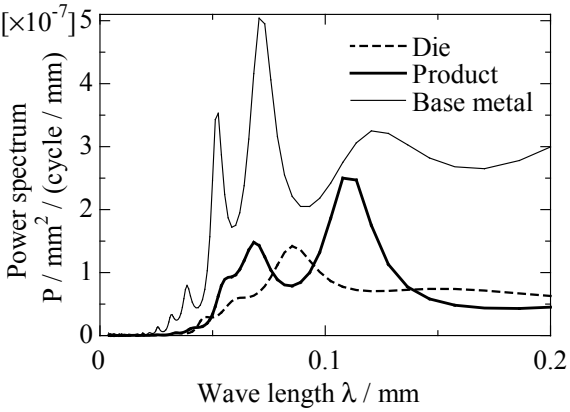

Fig. 8 Detailed power spectrum with 0–0.2 mm wavelength

processing. It is thought that the longer wavelength belonged to the large structures, e.g., surface waviness, which was removed successfully via smoothing. In addition, it is unclear what the shorter wavelength indicated. Nagaki et al. [8] proposed a model in which short roughness waves vanish and long waves are developed with plastic deformation under compression (See Fig. 9). The results of our study appear to support their model.

Only two peaks at wavelengths of approximately 0.101 and 0.0682 mm were observed on the finished part. A peak corresponding to a wavelength of 0.0682 mm appeared to exist on the original base metal. However, the peak at the wavelength of 0.101 mm did not appear to indicate any peaks on the surfaces of the die and base metal.

3.3 Microstructure and 3D Measurement of Surfaces

Figure 10 depicts the microstructure of the base metal surface and the processed product in contact with the die surface. Figure 11 illustrates the contour map compiled from the 3D measurement of the surfaces. Structures associated with the 0.101 mm wavelength were not observed in the microstructure. It has been reported that roughness waves with lengths 15–20 times crystal size are newly created during the plastic deformation on the free surface [6, 8]. Hence, there is a possibility that the above newly created wave can be associated with a peak of approximately 0.101 mm.

Besides, the compression of convex spots on the surface can shorten the concave part, as depicted in Fig. 12. In Fig. 11, the size of the convex spots, that is, red spots, and their intervals appear larger and shorter, respectively, after processing. In addition, the shift in the frequency of the peaks at shorter wavelengths after the processing can be explained by Nagaki's model, as illustrated in Fig. 9. Furthermore, it is thought that the power of the convex pattern can be reduced more easily than that of the concave pattern through compression. From these points of view, the

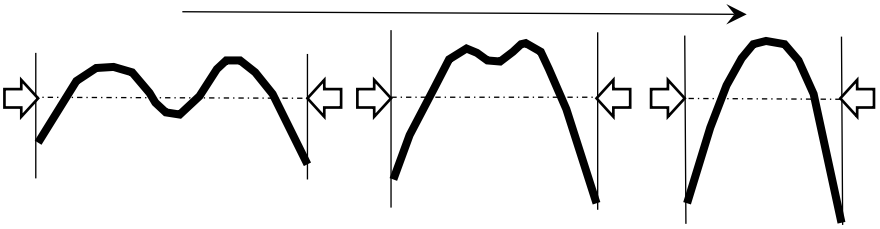

Fig. 9 Model of the change of a surface roughness wave in compression by Nagaki et al. [8]

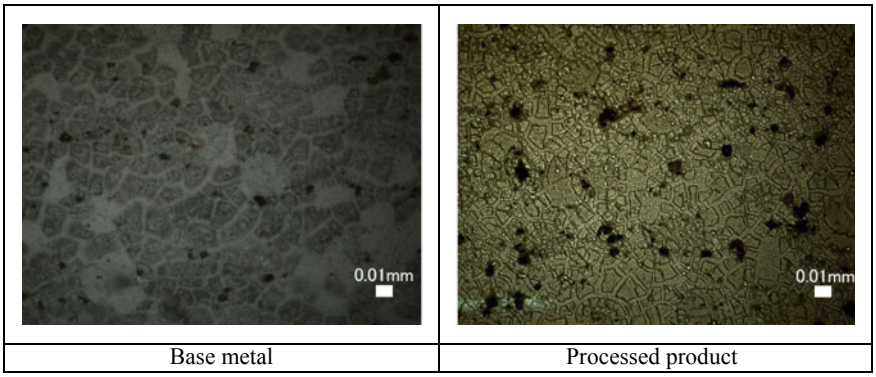

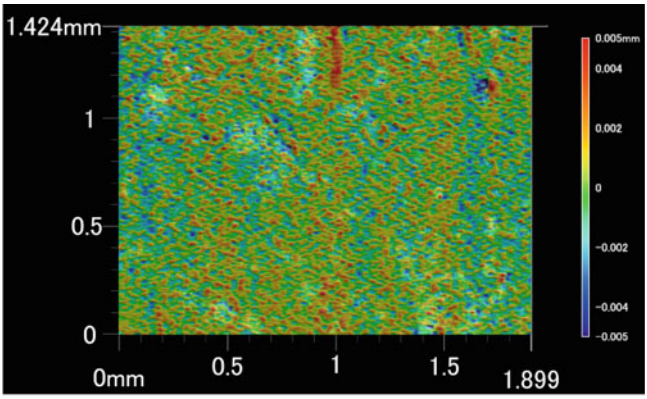

Fig. 10 Microstructure of the material surface. (Color figure online)

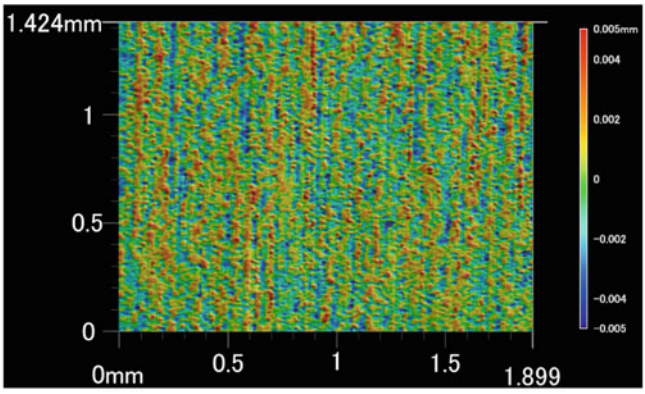
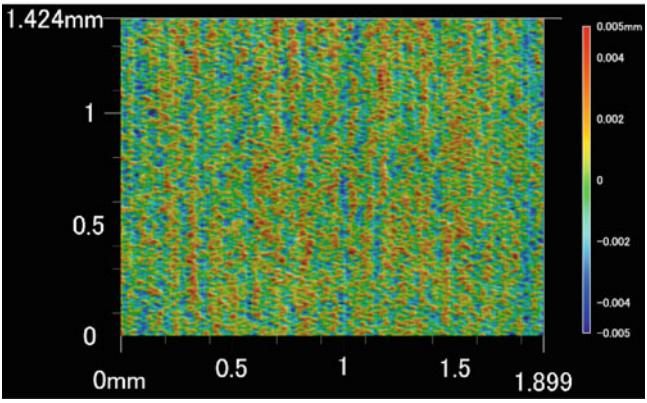
third strongest peak of the base metal is found to be associated with concave structures rather than with crystal size and remains after processing at the wavelength of 0.101 mm.



4 Summary

FSF was employed for transcription of the surface of a mirror-finished die onto a metal plate. It was confirmed that a mirror-finished surface of an electroformed nickel die was successfully transferred onto the surface of an A5083 aluminum alloy plate. Next, a non-contact 3D measurement system was used to evaluate the surface roughness of the product. A series of measured surface points was analyzed using MEM to evaluate the power spectra of the roughness waves of the base metal surfaces, product, and die Consequently,



(1) the Ra and Rz of the material plate surface were improved from 2 to 1 μm and 17 to 9 μm, respectively, by using a die with surface roughness and an Ra of 1 μm and Rz of 8 μm.

(1) Die

(2) Base metal

(3) Processed product.

Fig. 11 3D measurement of surfaces (counter map). (Color figure online)

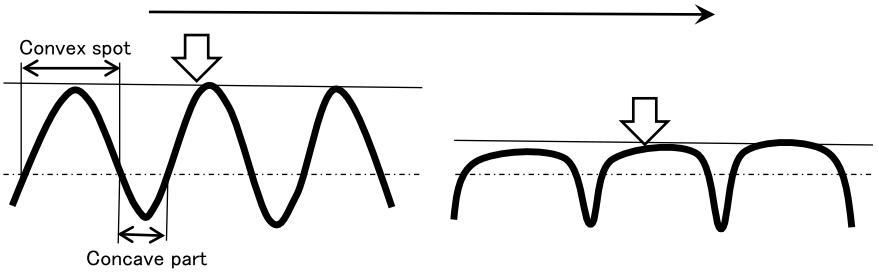


Fig. 12 Compression of convex spots of the surface and shortening of concave parts

(2) In the spectrum analysis, only one peak was observed at 0.0853 mm on the die surface, and multiple peaks were observed in the original base metal. However, the peaks at wavelengths longer than 0.2 mm and shorter than 0.06 mm were eliminated after processing. Only two peaks at wavelengths of approximately 0.10 and 0.0682 mm were observed on the finished product.

In our future work, we intend to utilize mirror-polished base metals to investigate the cause of the remaining peak on the finished product.

Combined Computed Tomography and Numerical Modeling for the Analysis of Bending of Additively Manufactured Cellular Sheets

S. Rosenthal, E. Jost, C. Saldana, T. Clausmeyer, M. Hahn, and A. E. Tekkaya

Abstract Applying additively manufactured (AM) metallic sheets with internal cellular structures are formed in a bending operation. This enables a higher degree of lightweighting potential due to design freedom and strain hardening. Computed tomography (CT) of those structures with wall thicknesses of 0.3 mm reveal manufacturing inaccuracies of the AM process between the nominal CAD and actual geometry. The CT-data shows that the geometric deviation of the unit cells is periodic. A surface model based on CT-data is used to evaluate volume-meshing strategies in a finite element model, benefiting from the periodicity of the core structure. Model simplifications due to a large number of elements within the simulation are presented and used to convert the CT-data into a volume mesh that can be used in a forming simulation. With the CT-based numerical model, the accuracy in predicting force–displacement response can be increased when compared to the ideal CAD-based model. The influence of the geometric deviation and its impact on the deformation behavior in a bending dominated forming operation is evaluated. It is demonstrated that accurate representation of the actual geometry in the numerical model is critical for a correct prediction of the bending behavior and the investigation of localization phenomena during deformation.

1 Introduction

Additive manufacturing (AM) as a process to produce semi-finished parts for a subsequent forming operation is a novel field of research. The combination of these two processes enables synergies, such as the production of complex parts with integrated functions and the increased strength by strain hardening through a subsequent forming operation. However, disadvantages such as long production times and small build chamber volumes are problems that have to be addressed. Rosenthal et al. [1] proposed a new process combination of additive manufacturing with a subsequent forming operation of additively manufactured sandwich sheets with internal cellular core structures. The feasibility of forming AM parts has been shown and the influence of anisotropic material properties on the deformation behavior was evaluated to be negligible [2]. The development and prediction of the forming behavior of additively manufactured sandwich sheets is more challenging due to different forming characteristics. The material properties of additively manufactured parts are dependent on the produced geometry [3], the process parameters, and build orientation.

The development of formable core structures requires the help of numerical simulations. To validate those simulations an accurate representation of the nominal geometry is necessary. Thus, computed tomography (CT) inspections were used to assess the as-built geometry and improve the prediction accuracy of the simulations. Due to the very fine, sub-millimeter, internal features of the sandwich sheets, a geometric deviation between the nominal CAD geometry and the AM sheets is present. The AM process suffers from manufacturing deviations of up to 0.088 mm on an EOS M290 machine [4]. On an absolute scale, this deviation may be small, but when dealing with part dimensions of 0.3 mm and smaller, this leads to differences of up to 30% and thus significantly influences local part performance. This geometric deviation leads to an insufficient agreement between the numerical simulation and the bending experiment of the sandwich structures. To investigate the effect of the geometric inaccuracy of the AM-produced parts on the bending response, X-ray CT is conducted.

X-ray CT is a non-destructive inspection technique that utilizes high-energy x-rays to visualize the internal structure and form of a component. CT is used to inspect the complex structures commonly created through AM for both geometric and internal defects [5]. Recently, CT has been leveraged for AM to gain a better understanding of the effects of structural heterogeneities innate to the manufacturing process on deviation from nominal mechanical performance, specifically in lattice or cellular structures [6]. As AM has grown in prominence, the need for non-contact metrological inspection has increased as well [7]. Thus, CT has been used as a common tool to address this need.

CT is increasingly being used to extract quantitative information about the as-built AM geometry and inform finite element models to more accurately predict component behavior, as done in this study. One significant issue in directly using CT volumes for modeling is the large datasets associated with CT and therefore an inability to create efficient models from a computational time perspective, with

many current models requiring super-computer clusters. To address this issue, much current research is using simplified or smoothed CT data to lower computational time. For example, Liu et al. [8] utilized CT to extract statistical data on geometric defects in architected lattice structures, showing the variation of strut characteristics typical of these components. Using this data, FE model geometry was modified to reflect the statistical variability of these characteristics and improve model prediction accuracy. Similarly, Hernández-Nava et al. [9] used computed tomography and image analysis methods to assess the variation of lattice structures and their effect on overall compressive deformation and failure mechanisms. They concluded that lattice defects and slight variations in strut diameters only have a small influence on the deformation behavior under direct compressive loading, but not in a forming operation.

Using this method, an accurate representation of the sandwich structure can be created and used in a numerical simulation. Since the geometry should be closer to the true geometry in the improved simulation, the majority of the remaining deviation between simulation and experiment should derive from the deviation of the material properties due to a different geometry and leave a difference between experiment and simulation. Thus, the focus of this paper is the influence of the manufacturing deviations on the bending response of additively manufactured sandwich sheets with internal core structures and the capability of the numerical simulation to predict the forming behavior based on the CT-data. The influence of geometric deviations between the nominal and real geometry is investigated to assess if further improvements on manufacturing accuracy or the material model lead to a better understanding of the deformation behavior of such sandwich sheets in a bending dominated forming operation.

2 Methods

2.1 Experiments

Bending experiments were done on a Zwick/Roell 2015 universal testing machine. A top die with a tool radius of $R_{\text{tool}} = 5$ mm was used in the experiments. The specimens rested on solid rollers to reduce the influence of the friction between the tool and the specimens. The distance of the rollers was set to $l = 37.3$ mm. The radius of the rollers was $R_{\text{B}} = 15$ mm. The desired tool displacement was set to 8 mm. The bending experiments were conducted with a constant tool velocity of $v_{\text{tool}} = 2$ mm/min (Fig. 1a).

The specimens were produced on an EOS M290 machine with default parameters delivered by EOS for a layer height of 20 µm as sheets with the dimensions 120 mm × 40 mm, from the stainless steel material EOS GP1 (1.4542/17-4PH). Figure 2 shows the geometry of the unit cells which were used in the present study—as unit cells and in the geometry of the full sheet. The sheets were cut down to smaller samples with a diamond saw blade to pieces of approximately 55 mm × 25 mm. Next to

the bending specimens single unit cells were produced from which the spherical sandwich sheets are designed (Fig. 2a). The unit cells are duplicated in the sheet plane to generate a full sandwich sheet (Fig. 2b). The unit cells are manufactured to enable the generation of high-quality CT-measurements to build a numerical model with the real geometry.

2.2 Computed Tomography

X-ray CT inspections were performed on samples in the as-built and deformed states. To accurately assess geometry, individual unit cells were inspected using a high-resolution, microfocus Zeiss Metrotom 800, which achieved a resolution of approximately 9 μm. Full-size bend samples were inspected using the higher energy

Table 1 CT inspection parameters

	Zeiss metrotom 800	Visiconsult XRH222
Resolution	9 μm	72 μm
Number of projections	1500	300
Inspected geometry (Size)	Unit cell (3.25 × 5.629 × 4 mm)	Bend Sample (50 × 20 × 4 mm)
Accel. Voltage	130 kV	221 kV
Pre-filtering	0.25 mm Cu	1 mm Cu

Visiconsult XRH222 CT in as-built and deformed states at a resolution of 72 μm to confirm the periodicity of geometric print defects, measure wall thickness, and observe global deformation. The high-resolution scan was used to construct simulation geometry and was determined to be representative of overall geometry when patterned due to the periodic nature of lattices geometries. CT Parameters from both inspections are summarized in Table 1.

All CT analyses were performed using Volume Graphics VGStudioMAX 3.2. Surface determination was done by establishing an initial ISO-50 threshold followed by a Volume Graphics advanced refinement technique. Using this determined surface, wall thickness measurements were made using a largest fitting sphere algorithm to quantitatively understand where and by how much the as-built part deviated from nominal geometry. CT volumes were converted to STL meshes using Volume Graphics and patterned for modeling.

Computed tomography was used to measure the real geometry of the additively manufactured specimens. The methodology (Fig. 3) is to prepare CT-scans of the single unit cells (Fig. 3a) and create a high-resolution surface model of the real geometry. Considering the large number of polygons of the CT-scan, the model needs to be simplified without losing or changing the geometry too much. Rosenthal et al. [1] showed that the surface roughness of additively manufactured specimens does not influence the load-bearing capacity significantly. Thus, the unit cells can be modeled without the need to consider the surface roughness, which will reduce the number of polygons drastically. This, in combination with a surface smoothing yields a surface model with approximately 30,000 polygons (Fig. 3b). Based on the surface model, a solid model with roughly 300,000 ten-node tetrahedral elements per unit cell was created (Fig. 3c).

2.3 Numerical Simulations

Numerical simulations were performed with Abaqus/CAE 2018. The mechanical boundary conditions are the same as in the experiment (Fig. 1a) with the difference of the implementation of symmetry boundary conditions for reduced computation

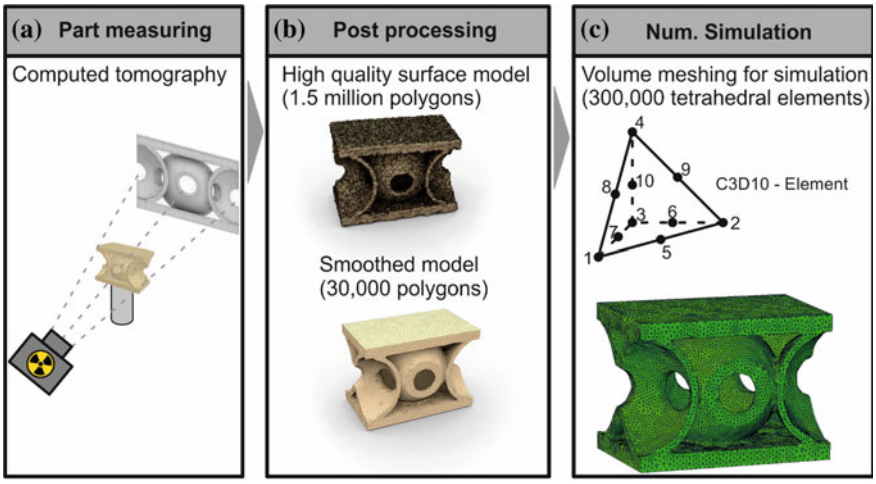

Fig. 3 Methodology for creating a volume mesh for the numerical simulation from the computed tomography scans. (Color figure online)

time. The model was simplified in a way that only two unit cells are used in the bending zone which are attached to a beam with a smaller number of volume elements (Fig. 1). Simulations were performed for:

(i) The nominal CAD-geometry, which was used to produce the specimens for the experiments.
(ii) The CAD-geometry, which was redesigned by the measurements taken from microscopic images of the structure
(iii) The geometry is taken directly from the high-resolution CT-scans of the single unit cells.

Simulations (i) and (ii) were meshed with eight-node hexahedral volume elements and reduced integration (C3D8R-elements). Simulation (iii) was done with the geometry taken from the CT-scans and meshed with ten-node tetrahedral elements (C3D10) since the geometry of the CT-scan necessitates the use of a free mesh generation. The material used in this study was the EOS stainless steel GP1 (17-4PH) and modeled with isotropic von Mises plasticity. The material behavior was characterized through tensile and in-plane torsion tests [10] (Fig. 1b). The stress–strain values were implemented in Abaqus in tabular order.

A convergence study revealed a mesh size of 0.3 mm as sufficient to model the bending operation with only a negligible influence on the load–displacement response (Fig. 4). Larger mesh sizes were not possible since the minimal wall thickness in the part was 0.25 mm and larger meshes led to failed meshing. In addition, the influence of the element formulation—eight-node hexahedral elements with reduced integration formulation (C3D8R-elements) and ten-node tetrahedral elements (C3D10) can also be neglected. The convergence study for the CT-scanned geometry yielded a mean

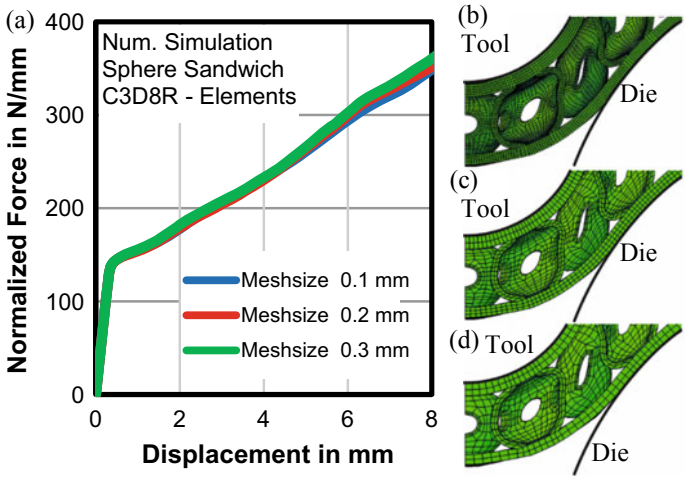

Fig. 4 Mesh convergence study. **a** Force–displacement response in the numerical simulation of the bending experiment with different mesh sizes. **b** Mesh size 0.1 mm, **c** Mesh size 0.2 mm, **d** Mesh size 0.3 mm. (Color figure online)

element size of 0.08 mm for a sufficiently accurate simulation. The mesh of the CT-scanned part needs to be that small to be able to model the small details and graded wall thicknesses of the real part.

3 Results and Discussion

3.1 Bending Experiments

The bending experiments were performed up to a tool displacement of 8 mm and led to a deformed specimen as depicted in Fig. 5. Three specimens were tested. The bending zone is clearly visible in the area where the tool was in contact with the part (Fig. 5a). The bending angle after the release of the tools was 55°. The bent zone under the punch exhibited a pronounced indentation. Clearly visible is the deformed core of the sandwich sheet. Due to the bending loads, shear deformation is introduced into the core as a result of the different strains in the top and bottom face sheet. The relative displacement led to a shearing deformation of the core. The transition from fully elastic deformation to plastic deformation due to bending is marked by the pronounced change of the slope of the force versus displacement curve at a displacement of 0.5 mm. The curve then exhibits a second almost linear, monotonically increasing section. The increase is not only due to the hardening of the material but also due to a kinematic influence.

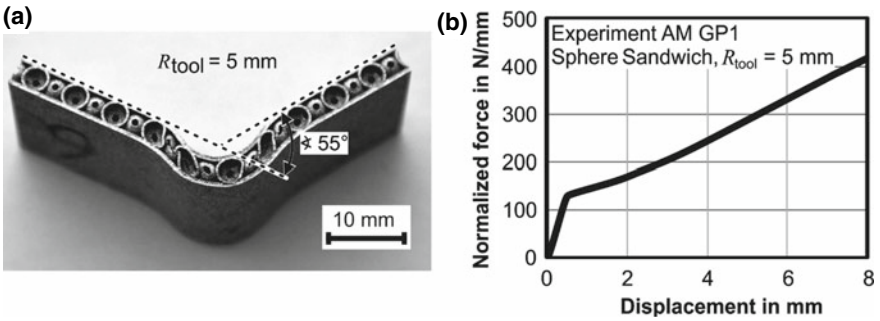

Fig. 5 Additively manufactured bending samples and corresponding load–displacement diagrams. **a** Tool radius $R = 5$ mm, **b** Experimental load–displacement diagram with $R_{tool} = 5$ mm, maximum tool displacement is 8 mm

3.2 Geometric Comparison

The specimens were investigated with CT-scanning methods and with optical microscopy. The aim is to investigate the geometric deviation of the built parts compared to the nominal CAD-geometries. The optical microscopy was done on slices in the mid-plane of a unit cell (Fig. 6a). The plane in which the wall thickness was investigated was estimated to be in the middle of a sphere. The geometric deviations are periodic across the single unit cells, which was revealed during the analysis of the CT-scans as well as during the investigations of the micrographs (Fig. 6b). As described in Sect. 2.2, the segmentation of the CT-scans yielded a surface model with roughly 1.5 million polygons, which was not possible to be transferred into a volume mesh for the numerical simulation. Therefore, the model was smoothed and edited such that a volume mesh could be generated (Fig. 3).

The CT-scans of the unit cells were compared to the nominal CAD-geometry (Fig. 7a), and the model that was used in the simulation (Fig. 7b) was compared against the nominal CAD-geometry (Fig. 7c). In general, the agreement between the CT-scans and the nominal CAD-geometry was good. During the manipulation of the high-quality surface model, the boundaries were flattened to be able to assign the correct boundary conditions at the symmetry planes. This yielded higher deviations at the boundaries of the CT-scanned part but a good approximation of the geometry in the

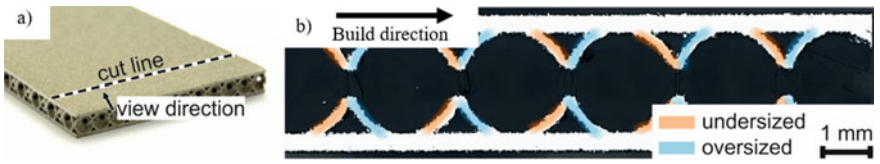

Fig. 6 **a** Area for the wall thickness measurements with optical microscopy, **b** periodic wall thickness deviation of the core wall thicknesses. (Color figure online)

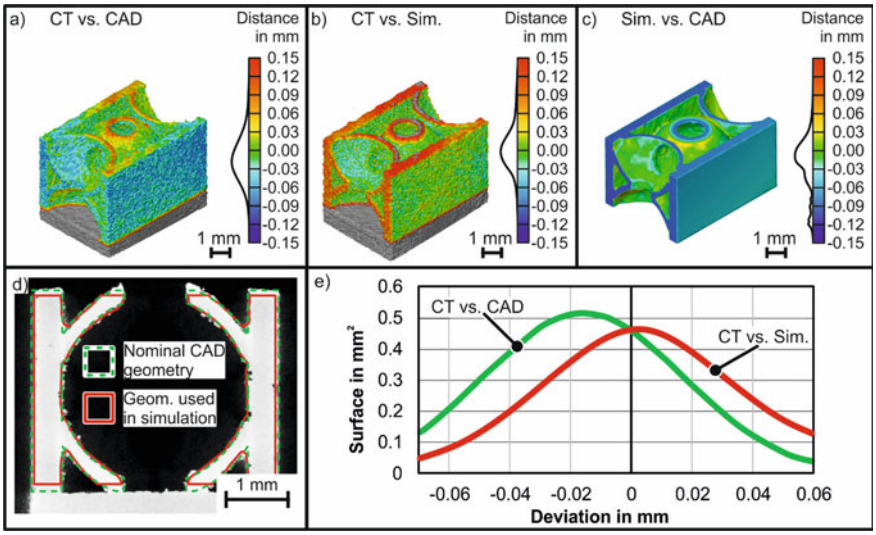

Fig. 7 Comparison of used geometries, **a** CT-scan versus nominal CAD geometry, **b** CT-scan versus model used in simulation, **c** simulation model versus nominal CAD-geometry, **d** Slice through the unit cell and overlayed geometries, **e** surface deviations. (Color figure online)

rest of the part (Fig. 7b). The comparison of the simulation model and the CT-scanned part with the nominal CAD-geometry revealed a slightly undersized real part.

3.3 Wall Thickness Measurement

The specimens were cut with a diamond sawblade and embedded into resin (Fig. 8c). The core wall thickness was measured ($n = 50$ measurements) and the thickness of the face sheet ($n = 10$ measurements) (Fig. 8a). The box plots (Fig. 8a) show the maximum, minimum, median, upper and lower quartiles, and mean values. The wall thickness of the core shows a large deviation of the measured values. The nominal value of the core wall thickness should be 0.25 mm. The mean value of 0.24 mm is close to that value but the scattering is large. The histogram (Fig. 8b) shows the thickness distribution and the absolute and relative frequency of the measured values. The mean value of 0.47 mm is under the nominal face sheet thickness value of 0.5 mm. The global distribution of the measured values shows a periodic deviation of the values. The core wall thicknesses are oversized in areas where the wall of the spheres grows toward the face sheet (Fig. 6) and undersized where the wall thickness grows into an unsupported area.

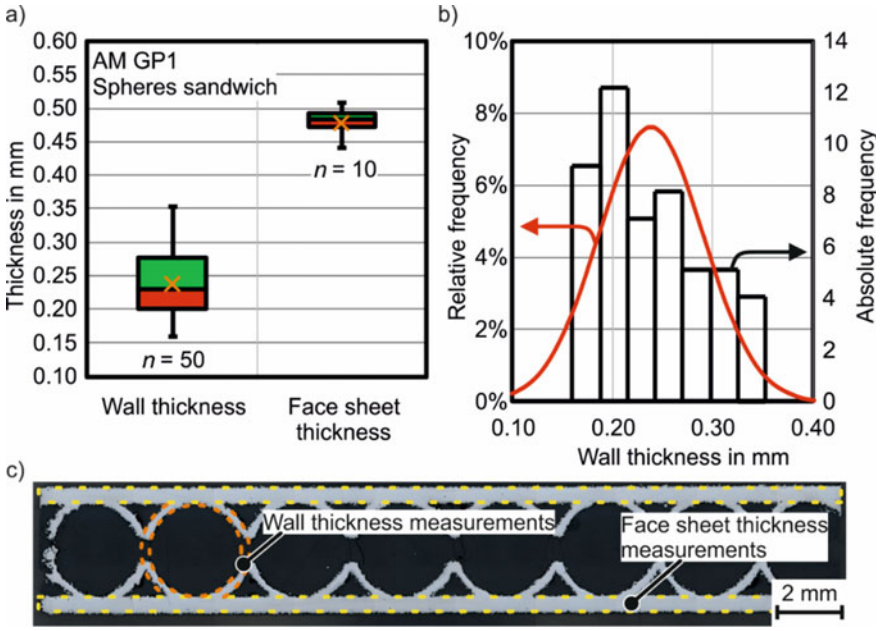

Fig. 8 Thickness measurements of the spherical sandwich structure. **a** Box-plot of the wall thickness and the face sheet thickness, **b** histogram of the wall thickness distribution, **c** picture of the cut sheet with locations of the measurements. (Color figure online)

3.4 Numerical Simulations

Three different simulation setups were done as described in Sect. 2.3. Models resulting from the nominal CAD-geometry, the geometry from the measurements made by optical microscopy, and the geometry resulting from CT-scans. The focus is to obtain the load–displacement response (Fig. 9) and the deformation behavior. The force is normalized to the width of the specimens to ease comparisons. Taking a closer look at the magnifications of the diagram (Fig. 9b) in the beginning of the experiment, the diagrams reveal different stiffnesses in the elastic range. The geometries tested in the experiment have a lower stiffness $^{\Delta F}/_{\Delta x} = 288$ N/(mm · mm) than the simulations predict (Fig. 10), where F is the force in the elastic range and x the corresponding displacement (Fig. 9b). The values for the stiffness calculations were taken from linear regression between 50 N/mm to 100 N/mm. The stiffness of the part simulated with nominal geometry had the highest stiffness with $^{\Delta F}/_{\Delta x} =$ 466 N/(mm · mm). With a stiffness of $^{\Delta F}/_{\Delta x} = 375$ N/(mm · mm) the other geometries were in between the aforementioned. Thus, the geometric deviation influences the stiffness of the geometry during the elastic deformation significantly. Additionally, Young's modulus used in the simulation overestimates the real material tensile

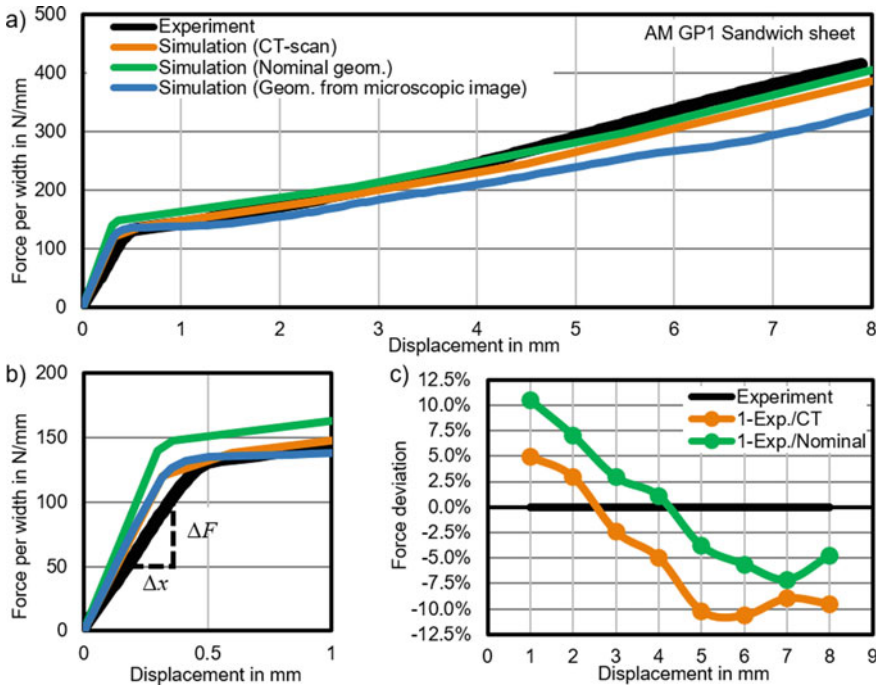

Fig. 9 Load–displacement diagrams of the bent spherical sandwich sheets in three-point bending, $R_{tool} = 5$ mm, maximum tool displacement is 8 mm, **a** experimental and numerical results, **b** magnification: 0 mm–1 mm displacement, **c** deviation between experiment and simulation. (Color figure online)

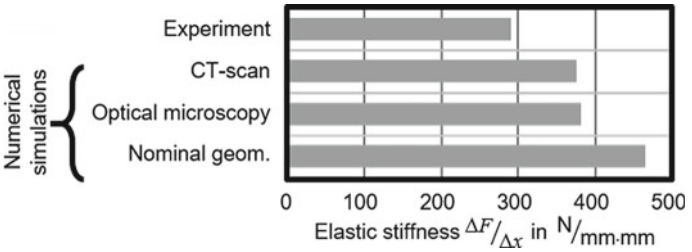

Fig. 10 Elastic stiffness of the spherical sandwich sheet in the experiments and simulations

behavior measured in tensile tests. Since the characterization was done for specimens without a core structure, the thermal history between the specimens with core structure differs from the dogbone specimens. The finer inner structure of the core possibly leads to a lower cooling rate, since the surrounding powder isolates the part and therefore probably yields a softer material behavior, which in return leads to a reduced Young's modulus. Similar results have been discovered during an inverse

parameter identification of the flow curve to compare the material properties of solid tensile tests and tensile tests with internal core structures.

The force at which the specimens started to deform plastically was nearly identical for the simulations with the geometries that were made from the CT-scans and the simulations with the geometries that were constructed based on the measurements done by optical microscopy. The geometry from the optical microscopy measurements showed a horizontal slope until 1.5 mm displacement. The core structure in this case collapsed under the normal loads at the beginning of the bending process since the wall thicknesses were too small to withstand the load from the tool. The simulation of the CT-scanned geometry overestimates the experimental loads at the beginning with a difference of 5% (Fig. 9c). After a tool displacement of 2.5 mm, the forces from the simulation started to underestimate the experimental loads. This is possibly caused by a different hardening behavior of the material in experiment and simulation. It is unlikely that the change in slope is a result of a different geometry, on the one side because the unit cell geometry is based on an accurate CT-scan. On the other side, the slope of the force–displacement from the simulations based on the CAD- and CT-scan geometry are almost parallel until a tool displacement of 6 mm, just shifted by approximately 5% (Fig. 9c). Therefore, further investigations need to be performed on the characterization of the materials flow behavior.

3.5 Deformation Behavior

CT-scans of the deformed bending specimens were performed after the experiments and are compared to the deformation states from the simulations (Fig. 11). Thickness variations of the ct-scan after the bending experiment possibly result from a lower resolution of the projections, therefore also the edges in the projections are not that crisp and sharp which leads to wall thickness overestimations of the resulting part. The influence is negligible, since the comparison is qualitative. The deformation behavior was qualitatively almost identical to each other. The regions right and left to the middle axis were deformed in a shear-dominated state. The initially spherical holes in the core deformed to ellipsoids, independently from the manner of geometry used in the simulation (Fig. 11a–c). The unit cell directly underneath the tool deformed under a compression load (Fig. 11a, c). This behavior cannot be investigated in the simulation based on the CT-scan (Fig. 11b) because the boundaries of the unit cell had to be trimmed to be used in the simulation (see Sect. 3.2). The bending angles and the radii were nearly identical.

Summarizing the evaluation of the deformation behavior, the deformation and mechanics were almost identical and independent of the methodology used to describe the geometry. One main deformation mechanism is shearing due to the relative movement of the face sheets.

4 Conclusion and Outlook

The investigations in this study dealt with the bending of additively manufactured metallic sandwich sheets and the influence of geometric deviations between the real and nominal CAD-geometry on the prediction accuracy of the bending forces in three-point bending. CT-scans of the 3D-printed specimens were performed to evaluate the additive manufacturing accuracy. It was found that there is a periodic pattern to the geometric deviations between the nominal CAD-geometry and the as-built parts. Numerical simulations using the geometry from the CT-scans showed a higher prediction accuracy of the bending forces, for displacements up to ~4 mm than the simulations that were performed with the nominal CAD-geometry. This is due to the fact, that the simulations were done with the real and correct geometry. Up to a tool displacement of 4 mm. the differences between experiment and simulation are approximately ±5%. The experiments show higher strain hardening values than predicted by the numerical simulations. The material for the simulation was characterized with flat tensile test specimens, and therefore, the material behavior in the fine cellular core of the sandwich sheet is assumed to be the same as a solid additively manufactured part. From the numerical results, it can be seen that the initial yield forces were very similar between the experimental and numerical results, but the forces in the further stages of the bending process were slightly different.

The deformation behavior is independent of the methodology that is used to create the geometry and mainly a result of shearing and relative movement of the face sheets. An important result of this study is that the use of CT-scans to describe additively manufactured geometry is a tedious and time-consuming task. This methodology results in FE-mesh with a high number of tethrahedral elements and therefore a very time-consuming numerical simulation. This results in a better approximation of the bending forces but does not show benefits in describing the deformation behavior of the core structure. It still needs to be investigated if the remaining deviation between experiment and simulation can also be attributed to an inaccurate description of the material behavior.

Future research will deal with the correct description of the material behavior in dependency of the geometry of the core structure, to further increase the prediction accuracy of the bending forces as well as unloading experiments to determine the springback behavior. Due to the different geometry of the sandwich core structure, different thermal gradients emerged inside the parts, which resulted in different cooling rates and therefore slightly different material behavior, which needs to be proofed in further investigations. This probably results in the remaining differences between experiment and simulation. Another field of research is the development of indicators to evaluate the strain to failure values to predict the maximum allowed strains during a bending operation.

Acknowledgments This paper is based on the results of the project TE 508/63-1, which is kindly supported by the German Research Foundation (DFG). The support of Christopher Saldana by the Dortmund Gambrinus-Fellowship to establish the scientific exchange is highly acknowledged. We thank Gerd Witt and Sebastian Platt of the Institute of Product Engineering, Universität Duisburg-Essen for providing the additively manufactured specimens.

Cutting Blades for Food Processing Applications Manufactured Using Innovative Spin Forming

Tim Rostek, Hanna Makeieva, and Werner Homberg

Abstract Cutting blades for various food processing applications are primarily manufactured by standardized grinding processes. This results, on the one hand, in time-consuming and hence expensive production and, on the other hand, in the surface roughness not being optimized in a microbiological manner. This leads to high healthcare costs for foodborne infections. Further, the strength of the cutting blades is additionally less-than-ideal, which causes a high expenditure on wear. Current research work at the Department for Metal Forming Technologies (LUF) is focused on innovative flow-forming processes which have a high potential for manufacturing parts with an excellent surface roughness in short process times. Along with the process-integrated thermal treatment, this is fundamental for the research and development of improved manufacturing technologies for high-performance cutting blades. This paper looks into innovative process strategies for manufacturing parts with locally graded characteristics, improved surface roughness characteristics, and greater strength of the cutting edge.

Keywords Cutting blades · Flow-forming · Incremental forming · High-strength steels · Work hardening

1 Introduction

Knives and cutting tools are used in a wide variety of applications in the food industry. Very different requirements are thus imposed on these knives. They include specific geometries, cutting-edge geometries, wear resistance, corrosion resistance, food safety, and manufacturing costs. For this reason, a large variety of knives exists.

The main focus of the research work carried out is on circular knives and sickle knives for the food industry. From a microbiological point of view, particularly smooth surfaces are required. These reduce the number of bacteria on the cutting

tool and the resulting contamination of the food clippings. This reduces the likelihood of food infections due to contamination, which currently also represents an economically significant problem [1]. A smooth surface also prevents clippings from adhering to the knife. This improves process safety. A high level of wear resistance is another requirement for knives. Knives in the food industry are subject to constant wear and have to be replaced as a function of their service life. This leads to downtimes in production and thus to a significant drop in productivity. To sum up, there is thus a need for knives which have a high surface quality and a high wear resistance. At the same time, these knives must be economical to manufacture.

The manufacturing process for knives for the food industry usually consists of several standardized but not adapted process steps. First of all, blanks made from sheet metal are usually thermally sliced. The wall thickness is typically 0.6–5 mm. The diameter of circular knives is typically in the range of 50–220 mm. Subsequently, a near-net-shape pre-deformation can be carried out. This applies in particular to the areas of the cutting edges. The parts are then further produced by grinding. A comparatively large amount of material is removed here. With a typical feed rate of 0.01 mm, the processing time for the production of sickle knives is approx. 1–1.5 h. In addition, heat treatment of the knives is customary in order to adapt the mechanical properties of the knives to their subsequent applications. The hardness of a knife is then in the range of 55–62 HRC. The surface roughness *Ra* is in the range of 1.4–2 µm.

The manufacture of knives for food processing requires a number of forming steps and grinding processes. These are not suitable for ensuring a very good surface quality. Furthermore, the process times are very long. This leads to considerable manufacturing costs, resulting in very high component costs. In addition, a great deal of grinding dust and contaminated cooling water are generated during processing. The appropriate form of cleaning is expensive and pollutes the environment.

The motivation for the research work being carried out is derived from this. The aim is to research a technology kit and associated manufacturing processes for the economical manufacture of industrial knives with a focus on the food industry as shown in Fig. 1.

On the one hand, the central starting point is the use of incremental flow-forming processes. These enable effective shaping, very good surfaces, and the introduction of a high degree of deformation. This is essential for effective work hardening of the material. Formed shapes can also be generated with process control.

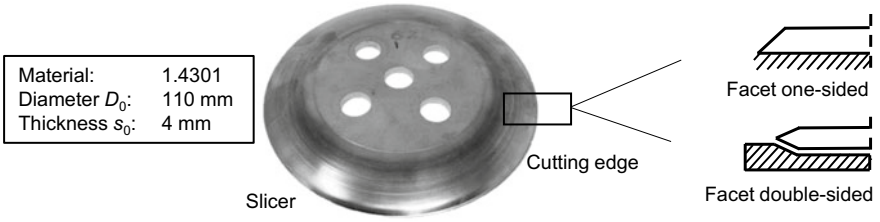

Fig. 1 Knife for the food industries and common facet designs

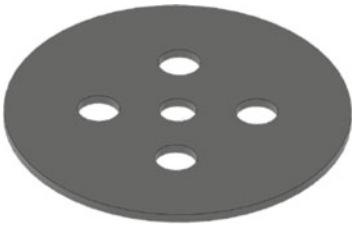
This enables a high variety of geometries to be generated economically. At the same time, hot forming or heat treatment can also be integrated. This is particularly important against the background of processing innovative steel materials. Furthermore, near-net shapes can be manufactured with good geometrical and dimensional accuracy.



On the other hand, the intention is to use innovative steel materials. Conventionally, primarily martensitic stainless cold work steels have been employed. These are chrome alloyed steels with a high carbon content and secondary hardening properties [2]. They can normally only be formed in the soft annealed condition. Stainless chrome steels with copper as an alloying element are becoming increasingly important for cost reasons [3]. Copper as an alloy element improves formability. Precipitation hardening and work hardening also enable a high strength to be achieved in the corresponding components [4]. This is analogous to maraging steels. The high copper content is particularly advantageous in terms of microbiological aspects (food safety). The high hardness through work hardening and the food safety of these materials are promising for the intended application [5].

A combination of incremental and possibly hot flow-forming processes with the processing of innovative steel materials thus offers a high potential for the cost-efficient production of improved knives. The near-net shaping achieved by means of rollers can reduce the costly machining work. Furthermore, a multitude of geometries can be flexibly produced for a low mechanical outlay through the kinematically controlled generation of the design. In addition, very good surfaces with antibacterial properties can be produced by the flow-forming process. In combination with innovative steel materials, it is possible to increase this potential still further. The high mechanical strength of these steels leads to an increased service life [6, 7]. This produces further cost advantages. Initial research into this is presented in this article.

2 Experimental Setup

The central element of knife production is the flow-forming of sheet blanks to produce a preform for the final grinding process. In this latter process, the cutting edge is sharpened. Round blanks for the experiments were thus cut out of sheet metal by means of laser cutting. Steels 1.4301 and 1.4112 were used as a material., as these materials are common materials for blades for food applications. The round diameter D_0 was 110 mm and the wall thickness s_0 was 4 mm. These are shown in Fig. 2. The corresponding openings are required for mounting on the spindle.

A friction spinning test rig was used for the flow-forming. This is an in-house design by the LUF. It contains a spindle with a holder for sheet blanks with a diameter D_0 of 110 mm. The blanks are centered using dowel pins. In addition, there are two supports that guide the rollers or supporting tool elements. In principle, heating can take the form of inductive heating. Corresponding induction coils can be put in position by industrial robots. In the puncture tests shown below, however, an acetylene–oxygen burner was initially used to heat the blanks shortly before the

Material:	1.4301, 1.4112

Thickness s_0:	4 mm

Fig. 2 Round blank sheet for experiments

forming operation. As an alternative, liquid nitrogen was used at a temperature T of −200° C in order to reduce the forming temperature T_f. The friction spinning test rig used is shown in Fig. 3. A spindle speed n of max. 3,000 rpm is set. The feed rate f was in the range of 10–50 mm/min. The spinning rollers had radii R of 1, 2, and 3 mm.

Two process routes were essentially investigated in the research work carried out. On the one hand, this was partial kinematic design generation and full kinematic design generation as shown in Fig. 4. In the former, a sheet metal blank is attached to a holder. The cutting edge is then formed iteratively using a roller. The cutting edge geometry is thus determined by the kinematic movement of the spinning roller and a shape-specific holder. The blank holder must correspond to the desired cutting-edge

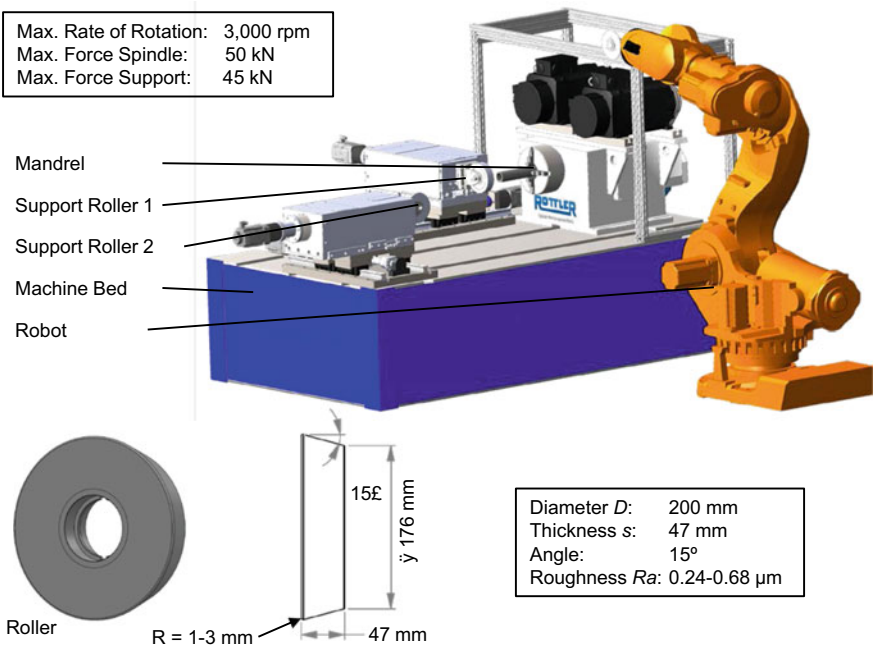

Fig. 3 Friction spinning test rig and roller geometry. (Color figure online)

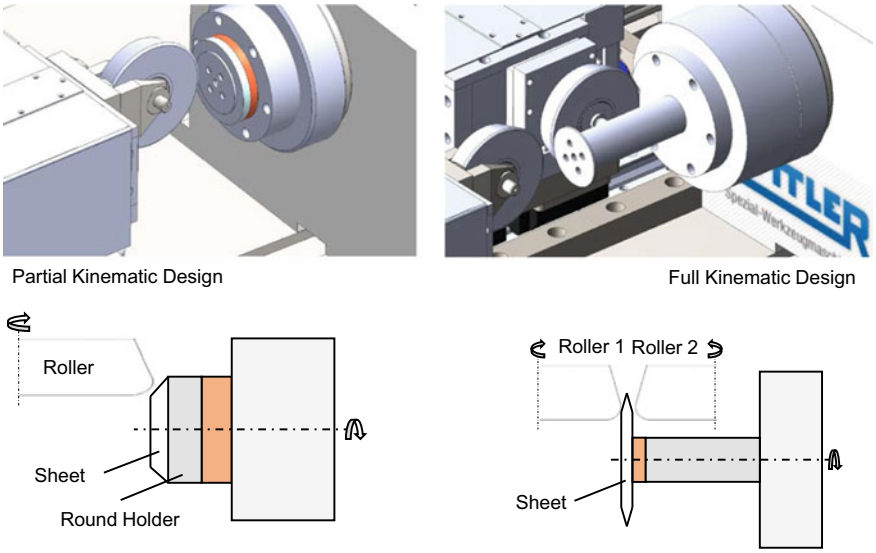

Fig. 4 Partial kinematic design and full kinematic design of flow forming of cutting blades. (Color figure online)

geometry. Different blank holders can thus be used to form different geometries. In the case of fully kinematic design generation, the circular blank is also firmly clamped. The geometry is equally dependent on the kinematic movements of the roller. At the same time, the forming is supported by a kinematically moving counter-roller. Shape-specific blank holders are thus no longer required for the round sheet blank. Nevertheless, an increased outlay results in tooling and adequate machines. At the same time, however, fully kinematic design generation permits significantly greater flexibility with regard to the respective cutting edge geometry without the use of different shape-specific blank holders.

Hardness measurements, metallographic evaluation, and roughness measurements were carried out in order to evaluate corresponding sample components. To this end, samples were taken orthogonally to the cutting edge and examined. Three measurements were carried out for hardness measurements and the arithmetic mean was formed. For the metallographic examinations, the samples were ground, polished, and constricted using Nital. For the roughness measurements, the cutting edge was scanned at three measuring positions for a length l of 5.6 mm. The measurements were carried out all around the circumference at a measuring angle of 10°. The standard deviation is 0.0056 µm. The individual measuring positions are shown in Fig. 5.

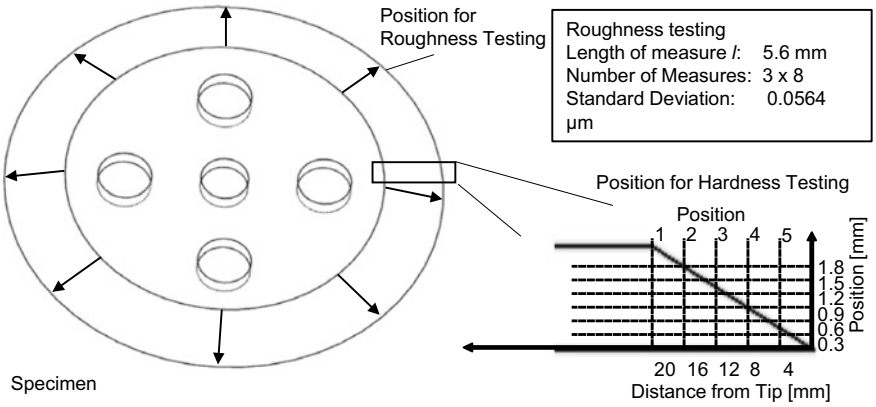

Fig. 5 Positions for roughness testing and hardness testing

3 Results

The results of the experimental investigations are presented below. These include, in particular, the attainable surface quality of the flow-formed surfaces. This is particularly dependent on the feed rate f and the roller geometry or roller dimensions. The microstructure and the resulting mechanical properties are a function, in particular, of the degree of deformation and the forming temperatures T_f. Basically, the cutting edges can be molded in the cold state. This shows that material 1.4112 has an increased springback by comparison to material 1.4301.

3.1 Surface Quality

The roughness *Ra* of the surface is approximately 3.0 µm in the initial state. The cutting edges were processed using various rollers. The spinning rollers have a radius R of 1, 2, and 3 mm. The feed rate f was varied in the range of 10–50 mm / s. The theoretical roughness Ra_{th} can basically be derived from the feed rate f and the tool radius R. Basically, the roughness is reduced with a high feed rate f and an increasing radius R. The relationship between the experimentally determined roughness and the feed rate f and the radius R is shown by way of example in Fig. 6.

The experimental results show that the roughness *Ra* is significantly reduced with an increasing radius R. The feed rate f also has a similar tendency. However, it is noticeable that the influence of the feed rate f decreases as the radius R increases. Furthermore, the processing time for the flow-forming process increases as the feed rate f becomes smaller. With regard to economical production with short process times, high feed rates f with larger radii R are suitable. This leads to a significantly

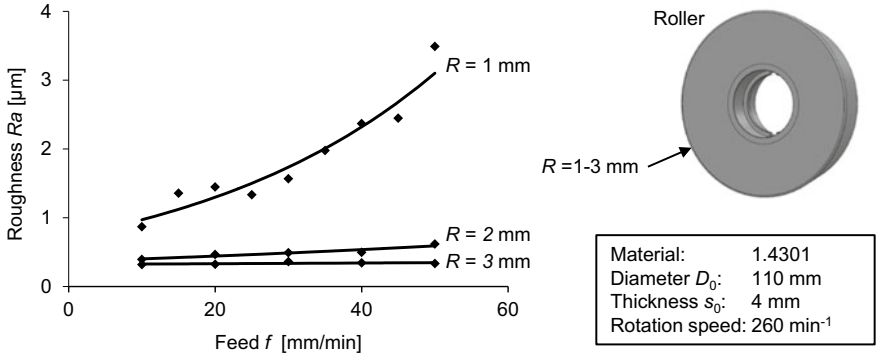

Fig. 6 Influence of feed rate f on the surface roughness *Ra* of a specimen of 1.4301

improved surface quality compared to the initial state. Furthermore, the most economical production possible should be feasible. The speed n has a minor influence on the surface roughness *Ra.* Accordingly, this should be chosen at a high level, aiming for a short process time. The influence of the forming temperature T_f has a minor influence on the resulting roughness *Ra.*

3.2 Mechanical Strength

Metallographic studies have shown that the texture of the structure is significantly influenced by the deformation. The shaping in the area of the cutting edge results in a finer grain structure. This is shown in Fig. 7. This applies, in particular, to material 1.4301.

The mechanical deformation of the material also changes as a result of the forming operation and the microstructure influenced by it. The strengthening increases with increasing deformation. Accordingly, areas that are in contact with the roller have a higher strength. This increases significantly in the direction of the cutting edge. Figure 8 illustrates this. As these areas have to endure the highest mechanical loads and are therefore subject to the highest wear, this is advantageous in terms of service life. Compared to conventionally manufactured knives, this should mean significant added value.

Similarly, the amount of deformation and the forming temperature T_f have a significant influence on the phase transformation from residual austenite to martensite. The higher the deformation, the more residual austenite is converted to martensite. However, this effect decreases significantly with higher forming temperatures T_f. Lower forming temperatures T_f below room temperature intensify this effect. This is shown in Fig. 9. Lower forming temperatures T_f are thus advantageous for

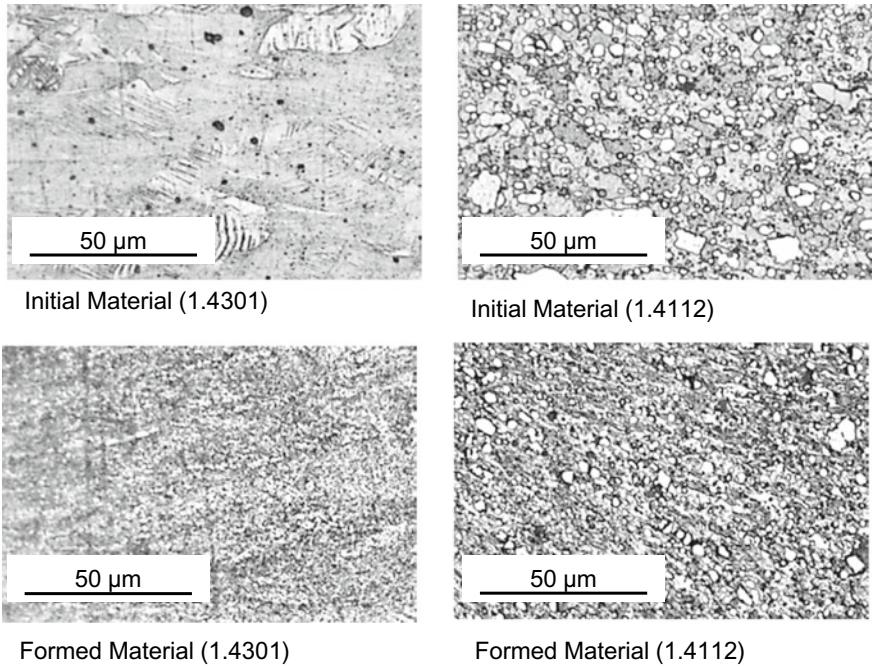

Fig. 7 Influence of deformation on the microstructure of parts made from 1.4301 and 1.4112

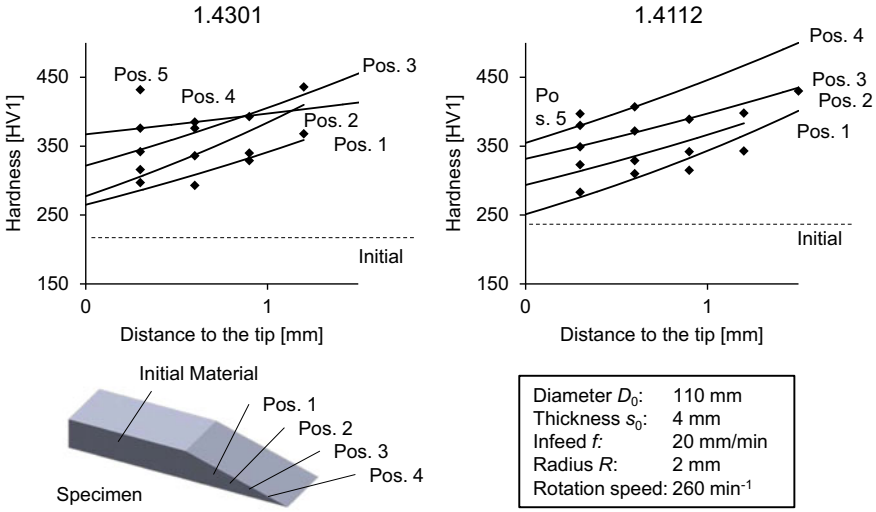

Fig. 8 Influence of deformation on the strength of parts made from 1.4301 and 1.4112. (Color figure online)

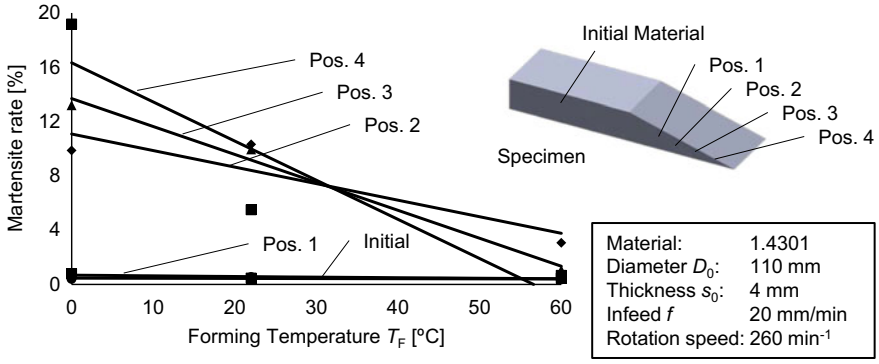

Fig. 9 Influence of forming temperature T_f on the martensite rate of parts made from 1.4301. (Color figure online)

this desired effect.

The above effect is shown in Fig. 10 in relation to the hardness of the material used in accuracy experiments. It becomes clear that the effect requires significantly less deformation, especially at lower temperatures T_f, in order to achieve high strengths. However, this does not change the maximum attainable strength. It can thus be deduced that lower forming temperatures T_F are suitable for high component strengths.

4 Summary

The experiments have shown that the preform for knives can be produced very well by means of flow-forming. On the one hand, very high deformation can be achieved by comparison to conventional processes. This significantly reduces the amount of grinding in subsequent process steps, thus enabling a significant reduction in process times as well as in the cost of material/machining and hence component costs. Furthermore, significantly better surface qualities can be produced. The roughness *Ra* of 0.3 µm is significantly better than that of conventional knives at 1.4–2 µm. This is associated with a better antibacterial effect. With regard to food safety, significantly better product properties are achieved. Greater forming is also achieved by the flow-forming process. In this way, suitable microstructural effects can be exploited. Cold forming opens up significant potential for higher component strengths. The component strength is targeted in the area of the cutting edge, which means it is increased in the area of the highest load in the application. This should reduce wear and improve service life. Further research work also includes the potential for improving product properties and cost-effectiveness. To sum up, however, it can be said that the research

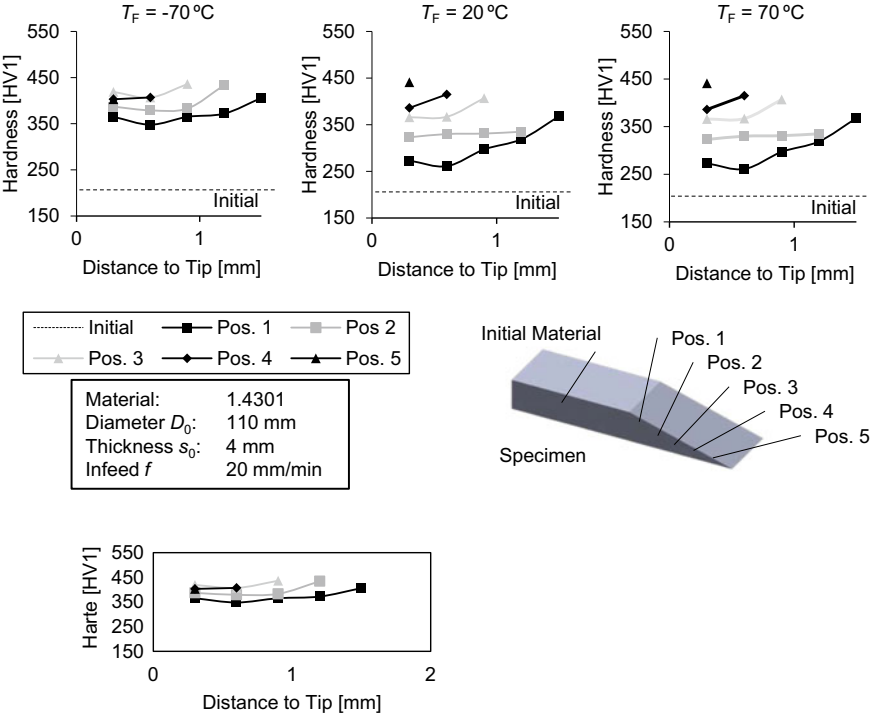

Fig. 10 Influence of forming temperature T_f on the strength of a part made from 1.4301. (Color figure online)

results achieved should make it possible to produce significantly improved knives for the food industry with improved cost-efficiency.

Influence of Axial Feed Rate on Shape and Thickness Changes During Multi-Pass Tube Spinning: Experiments and Modelling

Biplov K. Roy, Yannis P. Korkolis, Yoshio Arai, Wakako Araki, Takafumi Iijima, and Jin Kouyama

Abstract This research investigates the influence of axial feed rate on shape and thickness changes in multi-pass, mandrel-free tube spinning for producing a hemispherical shape at room temperature. The target shape is formed experimentally by 7 spinning passes from annealed, pure aluminium AA1070 tube. The experiments are conducted with two different axial feed rates, i.e. 2 and 7.5 mm/rev. It was found that increasing the axial feed rate generates lower elongation and higher thickness change. In every experiment, the tube wrinkled at some point during the process, due to the high radial feed. A 3D elastic–plastic finite element (FE) model of the multi-pass tube spinning process is described. The influence of the axial feed rate on axial wrinkling, tube elongation, and thickness change is discussed through the comparison between experimental and FE prediction results.

Keywords Tube spinning · Multi-pass · AA1070-O · Hemispherical shape · Axial feed rate

1 Introduction

During the past few years, new demands of the market caused the development of new methods of manufacturing seamless, dimensionally precise axisymmetric products like a pressurized spherical fuel tank. Tube spinning is one of the most popular incremental metal forming processes that satisfy the demanded agility and versatility of the market. The process is capable of using a variety of workpiece sizes

with a wide range of thicknesses [1]. In comparison with an alternative process, e.g. deep drawing, tube spinning exhibits low deformation force, low production cost, simple tooling, and increased process flexibility.

In the spinning process, the final part is obtained by the localized plastic deformation induced by the roller contact. Due to the complex and rotary incremental nature of the manufacturing process, it is essential to predict the effects of process parameters early-on in product development. Among the various process parameters of tube spinning, axial feed rate (mm/rev.) and radial feed rate (mm/pass) play a vital role in the successful manufacturing of the desired product. The axial feed rate (mm/rev.) is defined by the rate of roller movement in the axial direction to the rotational speed of the chuck, and the radial feed rate (mm/pass) is defined by the ratio of roller movement along the radial direction for each spinning pass. Previous researchers [2–5] performed experiments on tube spinning and reported that an optimum feed rate is important for the product quality. Numerous researchers [6–13] have conducted FE simulations of tube spinning to understand the effect of spinning parameters, e.g. feed rates in axial and radial direction, roller path and geometry and contact condition, etc. Process design for tube spinning is inherently difficult due to their complexity in many process control variables; the virtual process makes the use of process models highly attractive as a means of eliminating the need for trial error.

The main aim of this study is to investigate the influence of axial feed rate on shape and thickness changes in multi-pass, mandrel-free tube spinning for producing a target shape at room temperature. A finite element (FE) 3D model is developed for virtual process investigation, and its capabilities as a prediction method of the final shape and thickness of this process are analyzed.

2 Experiments

An annealed AA1070-O tube with outer diameter of 100 mm, average thickness of 3 mm, and overhang of 150 mm was selected to produce a target shape. The roller used had diameter of 158 mm and nose radius of 12.5 mm. The spinning experiments were performed on a computerized numerical control (CNC) spinning machine, at room temperature. A schematic of the experimental setup is shown in Fig. 1a.

The angle of attack angle of the roller with respect to the tube was kept at 45°. The axial and radial movement of the roller was controlled according to linear spinning pass as shown in Fig. 1b. A series of experiments were carried out for two different axial feed (AF) rates: 2 and 7.5 mm/rev. The radial feed rate was constant for each experiment, and equal to 5 mm/pass. The shape and thickness of the tubes after spinning were measured. For shape measurement, a 3D contact gauge (Model: Master3dGage™ with laser scanning marker accuracy of ±40 μm) was used. Thickness was measured by a point micrometre, from the free end.

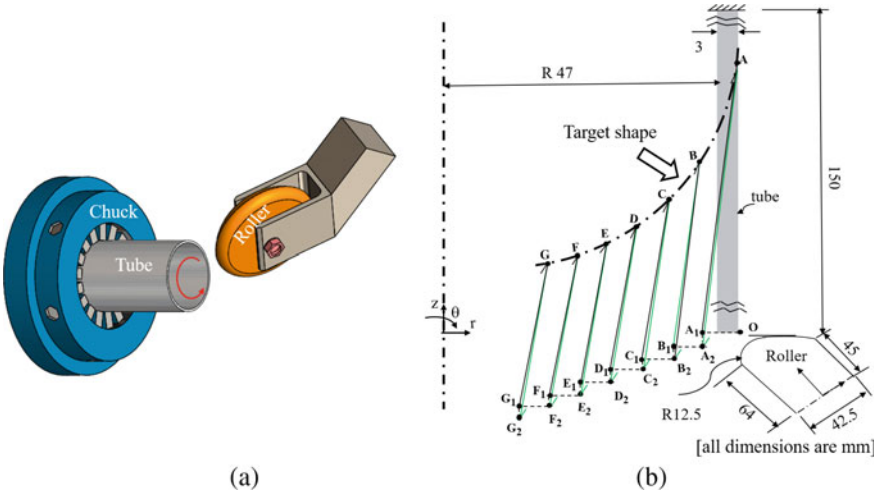

Fig. 1 **a** Schematic of the experimental setup, **b** Spinning pass and roller starting position. (Color figure online)

3 Finite Element Models for Tube Spinning

The explicit commercial FE code Abaqus 6.14 was used to simulate this process. The tube was considered an elastic–plastic deformable solid and the roller was modelled as a rigid analytical surface with the same dimensions and attack angle to the tube as in the experiment. Rate-independent, isotropic hardening using associated flow-rule based on the von Mises yield surface was assumed for the simulation. A Voce-type [14] large-strain hardening curve was fit to the experimental data of Ref. [15]. The fitted curve is shown in Fig. 2a, and the fitted Voce hardening equation parameters are listed in Table 1. The other material properties used in the model are listed in Table 2. Figure 2b shows the detailed arrangement of FE model for spinning. The geometry of the model replicated the geometry of the experiment exactly. For meshing, the C3D8R, continuum, 8-node linear brick element with reduced integration and hourglass control was adopted. The tube was discretized with 34,800 elements, with 104 elements along the circumference and 5 elements through the thickness. The mesh was refined in the contact zone and its nearby region (Fig. 2c).

The boundary conditions for this process were split into three stages as in the experiment: clamping the tube-end, rotating the tube, and performing the multi-pass tube spinning by the displacement of the roller.

The roller axial and radial movements were given according to the design spinning pass as shown in Fig. 1b. The penalty contact algorithm and Coulomb's friction law were adopted in this FE model. The friction between the tube and roller was assumed to be relatively low, so a frictionless status was adopted in this FE model. To reduce the computational cost, the deformable contact surface was divided into many parts,

each active during a different spinning pass, as shown in Fig. 2a. To speed up the simulation, the mass scaling method was adopted, using a scaling factor of 64.

4 Results and Discussion

4.1 The Influence of Axial Feed Rate on the Deformed Shape

The target shape progressively developed after 7 spinning passes. Figure 3 shows the outer shape of the tubes spun with low and high axial feed rates (AF 2 and 7.5 mm/rev.). The figure demonstrates that the deformed tube is wrinkled at a specific space on the hemispherical shape region, see the top magnified image in Fig. 3.

The figure also shows that the deformed tube in the conical region is elongated in the low axial feed rate case (AF 2 mm/rev.) and shortened at the high one (AF 7.5 mm/rev.), see the lower magnified image in Fig. 3. Therefore, it appears that the toolpaths examined in this study (see Fig. 1b) can provide approximately correct shapes, but still need improvement.

Figure 4 shows a comparison of the sectional view of final shapes in experiments and FE predictions. It confirms that the simulation predicts elongation and shortening with the change of axial feed rates as in the experiments. Furthermore, the FE model also predicts the wrinkled shape during multi-pass spinning. Figure 4 also illustrates that, in the case of high axial feed rate, the sectional view of the deformed tube is of poor quality (see Fig. 4a). In contrast, the surface quality of the deformed tube becomes smooth during low axial feed rate spinning (see Fig. 4b).

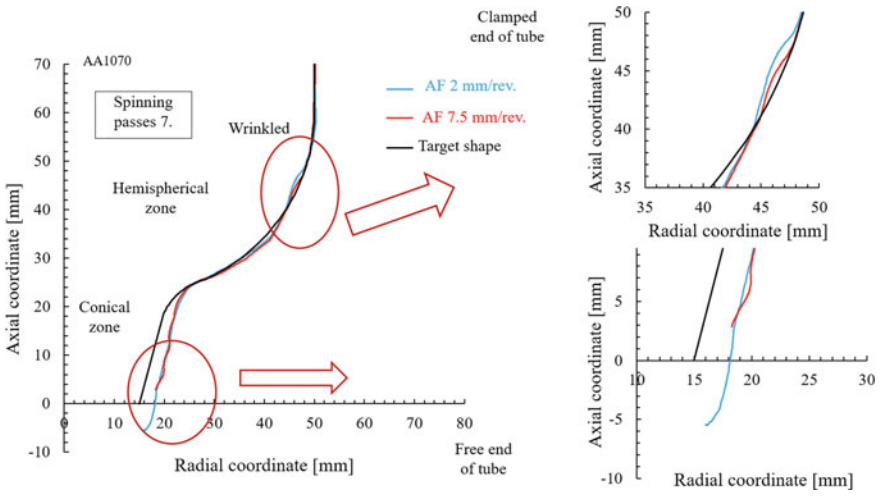

Fig. 3 Comparison of the tube shape at different axial feed rates. (Color figure online)

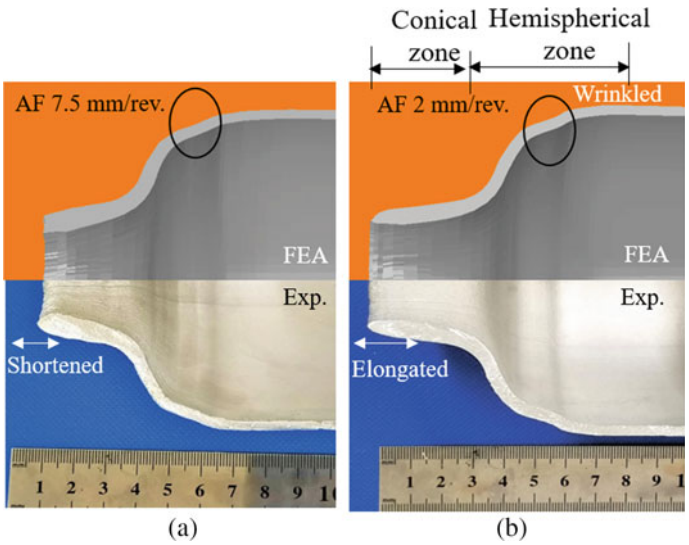

Fig. 4 Comparison of final deformed shape at different axial feed rates experiment and FEA predictions: **a** AF 7.5 mm/rev., **b** AF 2 mm/rev. (Color figure online)

4.2 The Influence of Axial Feed Rate on the Thickness Change

Figure 5 shows the influence of the axial feed rates on the thickness change of the deformed tube. Due to the limitation of the measuring thickness by micrometre, the simulated results are compared with the experiments on the free-end-zone only.

The figure shows that in the conical zone region, the change in thickness is lower during low axial feed rate (2 mm/rev.) than during high (7.5 mm/rev.). Previous researchers [3–7] also observed the same tendency during the spinning process. The FE predicts the thickness increase in the free end-zone quite well, as well as the influence of axial feed rate on the thickness change in the conical shape region. In the hemispherical zone region, the influence of the axial feed rate is quite low. The average deviation between predicted and measured thickness is approximately 5%.

5 Conclusions

This study analysed numerically and experimentally the shape and thickness changes at different axial feed rates for room temperature, mandrel-free, multi-pass spinning of AA1070 tubes. The intent was to develop a realistic virtual method for selecting spinning process parameters. In the future, this model will be used to determine the

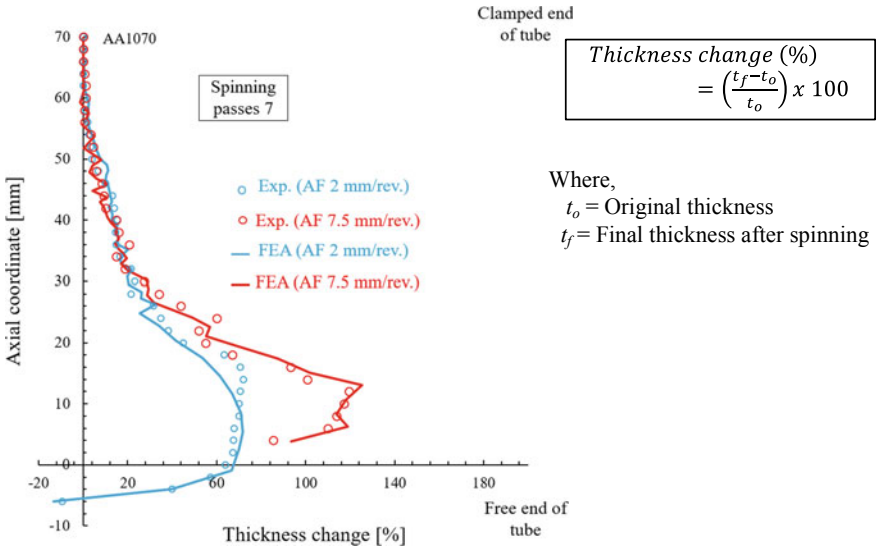

Fig. 5 Comparison of thickness changes experiments and FE prediction at different axial feed rates. (Color figure online)

optimum process parameters for producing a smooth product. The results lead to the following conclusions:

- The axial feed rates play a vital role in the shape and thickness change during tube spinning. A low feed rate produces higher elongation and lower thickness change than a high one.
- The 3D FE modelling of the spinning process can predict the significant plastic deformation of complex shape forming, including the shape and thickness with different axial feed rates.
- The large-scale thickness change occurred in the conical zone region due to significant diametral reduction both in the experiments and FE predictions.
- The FE predictions show that in the hemispherical zone, the thickness is insensitive to the axial feed rate.
- Both experiments and FE predictions show axial wrinkling in the same region due to the high radial feed rate.

A Brief Review on Theoretical Aspects of Bar Straightening with Recent Developments in Its Modelling, Simulation, Control System, and Stabilization

Sanjib Roy, Arun Kiran Pal, and N. K. Das Talukder

Abstract This paper presents a brief review of various research done on bar straightening. Bar straightening can be considered as a significant process in the value stream of bar production. The paper dealt briefly on various types of arrangements available in bar straightening process. The theoretical perspectives have been looked into in simplified manner. Residual stresses, curvature, and bending moment thereof due to reverse kinematic bending have been discussed. A system approach has been taken as how development on bar straightening process emerged over the years. The recent developments in bar straightening using modelling / numerical modelling give an insight of reduction in curvature after reverse bending. Simulation/Numerical simulation approaches in bar straightening process have been looked into. Key aspects like positioning of rolls and minimization of straightness errors have been considered. How control system is applied with Multi-Step Straightening Control System (MSSC) in reducing curvature has been discussed. The paper has been intended to present an overall view of bar straightening from inception till modern times.

Keywords Kinematic loading · Residual curvature · Straightness · Bauschinger effect · Cross-roll straighteners · Rollers

1 Introduction

Production of various types of beams and bars including round bars of various sizes and lengths are quite common requirement in industries as these are used many times directly as raw materials in fabrication of structures or sometimes used as a raw material to produce designed product as per specifications. Like many products as they come out from shop floor requires inspection to ascertain quality uprightness so that imperfections are within acceptable quality limits; the bars are of no exception. With the advent of high speed turning, straightness requirement of drawn bars

increased due to imperfections of drawing process. The imperfections of such drawn bars through drawing process essentially called for further straightening process.

Long bars as produced through various rolls are sometimes compromised with degree of straightness either at various sectional lengths or as a whole. It is therefore essential to look into the various quality aspects before the products are out of shop floor. Small diameter round bars are often intentionally coiled to save storage and transportation cost. Therefore, straightness of such products is indeed an issue before they are actually employed further into job, batch, or mass production.

The straightness of drawn bars is often compromised due to imperfections of the drawing process; therefore a straightening operation becomes essential. In production of long products, straightening process through rollers is often the terminal step [1]. Cross-roll straightening is quite a common straightening technique in which the bars are cyclically bent with varying amplitude. The round bars to be straightened are bent and simultaneously rotated as they pass between a set of two rolls, i.e. one being a convex while the other is concave or some other arrangements of cross-roll.

Theoretical aspects of bar straightening start with bending, more specifically reverse bending which is actually necessary to mend the already bent item. The concept of application of bending moment and consequent curvature in a beam is quite old [2]. Brazier indicated that bending moment increases as curvature increases initially in Bending moment–Curvature diagram and reaches a maximum value at a point then decreases even with the increase of curvature up to a certain point.

In case of round bars and tubes, on deformation, the circular shape of the cross section undergoes change and takes an elliptical shape. Deformation relationship can be established as done by Ades [3]. Determination of shape of cross section of tube is possible as a function of bending moment and longitudinal curvature by application of principle of least work when subjected to stress in the plastic range. Although both the works were primarily on the shape of tubes and on ovalisation of circular sections, sufficient indication is available on the relationship of application of the bending moment and curvature of bar when subjected not only in elastic range but also in plastic range. The present study is largely on solid bars.

2 Types of Straighteners

There are many different types of rotary straighteners [4] based on number of rollers, arrangements of rollers, types of rollers. In all the rotary straighteners, the rollers are usually of concave hyperbolic contour, but in some special cases, the cylindrical or drum type is used. There has been advancement over years in the design of bar straightening machines [5]. There are several types of cross-roll straightening machines with different roll arrangements. Various types of machines are in use. Each type has superior advantage in specific circumstances. Cross-roll straightening machine or reeling machines are most popular. In cross-roll straighteners, there are several combinations of idle and driven roll arrangements. Beside these machines,

there are section straightening machines and stretch straightening machines which are used for straightening purposes.

2.1 Section Straightening Machines

Section straightening machines are of cantilever design. These machines are based on the process of rotary straightening. Section Straightening Machine is known for its robust construction, high level resistance, and optimum stability. The Section Straightening Machines are used to straighten rolled steel sections like angle, channels, rounds, beams, etc. Straightening Rolls are made according to section. Some manufacturers use Adamite material (a kind of high carbon steel with carbon percentage ranging from 1.35 to 2%) for rolls [6].

2.2 Stretch Straightening Machines

Stretch straightening machines grip both ends of the bar and exert a certain amount of tension to the bar in order to straighten it. Extrusion stretch straightening and forming is a fast, economical, and accurate way to straighten and form large extrusions. This process involves stretching an extrusion to yield, followed by straightening and forming over a tool. Stretching profiles are made between the two heads, fixed and mobile. The movable head is usually set to the length of the expandable profile. The distance between the heads can be controlled through laser system [7].

2.3 Cross-Roll Straightening Machines

Cross-roll straightening machines are designed for straightening of both tubes and bars of circular cross section. The rolls are mounted at an angle to the line of pass. The material or bar rotates as it proceeds through the machine. Although there are several types, generally four basic types of cross-roll machines are in use which may be put as below [5]

1. Two-roll Straighteners or Reeling machines
2. Six-roll types (six rolls which are mounted in a set of three pairs)
3. Multi-staggered roll types having five, seven, or even ten rolls
4. Cluster-roll machines having seven rolls. A set of two-clusters each cluster is made of three-rolls and another roll at centre, i.e. deflecting roll.

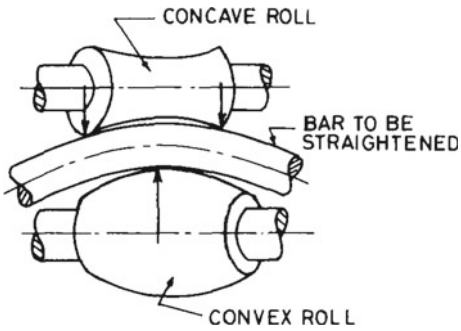

Fig. 1 Straightening of bar in a two-roll 'Air-Bend' machine

2.3.1 Two-Roll Bar Straighteners or Reeling Machines

Two-roll Bar Straighteners or bar straightening machines comprises one convex roll and one concave roll. The ends of concave roll act as horns while the convex roll can exert reverse load at centre of the bar to be straightened. The bending of round bar takes place across horns of the concave roll. Reeling machines are classified again into two types which are as below

(a) Free-bend straighteners or Air-bend straighteners
(b) Line-contact type rolls straighteners.

In free-bend or air-bend straighteners as illustrated in Fig. 1, the application of load is concentrated at a point [8, 9]. This means that loading pattern is actually like simply supported beam with a centralised load. The relevant equations of concentrated load acting on simply supported beam are useful here. The span of the horns may be considered as beam length.

On the other hand, in line contact roll straighteners, the bar happens to be deformed between a set of two rolls. The deformation so occurs can be considered as equivalent to conventional simply supported beam which is loaded uniformly over the length or simply uniformly distributed loading. Loading on the beam is across the span which may be called as 'beam length' of the bar. In this bar straightening machine, angular adjustment of rolls is possible from 5 to 10° for air-bend and 10°–20° for line contact roll straighteners.

2.3.2 Six-Roll Straighteners

As the name suggests, six-roll straighteners are having six rolls. The rolls are mounted in a set of three pairs as shown in Fig. 2. The beam length is more or larger in case of six-roll straighteners in comparison to free-bend or air-bend straighteners. However, loading is distributed but over a span of small length which is in line contact, i.e. near mid-span of the bar [8, 9].

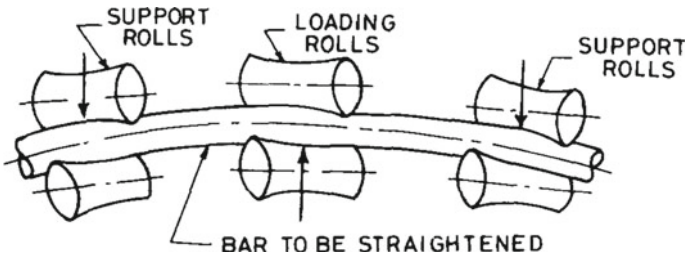

Fig. 2 Straightening of bar in a six-roll straightening machine

In this case, there are support rolls which are at the end and rolls at centre are actually the loading rolls. In this machine, mean value of angular adjustment of rolls is about 30°.

2.3.3 Multi-Staggered Roll Types Having Five, Seven, or Even Ten Rolls

As the name indicates these machines have staggered rolls and number of rolls is five rolls, seven rolls, or even ten rolls. The rolls are so arranged that it functions like practically number of "loading bays" and at each loading bay beam length is subjected to a point load or concentrated load and acting at opposite directions at consecutive bays. In this machine, angular adjustment of rolls is possible up to 35°.

2.3.4 Cluster-Roll Straighteners

In cluster-roll straightening machines, there are seven rolls which are arranged in a set of two-clusters of three-rolls each along with one roll at centre which is for deflecting purpose. The beam length of these machines is considered as simply supported. The concentrated point load is at mid-span. In this case, the beam length is as similar as six-roll straighteners. The beam length is also higher than free-bend straightening machines or air-bend straighteners.

2.4 Spinner Straighteners

Spinner straightening is the first process before cross-roll straightener. Spinner straightening is a process of straightening resistant materials mechanically as cold working. A typical application is in wire production. Wire is pulled through high speed, rotating rollers made of bronze which gives torsional twist resulting in condition of straightness. While feeding movement is given to the bar end but rotational movements are given to the dies. The resultant deformation leads to decrease in yield stress value which makes it strained and also softened. Initial curvature can

be eliminated by spinner straightening. As wire rods are usually available in coiled form, hence spinner straightening is quite helpful to straighten short-span curvatures which periodically exist [10].

2.5 Pulse Straightening

In this straightening system, high tensile wire which is to be straightened is pulsed in special machines which give magnetic pulse treatment taking into account the effect of hyper plasticity. The specific advantage of this machine is that it permits straightening of highest tensile wire. In this process, tensile yield stress is not altered. The process results in smoother surface of wire, hence less friction [11, 12].

There are two kinds of internal straightening methods in straightening machine, the first is rotary hub straightening, the other is parallel roller straightening [13].

2.6 Rotary Hub Straightening

In rotary straightening, the straightening block is usually installed in the straightening mechanism of the hub. Through high speed rotation and staggered arrangement of straightening blocks, the wire rod is bent many times in the process of moving forward, and gradually tends to be straight. This straightening method straightens the steel bar with good straightness and fast speed, but it causes damage to the surface of the steel bar [13].

2.7 Parallel Roller Straightening

The straightening method is parallel-roll type roller straightening CNC steel bar straightening machine. The wire rod steel bar meshes through two rows of staggered multi-wheel press roll groups, which directly deforms the steel bar to be straightened, so as to achieve the purpose of straightening. Although the speed of this straightening method is slightly slower than that of rotary straightening equipment, the straightness of steel bar can meet the construction requirements, and this straightening method does not damage the steel bar [13].

2.8 Skew-Roll Straightening Machine

This straightening machine is designed and built to straighten very small stainless steel medical tubing [14]. Using identical hyperbolic profiles of rolls, accurate tube

can be achieved [15, 16]. These machines are available in 3 × 3 skew roll designs or 5 × 5 skew roll designs. This straightening machine is designed and built to straighten very small stainless steel medical tubing.

These bar straightening machines individually have certain advantages and disadvantages. In order to make right selection of machine, it is necessary to consider the type of material being fed, the degree of straightness required, surface finish, machine capacity, and straightening speeds, etc. Two-roll straighteners are used for improving surface finish. The speed at which the process of straightening can be operated depends upon the degree of control that can be applied to the rotating material. All cross-roll straightening machines cause bar material to rotate during straightening operation. Obviously, a long badly bent bar cannot be rotated as fast as a short and fairly straight bar.

3 Theoretical Aspects

The concept of working on bar in plastic range prevailed well, and Tokunaga [4] reported that certain phenomenon of residual stresses is in place. Tokunaga stated that residual stress distribution in the bar by rotary straighteners represents alternate vortex of tensile and compressive stress zones around the centre of bar, which is not affected by repeated rotary bending. As the entire discussion is on straightening of bars, it is imperative that searches were on how better straightness can be achieved.

3.1 Straightness

Since, it is quite usual that available bars in market are seldom straight and degree of straightness varies. Degrees of straightness (commercial straightness) from 1 in 750 to 1 in 5000 can be achieved. Kemshall [5] indicated that degree of straightness depends on type of machine selected. Residual stress developed during straightening and straightness of finished bar depends on the applied loads in straightening machines [17]. In case, better straightness is to be achieved, then the bar in question has to be bent more severely at the point of application of load so that curvature reduces and consequently straightness improves [4]. These features of improvement of straightness were achieved through rolls, more specifically in cross-roll arrangements. It has been stated that multiple rotary bending helps improving degree of straightness. Rotary straighteners having oblique rollers are preferred to be used for straightening process of round bars.

3.2 Plastic Deformation

In the straightening machine, bars are subjected to elasto–plastic deformations as it undergoes alternate bending under high magnitude of loads [17]. Tokunaga stated that two zones surround the centre of the bar which undergoes no plastic deformation and retains initial deformations. Residual stress distribution of section of the bar and zones left by the compressive residual stress and tensile residual stress, respectively, surround the centre of the bar which do not undergo any plastic deformation. The residual stress of the plastic zone builds up residual moment to the centre of the bar.

The bending moment arising out of residual stresses rotates accordingly as sections change between pitch lengths (the length of bar advanced during revolution) of the bar in straightening. Tokunaga indicated that the bar and tubing straightened by rotary straightener can be considered as spring coil form which has very small coil diameter and pitch length. But the centre of this coil is affected by the core of the bar which is not straightened and retains the initial bend. Tokunaga inferred that bar and tubing are straightened more exactly which have smaller residual stress, when rotary straightener is used by a method which applies more severe bend. This involves more multiple rotary plastic bending at the period of the reducing bending moment.

In case of bar straightening, loads are applied externally. The deformation response of tubular structure or a bar may be analysed to assess structural integrity [17]. Using Ludwik power law equations [18], the effects of creep and plasticity are allowed for as an adjustment to initially elastic conditions. Stress (σ)—strain (ε) relationship can be expressed using Ludwik power law [19]:

$$\sigma = C\varepsilon^n$$

where C is constant stress,

n is an exponent of strain-hardening ($0 \leq n \leq 0.5$).

This can lead to pessimistic or conservative results of the structure [17]. Hence, for the purpose of realistic predictions, it is essential to have good 'constitutive relations' which may reflect true behaviour of material accurately. If the material in question can be considered that as it happens to 'remember' its previous loading history, then its subsequent behaviour can fairly be predicted with the help of related equations. This is indicated to some extent by Bauschinger effect [20].

3.3 Bauschinger Effect

Bauschinger effect is a phenomenon which is defined as reducing the proportional limit or elastic limit (elastic limit is actually slightly above the proportional limit) in compressive load or simply compression after following previous tension or tensile loading and vice versa. If the deformation caused is considered in one direction only,

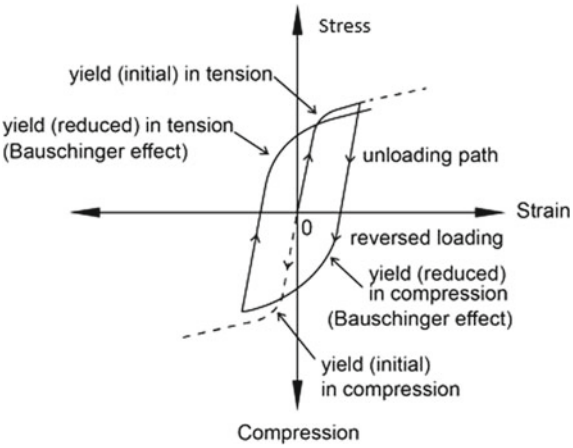

Fig. 3 Illustration of Bauschinger effect

reloading the specimen in simple compression will show the elastic limit appreciably smaller in magnitude than that of the previous yield point. This occurs whenever there is a reversal of stress. The lowering of the yield stress as indicated in reversed loading is primarily caused by the residual stresses. This residual stress is actually left in the specimen on a very small or microscopic scale due to the different stress states in the individual crystals of the material that the specimen is made of [18].

Bauschinger effect can be largely removed and it is generally neglected in the theory of plasticity assuming that the material is having identical yield stresses both in tension and compression, irrespective of cold work involved previously [18]. It is quite significant in bar straightening as bars are subjected to elasto–plastic bending and the process is subjected to cold working (Fig. 3).

4 Mechanics of Bar Straightening

Bar straightening process was in practice and various kinds of straightening machines were in operation at various industries [5]. In the United Kingdom, the Bronx Engineering Company, Lye, Stourbridge (Worcs) and Joshua Bigwood & Sons, Wolverhampton are considered pioneers in the advancement of design of straightening machines. Later on, there have been several manufacturers in various countries. The theoretical aspect initiated by Tokunaga was very much restricted to preliminary stage with measurement of residual stress calculation.

However, the design and development were not much supported by any kind of theoretical approach based on analysis of plasticity or involvement of the plastic deformation processes. Analytical approach of the straightening processes was

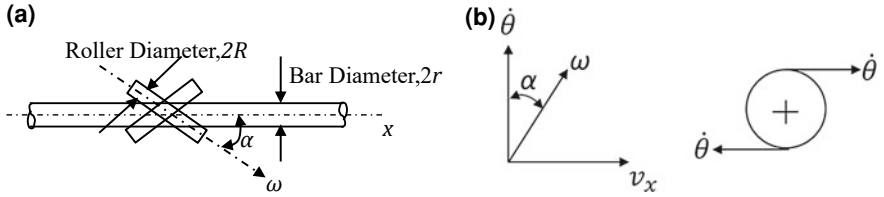

Fig. 4 **a** Sketch of Cross-Roll straightening process showing the angular arrangement of rolls [8, 9], **b** Throughput speed and angular speed of the bar has been shown [8, 9]

further enhanced by Yu and Johnson. Significant contribution was made in estimation of bar curvature after the process of cross-roll straightening [21]. Moment—curvature relationship was established in non-dimensional form. Curvature change by considering residual curvature and final curvature was developed.

4.1 Assumptions

The mathematical treatment of bar straightening proceeded with certain assumptions as below [22]

i. Elastic work hardening is present in the straightened bar.
ii. In pure bending condition, round bar's cross-sectional area is circular and neutral axis passes through the centre.
iii. Outside shapes of bars and tubing are round and tubing have uniform wall thickness.
iv. Cross section remains on a plane at right angles to the axis.
v. Variation of strain is proportional to distance from perpendicular point on neutral axis at any point in bar section.
vi. Material is considered as perfectly elastic–plastic, and its stress–strain relations in uniaxial tension is same as in compression. It has same elastic modulus and yield point both in tension and in compression.
vii. All stress components other than longitudinal direction are zero.

Detailing on motion of the bar through the various rolls has been elaborated by Das Talukder et al. [9] with substantial mathematical treatment [8, 9]. We consider Rollers with radius R, angular speed of bar being $\dot{\theta}$, and throughput speed of bar being v_x and cross-roll straighteners are set at an angle $\pm\alpha$ to the axis of the bar as indicated in Fig. 4a and b. Illustration of bar in motion through cross-rolls in straightening processes is shown in these figures.

Now, as bar's throughput speed, v_x is in the axial direction, and its rotation about its longitudinal axis at an angular speed $\dot{\theta}$, we can state as below [9] $\dot{\theta} = \frac{v_x cot\alpha}{r}$, where r is bar radius.

The bar speed can be expressed as $v_x = \frac{2\pi N R \sin\alpha}{60}$, where N is r.p.m. of rollers [23].

Considering any arbitrary point on outer surface of round bar at distance r from the centre which moves in a helix angle α, pitch length, p can be expressed as below [9].

$$p = 2\pi r \tan\alpha$$

The bars on proceeding through rolls rotate about their own longitudinal axis with the initial curvature plane which makes different angles at various different instants with loading plane and also progresses through the rolls. This is well explained in Fig. 5 [8, 9].

As bar progresses through the rolls, there will be corresponding variations of resisting moment or effective bending moment. In a span of pitch length, bar's osculating plane rotates 360°. Oscillation of effective bending moment or resisting moment will occur through one cycle (Refer Fig. 5). Effective bending moment will have variation. The effective bending moment is maximum at half the pitch length.

For simplicity, we assume the bar of uniform initial curvature. The curvature change-resisting moment of a bar can be drawn as indicated in Fig. 6 [8, 9].

The cross-rolls are so staggered that maximum loading moment M^* is developed while passing through the rolls and corresponding curvature change is κ^*. Residual curvature change, $\Delta\kappa_r$ or $\Delta\overline{\kappa}_r$ (in non-dimensional form) can be expressed as $\overline{\kappa}_r = \frac{\kappa_r}{\kappa_y}$. $\overline{\kappa}_r$ is equal and opposite to initial curvature [9]. The non-dimensional form of bending moment, M may be expressed as $\overline{M} = \frac{M}{M_y}$. Based on above diagram, we can

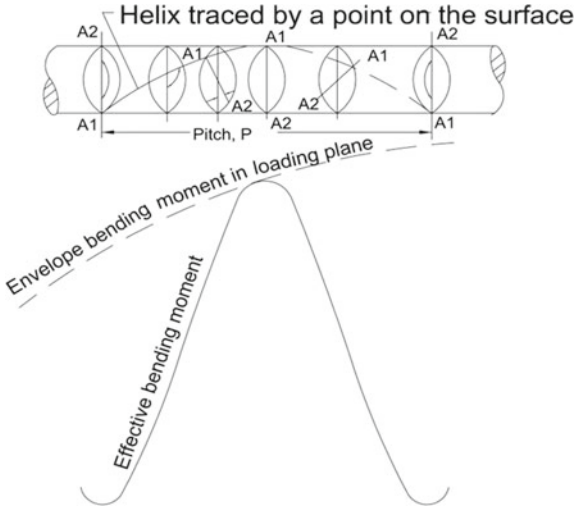

Fig. 5 Illustration of variation of resisting moment or effective bending moment in loading plane [8, 9]

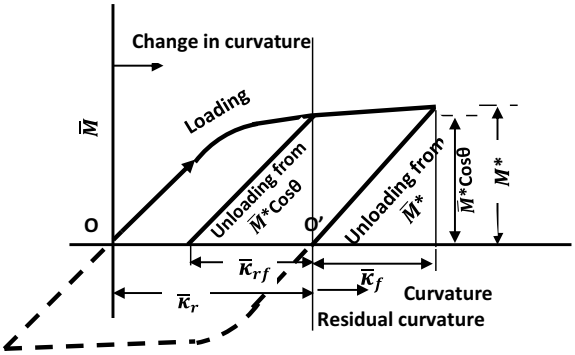

Fig. 6 Simplified relationship between resisting moment or effective bending moment in the bar and change in curvature [8, 9]

say that effective bending moment will be a component of bending moment which is acting in the plane of loading along with osculating plane. Therefore, effective bending moment,$\overline{m}$ can be expressed as $\overline{m} = \overline{M}\cos\theta$. Loading moment is developed at a distance of bar $\left(x - \frac{1}{2}l\right)$.

At the time, when a bar section approaches $x = \frac{l}{2}$, the curvature plane and loading plane may not have any angle or zero angle in between. In that case, effective bending moment in the plane of initial curvature will then not be equal to M^*. The effective bending moment as explained in the diagram will achieve such value only at a few sections. Such sections will be at pitch length distance, p of the bar [9].

Drawing of loading-moment curves repeatedly at pitch length interval over the bar length shall result in an envelope of curves which will give a distribution of effective bending moment over entire bar length as shown in Fig. 7. Considering $\overline{m}$ is the effective resisting moment with the highest value as $\overline{m}_h$ and $\overline{m}_{\,\mathrm{a}}$, $\overline{m}_{\,\mathrm{b}}$ being the largest value on ascending and descending sides, respectively [9]. We can say at a section BB of Fig. 7, $\overline{m}_{\,\mathrm{a}} = \overline{m}(1)$ and $\overline{m}_{\mathrm{d}} = \overline{m}(2)$. Also, $\overline{m}_{\,\mathrm{d}} > \overline{m}_{\,\mathrm{a}}$.

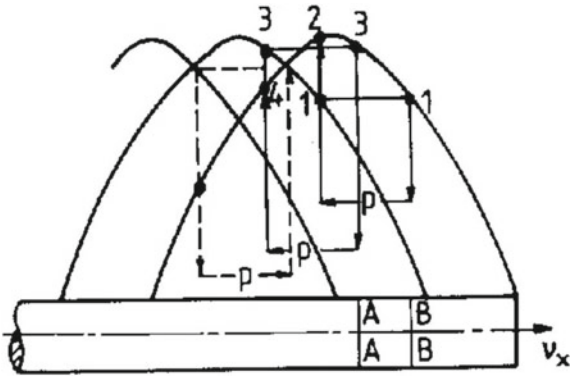

Fig. 7 Illustration of various points where the highest effective resisting moment will be available at various bar sections, viz., AA, BB, etc. [9]

It is to be looked into at section BB which corresponds to point 1 at the curve which is on ascending side. Now let us consider a measure of pitch distance p from point 1 up to corresponding point 2 on the curve which is on descending side. Thus, the highest effective bending moment, $\overline{m}_h = \overline{m}(2)$ [9].

But for section AA of (Refer Fig. 7), effective bending moment on ascending side is $\overline{m}_\mathrm{a} = \overline{m}(3)$ and effective bending moment on descending side, $\overline{m}_\mathrm{d} = \overline{m}(4)$ by taking a measure from pitch distance p, i.e. $\overline{m}_\mathrm{a} > \overline{m}_\mathrm{d}$ and thus $\overline{m}_h = \overline{m}(3)$.

5 Role of Rollers and Straightening Processes

In cross-roll straightening processes, the role of rollers is obviously quite significant. Hence, the profile of rollers is naturally of immense importance. Profile of tube-straightening rollers can be determined simply by application of envelop theory. There is always a requirement of straightening process in order to correct out-of-straightness and out-of-roundness even after accurate industrial process of production of steel tubes or bars [15]. It can therefore be stated that bending and unbending operations depend on rollers. Profile of roller is one of the significant factors. In six-roll type bar straighteners, skew-rolls are deployed. The supporting rollers happen to be driving rollers while loading rollers are actually driven rollers. To suit different tubes or bars, adjustment of skewed angle of rollers can be done. The distance can be adjusted between supporting rollers and loading rollers according to the different tube diameters and straightening force.

Several researchers worked on skew-roll straightening machine. Li et al. have provided a versatile technique and convenient method for the three-dimensional roller contour design and researched much on machining detail, i.e. on cutter path for the purpose of achieving three-dimensional curved surface of rollers.

In cross-roll straightening process, plastic bending will occur naturally. It is assumed that in reverse bending of the bars, for straightening and spring-back, a section having initial curvature shall finally be bent to another curvature. Wu et al. examined the condition of equivalent curvature in order to ease the study of curvature change in bar straightening process. Straightening process essentially involves multiple plastic reverse bending. This covers bars of different initial curvatures to the same final curvature [23].

Straightness improves significantly when bars pass through cross-roll arrangements [24]. Yali et al. considered rotation blocking mechanism of three-roller equal curvature rotation blocking straightening system. Most rods with small diameter less than 12 mm bars are usually supplied in coiled form. These rods of such diameters can be used after uncoiling and thereafter by straightening [24].

Hub-straightening machines, which are traditional, have usually low productivity in the industrial application. Such machines can barely meet the need of production demand. Although straightening speed improves significantly in parallel-roll straightening device, the subjected bar also rotates about its own axis while going through the straightening processes [24]. In such cases, the straightening accuracy is

compromised and becomes low. Therefore, to compensate the same, a roll-layout of equivalent curvature and standstill-locking straightening system is provided. By this way, it improves straightening speed and desired accuracy is reasonably ensured. It is feasible to deploy a mechanism of standstill-locking for large bending system. Yali and Herong deduced formula for standstill-locking torque which provides helpful theoretical backup for development of high speed straightening cutting machine [24].

6 Residual Stresses in the Process and Measurements

Due to straightening process, unfavourable residual stresses mainly occur in the final products; the effects appear in the cross-section during multiple bending [1]. With the introduction of numerical modelling in bar straightening processes, researches extended to the application of FEM. Non-linear analysis of residual stresses was conducted by Biempica in the rails [25]. Study was made for reduction of residual stresses by means of roller straightening. Finite element models can be used to understand the combination of effect of contact stresses and bending stresses under the rollers for changes in roller profile. Biempica [25] explained through application of various one-dimensional, two-dimensional, and three-dimensional finite element models. Application of one-dimensional models is quite simplistic and advantageous with respect to complex models. Computational time and effort is less to solve one-dimensional models [25].

Srimani et al. [30] studied and developed suitable methodology in straightening machine to estimate the straightness of finished product (rail) for a set of loading parameters. Straightness values were examined along the entire length. It has been noticed that both front and rear ends are actually subjected to loading which has different patterns in comparison to middle portion during passing through straightening machine. Straightness differs considerably near ends in comparison to other portions which are quite uniform [30]. The loading pattern and straightness will also be same in case of round bars. In the industrial application, a decision can be taken as to what portion of such long bars is acceptable on quality level. Srimani et.al. provided guidance for the minimum length of the rail at the ends, which need to be cut to achieve the straightness within the acceptable limit.

Prediction of residual stress state of cyclic softening during cross-roll straightening agrees qualitatively with experimental values [26]. Residual stress distribution has a beneficial effect apart from increasing straightness in bars of cross-roll straightening. Tensile residual stresses are induced in straightening process at surface of bar which is reduced considerably by previous drawing operation. The objective was to predict the evolution of the internal stresses qualitatively. On a section, the residual stress distribution is not symmetrical about the axial direction. As a whole, residual stresses are naturally in equilibrium in the bar.

7 Modelling/Numerical Modelling

It is said that a metal is actually no mere rigid or dead body. A material can be considered as endowed with a life of its own. This results in many complex processes which may go on within it. In a simple model produced for the Bauschinger effect during stress reversal, we can say that a metal may be considered as possessing a limited memory of its previous work hardening or past history [17]. Mathematically, the constitutive laws of stress–strain behaviour for engineering assessment depend on the following:

(a) Characteristics of deformation of the material
(b) Structural complexity and
(c) Spectrum of loading.

These constitutive models should take ideally the following into account:

- Non-linear response of stress–strain
- Behaviour of material with repeated cycling, viz., cyclic hardening, cyclic softening, or steady-state response
- Kinematic hardening or softening due to change in plastic slope
- Isotropic hardening or softening due to change in yield stress
- Relaxation of mean stress under strain control, or strain ratchet under stress control
- Bauschinger effect
- Other memory of past deformation.

Numerical modelling in cross-roll straightening emerged with researches by Mutrux et al. [26]. Processes of cross-roll straightening were studied in a simulated situation. There is significance of the research in a simulated form. It indicated that reduction of curvature can be predicted. In straightening processes of the bent rod, the plastic zone is propagated along the helix. Study indicated that bending of the bar can be controlled by changing the angle α between rolls and bar. Bending occurs more with smaller angle, α. Optimal value of angle α will be when degree of straightness is reached at the highest level. However, a realistic transition speed and also economic viability is to be ensured. The similitude between the stress state obtained in three points bending and in cross-roll straightening has been indicated and consequently inferred that by passing through the rolls, the curvature of a bent bar can be significantly reduced [27].

8 Simulation/Numerical Simulation

Simulation approach on rolls is now quite old. Although not directly on bar straightening using cross roller, experimental simulation of pass rolling was undertaken by Macura and Petruska [28]. Researches have been done on simulation of straightening operations. To straighten steel plates or strips, roller levelling is used after

final rolling and heat treatment or cooling operations [29]. An essential requirement for steel manufacturer is that after straightening, the result should show low residual stresses and the product is sufficiently flat in case of flat strips. The concept is applicable on round bars as well. Plate or strips are subjected to multiple forth and back bending sequences with decreasing roll penetration in roller levelling.

Simulated model of straightening process with schematic arrangement of rollers in straightening process was discussed by Srimani et al. [30]. However, in this case also, the bar used was rail. As the rails undergo alternate bending and subjected to elasto–plastic deformations in a straightening machine, it is subjected to high magnitude of loads. Simulated model is therefore immensely useful considering high magnitude of loads.

FE Simulation of cross-roll straightening was done by Mutrux et al. [26]. The deformation of the bar—the strain tensor field—between the rolls was obtained through a FE simulation. Mutrux et al. tried a better understanding of the straightening process through simulation. Strain tensor field approach was taken. Numerical simulation was used to study optimization of straightening regulation in heavy rail compound roll straightening processes. By using FEM software ANSYS/LS-DYNA, numerical simulation calculation was carried out by Song et al. Song et al. used a system of nine horizontal straightening rollers and eight vertical straightening rollers for a 60 kg/m heavy rail [31].

Finite Element Analysis (FEA) model is used often for a quantitative analysis. Huang et al. used sixty nodes on the cross-sectional outline with intervals of 6 degrees. Straightening nodes were selected and polar radius thereof was calculated. The quantitative analysis was for tolerance of roundness of the straightening bar. Model with nine roller straightening process has been used by Kaiser et al. [1]. Variation of curvature has been shown with position in straightening machine. Simulation of the roller straightening process has been discussed with respect to residual stresses and curvature trend [1].

Petruska et al. [32] discussed through a schematic view of typical multi-roller straightening machine and shown the distribution of longitudinal stress at initial state and residual stress after levelling. Computational simulation of cross-roll straightening of bars was done through models of bar-rollers contact at one-point and two-points.

9 Control System and Stabilisation

Geometrical stability of products and its assurance is a significant problem in manufacturing engineering for the success of further assembly work or automation-based assembly. In cold work metal forming, fluctuations of properties like yield stress, hardness, ductility, etc. of the input material contribute significantly to the geometrical shape of final product. Positioning of tools that causes bending can influence forming of material. In wire forming by cold work, appropriate corrections of position of bending tools can influence the process.

In bar straightening process, positioning of rolls plays an important role as bending moment and curvature depends on the same. The only precondition for stabilization system for wire bent products is that straightening machines are required to have sufficient number of rollers [33]. Nastran and Kuzman confirmed that several plastic bending is essential to reduce residual curvature. This has naturally necessitated the requirement of multi-step straightness and so Multi-Step Straightening Control system (MSSC) got importance in the process.

Minimization of straightness error in deflected shafts was studied by Kim and Chung [34]. To meet this purpose, multi-step straightening and three-point bending process for the MSSC was developed. Due to various processes involved, many manufactured shapes of parts are known to get deformed. Because of such deformation, straightness of shafts is degraded. Hence, to control the shaft's straightness, grinding operations become essential. Straightening machines so developed use bending processes for compensation of straightness error before grinding with an increased level of automation [34].

It can be seen that roller levelling took a significant place in bar straightening. Researches have been done on roller levelling process optimization [35]. Roller levellers have been considered as the most desirable elements for elimination of undesirable curvatures. Analytical study of Das Talukder et al. helps to eliminate unevenly distributed residual curvature along the axis or longitudinal direction of a pipe on dynamic load for various kinds of cross-roll levellers. The analysis revealed that to effect on straightness of levelled pipe, the most important factor is pitch [35]. In case of wires, residual stresses as generated in bending, straightening operations play a significant role in their mechanical properties. Measurement of various parameters is often considered important. Neutron strain scanning machines have been found used for this purpose [36].

10 Discussion

The theoretical aspect being the backbone of the process has been brought out with an understandable clarity. Various types of straighteners have been featured in simplified form. Although it is considered that materials will have uniform yield point for bending, in reality the bars may not have well-defined yield point, hence the unloading curves may not be straight lines. Mathematical treatment shows that considerable reduction of curvature is possible through straightening process. The review of bar straightening process concerning various aspects which were dealt by various researchers time to time has been briefly looked into with theoretical analysis. Reduction of residual stress can be done through roller straightening and prediction of residual stress state is possible. Researchers have gone into numerical modelling and created simulated situation and studied the process of straightening. Elasto–plastic deformation of high magnitude is difficult whereby simulated environment made it easier to study the same. Stabilization of geometrical shape is an ultimate necessity in any straightening process where many important parameters of bar straightening

featured. Roundness tolerance of bars in some cases can nearly be eliminated [37]. Positioning of rolls is considered important in the process. Specifically which roller in the process has more effect can now be understood easily. Multi-Step Straightening Control System found a place which is indeed a significant contribution in modernization of bar straightening process. This article may be considered as a consolidated work assimilating variety of areas related to bar straightening till date. This review paper has dealt with bar straightening from its historical concepts to present time contributions with important significance of simulation, measurement, control, and stabilization aspects briefly.

11 Conclusion

There have been consolidations of various key features of bar straightening process. Industrial bending-straightening operations may generate significant residual stresses. Modification of residual stress profile is done through cold working; therefore, theoretical aspects of straightening process play a significant role. Although in earlier times thrust was primarily on theoretical development, in recent time numerical modelling and simulation has helped to assess arrangement of rollers and draw conclusion on heavy-duty application of bar straightening [27]. Qualitative prediction on residual stresses and reduction of curvature is now much easier. Application of control systems in stabilization will improve commercial aspects of bar straightening due to minimization of straightness errors [34]. There has been discussion on most aspects of bar straightening in brief, hence it will now be possible to look into the areas of further work much easily. Researchers can look upon recent areas for further thrust and investigation on bar straightening which may be of immense benefit to the design and production engineers. It is obvious that probabilistic approach and statistical aspects have barely been dealt with although there is actually a lot of scopes.

Development of Anti-Loosening Bolts Based on Innovative Double Thread Mechanism

Teruie Takemasu, Toshinaka Shinbutsu, Shuichi Amano, and Jyo Shimura

Abstract Anti-loosening bolted joints were developed with an innovative double-thread mechanism composed of coaxial single and multiple coarse threads. The number of coarse threads of the multiple-thread was set to 3 (denoted as 3thread DTB-II), and its thread structure was fundamentally modified as follows: (i) one of the three multiple-thread grooves was removed for 3thread DTB-II specimens and one of the two remaining grooves shifted downwards by a half pitch (denoted 3-1thread DTB-IIB) and (ii) the depth of the multiple-thread grooves was reduced by up to 50% of the thread height (denoted 3-1thread DTB-IIC). FEM thread rolling simulations were performed using a dedicated die. The two kinds of modified DTB-II specimens were rolled precisely and the thread heights reached the target value at all cross sections. The forming states in the thread rolling experiments well matched the FEM simulation states. The performance evaluation tests demonstrated that the 3-1thread DTB-IIC specimens had sufficient tensile strength, and its anti-loosening performance exceeds the reference level given in DIN25201.

1 Introduction

It is well known that cyclic stresses or impact loading during service can cause the loosening and fatigue failure of bolted joints, possibly leading to serious accidents [1]. The loosening of bolted joints can be roughly divided into the non-rotational type, in which the axial force decreases without nut rotation, and the rotational type, in which return rotation of the nut occurs [2, 3]. Non-rotational loosening can easily be dealt with by additional tightening of the nut or a design change. In contrast, rotational loosening is an inevitable issue because it occurs suddenly in an environment with cyclic loading, severe vibration, and impact forces. Most commercially available anti-loosening screw parts exhibit macro slip on the nut-bearing surface when subjected to a severe transverse vibration load and cannot completely suppress rotational loosening because most of them only enhance the frictional force between the bolt and the nut or between the nut and the bearing surface [4–7]. In comparison, it has been proven that the double-thread bolted (DTB) joints having two types of coaxial screw thread with different lead angles have an excellent anti-loosening performance [8]. For such joints, a higher lead nut is first fastened, and then a lower lead nut is added to form a double nut structure. The anti-loosening mechanism of DTB is enhanced by a mechanical locking based on the interference effect of two kinds of nut with different loosening speeds.

DTB joints with a very simple structure composed of a single coarse thread and a single fine thread (denoted DTB-I), have been a major research target [9]. However, as DTB-I has become more widely used, various disadvantages associated with the fine screw thread have been pointed out by users, including troublesome torque management for each nut, insufficient strength of the fine thread, high manufacturing cost of rolling dies, and low durability. Bolt fasteners, denoted DTB-II, was then proposed based on an innovative double-thread mechanism composed of a single coarse thread and a multiple coarse thread [10, 11]. Nut fastening and torque management for DTB-II can be performed very easily since the inner multiple-thread nut, mounted first, is also rotated when the outer single-thread nut is tightened, solving most of the problems encountered with the conventional DTB-I. Thread rolling experiments and tensile strength tests were conducted on DTB-II specimens with 2, 3, and 4 threads on the multiple-threads, which were denoted 2, 3 and 4thread DTB-II, respectively, to evaluate the proposed double-thread structure. It is found that 3thread DTB-II formed relatively well, although the height of the screw thread profile of 2 and 4thread DTB-II did not reach the target level. The tensile strength of these DTB-II specimens tended to decrease with increasing number of multiple-threads, and 3 and 4thread DTB-II were damaged by the shear failure of the screw thread even with the double-nut structure. Accordingly, to solve these problems, the authors designed several kinds of modified DTB-II, in which the number of multiple-thread grooves superimposed on the single screw thread was selectively reduced to $m - 1$ (m: number of multiple-threads) or fewer from the m-thread DTB-II, manufactured them by thread-cutting, and carried out tensile strength tests. The shear

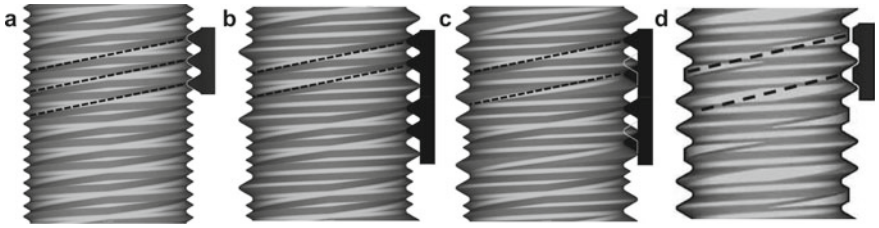

Fig. 1 Diagrams of screw thread structure of **a** 3thread DTB-II, **b** 3-1thread DTB-IIA, **c** 3-1thread DTB-IIB, **d** 3-1thread DTB-IIC

fracture of the screw thread of all DTB-II specimens mounted with double nuts was successfully suppressed by reducing the number of multiple-threads by at least one.

In this study, thread rolling FEM simulations and experiments were conducted on the two types of modified 3thread DTB-II (see below for description) to examine the material deformation state and forming accuracy. Several performance evaluation tests were then performed to determine the effect of the modified screw thread profile on the tensile strength and the anti-loosening performance of those DTB-IIs.

2 Methods

2.1 Screw Thread Structure of Modified DTB-II

Figure 1 shows a comparison of the screw thread structure of 3thread DTB-II [10] and those of the three modified types. Figure 2 shows the changes in the thread cross-sectional area ratio, ξ, of each DTB-II, which was calculated by dividing the thread cross-sectional area of three pitches at each angular position of DTB-II by that of the normal single screw-thread. Figure 1a shows the thread structure of the original 3thread DTB-II, and b shows that of the modified 3-1thread DTB-IIA, in which one thread groove was simply removed from the three thread grooves and the remaining two thread grooves were superimposed onto a single screw thread. With this modification, the minimum value of the thread cross-sectional area ratio, ξ_{min}, increased to approximately 55%, as shown in Fig. 2. However, since there are four consecutive small threads at the groove bottom at the 90° and 270° positions, at which thread shear fracture may initiate, 3-1thread DTB-IIA was excluded from further testing. One of the remaining two thread grooves was shifted downwards by a half pitch to be aligned at an equal pitch, as shown in Fig. 1c; this joint is denoted 3-1thread DTB-IIB or simply DTB-IIB [11]. For 3-1thread DTB-IIA, the complete screw thread appears at only the 0° and 180° positions, whereas 3-1thread DTB-IIB has one or two complete screw threads in three pitches at all cross sections. The ξ value of 3-1thread DTB-IIB changes at the 90° cycle, as shown in Fig. 2, which is half that of 3-1thread DTB-IIA, and ξ_{min} is 70%, which is twice that of 3thread

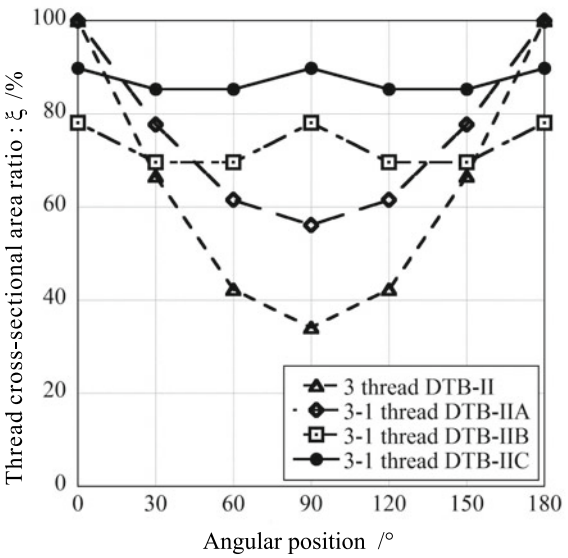

Fig. 2 Comparison of changes in the thread cross-sectional area ratio, ξ, of each DTB-II specimens, which was calculated from the thread cross-sectional area of three pitches at each angular position

DTB-II. However, a small-thread portion remains at the groove bottom for all angular positions, which reduces tensile strength. In order to completely remove these small threads, the depth of the multiple-thread grooves was reduced by up to 50% of the thread height, as shown in Fig. 1d; this joint is denoted 3-1thread DTB-IIC or simply DTB-IIC. With this modification, ξ_{min} increased up to 85% and improvements in tensile strength were expected.

2.2 FEM Simulation Model and Experimental

To reduce cost, DTB-II joints have to be manufactured using a mass production process. Thread rolling is most suitable for this task because of its productivity and widespread use. In the thread-rolling of DTB-II, both the single and multiple coarse threads should be formed simultaneously on a single rod axis through one rolling process. To realize this process, the authors developed a dedicated roller die (denoted DTB-II die) with a special groove profile, which has almost the same outline as that of the thread profile of DTB-II specimens in each corresponding cross section. Thread rolling simulations of M12 DTB-IIB and C were first performed using a 3D FEM model to examine the forming process of the screw thread. The commercial FEM code Simufact.forming ver.15 was used. Figure 3a and b show the FEM simulation model, in which the workpiece is an elasto-plastic cylindrical material and the rolling flat dies are rigid bodies. During processing, the two flat dies were moved synchronously in opposite directions (see arrows in the figure) and simultaneously pushed into the workpiece at the same constant speed. The total amount of indentation of the die,

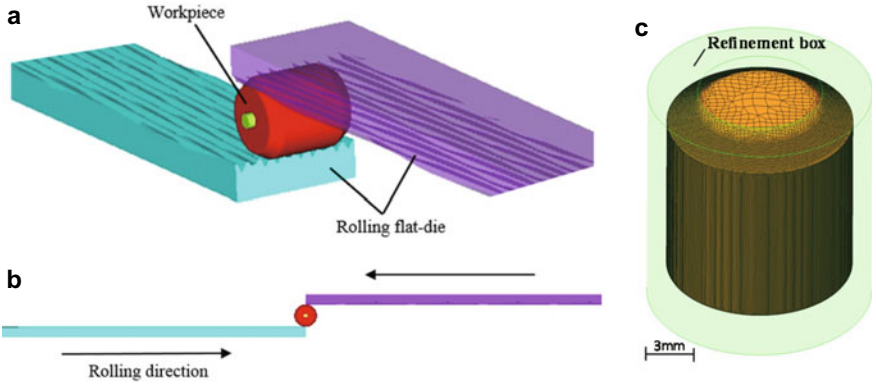

Fig. 3 **a** Perspective view of FEM model. **b** Side view. **c** FEM mesh of workpiece. (Color figure online)

δ_{max}, was set to a prescribed value for each DTB-II ($\delta_{max} = 0.56$ mm for DTB-IIB and $\delta_{max} = 0.62$ mm for DTB-IIC) until the workpiece was rotated 8 times; then, the dwelling process was performed for two rotations. Coulomb's friction law was assumed at the contact interface between the dies and the workpiece, and the coefficient of friction μ was set to 0.2. Figure 3c shows the initial FEM mesh of the workpiece with a diameter of $\phi 10.8$ mm. A semitransparent refinement box was placed in the region from an inner diameter of 8 mm to an outer diameter of 14 mm; this region is divided by hexahedron fine elements with a reference size of 0.4 mm. The height of the cylindrical workpiece was restricted to the 9-pitch length of a single screw-thread bolt to reduce calculation time and to avoid the effect of edge droop on thread forming around the central portion in the axial direction.

The thread rolling experiments of M12 DTB-IIB and C were conducted using a manual rolling machine with a two-roller die plunge feed (FA-16U, Nissei Co., Ltd.) under a die rotational speed of 62 rpm and a net processing time of 4 s, which included a 1 s dwelling time. The initial diameter of the workpiece and the final amount of the die radial feed were decided based on the screw thread forming state. A low-carbon steel bar made of DIN 17100 was used as the bolt material.

The methods and conditions of the several performance tests are described later.

3 Results and Discussion

3.1 Thread Rolling FEM Simulation and Experiments

Figures 4a and 5b show the equivalent plastic strain distribution, $\bar{\varepsilon}$, of thread-rolled DTB-IIB and C obtained from the FEM simulation, and Figs. 4b and 5b show the outer appearance of the samples used in the experiment, respectively. Figure 6a and b

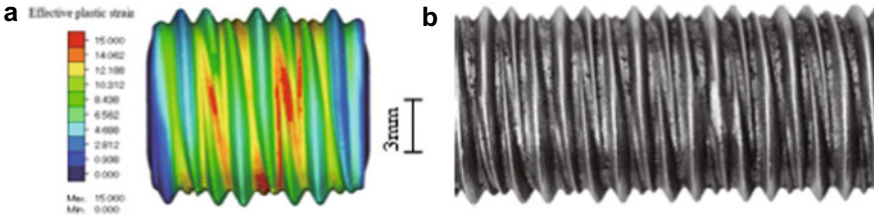

Fig. 4 **a** Equivalent plastic strain distribution of rolled 3-1thread DTB-IIB using FEM. **b** Rolled sample of 3-1thread DTB-IIB used in experiment. (Color figure online)

compare the filling state transition of the material at each representative angular position of the die grooves at each amount of die radial feed δ value obtained from FEM simulation. The final deformation state of each modified DTB-II in the analysis well agrees with that in the experiments, and the target screw thread profiles for both cases are obtained for the entire external surface. The thread forming state during rolling in the FEM simulation also progressed as expected. Therefore, both the multiple- and single-thread nuts were fastened easily and smoothly on the thread-rolled DTB-II specimens. However, the equivalent plastic strain distribution, $\overline{\varepsilon}$, of DTB-IIB is very high at the groove bottom and its maximum value reaches approximately 15. In contrast, that of DTB-IIC is very low and its maximum value is 7, less than half of that for DTB-IIB. Hence, in the thread rolling experiments conducted at room temperature, the material temperature immediately after the processing of DTB-IIB increased to 110 °C, whereas that of DTB-IIC increased to only about 70 °C. The reason is that the material filling of the two shallower die grooves located at the center of the 0° position and at the right of the 90° position of DTB-IIB completed in the early deformation stage of $\delta = 0.28$ mm and (surrounded by enclosed space with no room for overflow) then the material was over-rolled, as shown in Fig. 6a. The material near completely filled grooves flows along the same single screw thread to the unfilled deeper grooves, and this material flow in the circumferential direction causes severe shear deformation, leading to material surface peeling and shortening tool life. Many cutting chips appeared in the thread rolling process of DTB-IIB; considerably fewer chips were observed for DTB-IIC. Since the material deformation of DTB-IIC advances in the same manner as that of the normal single-thread bolt, in which the material mainly rises in the radial direction until 70% of $\delta_{\max}$ (δ0.47 mm), the thread forming state does not depend on angular position. Although material flow in the circumferential direction occurs after the shallow trapezoidal grooves located at the center of the 0° position and at the right of the 90° position of DTB-IIC are filled, as shown in Fig. 6b, its amount is much smaller than that for DTB-IIB, and there is no portion around the groove bottom where is excessively high. These results indicate that the thread rolling formability of DTB-IIC is greatly improved over that of DTB-IIB because of the good thread profile balance in the circumferential direction.

3.2 Tensile Strength Tests

The tensile strength tests of M12 rolled 3-1thread DTB-II specimens (denoted DTB-IIs) and a conventional rolled single-thread bolts were conducted using a hydrolic universal material testing machine (UH-300kN made by Shimadzu Corp.) equipped with a special rig with a self-aligning function in the axial direction. A test specimen mounted with double nuts or a single screw nut was placed in the rig and extended at a constant speed of 2 mm/min. The under-head full length of the bolt specimen was 110 mm and the length of the screw portion was 60 mm. The failure mode of all modified DTB-IIs mounted with double nuts was the breaking of the base material and the maximum loads were almost the same as that for the normal single-thread bolt. Here, the non-shear fracture condition of the screw thread was determined by mounting only a single screw nut with different heights, namely normal height (10 mm), 1.25 times normal height (12.5 mm), and 1.5 times normal height (15 mm). Figure 7a–c show the appearance of the fractured DTB-IIB and C with a single-nut structure, and Fig. 7d compares the load-stroke curves obtained from the tensile tests. All these tests were conducted three times under the same conditions; the same results were obtained in each trial. DTB-IIB was damaged by the shear fracture of the screw thread with the 1.25-times-normal-height single nut, and was fractured via necking of the base material with the 1.5-times-normal-height single nut. For DTB-IIC, breaking of base material with the 1.25-times-normal-height single nut and damage by shear fracture with the normal-height-single nut were observed. The maximum load reached approximately 90% (47 kN) in the case of base material breaking. Since the minimum and maximum values of the axial tension of the JIS M12 standard single-thread bolt are 14 and 25 kN [12], respectively, it is possible to use DTB-IIC even with the normal single-nut structure. Accordingly, DTB-IIB and C have remarkably improved tensile strength compared with that of 3thread DTB-II in the previous study [10]. The axial load of DTB-IIC is almost equal to that of the normal single-thread bolt because of the elimination of the small threads at the groove bottom.

3.3 Vibration Loosening Tests

Comparative vibration loosening tests were conducted using the conventional M12 DTB-I and modified M12 3-1thread DTB-IIB and C with a double-nut structure. A Junker test bench (J120T, Vibrationmaster), shown in Fig. 8a, was employed to analyze the self-loosening behavior of secured bolted joints [13]. This apparatus can specify the state in which a bolted joint loses its axial preload when subjected to shear loading by transverse vibration. The transverse displacement and the oscillation frequency were set to 1 mm and 12.5 Hz, respectively, which are the most extreme conditions for this apparatus. The initial axial preload, P_0, of the modified DTB-IIs was set by adjusting only the tightening torque of the outer single nut to be

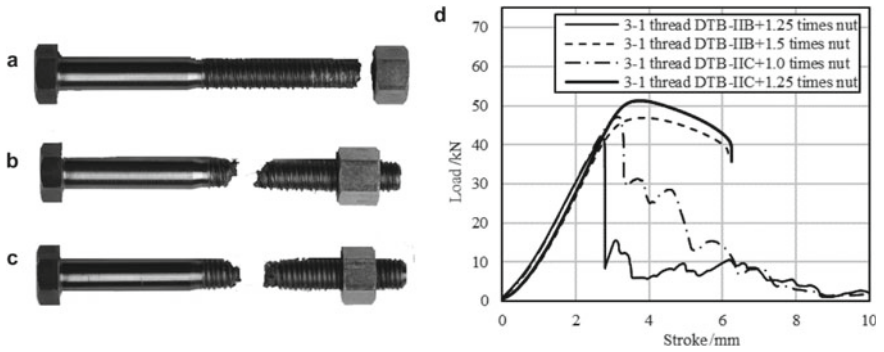

Fig. 7 Tensile strength test results of **a** 3-1thread DTB-IIB with 1.25-times-normal-height sigle nut, **b** 3-1thread DTB-IIB with 1.5-times-normal-height single nut, **c** 3-1thread DTB-IIC with 1.25-times-normal-height single nut. **d** Stroke-load curves obtained from tensile tests

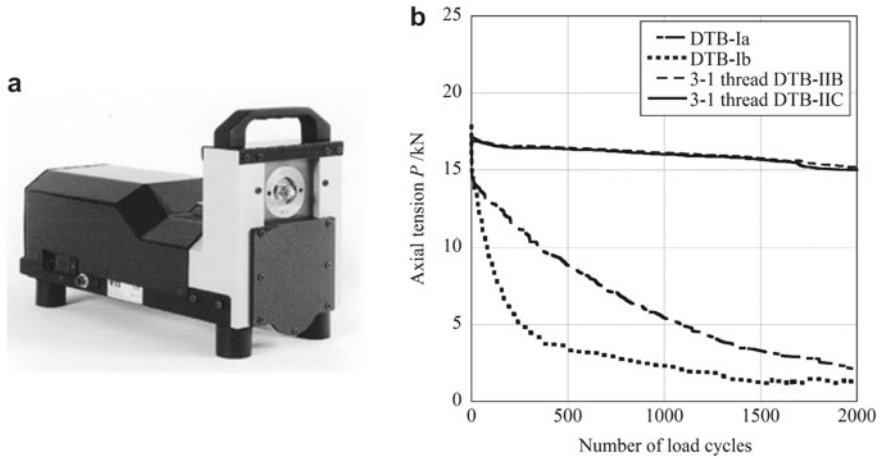

Fig. 8 **a** Junker vibration loosening test bench. **b** Axial tension versus number of load cycles in Junker's vibration loosening tests

fastened later. The proper P_0 for a bolted joint with a nominal size of M12-1.75 is prescribed to be approximately 20 kN in JIS strength class 4.8. However, since the anti-loosening performance of the modified DTB-IIs was so high that the axial force hardly decreased when tightening was conducted with the specific axial load, the bolt head shank exhibited shear fracture during testing. P_0 was thus set to a slightly lower value, within the range of 17–18 kN. A test was considered to have completed when the total number of oscillations exceeded 2000 cycles (about 160 s) or when it became apparent that the bolted joint had loosened. Figure 8b shows the variation in the axial load of the conventional DTB-I and modified DTB-IIs with the number of load cycles in the Junker vibration test. Here, DTB-Ia denotes the case where the inner nut was rotated back according to the regular instruction, and DTB-Ib denotes

the case where that procedure was omitted. The final residual rate of the axial load was approximately 15% for DTB-Ia and 10% for DTB-Ib. In contrast, those for the two DTB-IIs were larger than 85%, which is considerably higher than those for DTB-I and exceeds the reference value of 80% given in DIN25201. A detailed comparison of the changes of the axial load indicates that the rates of both DTB-Ia and DTB-Ib suddenly drop by about 4 kN immediately after the starting point; then, that of DTB-Ia continues to decrease with a nearly constant slope, whereas that of DTB-Ib rapidly decreases for about 300 cycles and then decreases very gradually. The rates of both DTB-IIs are almost constant after an initial decrease of about 1 kN. The reason for this significant difference is as follows. (i) The loosening speed ratio between the inner nut and the outer nut of DTB-IIs is 3:1, which is larger than that of DTB-I (2:1). (ii) The outer nut of DTB-IIs with a single coarse screw thread can hold the axial load of a bolted joint more strongly than can DTB-I with a single fine screw thread.

4 Conclusions

1. The rolling formability of the modified 3-1thread DTB-II specimens was considerably improved. Since the material deformation of DTB-IIC advanced in the same manner as that of the normal single thread bolt up to 70% of the total amount of die radial feed, the over-rolled area was greatly decreased around the thread groove portion and the material temperature immediately after the processing was much lower compared with that for DTB-IIB (70 °C vs. 110 °C).
2. The tensile strengths of DTB-IIB mounted with a 1.25-times-normal-height single-thread nut and DTB-IIC mounted with a normal-height single-thread nut reached the range of 14–25 kN prescribed by JIS.
3. It is found that both DTB-IIB and DTB-IIC have outstanding anti-loosening performance, as determined using Junker vibration loosening test. The final residual axial loads were kept at more than 80% after the prescribed 2000 cycles by adjusting only the tightening torque of the outer single nut to be fastened later.

Study on Precision Forging Methods of Difficult-to-Knockout Components with Non-parallel Internal Grooves

Luyi Han, Guangchun Wang, Xin Wang, and Zhao Liu

Abstract Due to the difficulty of knock-out and complex metal flow law caused by the non-parallel internal grooves, the manufacturing of the cross groove CVJ (constant velocity universal joints) outer races mainly relied on machining. Taking the VL-type outer race as a case study, this paper made an exploratory study on the precision forging of these difficult-to-knockout components. A retractable forming mandrel was developed based on which the metal flow behavior through different metal forming methods, including the multi-ram forging and closed backward extrusion, had been researched. The effect of billet shape on forgings and metal flow were analyzed for the multi-ram forming process, and the deformation load and press on the mandrel were focus of the closed backward extrusion method. Influenced by the V-shaped cross grooves, the filling conditions and the pressure distribution between adjacent grooves exhibited regional differences.

Keywords Cross groove CVJ · Precision metal forming · Multi-ram forging · Closed backward extrusion · Material flow behavior · Forming pressure

1 Introduction

Due to the problem of knockout, the cross grooves which are not parallel to the axial direction of workpiece are conventionally machined after forging. And the CVJ (constant velocity universal joints) is a component [1] for connecting the wheel part of a car and the drive shaft, and the batch of those components is large. Geometrically, it can be divided into parallel and non-parallel forms through internal grooves. Among them, the products with parallel grooves have achieved to be produced by metal forming [2]. For such products with non-parallel internal grooves, such as VL-type

CVJ, due to the difficulty of knockout caused by their geometric asymmetry, they can only be processed by milling, grinding and finishing methods, but it is still different to achieve the direct production by metal forming which has become a bottleneck restricting the processing efficiency and production quality of such products.

Compared with mechanical production methods such as milling, metal forming has the advantages of high efficiency, reducing material waste, and improving product performance [3]. In recent years, precision forging has been widely used for the production of mechanical parts with complex geometries. This type of near-net forming method has been studied to wider application in actual industrial production since the high efficiency and high precision of its products [4, 5].

For precision forging of hollow cylindrical workpieces, extrusion is generally adopted [6]. And forgings with concave structures on the external structure, multi-ram forging methods [7, 8] or closed extrusion methods [9, 10] are generally used. There are different characteristics of metal flow in whole or in part under multi-directional press for the above-mentioned methods. The forgings have prominent flow line characteristics, good product performance, and good dimensional accuracy. This kind of forging method has higher requirements for equipment due to the large forging load and complicated die structure. For the workpieces with radial geometric features in the cavity, of which the forging load is directly applied in the radial direction to achieve the radial reduction of the billet and then the internal geometric features are radially forged. Compared to the closed extrusion, the forming load of radial multi-ram forging will be significantly reduced, but this radial forging processing method has higher requirements on the relative movement between the dies and the accuracy of mechanical control.

This paper takes the VL-type CVJ outer race as the research object, and carries out researches on the precision forming method of difficult-to-knockout parts with non-parallel internal groove structure. The non-parallel grooves in the cavity make it impossible to achieve a smooth demolding of the inner mandrel after forging. Combining the structural characteristics of these components, a inner mandrel with retractable ribs is designed in this paper, which can shrink the ribs at the end of forming to achieve smooth knockout. Based on this, two corresponding forming methods—closed backward extrusion and multi-ram forging—are proposed. In order to achieve precision forging of VL-type CVJ workpieces, the exploratory simulation study is carried out.

2 The Objective Products and Design of Die

VL-type CVJ currently used in automobiles can be divided into two forms with bottoms and through holes, as shown in Fig. 1. Among them, the CVJ with a bottom as illustrated in Fig. 1a can be connected to the automobile shaft through a sliding pin, and the another type CVJ, shown in Fig. 1b, is generally connected by bolts. Compared with the parallel slide type, the VL-type CVJ has a longer track grooves, which can effectively reduce its axial size. The specific dimensions of these two

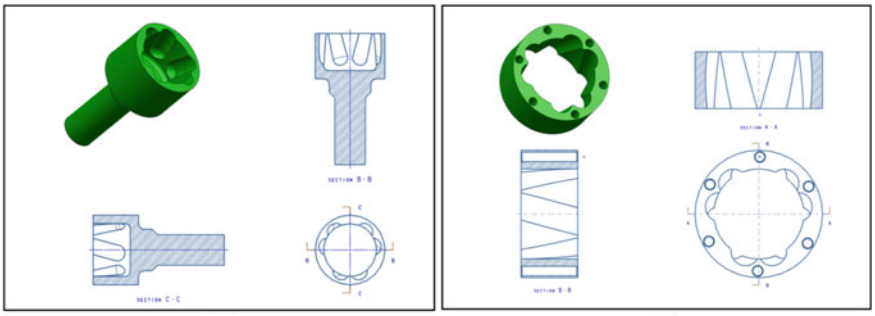

Fig. 1 The objective components, **a** VL outer race with a bottom, **b** VL outer race without a bottom. (Color figure online)

Table 1 The geometric parameters of the CVJs

	Outer diameter	Inner diameter	Axial height	Depth of hole cavity	Corner radius	Volume
CVJ with a bottom	84 mm	63.6 mm	50 mm	45 mm	5 mm	140,539.73 mm^3
CVJ without a bottom	84 mm	63.6 mm	40 mm	40 mm	0 mm	72,796.54 mm^3

objective CVJ are shown in Table 1. Both on the inner walls of these two CVJs, there are 3 pairs of V-shaped symmetrical slide. After forming, the metal will be close to the surface of the die, and the inner mandrel can't be knocked out from the forgings since it will be stuck in these slides.

In order to solve the problem of knockout after the VL-type CVJ is forged, this paper first designs a mandrel die with retractable ribs. As shown in Fig. 2a, this retractable mandrel is mainly composed of four parts, of which the push rod cooperates with the mandrel die, when the push rod is pushed down to the maximum position, the six retractable ribs in the mandrel can be fully expanded. After the forming is completed, the push rod can be reset by the springback device, and the retractable ribs are driven to shrink into the mandrel die by the push rod to achieve smooth knockout.

In this paper, the different forging processes for the above two structures VL-type CVJ are simulated. The simulation of the forging process does not consider the subsequent knockout problems, it means that the scalability of the six ribs on the mandrel does not need to be considered, therefore, the mandrel is simplified into a one-piece structure during the simulation, as shown in Fig. 2b and c. The die shown in Fig. 2b is used for closed backward extrusion of VL-type CVJ with a bottom, and the die illustrated in Fig. 2c is used for multi-ram forging of VL-type CVJ without bottoms.

3 Precision Forging Methods

3.1 Multi-Ram Radial Extrusion Process

The number of punches in the multi-ram radial forging process proposed in this paper depends on the number and pattern of non-parallel grooves in the cavity. For the CVJ with three pairs of V-shaped inner grooves as shown in Fig. 1b, it is suitable to adopt three punches for radial forging, and the die setup is shown in Fig. 3. The axial length of the mandrel rib is 41 mm, which is greater than the effective height of the forging

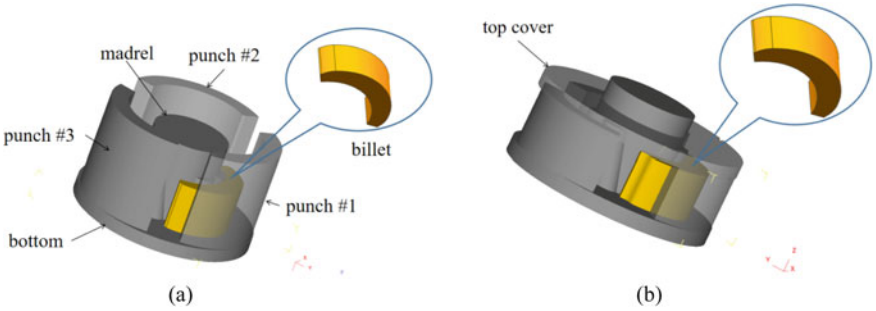

Fig. 3 Layout of dies. **a** Dies assembly without top cover. **b** Die assembly with top lid. (Color figure online)

raceway by 40 mm. The punch is a 118° arc-shaped structure with an inner diameter of 90 mm and corner edges of R2mm. According to the analysis of the geometric relationship, the force of the billet is symmetrical under the action of the punches. In order to improve the efficiency of the simulation calculation, the billet is modeled as one-third according to the 120° equally, and the symmetry plane is set at the cutout.

This three-punch radial forging process has two options. The first is an open top type, which allows the metal to flow in the axial direction at the same time the metal radial flow to fill the grooves during the radial pressure of the punch. As shown in Fig. 3a, the three punches radially feed to compress billet synchronously, and the billet metal radially reduces the diameter while flowing upward to fill the groves. In this way, the axial length of the punches needs to be much higher than the height of the workpiece in order to achieve radial restraint on the material during the forming process. The axial length of the punches in this paper is set to 60 mm.

Another way is to set a top cover on the upper end of the ribs to restrict the axial flow of the metal. In the process of pressurizing the punches, similarly, the metal firstly flows upward in the axial direction while reducing the diameter, and the axial flow of the metal stops when it contacts the cover. So the metal will be forced to flow toward the area that needs to be filled in the radial direction, and a small amount of excess metal will form flashes along the gap between the punches. The corresponding punch height in this way is 44 mm.

In order to prevent the formation of flashes between the punches and reduce the forging pressure by using the divided flow, the billet is designed into a hollow cylinder with unequal thickness, in which the thickness enveloped by the punches is the largest. On the other hand, the thin-walled concave area of the billet should avoid metal folding during the forging process. In order to optimize the outer shape of the final forging, as illustrated in Fig. 4, two types of billet are designed in this paper. The plan A mainly highlights the difference between the material thickness of the enveloping part and the concave area, ensuring that as the punch is pressed down in the radial direction more material can flow into the V-shaped grooves area. As for Plan B, in order to achieve a smoother material flow, the rounded corners between the convex area and the concave area of the blank are greatly increased, and

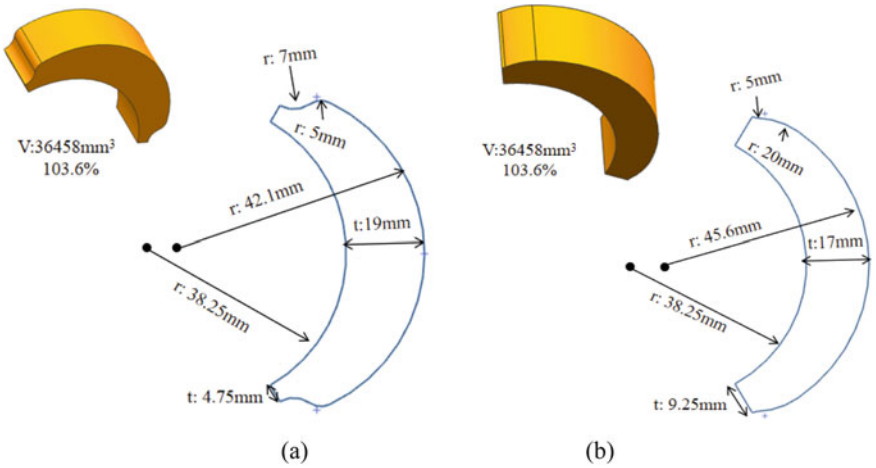

Fig. 4 Geometry design of the billet. **a** Plan A, **b** Plan B. (Color figure online)

the changes in material thickness between the convex area and the concave area of the billet are smoother.

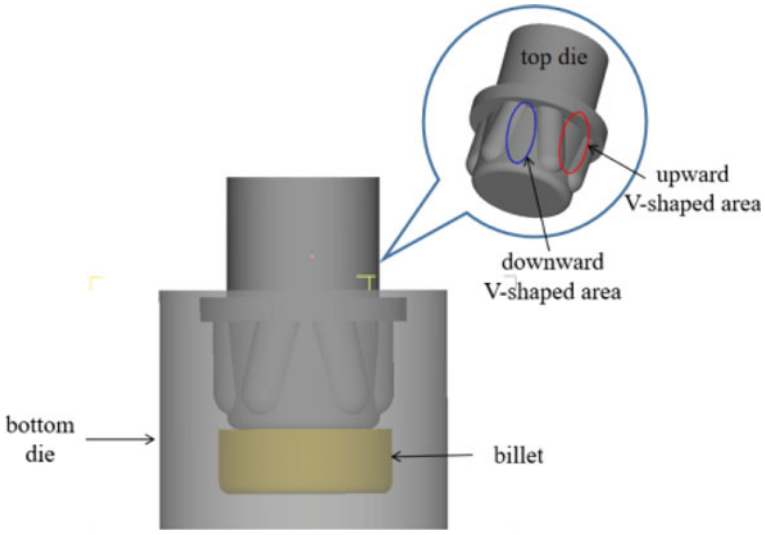

Fig. 5 Setup of the extrusion. (Color figure online)

3.2 Closed Backward Extrusion Process

For the forming of VL-type CVJ with a bottom, this paper proposes a closed backward extrusion method. During the extrusion process, the constraint structure forges the billet in a closed form. And the structure of the simulation dies is shown in Fig. 5. The cylindrical billet has an outer diameter of 83.5 mm, which is convenient for placing in the bottom die with an inner diameter equal to the outer diameter of the forging of 84 mm. According to the principle of constant volume, the height of the cylindrical blank is 26 mm. And the bottom die is designed as an 85 mm deep hole cavity with an inner diameter of 84 mm and a R5 round corner. For the top die used in this method, on the basis of the mandrel structure proposed in the Sect. 2, in order to prevent the underfilling of the up-turned V-shaped area (red area shown in Fig. 5) caused by the upward flow, a fixed cover structure is added on the top of the rib.

4 Simulation Results and Discussion

In this paper, the forging process of VL-type CVJ is simulated by commercial software Deform-3D, AISI-1055 is selected as the material of billet, for dies the material is set to AISI-H-13. The initial temperature of the material is set to 1200 °C and the number of elements of the whole workpiece is set to 150,000, and the corresponding grids of one-third part is 50,000. For the mesh distortion caused by the large deformation of the metal, remesh and target volume techniques are adopted during the forging process. The heat transfer coefficient is set to 11 N/sec/mm/C, and for all contact surfaces of billet and dies the shear friction model is used with the friction factor is set to 0.3. In the backward extrusion process, the pressing speed of the mandrel is 50 mm/s, and the simulation stops when the distance between the bottoms of the mandrel and the deep hole is 5 mm in the Z-direction. In the multi-ram forging simulation, the punch simultaneously presses the blank at a speed of 50 mm/s until it completes the whole stroke.

4.1 Analysis of the Multi-Ram Radial Extrusion Process

First, in order to explore the effect of the billet shape on the forgings, the billets of Plan A and Plan B were used in the simulation of the multi-ram forging method with the top cover. The results are shown in Fig. 6. The volume of the both billets was set to 36458 mm^3. Both forgings formed by the two billet schemes appear flashes in the recess, as highlighted by the red oval in the Figure. The difference is that the metal of Plan A shows a strong tendency to flow radially inward, while the metal of Plan B flows radially outward. Through point tracking analysis at the deepest of the two concave areas, it can be seen that the folds of Plan A are located inside the volume

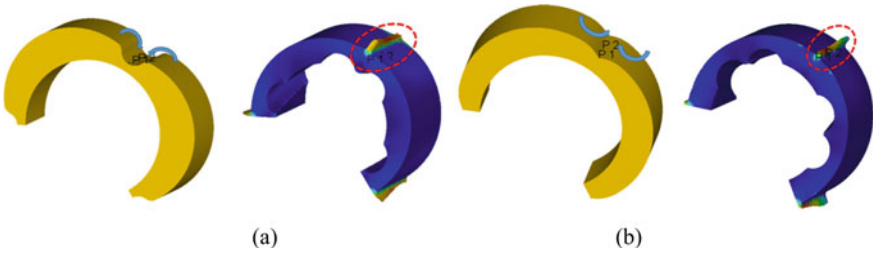

Fig. 6 Folding results of different billet. **a** Plan A, **b** Plan B. (Color figure online)

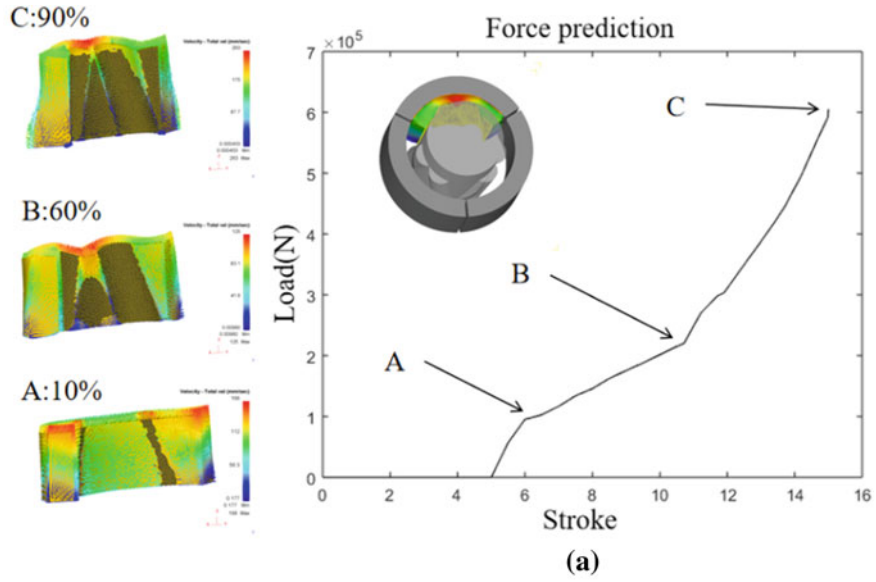

of the forged part, however, the folds of Plan B have been extruded to the flash part, so that the forgings can eliminate the effects of metal folding after machining.

According to the above simulation, it can be seen that the shape of the billets plays a crucial role in the quality of the forgings. The billet in Plan B can effectively eliminate the impact of metal folding and ensure the quality of the forgings. From that point, the billets in plan B are adopted in the following simulations.

Figure 7 shows the results of the two types of multi-ram forging method mentioned in Sect. 3.1. And the billet volume of the type without top cover is set to 37,866 mm^3.

In this paper, the contact rate between the inner wall of the forging and the mandrel is used as a criterion for evaluating the filling condition during the forming process. It can be seen from the simulation results that the filling rate of the final forging is about 90% through the scheme without the top cover, and the metal filling rate reaches 100% when the top cover is added. In the way without the top cover, due to more metal being pressed, the load of the die increases greatly in the initial stage. In this stage, the metal begins to contact the ribs portion of mandrel. With the feed of the punches, the metal slowly flows upward, and the contact rate of the inner wall increases. In this process, the increase in the load of mandrel is slower. At point B, the metal flows to the area near the tip of V-shaped grooves, and the load of the mandrel increases rapidly again. Finally, the metal will flow through the range of the ribs, but the intersecting line areas between the upper part of the grooves and the cylindrical inner wall are still difficult to be filled, which will cause the size defect of the forgings so that it‘s difficult to meet the application requirements.

After the top cover is added, in the initial stage of forging, similarly the metal first contacts the ribs portion of the mandrel, and the load on the punches slowly increases. Until the contact rate of the groove reached about 85%, when the metal began to contact the cover, the load begins to increase sharply. After that, the metal began to flow to the intersecting line areas, this is considered to be the most difficult part to fill the VL-type CVJ. In order to fill in this area, the forging load increases by about 4 times after the cover is added.

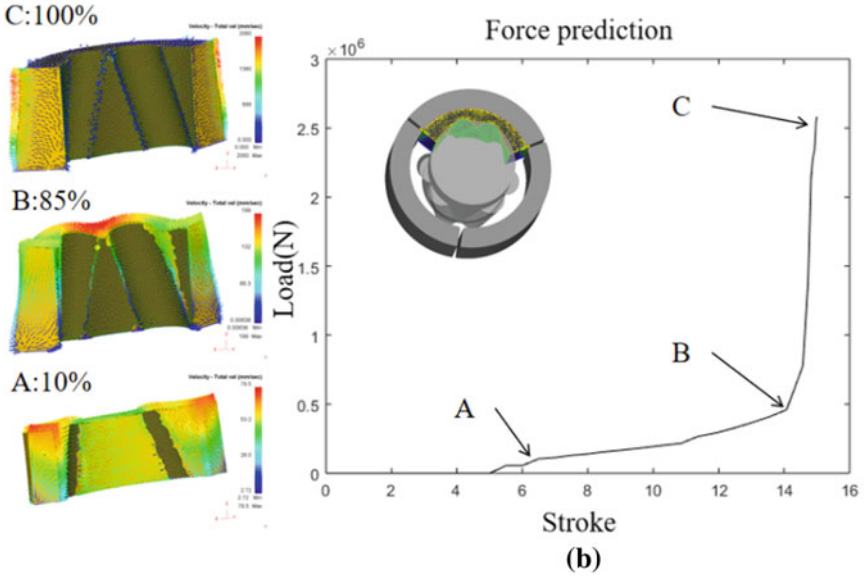

Fig. 7 Forging results of the 3-rams forming. **a** Forging without top cover, **b** Forging with top cover. (Color figure online)

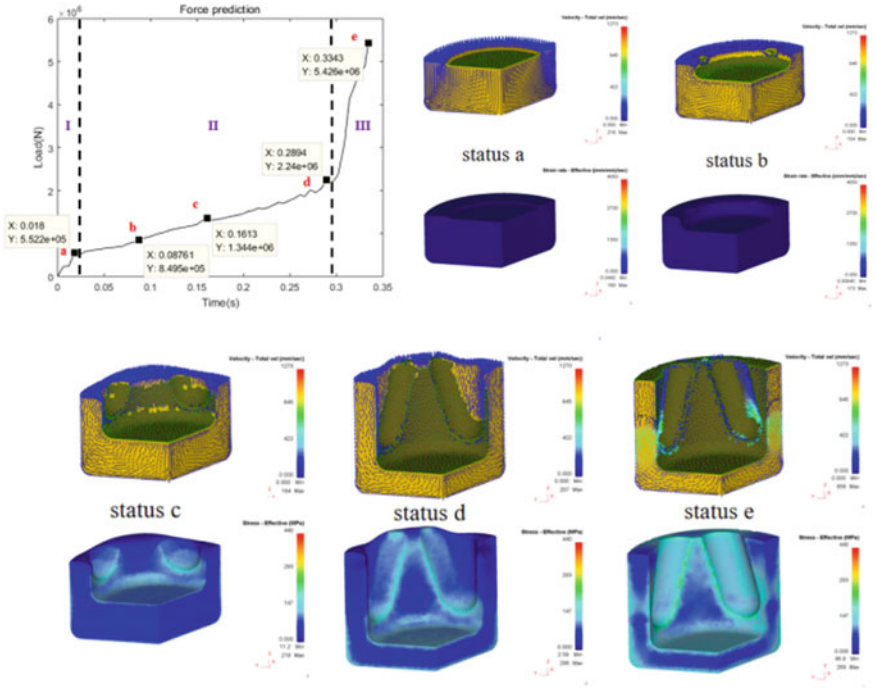

Fig. 8 The forming condition of extrusion. (Color figure online)

4.2 Analysis of the Closed Backward Extrusion

In the closed backward extrusion of the VL-type CVJ with a bottom, the filling process can be divided into 3 stages, as shown in Fig. 8. In the initial stage of extrusion, the bottom surface of the mandrel starts to contact the billet, and the load on the mandrel begins to increase significantly. In this process, the stress value is small and the distribution is relatively uniform. The second stage begins with the metal completely passing through the corner edge of mandrel, at this stage, the material begins to flow upward into the area between the bottom die and mandrel and the forming load rises steadily with the increase of the billet height. Due to the special geometry of the mandrel, the metal flow state is different from that of hollow cylindrical parts, the cavity is divided into 6 regions by the ribs-three upward V-shaped regions and three downward V-shaped regions. From the filling state change of status b to status c, it can be seen that the downward V-shaped area has been in a good contact state during the upward flow of the metal, while the upward V-shaped area is only full at the bottom, and most of the upper area has never been filled. And due to the division of the flow space by the V-shaped ribs, the top end surface of the billet is uneven (status d). At this time, the stress in the area of the intersecting lines of the downward V-shape grooves and cylinder wall is the largest. The third stage

is the closed backward extrusion stage, which starts from the upper end of the billet contacting the cover of the punch to the end of extrusion. When the metal contacts the top cover, the downward V-shaped area is completely filled, but nearly half of upward V-shape area is still not filled. Therefore, as the mandrel continues to press, the metal mainly flows into the area between the upward V-shape area until it is fully formed (status e). The load increased sharply at this stage, its maximum load is about three times that of multi-ram forging. And the stress near the intersecting line is more concentrated than that of its adjacent area.

5 Conclusions

1. In this paper, a simulation study of the three-punch radial forging and backward extrusion processes is performed for the VL-type CVJ. The three-punch radial forging directly affects the metals from the radial direction, and the geometry of the billets plays a crucial role in the quality of the final forgings. The closed backward extrusion mainly relies on the axial flow of the metal to fill the entire forging.
2. In the process of multi-ram forging, it is difficult to fill the area around the intersecting line area of the upward V-shape grooves and cylinder wall without the top end constrained. After adding the cover to restrict the axial flow of the metal, the entire groove area can be filled with a smaller amount of billet, but the corresponding load is increased by about 4 times.
3. For closed backward extrusion, due to the special geometry of the workpiece, the downward V-shaped areas are always formed firstly, and the upward half of the workpiece is not formed until the metal contacts the cover of the mandrel. At the same time, forging load continues to increase as the metal rises, and its value is about three times that of multi-ram forging. The stress is concentrated in the intersecting area of grooves and cylinder. So during the design of the dies, these areas need to be chamfered to facilitate the flow of the metal and reduce the stress concentration.

Incremental Grooving of Thin-Walled Tubes Filled with Discrete Media

Hao-Xing Tang, Tong Wen, and Xia Chen

Abstract To control the undesired deformations like section-distortion and springback during incremental tube wall grooving, we examined the effect of discrete fillers on the deformation of thin-walled tubes during forming. Al6061 tubes with outer diameter of 38 mm and thickness of 1 mm were used in the studies, with silica sands as the fillers. Generalized plastic mechanics was employed to analyze the coupled deformation of the composite structures of discrete media filled tubes; the aggregation of sands was assumed to be compressible continuous body, of which yield behavior was described by the Drucker–Prager criterion. The results proved that compared with hollow tubes, the forming accuracy of incremental tube grooving can be improved under the support of fillers. Specifically, the maximum springback was reduced by more than 3.9%, and the section-distortion also decreased. Moreover, a special deformation mode, the prism-shape distortion, was found to occur when the tool feeding step was large.

Keywords Thin-walled tube · Incremental grooving · Springback · Discrete filler · Defect

1 Introduction

Thin-walled tubular parts are widely used as structural and functional components in the fields of transportation, household appliance, aerospace, etc. In practice, there are large demands of small-batch tubular parts and meanwhile, the geometries become more and more complicated [1].

As a flexible sheet metal forming technology that can satisfy the requirements of efficiency and cost in small lot productions, incremental sheet forming (ISF) has been extended to the manufacturing of tubular parts in recent years [2–4], e.g., to conduct tube end expansion/flaring, reduction, tapering, crimping, bulging, hole flanging on tube wall, etc. Due to the nature of hollow structures and deformation features of

https://doi.org/10.1007/978-3-030-75381-8_183

these processes, the forming accuracy varies with different processing strategies [5, 6]. Main failures, including distortion, unevenness, buckling/wrinkling, and fracture, were investigated from the aspects of force and deformation behavior [7, 8]. Among, springback is the primary factor bringing about geometric deviations from the desired shape. In order to reduce the defects caused by springback, a couple of prediction and compensation models have been proposed [9–11]. However, it is still difficult to obtain a workpiece with acceptable accuracy by conventional incremental sheet forming, especially when the single-point configuration is utilized.

In this paper, we examined the influence of discrete fillers on the deformation of thin-walled tubes during incremental tube grooving. The main aim is to verify the potential of filled media on the control of undesired deformations, such as section-distortion and springback.

2 Analysis Method

To examine the deformation behavior of tube wall under simple and complicated loading, and clarify the effects of filled media on wall deformation during incremental grooving, experiments of dot-denting under lateral pressure and incremental tube grooving, as shown in Fig. 1, were designed. Al 6061 tubes with size of Φ38 mm (outer diameter) × 1 mm (thickness) × 200 mm (length), were used.

Considering the performance, acquirability, recyclability and cost, powdery silica sands with average size of 200 meshes were used as fillers. The silica sands were sealed inside the mother tubes by plugs at both ends before operation. Bar tools with diameter of 10 mm and hemispherical head were used.

Dot-denting tests were conducted on a universal material testing machine (Fig. 2a), where the bar tool moves down at a uniform velocity of 0.1 mm/s to dent the tube wall, with the desired total denting depth of 11 mm. For incremental tube grooving, the mother tubes were horizontally fixed on the lathe chuck (Fig. 2b). The expected depth H of circular groove is from 0.5 mm to 4 mm. During forming, the tubes circumferentially rotate at a speed of 45 rad/min, at the same time the bar tool is radially fed.

Numerical simulations were conducted in ABAQUS®. According to the theory of generalized plastic mechanics, the aggregation of discrete sands is assumed to be

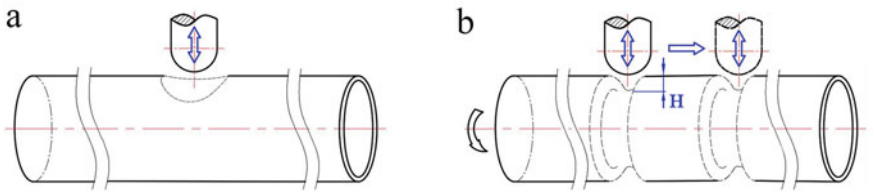

Fig. 1 Schematic of the experiments: **a** lateral dot-denting; **b** circular groove. (Color figure online)

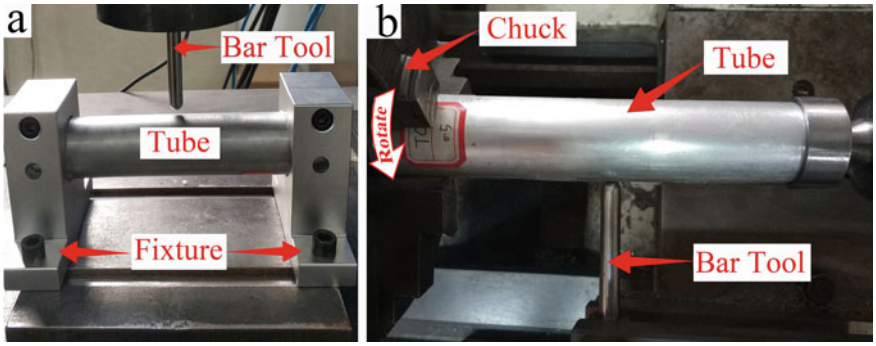

Fig. 2 Experimental sets: **a** lateral dot-denting; **b** incremental tube wall grooving. (Color figure online)

compressible continuous body, and the yield behavior is described by linear Drucker–Prager (D-P) model, which can be written as [12]

$$Fs = t - p\tan\beta - d = 0 \tag{1}$$

where Fs is the function of yield surface, t is the deviatoric stress, p is the equivalent pressure, β is the material's internal friction angle and d is the material's cohesion.

The internal friction angle was tested using a model ZBQ-4 strain-controlled direct shear apparatus [13], and the yield stress can be written as

$$\sigma = d/(1 - \frac{1}{3}\tan\beta) \tag{2}$$

Mechanical parameters as listed in Table 1 were used in the numerical analysis. Coulomb's friction law was applied to the interface between bar tool and tube wall. General machine oil was used as lubricant, and the friction coefficient μ is 0.15.

Table 1 Mechanical parameters of the fillers and Al 6061

Item	Silica sand	Al 6061
Density ρ (kg/m^3)	1500	2900
Elastic modulus E (MPa)	50	68,900
Poisson ratio v	0.33	0.4
Internal friction angle β (°)	28.7	–
Cohesion d (kN)	81.75	–

3 Results and Discussion

3.1 *Deformation Feature of Tube Wall During Dot-Denting*

Figure 3 shows the dot-denting results of hollow and filled tubes. It can be seen that the silica sands do not change the basic wall deformation mode, which can be approximately described by the plastic hinge model [14].

Since the fillers give support to the wall during forming as in a two-point ISF process, the section-distortion can be reduced, as the displacement distributions shown in Fig. 3.

Figure 4 shows the wall thickness distribution of the dented tubes. Under the compressing of bar tool, the discrete silica sands gradually become denser; consequently, the constraint and friction force of the filler increase, resulting in a decreased fluidity of the filler and less uniform distribution of wall thickness.

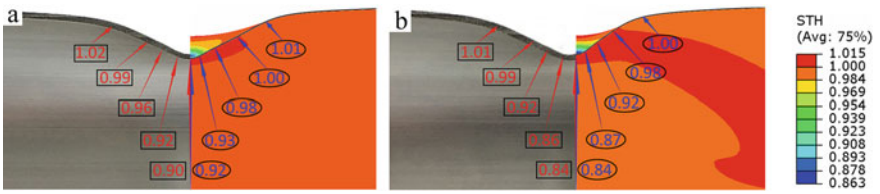

Fig. 4 Comparison of the wall thickness (STH) distribution of dot-dented tubes. **a** hollow; **b** filled. (Color figure online)

3.2 *Deformation Features of Tube Wall During Incremental Grooving*

Figure 5 shows the experiment results of incremental grooving with various denting depths. It can be seen that circular grooves on tube wall were formed under both conditions.

Grooves on filled tubes are relatively more inerratic and smooth, compared with those on hollow tubes. With same feeding distance of the tool, the obtained groove depth on hollow tubes is shorter due to larger springback deformation.

Figure 6 compares the springback amounts of the tube walls grooved with different depths in the experiments. The springback values are calculated by comparing the expected and actually obtained grooving depths. It can be seen that the deeper the groove is, the greater the springback will be. When the filler is employed, the structural stability increases and springback decreases. On average, springback of the filled tubes was reduced by 3.9% compared with that of hollow tubes.

Figure 7 shows the typical defects found in the experiments. When the wall deformation reaches the limit of material, fracture occurs as shown in Fig. 7a. With the filled silica sand, the material flow of tube wall is obstructed and fracture is easier to take place. The nonuniform (or roundness deviation) as shown in Fig. 7b is mainly caused by the bending of mother tubes under the lateral pressure of tool. Figures 7c and 8 show a special failure mode, prism-shape distortion, taking place under certain condition where the formed circular grooves present a section view of polygonal shape,

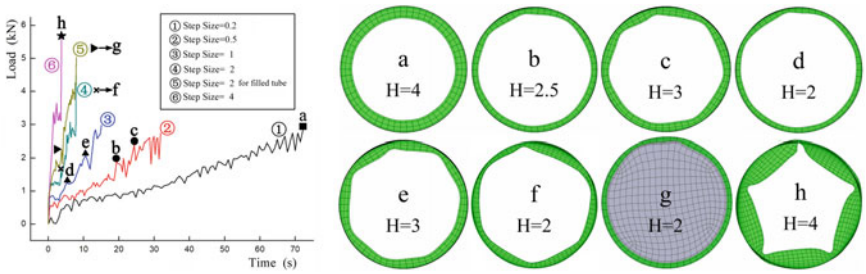

Fig. 9 Forming loads and cross-section shapes of the formed grooves under different conditions. (Color figure online)

especially hexagon or pentagon. In the following, we will discuss the occurrence conditions of such defect.

3.3 Occurrence Conditions of the Prism-Shape Distortion

For thin-walled structures, instability would take place when the load exceeds the limitation of structural stiffness. Instability would lead to unexpected deformation of the wall.

Since the load in incremental sheet forming is directly affected by the feeding velocity of tool, we designed testing groups with the step sizes of 0.2 mm, 0.5 mm, 1 mm, 2 mm, and 4 mm, respectively. The target grooving depth is 4 mm. In the group with step size of 2 mm, hollow and filled tubes were used.

Figure 9 shows the simulated results of the loads and wall deformation under different conditions. It can be seen that the simulation can exactly reflect the phenomenon of prism-shape distortion. For the case with step size of 0.2 mm, no defect occurring throughout the course and the formed groove shape is perfect. When the step size increases, the forming load increases and the critical groove depth without defect decreases, as shown in Fig. 9b and d. In the cases with large step sizes, for example, larger than 1 mm, the cross-section shape becomes more irregular, see Fig. 9c, e, f, and h.

The simulated results in Fig. 9f and h correspond well with the experiment results in Fig. 8b and c. The compressing force on tube wall increases with the step size increases, and then the wall collapses quicker; the cross-section shape evolves toward less number of sides, e.g., from hexagon to pentagon. Compared with the hollow tubes, the composite structure of filled tube has higher integral stiffness, which delays the wall collapse under same conditions (Fig. 9g). Therefore, reducing the step size and using fillers can prevent cross-section distortion during grooving.

4 Conclusions

(1) Tube wall grooving can be performed by the dieless incremental forming with a simple hemispherical bar tool. Typical defects include cross-section distortion, nonuniform, springback , and wall fracture.
(2) Similar to the two-point ISF processes, the accuracy of incremental tube wall grooving can be improved under the support of fillers. In the current study, the maximum springback was reduced by more than 3.9%, and the section-distortion also decreased.
(3) Radial collapse of the tube wall caused by large forming load under large feeding step of the tool is the dominant reason for the occurrence of the special defect mode of prism-shape during tube wall grooving. Reducing the feeding step size and filling discrete media can prevent the defect.

Vacuum Hot-Roll Bonding of Titanium and Carbon Steel Using Pure Iron Interlayer

Chao Yu, Hong Xiao, and Xiao Liu

Abstract In this paper, the effect of a pure iron interlayer on the properties of the multi-pass hot-roll bonding titanium/carbon steel plate was studied. The mechanical and microstructural properties of the composite plate were investigated by optical microscopy and scanning electron microscopy, as well as tensile-shear, bending, and tensile tests. The results show that when the reduction ratio is below 18%, the shear strength of the interface is higher with the pure iron interlayer than without it. At 35% reduction, the shear strength is similar in both cases. At a reduction ratio of 68%, with the pure iron interlayer, fracture of the bonding interface occurs on the titanium matrix, whereas without the pure iron interlayer, fracture occurs on both the titanium matrix and the compound layer on the interface; the pure iron interlayer improves the bending and tensile properties of the titanium/carbon steel plate appreciably.

Keywords Titanium · Steel · Pure iron interlayer · Hot-roll bonding · Properties

1 Introduction

Titanium clad steel plates not only have the corrosion-resistant of titanium but also have the weldability, formability, and thermal conductivity of carbon steel, and it also saves precious titanium metals [1, 2]. Due to these characteristics, titanium-clad steel plates are widely used in the petrochemical, shipbuilding, marine industries, and nuclear industry, among others [3–5]. Currently, several methods have been used to manufacture titanium-clad steel plates, such as diffusion bonding, explosive welding, and rolling bonding.

Compared with the diffusion bonding and the explosive cladding methods, the rolling bonding method can produce large-sized and thin titanium clad steel plates with high production efficiency, low pollution, and low energy consumption [6, 7]. In the production of titanium clad steel plates, the formation of brittle compounds

such as TiC, FeTi, and Fe_2Ti on the interface may cause the degradation of mechanical properties [8, 9]. Many studies used Cu, Ni, and Nb interlayers to prevent the formation of TiC, FeTi, and Fe_2Ti compounds and improved the mechanical properties of the titanium-steel plate. Zhao et al. [10] studied the interfacial structure and mechanical properties of hot-roll bonded joints between titanium alloy and stainless steel using copper interlayer. The maximum tensile strength of 343 MPa was obtained at a bonding temperature of 780 °C and the reduction of 20% due to the smaller volume fraction of brittle intermetallics. Yan et al. [11] used a nickel interlayer in hot-roll bonding of titanium alloy and stainless steel. The maximum tensile strength of 440 MPa was obtained at a bonding temperature of 760 C and a reduction of 20%. Ti_2Ni and $TiNi_3$ appear on the fracture surface, and the fracture occurs at the transition layers, which mainly consist of the intermetallic. Zhao et al. [12] carried out a hot-roll bonding between titanium alloy and stainless steel in a vacuum using niobium interlayer. The maximum interface tensile strength of ~417.5 MPa was obtained at a bonding temperature of 900 C and a reduction of 25%. The tensile fracture occurred in the niobium interlayer and had the characteristics of plastic fracture. However, because of high costs, these materials are not widely used in the production of titanium-clad steel plates. Yu et al. [13] used a pure iron as interlayer in the hot-roll bonding of titanium/carbon steel plate with a single pass reduction ratio of 25%, the properties of the plate with and without pure iron interlayer were compared. Yu found that, using the pure iron interlayer and at a bonding temperature of 850 C, the formation of the TiC and FeTi compounds are effectively prevented. The shear strength of the bonding surface reaches a maximum of 237.6 MPa and it is higher with the pure iron than without it (~197.9 MPa) under the same rolling process.

The above studies used a single pass reduction ratio to bond the titanium and steel at different temperatures; however, multi-pass rolling is often required in the industrial production in order to obtain a large and wide composite plate. The properties of the composite plate will also change in the multi-pass rolling process. It is necessary to study the performance of the composite plate after multi-pass rolling. Therefore, in this paper, the effect of the reduction ratio on the properties of the hot-roll bonding titanium/carbon steel plate with pure iron interlayer is studied, and the bending and tensile tests of the composite plate are carried out to study the mechanical and microstructural properties after multi-pass rolling.

2 Experiments

The assembly pattern is shown in Fig. 1, in which the thicknesses from top to bottom are 6 mm (carbon steel), 3.7 mm (titanium), 1 mm (pure iron), and 5 mm (carbon steel). The chemical compositions of these materials are presented in Table 1. Before assembling the billet, the oxides on the surfaces of the metals were removed via grinding machine, and then, the surfaces were repeatedly cleaned with acetone and alcohol and immediately dried. While the exterior of the assembled billet was welded,

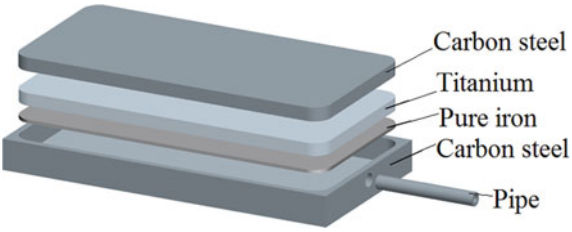

Fig. 1 Assemble pattern. (Color figure online)

Table 1 Chemical composition of the raw materials

Materials	Composition (wt.%)									
	C	Si	Mn	P	S	O	N	H	Ti	Fe
Titanium	0.012	–	–	–	–	0.07	0.01	0.008	Bal.	0.062
Carbon steel	0.127	0.162	0.382	0.015	0.008	–	–	–	0.01	Bal.
Pure iron	0.002	0.02	0.05	0.007	0.003	–	–	–	–	Bal.

argon gas was blown into the billet through a pipe to prevent internal oxidation at high temperatures caused by the welding. Next, the pressure inside of the billet was brought to 0.1 Pa through the pipe using a vacuum pump, at which point, the pipe was sealed. The size of the assembled billet was 100 mm × 50 mm × 15.7 mm. Because the phase transition temperature of titanium is 882°C, the mechanical properties of the titanium change radically near this temperature. Above 882°C, Fe readily dissolves in titanium to form Fe_2Ti and FeTi compounds. Therefore, in order to stabilize the mechanical properties of titanium during rolling, the heating temperature of the billet was chosen to be 850°C to limit both the deformation resistance during rolling and the formation of Fe_2Ti and FeTi compounds. The billets were heated in a furnace for 2 h, rolled at a speed of 50 mm/s, and cooled to room temperature in air. The rolling reduction ratios were 8%, 18%, 35%, 54%, and 68%, among them, the reduction rate of 8%, 18%, and 35% is single-pass rolling, 54% (35% + 30%) and 68% (35% + 30% + 30%) are two passes and three passes rolling respectively. To exclude the influence of air entry and other accidental factors on the experimental results (e.g. the entry of air will cause the formation of oxides at the interface during heating, which will significantly reduce the bonding strength), three billets were rolled at each temperature, and the experiments were repeated to ensure that at least two experimental datasets were reliable.

The tensile-shear, bending, and tensile tests were carried out using an Inspekt Table 100 kN instrument. The speed was 1 mm/min. The tension-shear (6 samples), bending (6 samples) and tensile (6 samples) test samples are shown schematically in Fig. 2.

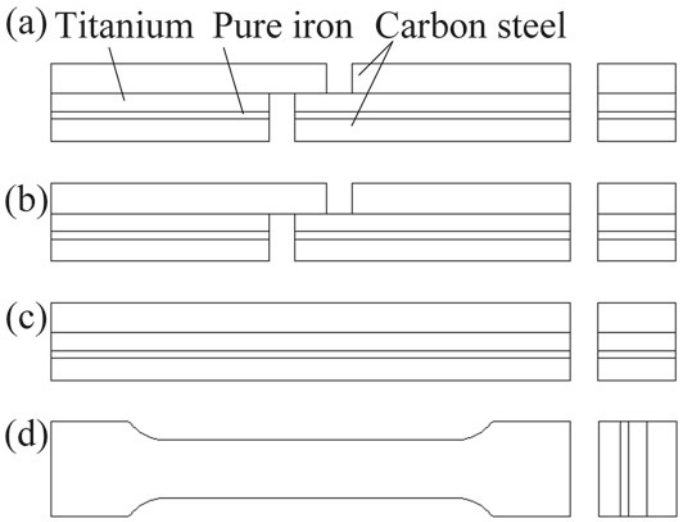

Fig. 2 Schematic of the test samples: **a** measuring the tension-shear strength of the side without the pure iron, **b** measuring the tension-shear strength of the side with the pure iron, **c** bending test sample, **d** tensile test sample

3 Results and Discussion

3.1 Interfacial Structure of Titanium/Carbon Steel Clad Plates

Secondary electron images of the interfaces are shown in Fig. 3. At an 8% reduction ratio and without the pure iron, there are some pores on the interface, as shown in Fig. 3a. On the other hand, with the pure iron, the interface is smooth and has no pores, as shown in Fig. 3b. This indicates that at the 8% reduction ratio, the pure iron combines with titanium better than carbon steel combines with titanium. When the reduction ratios are 35 and 68%, there are no pores on the interface, and grain refinement occurs on both the carbon steel and pure iron sides, as shown in Fig. 3c,d,e, and f. From Fig. 3f, it can be seen that at a reduction ratio of 68%, some pearlites are formed on the pure iron side, indicating that C atoms have diffused from carbon steel to pure iron.

Figure 4 shows the secondary electron images and element surface scanning analysis images of the fracture surface on the pure iron side using the pure iron at a 68% reduction. Fe element is not found by the element surface scanning. As shown in Fig. 4b, with using the pure iron, the fracture surface is full of Ti, and as shown in Fig. 4c, there are a large number of dimples distributed along the fracture surface, which is characteristic of ductile fracture. This indicates that the fracture absolutely occurs on the titanium matrix. This indicates that the strength of the bonding surface

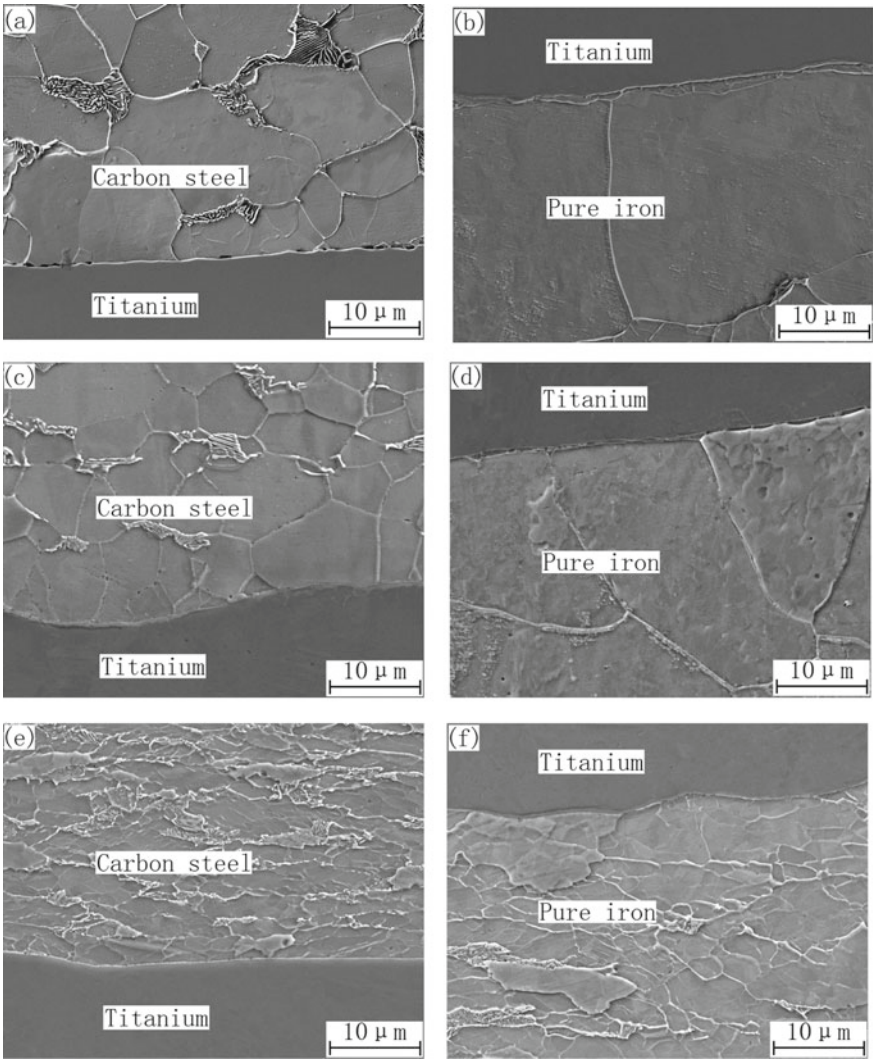

Fig. 3 SEM images of the bonding interface at **a** and **b** 8%, **c** and **d** 35%, **e** and **f** 68%

is high and between the pure iron and the titanium is also high. The strength of the pure iron matrix was intensified for the increase of the pearlite and the grain refinement as shown in Fig. 3f.

Without using the pure iron, the fracture surface on the carbon steel side at 68% is shown in Fig. 5a. The elements' distribution is shown in Fig. 5b and c, there is a large amount of Ti and a smaller amount of Fe distributed on the fracture surface. The microstructures of these two main element distribution regions are, respectively, shown in Fig. 5d and e. Figure 5d reveals brittle fracture characteristics on the surface,

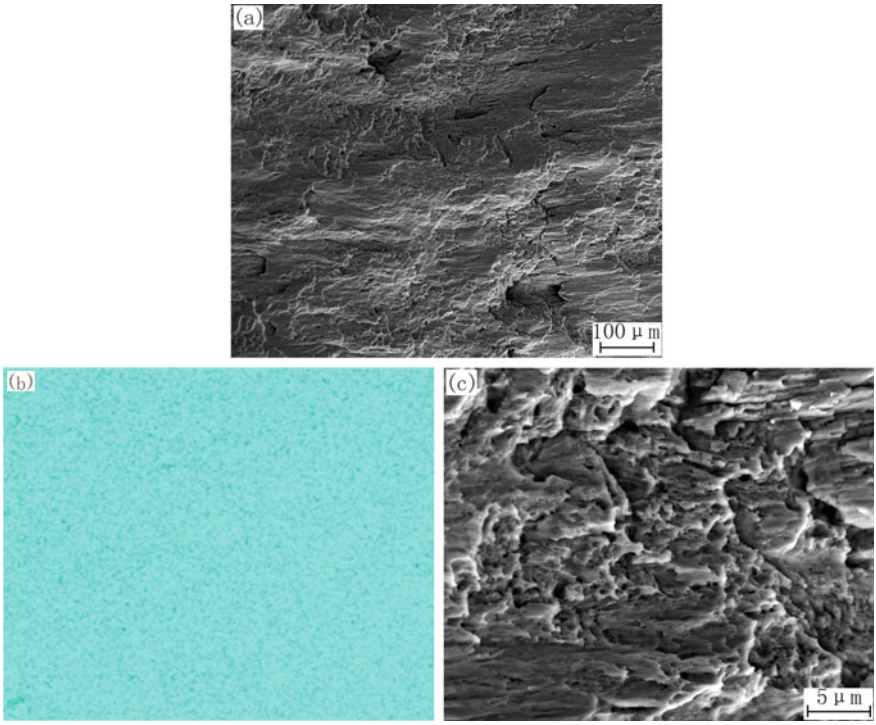

Fig. 4 SEM images of the fracture surface on the pure iron side at 68%: **a** overall morphology, **b** Ti distribution on Fig. 4a, **c** microstructure of the fracture surface. (Color figure online)

indicating that brittle intermetallic compounds have been formed there. Figure 5e presents obvious ductile fracture features with many dimples. The results indicate that fractures occur mainly on the Ti matrix, though some occur in the brittle region at the interface.

Figure 6 shows the element distribution profiles across the interface at a bonding reduction ratio of 68%. The Ti and Fe diffusion distances are similar for both interfaces and are approximately 1.5 μm. Comparing the intensity of C across the interface between Fig. 6a and b, it can be seen that, without the pure iron, the C is concentrated near the interface. Conversely, with the pure iron, such concentration is not as obvious. This shows that adding the pure iron interlayer can effectively reduce C diffusion to the interface from carbon steel, thus reducing the formation of brittle compounds TiC on the interface.

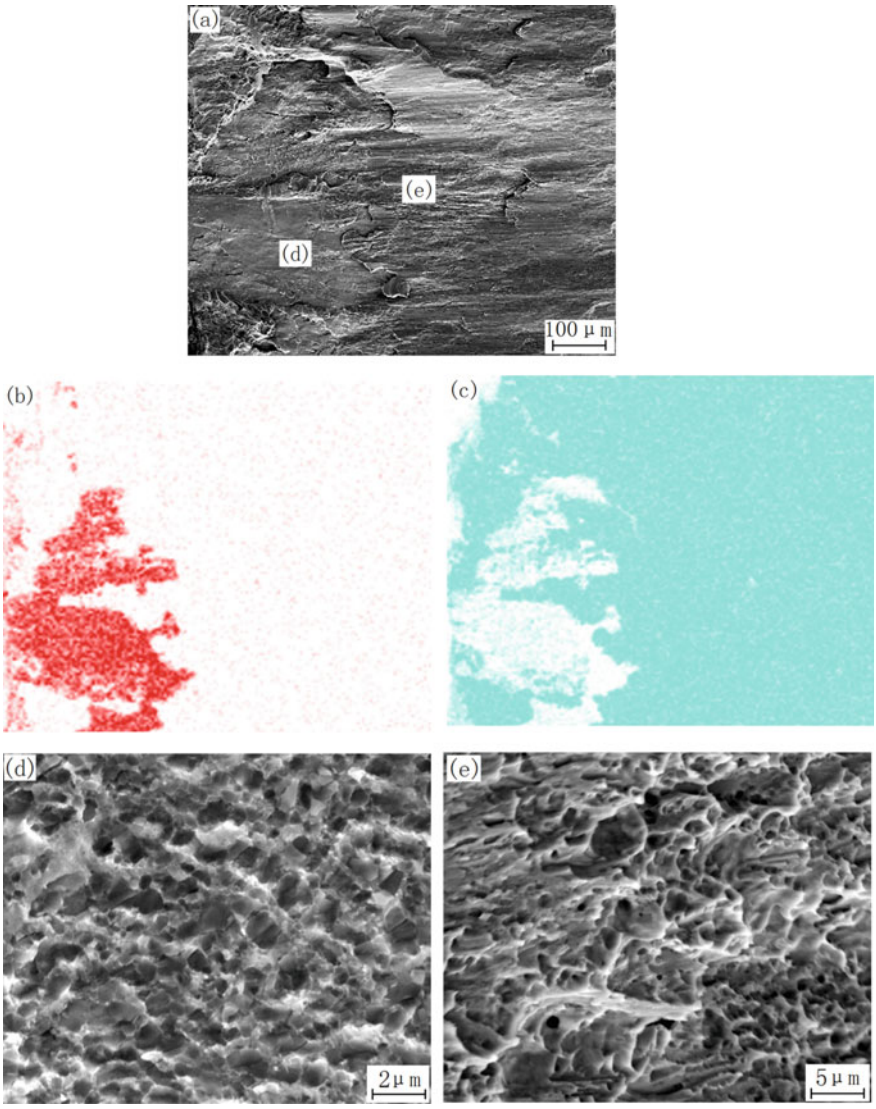

Fig. 5 SEM images of the fracture surface on the carbon steel side at 68%: **a** overall morphology, **b** Fe distribution on Fig. 5a, **c** Ti distribution on Fig. 5a, **d** and **e** microstructure of areas selected from Fig. 5a. (Color figure online)

3.2 Mechanical Properties of Titanium/Carbon Steel Clad Plates

The effect of the rolling reduction ratio on the interfacial shear strength of titanium clad steel plate with and without the pure iron interlayer is shown in Fig. 7. When the

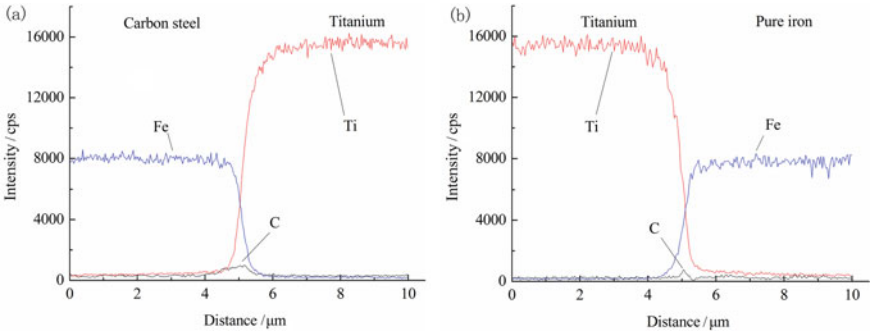

Fig. 6 Element distribution profiles across the interface: **a** between carbon steel and titanium, **b** between titanium and pure iron. (Color figure online)

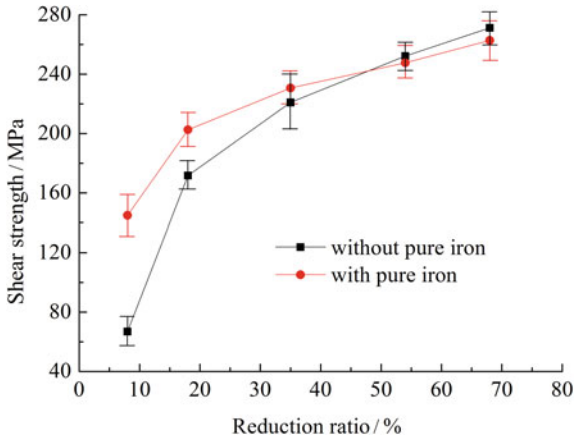

Fig. 7 Effect of reduction ratio on the shear strength of titanium clad steel plates. (Color figure online)

reduction ratio is between 8% and 68%, the shear strength of the interface increases with an increase in reduction ratio: without a pure iron interlayer, the shear strength increased from 66.9 MPa to 271.2 MPa, and with a pure iron interlayer, the shear strength increased from 144.8 MPa to 262.8 MPa. When the reduction ratio is less than 18%, the shear strength is much higher with the pure iron interlayer than without it. When the reduction ratio is greater than 35%, the shear strengths on both sides are similar. The shear strength of the interface reaches the standard value of 140 MPa from the GB/T 8547–2006 type 1 titanium clad steel plate when the reduction ratio is 18% without the pure iron interlayer and 8% with it. The shear strength reaches the standard value of 196 MPa from the type 0 titanium-clad steel plate when the reduction ratio is 35% without the pure iron interlayer and 18% with it. It can be concluded that the addition of the pure iron interlayer improves the shear strength of the composite plate at small reduction ratios. When the reduction ratio is large, the shear strength of the interface on both sides is close to the shear strength of the titanium matrix, meaning the effect of the pure iron interlayer on the shear strength

is not as obvious. This is due to the low deformation resistance and the good metal fluidity of the pure iron interlayer, when the reduction ratio is small, the pure iron can contact the titanium and the steel more closely, making the pores on the interface disappear, as shown in Fig. 3a and b. The close contact can promote the diffusion of elements, so as to improve the bonding strength. When the reduction ratio is large, without the pure iron interlayer, the titanium and the steel can also contact closely, making the pores disappear, as shown in Fig. 3c. The amount of compounds at the interface of both sides is not much, and the shear fractures almost occur on the side of the titanium matrix, so the shear strength of both sides is relatively close.

Figure 8 shows the macro photographs of a bent specimen at a reduction ratio of 68%. Whether the pure iron is on the interior or the exterior, there are no macroscopic cracks after bending. An optical specimen was taken from the bent specimen to observe the microstructure, which is shown in Fig. 9. Without the pure iron, there are some microcracks on the titanium side whether the pure iron is on the interior or the exterior as shown in Fig. 9a and d. Because the amount of deformation is greater on the outside than on the inside, there are more cracks on the outside. With the pure iron, no microcracks were found on the interface as shown in Fig. 9b and c. Therefore, when titanium and carbon steel are composited by hot rolling, brittle compounds are easily formed on the interface. The poor plasticity of such compounds results in the formation of microcracks during bonding. This suggests that the addition of a pure iron interlayer can effectively inhibit the generation of compounds, thereby improving the bending performance of the composite plate.

Tensile specimens were taken along the rolling direction of the composite plate with a 68% reduction ratio. The tensile test results are shown in Fig. 10. Take one of the specimens as an example, without the pure iron, when the strain was 0.185, carbon steel and titanium became divided, resulting in the invalid. With the pure iron, when the strain was 0.192, the pure iron and titanium became divided, and

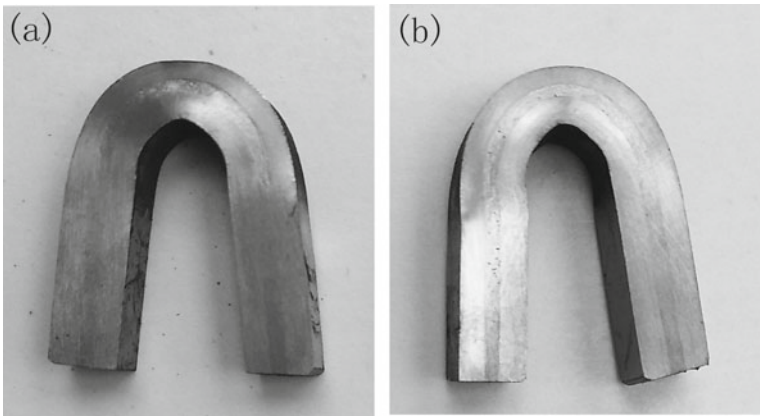

Fig. 8 Macro photographs of bent specimen: **a** pure iron is on the interior, **b** pure iron is on the exterior

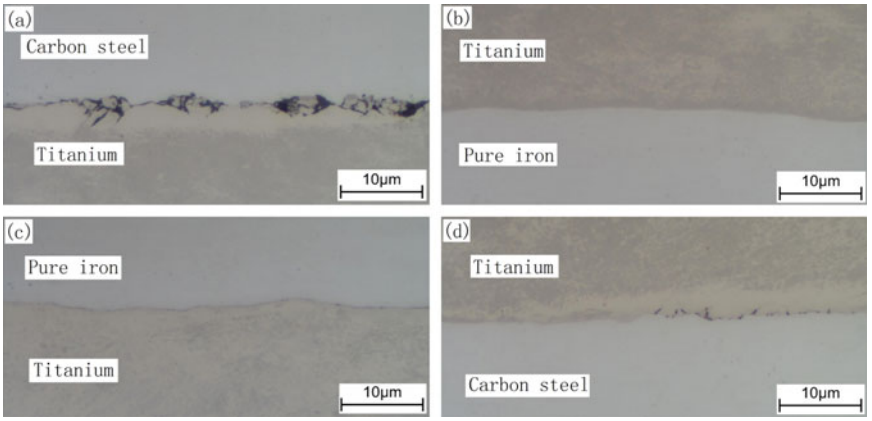

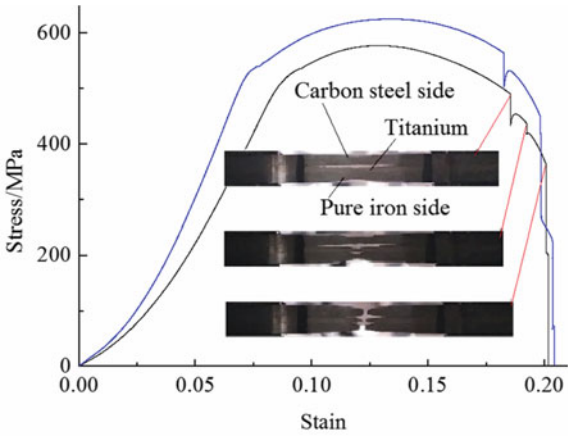

Fig. 9 Optical micrograph of bent specimen: **a** and **b** pure iron is on the interior, **c** and **d** pure iron is on the exterior. (Color figure online)

Fig. 10 Tensile test results. (Color figure online)

the crack length of the side without pure iron is significantly longer than that of the side with pure iron. When the strain was 0.202, the composite plate underwent overall fracture. This indicates that since adding a pure iron interlayer can effectively prevent the formation of brittle compound TiC, crack sources are reduced on the interface during tensile deformation. Therefore, with the pure iron interlayer, the tensile properties are improved, and the divided invalid is relieved.

4 Conclusions

Titanium/carbon steel plates were fabricated by multi-pass hot-rolling to compare the effect of the pure iron interlayer on the microstructures and mechanical properties of the clad plates under different reduction ratios. Based on the results, the following conclusions are drawn:

1. The bonding strength of the interface increases with the reduction ratio on both sides with or without the pure iron interlayer. When the reduction ratios are small, the pure iron interlayer can improve the bonding strength of the composite plate. When the reduction ratio is large, the effect of the pure iron interlayer on the shear strength is not as obvious.
2. The pure iron interlayer can prevent the diffusion of C element in carbon steel to the titanium side, thus reducing the formation of brittle compound TiC at the bonding surface. Therefore, the bending and tensile properties of the composite plates are improved.

Investigation on the Whole Forming Process of Super-Large Flat Ring

Dan Xie, Wujiao Xu, Yu Wang, and Rui Chen

Abstract The main concerns of forming a super-large rectangular ring are forming accuracy, rolling stability, uniformity of deformation, and accordingly the distributed microstructure and related mechanical property of the rolled ring. In this paper, a flat ring with a diameter of 9 m is taken as an example, which is the bearing ring of a carrier rocket. To meet the requirements of formation and performance, the whole forming process, including multidirectional forging, punching, reaming and ring rolling is investigated step by step. Due to the poor internal quality of large ingot, three multidirectional forging schemes are compared in order to improve the internal quality of the ring billet. For the reaming process, four different reduction amounts per pass are designed to control the end surface quality of the reaming operation part. To refine grain and minimize the anisotropy of the rolled ring, the ring rolling process is divided into high-temperature rolling and low-temperature rolling, the feeding strategy of which are studied respectively. Based on the FORGE software platform, the simulation results show that the seven upsetting and six stretching process, 30% reduction per pass, and the optimized feed strategy are the optimal multidirectional forging process, reaming process, and ring rolling process.

Keywords The whole forming process of ring · Multidirectional forging · Reaming · Ring rolling

1 Introduction

Super-large ring parts are widely used in the fields of wind energy, nuclear energy, petroleum, and aerospace, and its manufacturing technology has a great impact on the independent development of energy and major mechanical equipment. The whole forming process of a super-large ring is shown in Fig. 1, which is divided into multi-direction upsetting, punching, reaming and ring rolling (e.g. [1]).

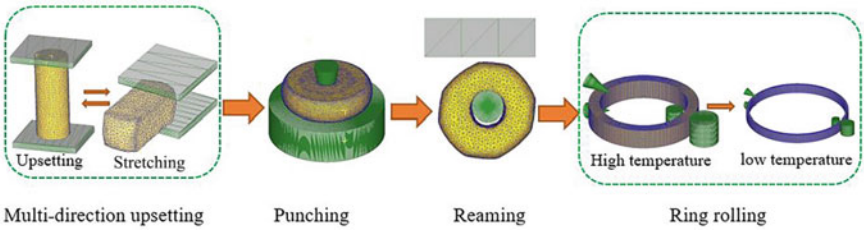

Fig. 1 The whole forming process of super-large ring. (Color figure online)

In the process of casting cooling, the temperature distribution of large diameter ingot is uneven and the cooling rate is greatly reduced, which leads to the phenomena of uneven microstructure, coarse grain, and segregation of chemical composition in large diameter ingot. Therefore, it is necessary to increase the plasticity of ingot by forging billet and improve the uniformity of material microstructure and the grain refinement degree, so as to improve the comprehensive properties of the material. The properties of material are improved due to the flow of material in the multi-direction upsetting process and the reaming process, so the multi-direction upsetting process and the reaming process need to be studied. Yamamoto [2] reported that multidirectional forging can cause continuous static recrystallization. Miura et al. [3] revealed the improvement of AZ61Mg alloy mechanical properties by multidirectional forging.

The ring rolling is a kind of advanced manufacturing technology used for producing all kinds of seamless rings. Through feed and rotation of the rolls, the deformation behavior of the ring is caused by the reduction of wall thickness, the expansion of diameter, and the forming of cross-section (e.g. [4, 5]). The working conditions of super-large ring parts are poor, such as high or low temperature, corrosion, external force impact, radiation, uncertain external force load, and so on, so the requirements of ring internal microstructure and properties are higher. Because the rolling process of a large flat ring is more complex, in order to ensure the forming and properties of a large ring, the following points should be paid attention to: (1) the stability of ring rolling process; (2) the coordination between ring growth speed and ring cross-section forming; (3) the control of ring microstructure and properties (e.g. [6]). Xu KH et al. [7] studied the rolling process of 9 m super-large ring and realized the precise control of roundness and size. He et al. [8] proposed an improved process for grain refinement of large 2219 Al alloy rings, which can improve the mechanical properties of ring. So super-large ring rolling is generally used for high-temperature rolling and low-temperature rolling. The low-temperature rolling is mainly to refine grains and improve the properties of ring.

Although the seven-heading six-stretching process, reaming process, and rolling process of ring have been studied by many researchers, the whole forming process design of super-large ring is not yet comprehensively researched. Therefore, in this paper, the whole process design of super-large 2219 Al alloy ring is studied.

Table 1 The multidirectional forging process and billet parameter

Parameters	Values
Billet parameters (mm)	Ø 1220 × 3110
Punch velocity (mm/S)	15
Friction coefficient	0.3
Billet temperature (°C)	500
Die temperature (°C)	350

Heat transfer coefficient (convection) (W/(m^2 K))	20

2 Design of Multidirectional Forging Process

The billet of the super-large ring is formed by casting. Due to the large size of the ingot, the internal quality of ingot is poor. In order to improve the internal quality of billet, multidirectional forging is used to modify the billet. Three kinds of multidirectional forging processes are designed, including direct upsetting, four upsetting and three stretching, and seven upsetting and six stretching. According to the multidirectional forging process and billet parameter listed in Table 1, the multidirectional forging process was simulated under FORGE software platform. The finite element mesh, considering the simple shape of ingot, is divided by an adaptive meshing technique in FORGE software. To speed up the computation, the rolls are set as steel body. The material of ring is 2219 Al alloy, and its flow stress curve is established by Wang et al. [9].

In order to obtain fine and uniform internal microstructure, the temperature uniformity and strain uniformity of forgings are used as the index to judge the multidirectional forging process, which was reported by Zhou et al. [10]. Figure 2 shows the temperature distribution and equivalent strain distribution of these three multidirectional forging processes. The temperature standard deviation and equivalent strain standard deviation of these three multidirectional forging processes are listed in Table 2. The temperature standard deviation and equivalent strain standard deviation of seven upsetting and six stretching are the lowest, so the seven upsetting and sixth stretching process is the best process.

3 Design of Reaming Process

The outer diameter and wall thickness of the ring billet need to be limited to a certain range because of the limitation of force and energy of ring rolling mill equipment, so it is necessary to obtain reasonable ring billet by reaming. The reaming process is a

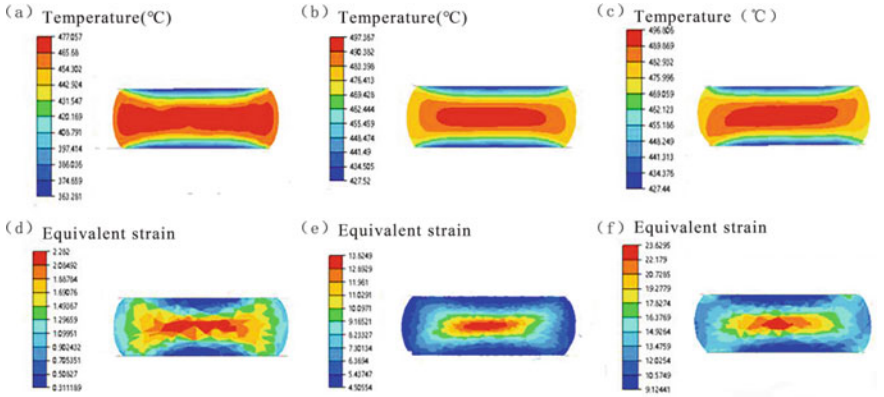

Fig. 2 Temperature distribution of direct upsetting (**a**), four upsetting and three stretching (**b**), seven upsetting and six stretching (**c**); and equivalent strain distribution of direct upsetting (**d**), four upsetting and three stretching (**e**), and seven upsetting and six stretching (**f**). (Color figure online)

Table 2 The temperature standard deviation and equivalent strain standard deviation of these three multidirectional forging processes

Multidirectional forging process	Temperature standard deviation	Equivalent strain standard deviation
Direct upsetting	25.19	2.0744
Four upsetting and three stretching	16.85	0.447
Seven upsetting and six stretching	16.54	0.22326

metal forming process in which the hollow billet is gradually compressed along the circumferential direction by using the mandrel and the upper anvil board to reduce the wall thickness and expand the diameter of the hollow billet. Due to the large deformation of large-scale ring billet in the reaming process, fishtail defects are easy to appear on the end face of ring billet. Therefore, the reasonable wall thickness reduction amount per revolution is the key parameter to control the end surface quality of ring billet.

A reaming model was established under FORGE software platform, which is illustrated in Fig. 1. Due to the heat treatment of billet before the reaming process, the flow stress curve is the same as that of the multi-direction upsetting process. The reaming process and hollow billet parameter are listed in Table 3. Four different wall thickness reduction amounts per revolution are designed, which are 15%, 20%, 25%, and 30% of wall thickness per revolution, respectively. The forming condition of the end surface of the ring billet is shown in Fig. 3. According to the analysis of the fishtail amount (FT) of the end surface of ring billet after reaming with different reduction amounts per revolution, the fishtail amount (FT) with 30% reduction per revolution is the lowest. On the one hand, the increase in the reduction amount per revolution increases the deformation of the material in the axial direction, thus increasing the

Table 3 The reaming process and hollow billet parameter

Parameters	Billet parameters (mm)	Punch velocity (mm/s)	Friction coefficient	Billet temperature (°C)	Die temperature (°C)
Values	Ø 2840 × Ø 900 × 660	15	0.3	500	400

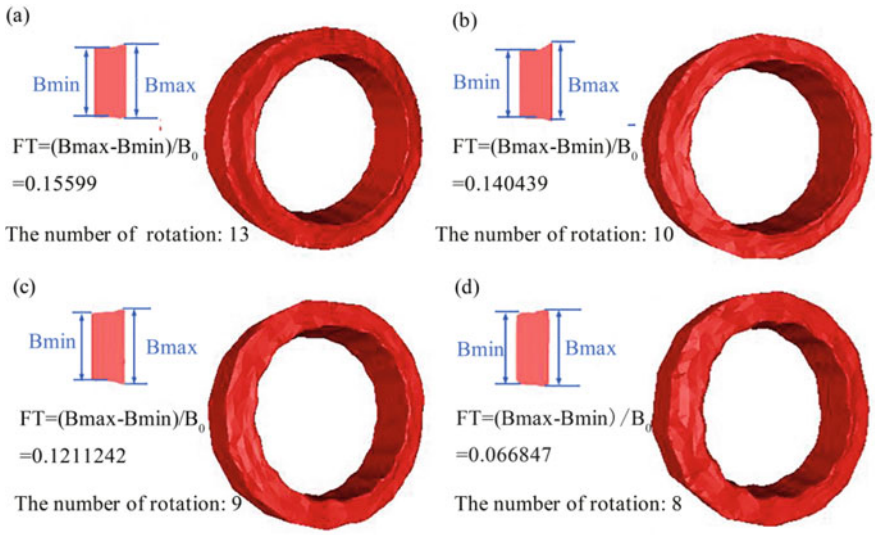

Fig. 3 The end surface of the ring billet under 15% of wall thickness reduction (**a**), 20% of wall thickness reduction (**b**), 25% of wall thickness reduction(**c**), and 30% of wall thickness reduction (**d**). (Color figure online)

fishtail amount (FT) of ring billet; on the other hand, the increase in the reduction amount per revolution reduces the number of reaming revolution, which lead to the decrease in the fishtail amount (FT) of ring billet. The reason why the reduction of the number reaming revolution decreases the fishtail amount is that the accumulative deformation material in the axial direction is decreased.

4 Design of Ring Rolling Process

4.1 Radial Feed Curve

In ring rolling process, the radial feed of the mandrel makes ring wall thickness thinner and material flow circumferentially, which leads to the growth of ring diameter. Therefore, the growth speed of ring outer diameter is related to the feed speed of

mandrel. The growth speed of ring outer diameter is related to the dynamic contacts and collisions between ring and rollers, which affects the properties of ring and the rolling stability of ring. In order to ensure the rolling stability of super-large ring parts, the radial feed speed is controlled to adjust the growth speed of ring outer diameter. According to the principle of ring volume invariance in ring rolling process, the axial width expansion in ring rolling is ignored, Ref. [11] reported the relationship between ring outer diameter growth speed and radial feed speed is deduced, as follows:

$$v_D = \left(\frac{D_0 + d_0}{2} \frac{H_0}{\left(H_0 - \int_0^T v dt\right)^2} - 1 \right) \tag{1}$$

where D_0, d_0, and H_0 are the initial outer diameter, inner diameter, and wall thickness of the ring, respectively. T is the rolling time. v is the feed rate of mandrel, and v_D is the growth speed of ring.

According to the actual production experience, the growth speed of super-large flat ring should be controlled in the range of 6 mm/s, and the limit value of radial feed rate should be calculated by Eq. (1), so that the reasonable radial feed rate range can be obtained. Considering the super-large flat ring rolling instability in the middle and late rolling stage and the increase in rolling instability with an increase in rolling time, the high temperature rolling of ring is divided into the initial stage of ring rolling, the rapid stage of ring rolling, the stable stage of ring rolling, the deceleration stage of ring rolling, and the whole round stage of ring rolling. Rapid rolling stage is to decrease the rolling time, and the stable rolling stage and the deceleration rolling stage are to control ring rolling stability. Due to the decrease in ring temperature in the late rolling stage and the increase in deformation resistance, the ring rolling instability is seriously increased. Because a low radial feed rate can reduce the rolling forces, and the drop of rolling forces can increase the stability of ring rolling, the radial feed rate in the low temperature rolling of ring should be designed to be uniformly decelerated considering the increase in rolling instability in late ring rolling stage.

According to the range of radial feed rate, reasonable rolling time and the characteristics of different rolling stages in the high-temperature rolling and the low-temperature rolling processes, the radial feed curve of ring is designed as shown in Fig. 4a. A 3D-FE model for the super-large ring rolling was established under FORGE software platform, as shown in Fig. 1. Due to the heat treatment of ring billet before ring rolling, the flow stress curve is the same as that of the multi-direction upsetting process. The simulation parameters including the rolling process and ring billet parameters are listed in Table 4. The cross-section forming condition of the high-temperature rolling and the low-temperature rolling is shown in Fig. 5. Because the stability of ring rolling affects the deformation of ring, the ring cross-section can be used as an index to judge ring rolling stability. According to the cross-section forming condition of ring in the high-temperature ring rolling shown in Fig. 5a, the ring end surface has the smaller fishtail amount (FT) and meets the cross-section requirements of forging, and the ring rolling process is basically stable. The ring end

surface in the low temperature rolling process has a large fishtail amount (FT) and serious burr and does not meet the cross-section requirements of forging, as shown in Fig. 5b.

4.2 Axial Feed Curve

Through analyzing the ring rolling process, the ring has strong up and down movement in ring rolling process, which results in the burr in the ring end surface. The main deformation and growth stage of ring is in the initial stage of ring rolling due to the larger radial feed amount, so the axial feed rate in the early rolling stage is increased to control the axial rolling stability of ring in the early rolling stage. Due to the increase of ring rolling stability with the decrease in rolling time in the late rolling stage, the increase in axial feed rate also can improve the rolling stability and ring end surface condition by reducing the rolling time. Considering the increase in rolling forces in the late rolling stage, the axial feed rate should be decreased with the rolling time. Therefore, the axial feed curve is optimized, as shown in Fig. 4b. Figure 6 shows the cross-section forming condition of ring and the fishtail amount (FT) of ring end surface with different axial feed curves. For the optimized axial feed curve, the fishtail amount is significantly reduced and the ring cross-section meets the cross-sectional requirements of ring. The reason is that the higher axial feed rate in the early stage of low temperature rolling and the shorter rolling time reduce the up and down movement of ring.

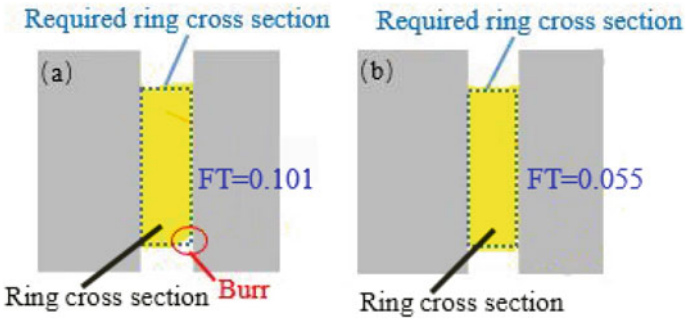

Fig. 6 The cross-section forming condition of low-temperature ring rolling under the axial feed curve (**a**) and the optimized axial feed curve (**b**). (Color figure online)

Fig. 7 The production process of the super-large ring. (Color figure online)

5 Practical Production

Based on the optimized process parameters obtained in Sects. 4.1 and 4.2, the super-large ring was successfully produced, and the technical requirements can be met, which verify the optimum parameters determined in the simulation. The production process of the super-large ring is shown in Fig. 7.

6 Conclusions

In this paper, the design of multidirectional forging, reaming and ring rolling had been researched. Seven upsetting and six stretching is the better multidirectional forging process, which can improve the internal quality of ingot and make the microstructure more uniform. According to the analysis of the fishtail amount of different wall thickness reductions per revolution, 30% wall thickness reduction per revolution is the better reaming process. According to the feed curve of the mandrel that is designed based on the feed rate range of mandrel, the rolling time and the characteristics of different rolling stages in the high-temperature rolling and the low-temperature rolling processes and the optimized axial feed curve, the cross-section of ring meets the requirements.

Development of a New Printing Method Using Soft Material Tools

Yasuharu Yoshikawa and Yusuke Masegi

Abstract A new printing method for metal using soft material tools has been developed. This method uses paper or plastic film with a fine pattern produced by the laser printer as a printing tool. The aluminum disc is compressed with a soft material tool between the upper and lower flat dies. In order to print with high accuracy with a uniformed pattern onto a metal surface, the effects of the process conditions on printing have been investigated. Experimental results using the soft material tools showed that the good condition for high accuracy was changed by the combination of the average pressure and the workpiece shape. The new printing method can print patterns easily onto the metal workpiece. The pattern can be observed from each workpiece surface. When using paper, the surface profiles of the workpiece are not clear because the printed pattern is hidden by the surface roughness of the paper. When using the PET film, the surface pattern can be clearly observed. The average pressure is needed to print the pattern clearly and uniformly. When decreasing the diameter and thickness ratio D/t of the workpiece, the required average pressure is decreased.

Keywords Transfer printing · Surface asperity · Soft material

1 Introduction

Coining is used to produce a wide range of parts with high accuracy on coins, medallions, gears, and medical devices. The die of coining has a high accurate cavity formed by fine cutting, electric discharge machining, laser milling, and photolithography. When producing small amounts, the forming process of the die is the cause of high cost.

Nishi and Fujita proposed another printing method where the leaf asperity is printed onto the titanium sheet using shock waves by explosive forming [1]. This printing method can print onto the thin metal workpiece uniformity. Ike reported

the effect of contaminants such as ceramic particles, fiber, and hair between the die and workpiece in coining [2]. The oil between the tool and the workpiece can deform the surface of the metal workpiece when the oil is pooled in the cavity on the surface, which shows that the soft material can be a printing tool in a high-pressure environment.

This report describes a new printing method onto metal using soft materials for the tool. In this method, the fine pattern is printed using soft materials such as paper or a plastic film. The reversed fine pattern produced by the laser printer is used as the printing tool. The toner (A colorant powder for heat transfer printing) is placed on the paper or film surface by laser printing, therefore the controlled asperity is formed. The workpiece of the disc shape and the soft material are compressed using metallic dies. By using this method, small to large amounts of production can be done quickly at low costs. The influence of the parameters (average pressure, disc dimension, and soft tool materials) for printing accuracy and uniformity has been researched.

2 New Printing Method

Figure 1 shows the outline of the newly developed printing method. A disc workpiece and a soft material with fine patterns are set on the lower die. Then the workpiece is compressed between the upper and lower dies with the soft material tool. During the experiment, the compression load was measured by the Amsler Universal Testing Machine. After compression, the soft material tool was released from the workpiece.

The upper and lower dies have a diameter of 60 mm and a height of 25 mm. TiCN is coated on the upper and lower dies, made of the cold working die steel with a roughness of 0.15 μmR_a. The soft material tools are plain paper, kent paper, coated paper (90 and 135 kg of unit weight), and PET (polyethylene terephthalate) film. The fine patterns of concentric circles with a 0.5 and 1.2 mm of pitch, as shown in Fig. 2, are formed by the laser printer on these soft materials. There is toner on the printed area. The toner is composed of styrene/acrylate copolymer, wax, carbon black, and Sirica. Figure 3 shows the surface profile of the laser-printed PET film. The width and the thickness of the circle lines are 295 μm and 4.90 μm, respectively. The workpiece material is a pure aluminum A1050-O (Japanese Industrial Standard). The workpiece sizes are 12, 24, and 36 mm in diameter, 1 mm in thickness with the surface roughness of 0.343 μmS_a. The experiments were carried out in a dry condition with the workpiece ultrasonically cleaned with acetone. The average compression pressure, calculated from the maximum compression load, and the initial contact area were changed. The printing accuracy was analyzed using measured surface profiles.

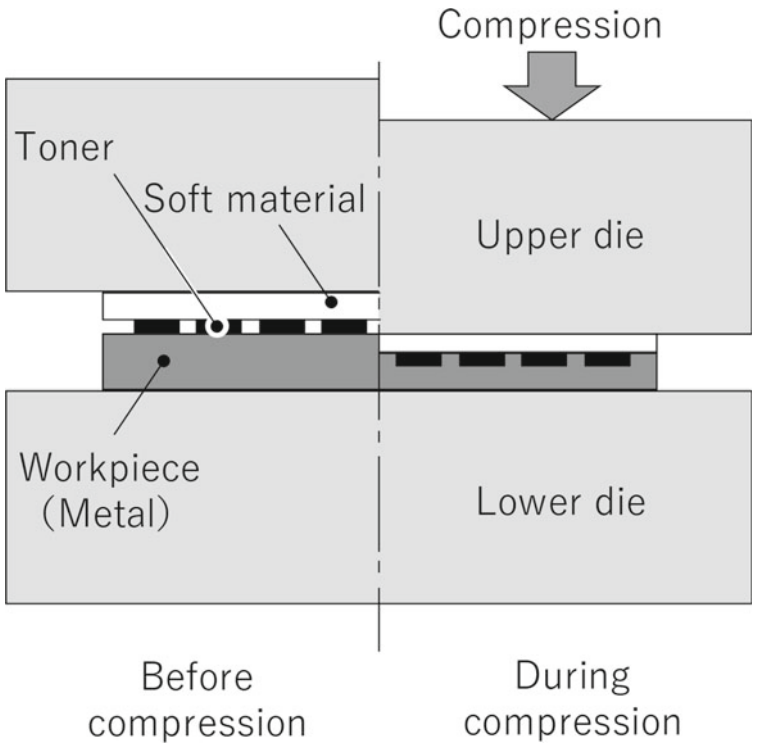

Fig. 1 Schematic diagram of new printing method

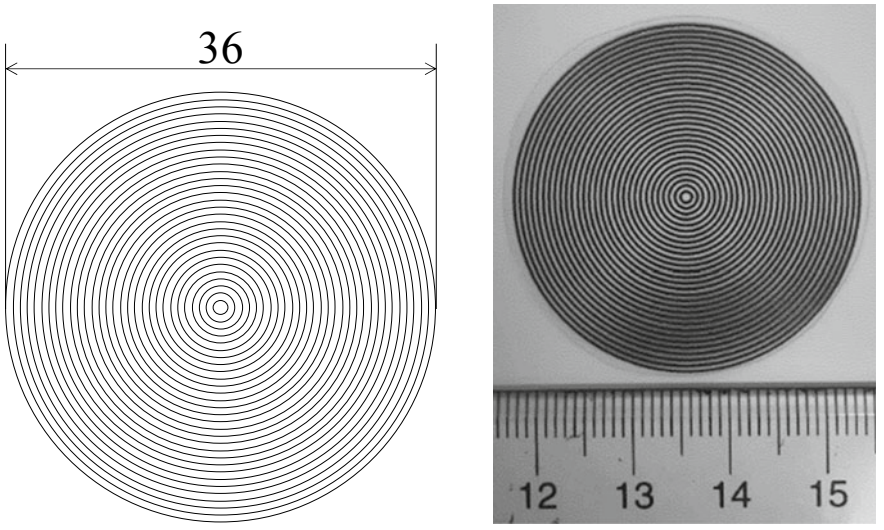

Fig. 2 Pattern printed by laser printer (in case of 36 mm of diameter)

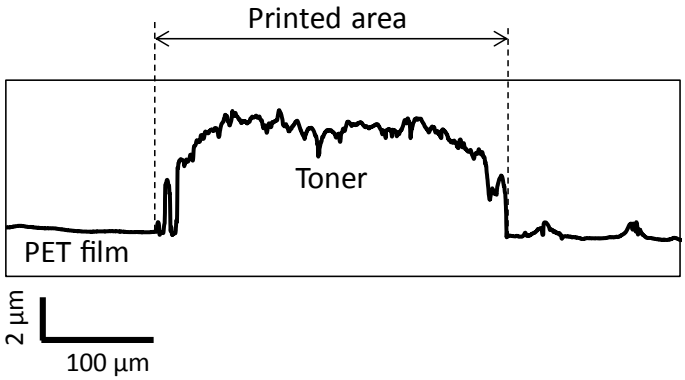

Fig. 3 Surface profile of laser-printed PET film

3 Experimental Results

3.1 Tool Materials

Figure 4 shows the surface image of the workpiece printed by each soft material to 24 of the diameter and thickness ratio D/t with 295 MPa of the average pressure. The left side of this figure is the center of the workpiece and the right side is the outer side of the workpiece. The new printing method can print patterns onto the metal workpiece. The concentric circle pattern can be observed from each surface. Figure 5 shows the surface profiles printed by each soft material. The surface profiles using all four different kinds of paper were not clear because the printed patterns were hidden by the surface roughness of the paper. The surface pattern of using the PET film was clearly observed.

3.2 Average Pressure and Dimension of Work Piece

The surface profiles have measurements of 1.8 mm of the length at each position as shown in Fig. 6. Figure 7 shows the surface profiles of each average pressure at three different positions. From the profile of $p_a = 51.1$ MPa, the printed pattern was changed gradually by the position. The center of the pattern on the workpiece was not shown clearly. The patterns at each position became clearer by increasing the average pressure. The depth of the patterns in the same position seemed to be the same level in more than 197.0 MPa of the average pressure. However, the depth at the edge was marginally deeper than in the center. Figure 8 shows the surface profiles with 24 of D/t in each of the average pressures. The patterns at the edge were deeper than that of the center. It became clearer by increasing the average pressure. When

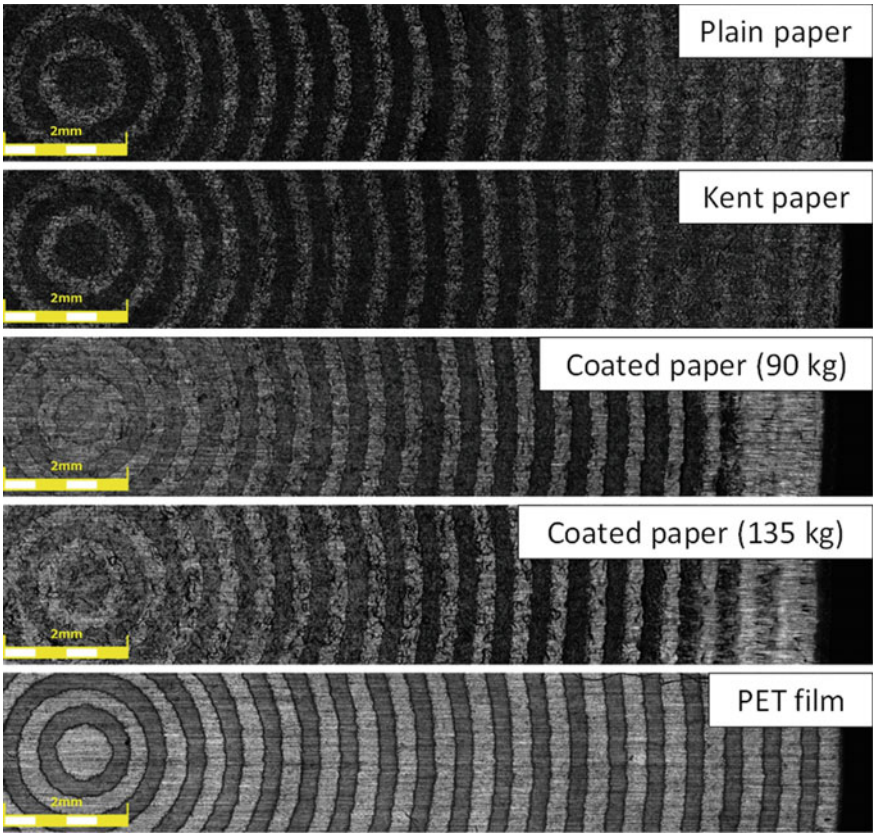

Fig. 4 Optical images of printed surface by each soft material. ($D/t = 24$, average pressure $p_a =$ 295 MPa). (Color figure online)

using more than 221.7 MPa of the average pressure, the depths of the patterns in the center seemed to be of the same level as those at the edge. Figure 9 shows the surface profiles with 12 of D/t in each average pressure. The patterns at the edge were deeper than that of those at the center with the same trend as 24, 36 of D/t. The patterns became clearer by increasing the average pressure. The depth of the patterns was uniform in the case of using more than 106.4 MPa of the average pressure.

From these results, the average pressure was needed to print the pattern clearly and uniformly. The required average pressure was decreased by decreasing the D/t of the workpiece. Ike showed that the transfer accuracy increased if the work material was yielded by compression [3, 4]. The high precision and uniform printing were difficult when using a high D/t because of the high friction condition. The results of this experiment using the new printing method were the same as the performance of the usual coining.

4 Conclusion

The new printing method using soft materials as the tool was proposed for forming the pattern on the metal surface. The experiment was performed using paper and PET film to aluminum. The results are as follows.

- The surface geometry of the soft material was printed onto the surface of the aluminum disc. The clear patterns were observed in the case of using the PET film.
- In order to print the clear and uniform patterns, sufficient pressure was needed for each D/t. The required average pressure was decreased by decreasing the D/t of the workpiece.

Plasticity Improvement of CNTs/Mg Nanocomposite Materials Processed by Combining Friction Stir Processing and Ultrasonic-Assisted Extrusion

Qian Zhang, Lehua Qi, Jiming Zhou, Jun Luo, and Junhao Liang

Abstract It is hard to maintain high plasticity for metal matrix composite while increasing their mechanical properties. A new process for preparing carbon nanotubes (CNTs) reinforced magnesium nanocomposites (CNTs/Mg) was developed, which combined friction stir processing (FSP) and ultrasonic-assisted extrusion. It is interesting that the mechanical property of CNTs/Mg nanocomposite materials is improved greatly compared with the supplied Mg alloy at the same time while the plasticity is preserved. The plasticity improvement mechanism is explained from the effect of interface bonding and the liquid–solid extrusion process by different microstructure analyses. HRTEM analysis shows that the Al_2MgC_2 phase at some interfaces between Mg matrix and CNTs is formed, which contributes to good composite interface bonding. Liquid–solid extrusion process can densify the composite and generate severe plastic deformation which is very useful for plasticity improvement.

high aspect ratios, and stable chemical properties [2]. It provides a new opportunity for the development of magnesium composite material. The carbon nanotube reinforced Mg matrix composite has both advantages of the Mg alloy matrix and the CNTs, such as lightweight, high specific strength, high specific stiffness, low coefficient of thermal expansion, excellent shock absorption performance, good dimensional stability, etc. So it is a structure–function integrated material and has potential application prospects in aerospace, military vehicles, and electronic packaging.

However, CNTs are easily tangled and agglomerated under the influence of Van der Waals forces due to the small diameter and the large surface energy, which is seriously adverse for the uniform dispersion of the CNTs in the Mg alloy. The agglomerated CNTs also reduce the mechanical properties of the CNTs/Mg composite. Therefore, lots of scholars are seeking an effective method to improve the dispersibility of CNTs in Mg alloys.

Now the processes for dispersing CNTs in Mg alloys mainly include the stirring casting method [3–5], the melt infiltration method [6–8], the powder metallurgy method [9, 10], and the friction stir processing (FSP) method [11, 12]. In our works, a new method is proposed to disperse CNTs in the Mg alloys. First, the CNTs are predispersed in the Mg alloy by FSP. FSP is a good way to disperse the CNTs to small clusters. Then the alloys mixed with CNTs are melted during the ultrasonic process. After that, microscopic defects are reduced in the as-cast composite materials through liquid–solid extrusion process. This work provided a new way to fabricate CNTs/Mg composite with excellent mechanical properties and plasticity.

2 Experimental Details

2.1 Materials

The matrix of the composite is commercial AZ91D alloy. The reinforced material is multi-walled carbon nanotubes (10–20 nm in diameter and approximately 30 μm in length, purity > 95 wt.%, Chengdu Organic Chemicals Co. Ltd., Chinese Academy of Sciences, Chengdu, China).

2.2 Experimental Process

2.2.1 FSP

CNTs need to be pre-dispersed in magnesium alloys. The CNTs/AZ91D predispersed magnesium alloy blocks were fabricated by FSP. The experimental schematic is shown in Fig. 1.

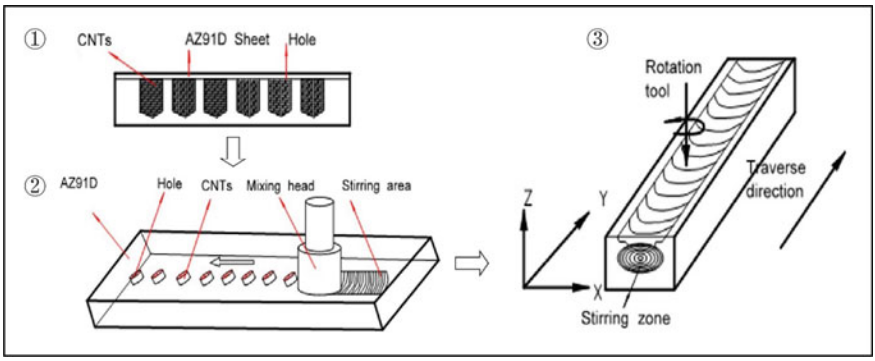

Fig. 1 The experimental schematic of FSP. (Color figure online)

First, blind holes are uniformly drilled on the AZ91D alloy plate, and CNTs are filled in the holes. Then the plate is fixed on the friction stirring device. The stirring head is rotated at a certain speed (800 ~ 1000 rpm) and travel speed (10 ~ 40 mm/min). The CNTs are mixed with AZ91D alloy by rotating friction. The entire operation process is under an argon protective atmosphere. About 4 wt.% of CNTs are added into AZ91D. After FSP processing, the mixed magnesium composite plate is shown in Fig. 2. The region of red circle is the stirring zone.

In order to get more uniformly dispersed CNTs in the stirring area, the stirring area is processed repeatedly for multiple passes. Finally, the FSP area is prepared as a sample by wire cutting, and the samples are used for the next ultrasonic processing step.

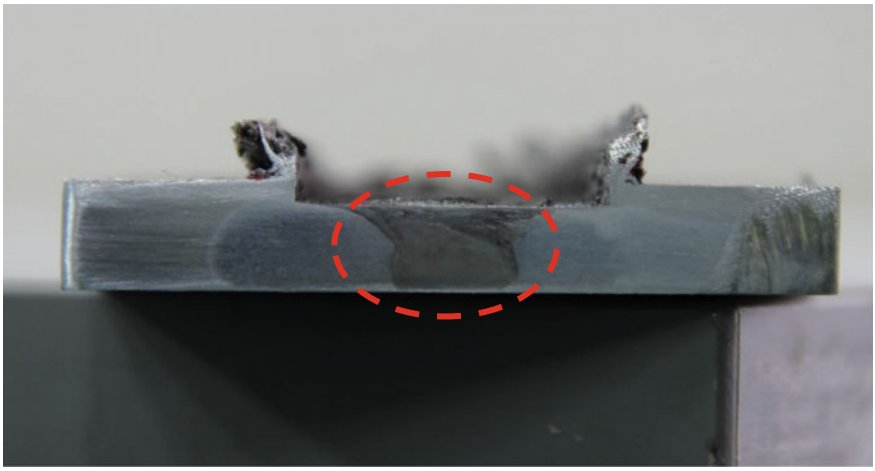

Fig. 2 Cross-section of 4 wt.%CNTs/AZ91D pre-dispersed plate by FSP. (Color figure online)

2.2.2 Ultrasonic Processing

Ultrasonic treatment is an efficient and pollution-free treatment method. The ultrasonic effect on the dispersion of nano-scale reinforcement is obvious [13]. It can produce acoustic cavitation and acoustic flow effects and then remove debris, refine grains and dispersion effects.

After the CNTs are pre-dispersed in magnesium alloy, the mixed block samples are put into the melting magnesium alloy. In order to improve the dispersibility of the CNTs, the ultrasonic treatment is applied.

The schematic diagram of the as-cast CNTs/AZ91D composite material preparation device is shown in Fig. 3. This device is mainly composed of a heating furnace, an ultrasonic amplitude rod, and a crucible. During the melting process, the ultrasonic transducer needs to be water-cooled to prevent damaging the piezoelectric ceramic. The preparation processing steps of the as-cast CNTs/AZ91D composite are as follows:

(1) Pre-heating the iron crucible to the temperature of 200 °C. The AZ91D magnesium alloy is placed in the iron crucible, and argon is introduced to prevent the magnesium alloy from oxidizing, and then continue heating the crucible to 700 °C for 10 min.
(2) The cleaned composite pre-dispersion blocks are put into the molten magnesium alloy and stirred for 3 ~ 10 min. Then the ultrasonic rod is immersed into the melt and removed after the ultrasonic procession. At last, the composite material melt is poured into a steel mold (length: 120 mm, diameter: 45 mm) preheated at 300 °C.

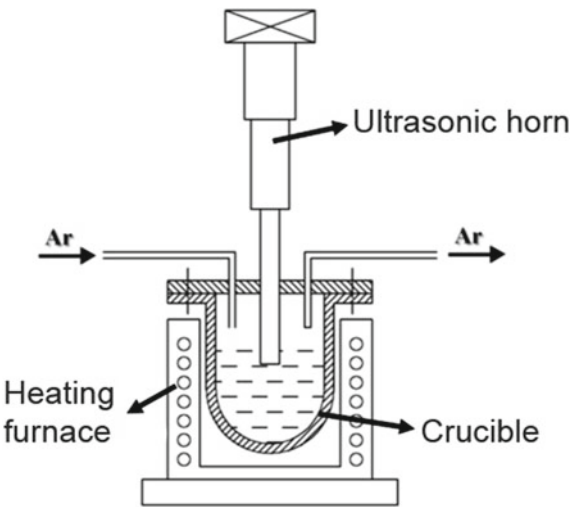

Fig. 3 The preparation device of CNTs/AZ91D composite

2.2.3 Liquid–Solid Extrusion Process

The liquid–solid extrusion process is a new metal matrix composite forming process developed in recent years to fabricate composite tubes and bars. This process integrates solidification, heat conduction, and plastic deformation into one process. It belongs to a non-linear, multi-variable time-varying system, which has fewer processes and a lower cost. Because of these advantages, it is widely applied in fabricating metal matrix composites.

Based on the process and equipment of our previous research, the as-cast CNTs/AZ91D composites are treated through liquid–solid extrusion process. The process is as follows:

(1) The extrusion mold is preheated, and then the as-cast CNTs/AZ91D composite is heated to the extrusion temperature. After that, the as-cast CNTs/AZ91D composite is extruded out at certain extrusion temperatures and speeds;
(2) Finally, T6 heat treatment is performed on the composite extruded bar (400 °C solution treatment 24 h then 168 °C aging treatment 16 h) to improve the mechanical properties such as tensile strength, yield strength, and hardness of the composite.
(3) The AZ91D alloy is also treated in the same extrusion and heat treatment condition for comparison.

The AZ91D alloy and CNTs/AZ91D composite bars are processed into standard cylindrical specimens as the requirements of GB/T228-2002. There are three specimens per group. The tensile test is carried out on the CMT5304-30KN testing machine with a tensile speed of 0.2 mm/min. The specimen specification is shown in Fig. 4.

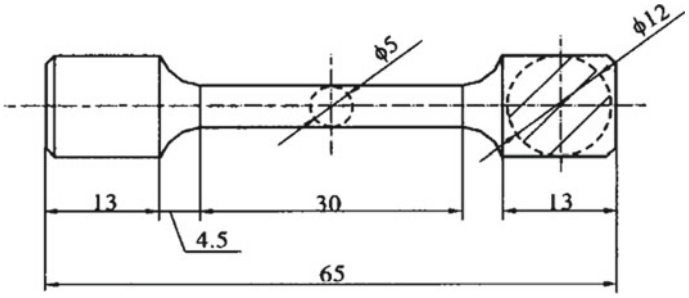

Fig. 4 The specification of tensile specimen

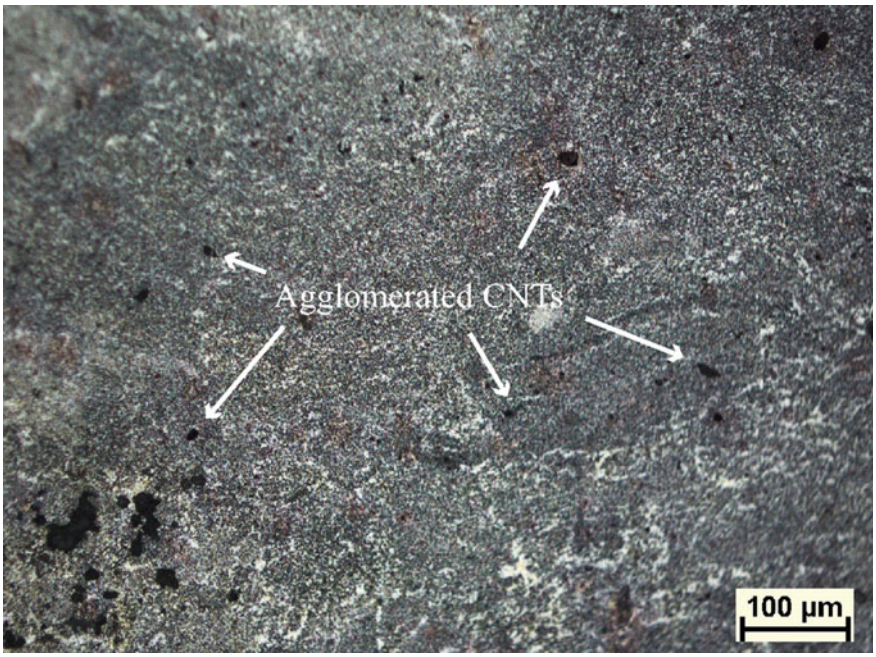

Fig. 5 Microstructure of CNTs/AZ91D pre-dispersed block preform in stir region. (Color figure online)

3 Results and Discussion

3.1 The Effect of FSP on the Dispersion of CNTs

Figure 4 shows the microstructure of the CNTs/AZ91D pre-dispersed block in the stirred region after FSP. The black region in the pre-dispersed block is CNTs and the white region is magnesium matrix. We can observe that the CNTs are well bonded to the magnesium matrix, and black spots of different sizes appear locally in the picture. These black spots are agglomerated CNTs, as shown by the white arrows in Fig. 5. The FSP did not make micro-size CNTs well dispersed because of the high content of CNTs. Therefore, the following process to further disperse the CNTs by ultrasonic processing is necessary.

3.2 Tensile Strength and Plastic Properties of Liquid–Solid Extrusion CNTs/Mg Composites

Figure 6 shows the mechanical properties curve of extruded AZ91D alloy and extruded CNTs/AZ91D composites. We can observe that the tensile strength of

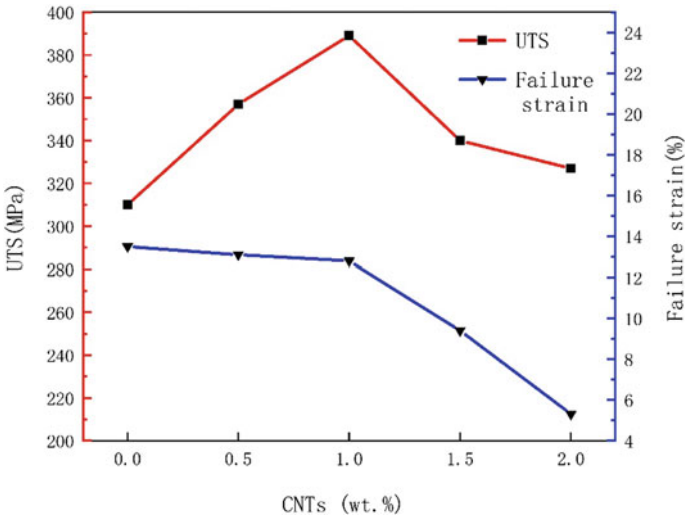

Fig. 6 Mechanical properties curve of extruded AZ91D alloy with and without CNTs. (Color figure online)

extrusion CNTs/AZ91D composites is improved and the plasticity preserves when the CNTs content is less than 1wt.%

When the content of CNTs is 1.0wt.%, the tensile strength of the composite reaches 390 MPa. It is significantly improved compared with the magnesium alloy (310 MPa), about 25.8%. The most important is that the fracture strain of the composite material is almost not reduced compared with the magnesium alloy, which indicates the extrusion CNTs/AZ91D composite still maintains good plasticity.

When the CNTs exceed 1.0 wt.%, the strength and plasticity of the composite decrease. Figure 7 shows the tensile fractograph of AZ91D alloy and 1.0 wt.% CNTs/AZ91D composite. It can observe that a large amount of cleavage planes and

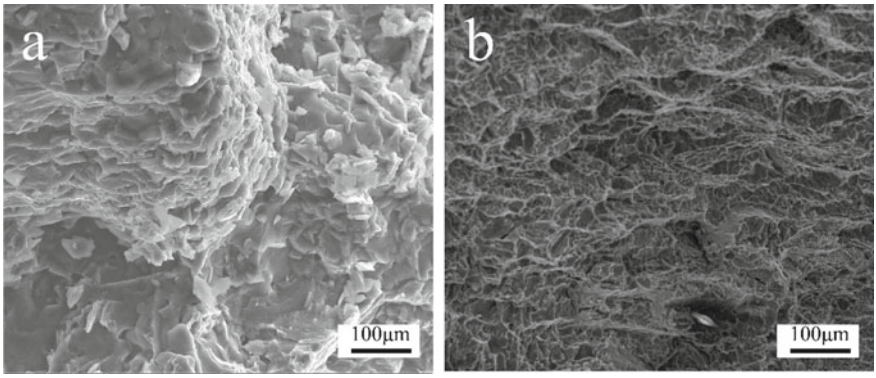

Fig. 7 Fractograph of **a** AZ91D alloy and **b** 1.0 wt.% CNTs / AZ91D composite

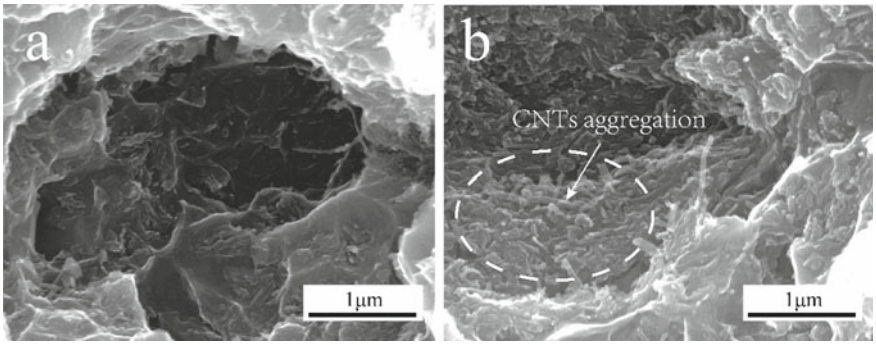

Fig. 8 SEM image of tensile fractograph of **a** 1.0 wt.% and **b** 2.0 wt.% CNTs/AZ91D composites. (Color figure online)

tearing edges appear at the fractograph of AZ91D alloy, which indicate the brittle fracture, as shown in Fig. 7a. On the other hand, 1.0wt.% CNTs/AZ91D composite shows a large amount of dimples and tearing edges at the fractograph, which are the ductile fracture given as in Fig. 7b. Some scholars [14] found that the addition of CNTs in the fabrication of CNTs/Mg composites caused the plastic property decline of composites. This is due to uneven interface bonding. Stress concentration occurs at the interface. Therefore, we can consider that the new fabrication method (especially the liquid–solid extrusion process) improves the interface bonding. It transforms the fracture mechanism from brittle fracture to ductile fracture, which leads to the strength of the composite be improved while the failure strain is maintained.

Figure 8 shows the tensile fractograph of 1.0 wt.% and 2.0 wt.% CNTs/AZ91D composites. CNTs of 1.0 wt.% CNTs/AZ91D composite were pulled out at the fracture region (Fig. 8a). It indicates that the interface between CNTs and magnesium alloy is well bonded. There is no CNTs aggregation found at the fractograph, so that CNTs are well dispersed in magnesium alloy. In the white circle of Fig. 8b, CNT aggregations are observed in the fractograph of 2.0 wt.% CNTs/AZ91D composites. The CNT clusters affected the wettability between magnesium and CNTs. It can introduce porosity and crack defects that should be the main reason for the decline in tensile property of 2.0 wt.% CNTs/AZ91D composites.

3.3 The Interface Between CNTs and AZ91D

Figure 9 shows the HRTEM micrograph of CNTs/AZ91D composites. It can observe that dark areas appear at the interface between CNTs and magnesium alloy. After FFT of the black rectangle area in the figure to obtain a diffraction spectrum, the calibration of IFFT image shows that the crystal plane spacing on the (102) plane is 0.207 nm, and the crystal plane spacing of the (101) plane is 0.260 nm. These results are consistent with Al_2MgC_2 phase. In some scholars' researches [15, 16],

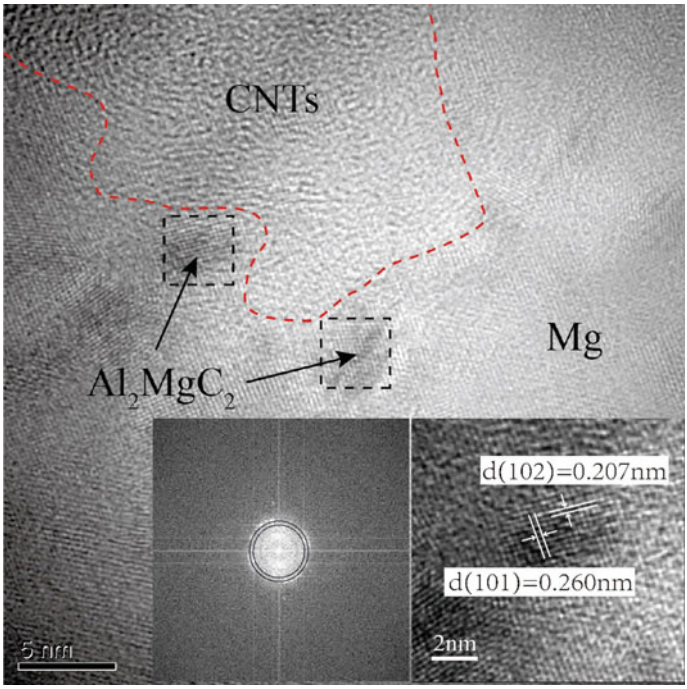

Fig. 9 HRTEM micrograph of CNT/AZ91D composites. (Color figure online)

the Al_2MgC_2 phase helps to produce moderation interfacial adhesion, which can improve the tensile strength and plasticity properties of the composite.

4 Conclusion

(1) CNTs reinforced AZ91D composites were prepared by FSP and ultrasonic treatment assisted with liquid–solid extrusion. Uniform distribution of CNTs in magnesium alloy was achieved.
(2) The extrusion CNTs/AZ91D composite has the highest tensile strength at 1 wt.% CNTs, which can reach 390 MPa, about 25.8% improved compared with AZ91D.
(3) The addition of CNTs can keep good plastic property while improving the tensile strength of composite at proper CNTs content. Al_2MgC_2 was found at the interface between CNTs and Mg. It is beneficial to the formation of good interfacial adhesion.

Residual Stresses in Metal Forming

Complementary Methods for Assessment of Residual Stress Fields Induced by Rotary Swaging of Steel Bars

Dhia Charni, Svetlana Ishkina, Jérémy Epp, Marius Herrmann, Christian Schenck, and Bernd Kuhfuss

Abstract The process investigated in this paper consists of cold rotary swaging of steel bars. In recent work, surface residual stresses were found to be sensitive to process parameters and their fluctuations, leading to variations of residual stresses at different length scales. To properly evaluate the residual stress states in rotary swaged bars, several complementary measurement techniques were applied. Complementary to surface X-ray diffraction measurements, the applicability of micromagnetic methods was evaluated for fast mapping of local residual stress distribution at the surface with a spatial resolution down to 20 μm. Additionally, an evaluation of the full residual stress profile over the cross-section was achieved by neutron diffraction. The combination of the different methods thus allowed a complete characterization of the generated residual stresses at different length scales. Furthermore, a 3D FE-model was developed and process simulation using the Chaboche material model was carried out to investigate the residual stress generation and compare the results with the experimental data. The results show an overall good agreement of the experimental data with the simulation results.

1 Introduction

For reducing and profiling, the cross-section of bars and tubes, rotary swaging is a common incremental cold forming process. The axisymmetric workpiece is fed into the swaging head. Therefore, the part is incrementally processed by continuously radial strokes of the oscillating dies during their rotation, see Fig. 1. Rotary swaging as manufacturing process is gaining more prevalence, in particular, across the automotive and aerospace industry [16], thanks to its versatility against the increasing demand for lightweight components [15]. Especially, hollow shafts with an advantageous development of the wall thickness enable a cost-effective production of lightweight components with an optimal use of material resources. Besides the advantage of producing near net shape workpieces, rotary swaging leads to products with close tolerances and good surface roughness [13].

Rotary swaging induces complex material flow history depending on the process control, inducing material modifications such as work hardening and residual stress fields [1]. In past studies, surface residual stresses in rotary swaged tubes were found to be sensitive to process parameters [3] as well as their fluctuations, leading to variations of residual stresses at different length scales [10].

In order to evaluate the residual stress fields induced by rotary swaging in a comprehensive way, several complementary measurement techniques can be applied both at the surface and in the volume. Laboratory X-ray diffraction methods are the state of the art for the investigation of residual stress fields [14]. This method is non-destructive but only for residual stress analysis in the first few micrometers beneath the surface, hence, destructive local material layer removal is needed to analyze residual stress depth distribution. On the other hand, non-destructive micromagnetic methods at the microscale have been continuously developed for residual stress analysis [20], offering an important gain of time compared with conventional X-ray diffraction methods. The principle of the micromagnetic method is based on the analysis of Barkhausen noise, crystalline lattice distortion induced by residual stress field with the movement of Bloch walls and with domain rotations during external

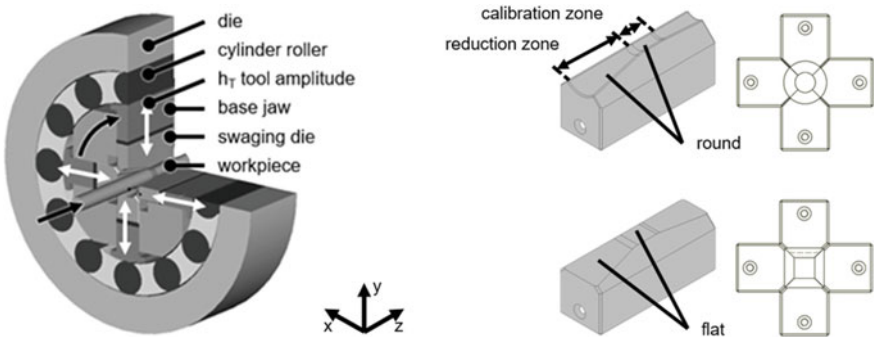

Fig. 1 Illustration of the swaging head for infeed rotary swaging and die geometry features. (Color figure online)

magnetization processes [7]. This method is already well established at macroscopic scale using large probes and has the capability of detecting varying compressive residual stress as for example in shot-peened samples based on Barkhausen noise analysis [11]. However, the application of the micromagnetic method at microscale with the so-called Barkhausen Noise and Eddy Current Microscope (BEMI) still needs to be established for 2D mapping of property variations with high spatial resolution [19]. However, both X-ray diffraction and micromagnetic methods have limitations in terms of penetration depth for non-destructive residual stress analysis. An evaluation of the full residual stress state over the cross-section of steel bars can be achieved via neutron diffraction, which allows the evaluation of different process conditions at global scale [9]. However, the application of this method is limited by the access to neutron sources, which is generally not more than few days per year. Moreover, it can be restricted by the size of the gauge volume leading to low spatial resolution and when scanning thin components due to spurious strain, which affects near surface strain analysis [17].

In this study, the complementary techniques for the residual stress measurement in cold-formed steel bars processed by different parameters are examined and combined for full description of residual stress state generated by the process. In particular, the applicability of non-destructive micromagnetic and neutron scattering methods was investigated and compared. On the other hand, finite element methods were employed to allow a validation of the model by the obtained experimental data.

2 Experimental Methods

The present study has been performed on residual stresses generated by rotary swaging of steel bars. The residual stresses were then analyzed both at the surface and in the entire volume using different measurement methods. For surface stress measurement, XRD and micromagnetic methods were used on rotary swaged bars processed with varying parameters. For the residual stress analysis in the volume, Neutron diffraction was used and compared with the simulation results.

2.1 Process and Material Preparation

The semi-finished part used in the present study was a low carbon low alloy structural steel bars S355, manufactured by cold drawing with a ferritic–perlitic microstructure. To eliminate any pre-existing residual stresses and cold working before rotary swaging, the samples were normalized in a vacuum furnace by gradual slow heating to 890°C and maintaining the temperature for 5 h before slow cooling to room temperature. This also ensures a homogeneous ferrite–pearlite microstructure.

Rotary swaging experiments were performed on bars with an initial length of $L_0 = 300 \pm 0.85$ mm and an initial diameter of $d_0 = 20 \pm 0.30$ mm, under different

Table 1 Experimental setup

Sample	Stroke following angle	Feed per stroke	Die surface shape	Lubrication
BR (standard)	Not controlled	0.46 mm/stroke	Round	Yes
BFd	0°	0.92 mm/stroke	Flat	No
BFl	0°	0.92 mm/stroke	Flat	Yes

process setups, see Table 1. Three different rotary swaging setups were used for the analysis. The first one, which is the standard setup, consists of a reduction of the workpiece diameter to $d_1 = 15$ mm using round swaging dies made of powder metallurgical ASP®2023 steel, which have a round-shaped surface in the calibration as well as in a reduction zone (see Fig. 1), BR in Table 1. An incremental feed of 0.46 mm/stroke was used and the workpiece was lubricated continually during the process using mineral oil Condocut KNR 22. For the second and third process setup, the workpiece was formed with flat swaging dies (flat-shaped calibration and reduction zones) made of 1.2379 steel, see Fig. 1. The combination of these dies with a stroke following angle $\Delta\varphi = 0°$ led to producing a square section workpiece with an edge length of $d_1 = 15$ mm [10]. A higher incremental feed (0.92 mm/stroke) was used to reduce the high back-push stresses that could damage the machine parts. No lubricant was added for the second process setup and a stream of lubricant was used on the workpiece surface for the third process setup. The reduction zone of the round dies is spray-coated by a tungsten carbide layer to increase the effective friction between the swaging dies and the workpiece during the process, reducing the axial reaction force. The samples were fixed using hydraulic clamps before being axially fed into the swaging unit by a distance of $z = 130$ mm. Once the axial feeding is achieved, the rotation of the swaging axle was stopped to prevent additional strokes from affecting the already processed surface while pulling the workpiece out of the swaging unit.

2.2 Process Simulation

For a realistic modeling of complex forming processes, a three-dimensional FEM-Model is required. This representation allows the consideration of all flow directions of the material and influencing variables.

The model for the simulation of infeed rotary swaging was developed with ABAQUS Vers.6.14. To account for the dynamic character of the process, Abaqus/Explicit numerical method was used. Four dies were modeled as rigid bodies and the workpiece as a deformable body. The mesh of the workpiece consisted of linear elements (C3D8R) using distortion control and hourglass control. The length of the edge in an analyzed region was set to 0.5 mm. Figure 2 shows an assembly of the performed simulations with the workpiece and the four dies. The experimental

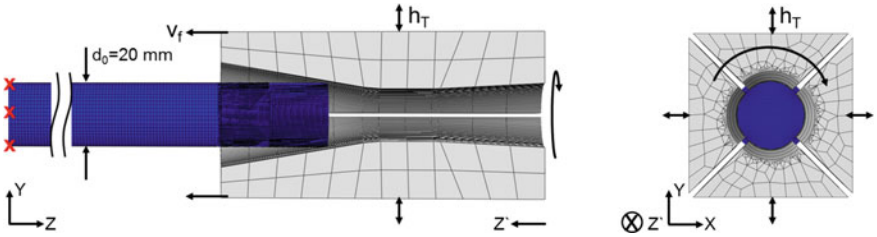

Fig. 2 Design of 3D rotary swaging model. (Color figure online)

process showed low heat generated by the plastic deformation (less than 120 °C) [6]. As a result, the process was considered to be adiabatic.

Similarly to BR process setup, the workpiece was processed from bars with an initial diameter of $d_0 = 20$ mm to a final diameter of $d_1 = 15$ mm. The initial length of the workpiece was $L_0 = 300$ mm. The dies oscillated with a stroke $h_T = 1$ mm with a frequency of 37.5 Hz. For the purpose of simulation time reduction, a feed velocity of $v_f = 2000$ mm/s which is equivalent to the feed per stroke of $l_{st} = 0.92$ mm/stroke was used. Also, contrary to the experimental process, the end of the workpiece was fixed and the dies were rotating and at the same time moving across the workpiece in Z'-direction, assuring the same relative movement as in the real process. The contact conditions between the workpiece and dies were simplified in the simulation by the use of coulomb's law with a constant friction coefficient of the tangential behavior $\mu = 0.1$ in penalty contact method. In order to calculate the residual stresses induced in the process, a static general spring back step with completely removed swaging dies was introduced and realized at the end of the dynamic explicit analysis [18]. To take into account the Bauschinger effect caused by the incremental forming, a non-linear combined hardening material model was chosen in ABAQUS. According to the Chaboche approach [12], a combined kinematic and isotropic hardening model was used. The coefficients of the isotropic hardening were obtained from a cyclic tensile-compression test of an hourglass-shaped annealed sample, which was also simulated with the same parameters for the validation of the obtained material model see Fig. 3a. The samples were cut from the same batch of the semi-finished samples

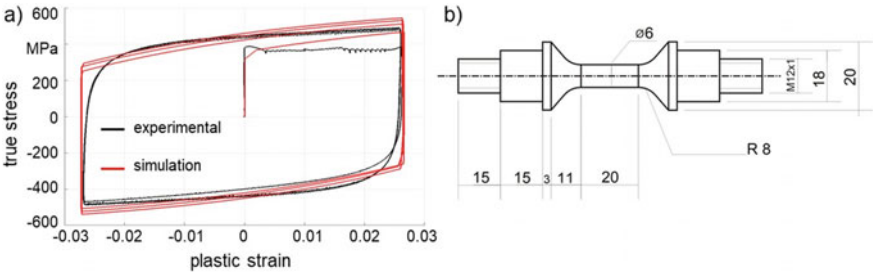

Fig. 3 **a** Validation of the material model, **b** Hourglass sample geometry. (Color figure online)

used for experiments with the dimensions shown in Fig. 3b. The initial yield stress $\sigma_0 = 357.3$ MPa and the parameters used in the isotropic hardening model $Q_\infty = 104.08$ MPa and $b = 2.78$ were determined. For the kinematic hardening by means of "Half Cycle" data type with three back stresses, a yield stress, and plastic strain were carried out using cyclic tension/compression test of annealed samples.

During the cyclic tensile-compression test, bending of the hourglass sample was observed while applying compressive stress, resulting in a progressive shift of the measured stresses with each compression cycle, therefore, only three cycles were taken into account to limit the errors.

2.3 Residual Stress Measurement Methods

2.3.1 X-ray Diffraction

The residual stress measurements were performed with a commercial 8-axis diffractometer Type ETA 3003 from GE inspection technologies, equipped with a position-sensitive detector. A beam of 1 mm diameter of Vanadium filtered Cr-Kα radiation was used. All residual stresses were calculated using the $\sin^2\psi$-method on the {211} diffraction peak of α-iron along 13 χ-angles between $-45°$ and $+45°$ and X-ray elastic constant $½\,S_2 = 5.81\ 10^{-5}$ MPa^{-1} [14]. Surface residual stress measurements were performed by XRD on different bars with different homogeneous residual stress states for the micromagnetic method calibration. Moreover, complementary semi-destructive residual stress measurements were performed by XRD with successive electrochemical layer removal using a solution of H_3PO_4 and H_2SO_4 to determine residual stress depth profile below the surface. No correction of the effect of layer removal was applied. The data were also taken into account for the determination of the stress-free lattice parameter d_0, using the force balance method on a combined X-ray/neutron dataset [21]. Moreover, for the evaluation of surface residual stress homogeneity, the biaxial residual stress state was measured at the surface along a path of 40 mm in axial direction with a step size of 1 mm.

2.3.2 Micromagnetic Method

Measurements of residual stresses were performed using a Barkhausen noise and Eddy current Microscope (BEMI) combined with a 3MA micromagnetic testing system from IZFP Saarbruecken, Germany equipped with a 3-axes positioning system [20]. The sample was fixed on an electromagnetic yoke with a Hall probe underneath the holder see Fig. 4. The magnetization of the sample was applied using a magnetization function generator and an amplifier with a magnetization field strength of 0–125 A/cm and frequencies up to 250 Hz. A spatial resolution of 20 μm could be achieved and the probe position movement had an accuracy of 10 μm in x, y, and z directions. The device was equipped with an Eddy current testing

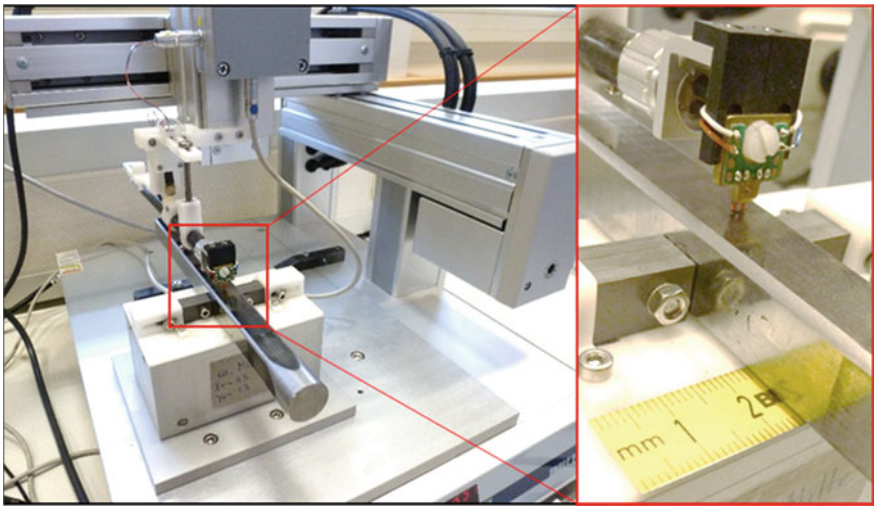

Fig. 4 Barkhausen noise and Eddy current microscope setup. (Color figure online)

unit and a Barkhausen noise measurement unit, which could be used and controlled separately or simultaneously by the computer. The parameters used for the EC and BN analysis are illustrated in Table 2. Since this method aims for fast analysis of property distributions and due to limited space on the BEMI mounting system, only the tangential residual stress component was considered. For this, a calibration of the system was achieved using regression analysis with three reference samples with known homogeneous residual stresses at the surface measured by XRD [4]: annealed state (0 MPa), two rotary swaged bars produced by two different parameters using flat dies and a following stroke angle $\Delta\varphi = 0°$ [10], inducing two different homogeneous compressive tangential residual stress at the surface (−200 MPa and −320 MPa). The magnetic Barkhausen noise parameters and Eddy current parameters were measured along a grid at the surface of the reference samples of 2×10 mm^2 dimensions with a step size of 50 µm in x-direction and 250 µm in y-direction

Table 2 Barkhausen noise and Eddy current analysis parameter setup

Parameter	Setting
Global magnetization frequency	100 Hz
Eddy magnetization amplitude	15 A/cm
Eddy current analysis frequency	500 kHz, 1 MHz, 2 MHz, 4 MHz
Barkhausen magnetization amplitude	30 A/cm
Low and high pass for the Barkhausen noise analysis	100 kHz, 1 MHz

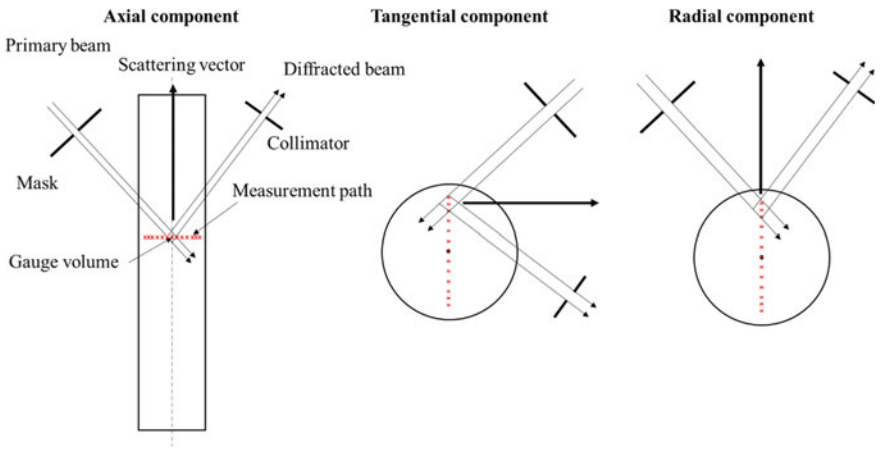

Fig. 5 Neutron diffraction experimental setups in all three stress measurement directions, together with the measured profile line along the cross-section. (Color figure online)

resulting in a dataset averaging 1800 points for each reference sample. For every point, 10 successive measurements were taken and averaged. The measurement time of this magnetic method was less than 1.5 s per point leading to a total of 45 min for one full 2D map.

2.3.3 Neutron Diffraction

Residual stress distributions have been measured by neutron diffraction using the instrument E3 at the reactor BER II (Helmholtz-Zentrum Berlin) using $2 \times 2 \times 2$ mm^3 gauge volume. The {211} diffraction peak of α-iron at 78° with a wavelength of 0.1486 nm was analyzed to determine the lattice spacing $d_{\{211\}}$. Measurements were performed in three principal stress directions, axial, radial, and tangential, see Fig. 5. The measured depth profile was located at an axial position 20 mm away from the last stroke and consists of 17 points along a centered path of 14 mm with step sizes ranging between 0.5 mm and 1.5 mm. The measurement time for a single measurement was between 300 and 2200 s. To control the size of the gauge volume, a mask with a square cross-section was used at the primary beam and an oscillating collimator of 2 mm in width with no height limitation was used in front of the detector. The stress-free lattice parameter d_0^{hkl} was measured at small cubes of the same material ($2 \times 2 \times 2$ mm^3) prepared by electro-discharge-machining. Complementary destructive residual stress measurements were performed by XRD to calculate the residual stress depth profile near the surface. These data took also into account the determination of the stress-free lattice parameter d_0 using the force balance method on a combined X-ray/neutron stress dataset [5]. The analysis of the diffraction pattern was performed using the Software Stresstex developed by C.

Randau of FRMII/TUM. The diffraction peak was obtained by integrating the two-dimensional diffraction frames. The fitting of the diffraction pattern was performed using pseudo-Voigt function after background subtraction. After the fitting, the strain ε_i^{hkl} was calculated using Eq. 1 from the measured diffraction peak position resulting into the d_i^{hkl} through Bragg's Law Eq. 2.

$$\varepsilon_i^{hkl} = \frac{d_i^{hkl} - d_0^{hkl}}{d_0^{hkl}} \tag{1}$$

$$n * \lambda = 2d_{hkl} * \sin\theta \tag{2}$$

Based on the three determined strain components, the residual stresses could be calculated through Eq. 3 in the considered direction where ε_r^{hkl}, ε_θ^{hkl}, and ε_z^{hkl} are the strain in the radial, tangential, and axial direction respectively. The residual stresses were obtained by using the elastic constants $1/2S_2^{hkl} = 5.8181 * 10^{-6}\text{GPa}^{-1}$ and $S_1^{hkl} = -1.2727 * 10^{-3} GPa^{-1}$.

$$\sigma_r = \frac{1}{1/2S_2^{hkl}} \left[\varepsilon_r^{hkl} - \frac{S_1^{hkl}}{1/2S_2^{hkl} + 3S_1^{hkl}} (\varepsilon_r^{hkl} + \varepsilon_\theta^{hkl} + \varepsilon_z^{hkl}) \right] \tag{3}$$

3 Results and Discussion

3.1 Surface/Surface-near Residual Stress Distribution

The biaxial residual stress state measured by X-ray diffraction at the surface along the axial direction of the round and flat rotary swaged samples are presented in Fig. 6a.

On the sample Br, both residual stress distributions are fluctuating along the surface between −250 MPa and −620 MPa in the axial direction and between −280 MPa and −450 MPa in the tangential direction. These fluctuations seem to have a periodic shape along the axial direction of the sample. These rotary swaging signature fluctuations are also reported in previous works on surface residual stress state of rotary swaged tubes and bars of the same steel grade [10]. In contrast, the surface residual stress measurements on sample BFd show homogeneous distribution of both residual stress components. The surface axial residual stress is around −400 MPa and the tangential surface residual stress is at −350 MPa. Previous work has shown congruent surface residual stress homogeneity properties examined on rotary swaged tubes by both process setups [10]. Similarly to tubes, it was also found that these surface residual stress fluctuations disappear under 300 μm below the outer surface of rotary swaged bars. Additionally, it was shown that the feed per stroke parameter has no influence on the residual stress generation below 300 μm from the surface

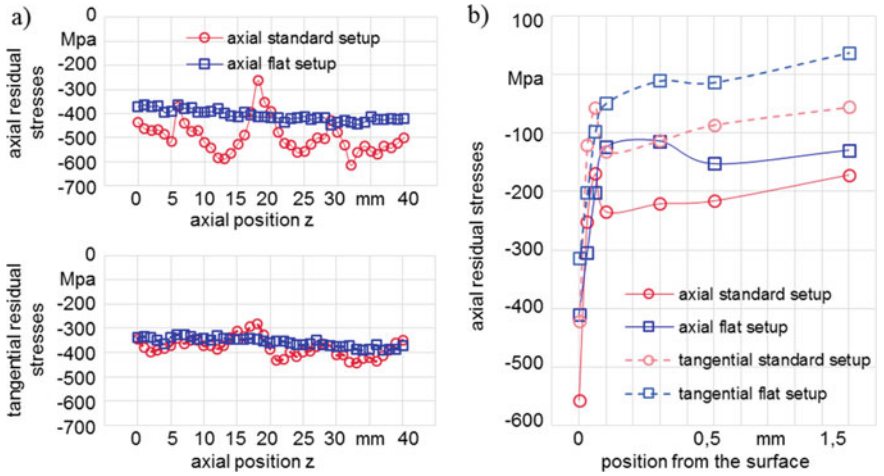

Fig. 6 **a** axial and tangential residual stress distribution at the surface of rotary swaged bars along the axial direction for different process setups (BR: standard setup, BFd: flat setup). **b** axial and tangential residual stress depth profile for different process setups. (Color figure online)

for process standard setup. Complementary to the surface residual stresses, residual stress depth profiles by destructive XRD are shown in Fig. 6b. The residual stresses in both directions for both process setups changed drastically in the first 50 μm under the surface before stabilizing at low compression for deeper positions.

The results of micromagnetic measurements are compared with X-ray diffraction data as a reference. Two different calibration functions were determined, one using Barkhausen noise analysis and Eddy current and one using only the Barkhausen analysis. Figure 7 shows the tangential residual stress distribution measured by micromagnetic analysis at the surface of a rotary swaged rod using flat dies setup featuring high fluctuating back-push loads (BFl).

The calculated tangential residual stress distributions measured by both calibration setups have similar shape and values as shown by the XRD data with the residual

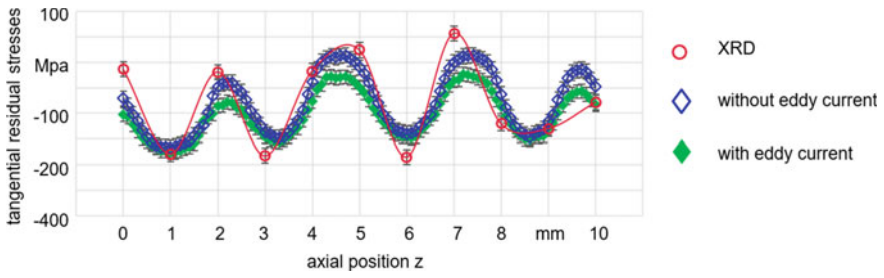

Fig. 7 Surface tangential residual stress measured by XRD and micromagnetic methods on sample BFl. (Color figure online)

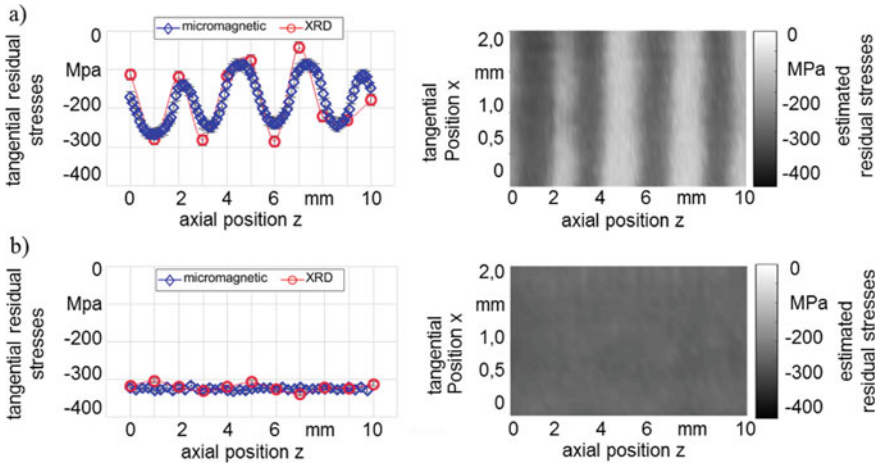

Fig. 8 Surface tangential residual stress measured by XRD and micromagnetic method without Eddy current. **a** sample BFl, **b** sample BFd. (Color figure online)

stresses calculated with only Barkhausen noise analysis having a better agreement, with discrepancies generally below 50 MPa. Scan of the surface of the sample BFl using Barkhausen analysis is shown in Fig. 8.

Due to the high spatial resolution, the micromagnetic results show much clearer periodic fluctuating tangential residual stress distribution shaped like sinusoidal curve. The micromagnetic method seems to have a good accuracy when it comes to measuring low compressive residual stresses with small differences. Similar to the results of BFl sample, surface residual stress at BFd sample shows good concordance between the XRD results and the Barkhausen noise analysis results, highlighting the potential of the micromagnetic method for fast homogeneity examination. However, it has to be kept in mind that the measured signal could also be influenced by variations of the local material properties such as microstructure, dislocation density, and chemical composition, as well as surface topography. Therefore, a prior careful calibration to the target property is still essential. This method remains very accurate while considering the significant reduction of measurement time gain in comparison with the XRD method, while at the same time, offering the benefits of high spatial resolution. On the other hand, it was not possible to analyze surface residual stress distribution using the present setup on round rotary swaged bars. This could be explained by a possible geometry effect taking part in the measured Barkhausen signal [2].

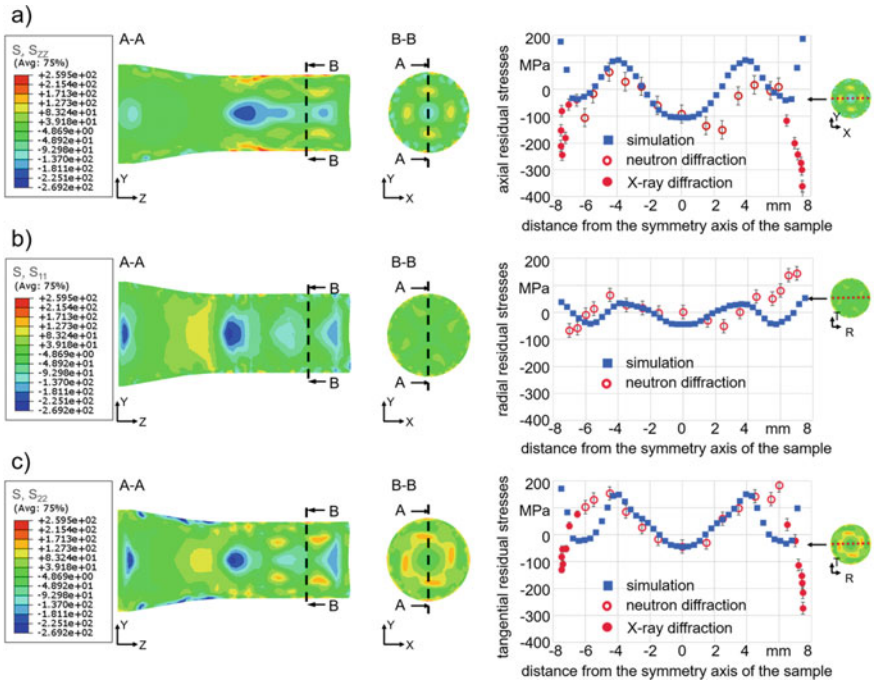

Fig. 9 FEM results of residual stress field and depth profile in a cross-section B-B of a rotary swaged bar using standard parameters (BR), compared with neutron and XRD data; **a** axial residual stresses, **b** tangential residual stresses, **c** radial residual stresses. (Color figure online)

3.2 Residual Stress Distribution in the Volume

The FEM results of residual stresses distribution were determined in the longitudinal section A-A as well as in the cross-section B-B of the bar, as shown in Fig. 9. The axial residual stress component was analyzed by means of the axial stress component S_{ZZ}. These values were obtained for each element node along the cross-section. Radial and tangential residual stresses were obtained in a cylindrical coordinate system. Thus, the values of the stress component S_{11} and S_{22} in the simulation were analyzed as the radial and tangential components of residual stresses respectively.

The through-thickness residual stress neutron data in a standard rotary swaged bar are presented in Fig. 9, combined with near-surface XRD data and compared with simulated residual stress results. Both experimental and simulation results show a compression concave shape around the center of the sample, surrounded by two symmetrical tensile residual stress peaks below the surface in all three principal directions. As expected, the neutron data show low residual stress field in normal direction (mostly between 80 MPa and −50 MPa), which confirms the reliability of the measurements and of the subsequent evaluation procedure, including the stress-free lattice parameter d_0 determination. Additionally, the simulated residual stress

distribution in the whole cross-section shows axial and tangential residual stress tensile peaks, which corresponds to the areas under the center of the die strokes. At the surface, eight tensile peaks can be spotted around the surface, which correspond to the die imprints between two successive strokes. This effect could be attributed to the causes of residual stresses fluctuation at the surface during standard rotary swaging setup. This stroke effect could be eliminated during the flat rotary swaging setup by controlling the stroke following angle ($\Delta\varphi = 0°$), resulting into homogenous surface residual stresses. By comparing simulation and neutron diffraction results, it can be seen for all three principal residual stresses that the simulation gave similar trends and values below 1.0 mm from the surface. In contrast, axial and tangential residual stresses obtained by XRD strongly differ from the simulation results near the surface. These discrepancies can be attributed to several factors influencing the simulation results. First of all, it may be associated with the highly simplified model of friction conditions. In real process, round dies with WC–Co (tungsten carbide-cobalt) layer [8] in the reduction zone were used, which can influence the material flow at the surface of the workpiece. Furthermore, particle abrasion and lubricant as well as microstructure inhomogeneity were also not considered in the simulation. Another aspect is that the material flow differs between simulation and experiment. In the simulation, the axial stiffness in z'-direction is given by the (static) stiffness of the workpiece, which is significantly higher than in the experimental setup. The material flow in this direction causes upsetting of the workpiece (diameter increase of about 19 μm in the simulation). In the machine, the clamping and the feed devices provide (dynamic) stiffness that is low enough to prevent any upsetting. Consequently, the material flow differs between simulation and experiment with a higher difference at the surface than in the core of the workpiece. Finally, the employed mesh size for the considered process was optimized regarding the simulation time and therefore the mesh size was too large to achieve reliable simulation results at the very surface. Nevertheless, simulation results and measurements are in the good agreement below the surface.

4 Conclusion

In this study, complementary residual stress measuring techniques were used and compared with FEM simulation, namely XRD, neutron diffraction and micromagnetic method, allowing the experimental analysis of residual stress fields at different length scales. Rotary swaged components processed with two different geometries were investigated and the obtained experimental data were then compared with FEM simulations in order to validate the model. The following conclusions can be drawn:

- The micromagnetic method proved to be successful at measuring surface residual stresses, offering both shorter measurement time compared with X-ray diffraction method as well as higher spatial resolution.

- The micromagnetic method can be a good replacement or at least complementary method for X-ray diffraction method for fast surface residual stress homogeneity.
- The simulated residual stress analysis using the Chaboche material model showed good agreement with experimental data in the volume below 1.0 mm from the surface. Through the validated model for bulk residual stress development, modified process conditions for residual stress optimization can be analyzed.
- The discrepancies between the simulated and measured residual stresses by means of X-ray diffractions near the surface could be mainly attributed to the simplification of the friction condition and of the process model. Further investigations are needed to study the corresponding effects.

Investigations and Improvements in 3D-DIC Optical Residual Stress Analysis—A New Temperature Compensation Method

Frederik Dahms and Werner Homberg

Abstract Highly accurate in-situ measurement of geometric and mechanical quantities is now a requirement for the production of complex and, in particular, incrementally manufactured components. A current research project at the Chair of Forming and Machining Technology (LUF) is thus investigating the application of a 3D digital image correlation measuring system for in-situ residual stress measurements based on the hole-drilling method. The corresponding investigations have initially proven the basic feasibility of the system. It is also shown that the measurement result is affected by thermal influences, unintentionally introduced vibrations, and air flow. These influences can be compensated to a high degree through the appropriate countermeasures. A compensation method is thus presented, taking the example of thermal loads.

Keywords Residual stress measurement · Hole-drilling method · 3D digital image correlation · Friction spinning · Thermal strain

1 Introduction

Economic and ecological constraints are necessitating the development and production of complex and multifunctional components. Against the background of an equally widespread desire for flexibility, incremental manufacturing processes are increasingly becoming the focus of interest. A good example of this is the friction-spinning process [1]. The friction-spinning process is an incremental forming technology based on the principles of metal-spinning, flow-forming, and friction welding [2]. Friction-induced heat leads to an increase in the ductility of the workpiece. This can be used to produce complex workpiece geometries and also to improve their mechanical properties [1–3]. Complex thermomechanical conditions can, however, lead to non-uniform residual stress distributions. Preliminary investigations indicated these non-uniform residual stress distributions

in the tangential and radial direction of tubular workpieces with a radial flange from AW 6060 through X-ray diffraction (XRD) measurements. For procedural reasons, the XRD method is unable to evaluate non-uniform residual stress distributions that vary over the depth [4]. Metallographic investigations, however, show that these workpieces have a non-uniform degree of deformation distribution over the wall thickness [2]. A depth evaluation of the residual stress distribution would thus make sense. One means of achieving this is through the incremental hole-drilling method, in which the residual stress distributions inside the workpiece can be deduced by strains close to the surface that are released by hole-drilling [5–7]. The drawbacks of this method include the major outlay on apparatus and the time required for the preparation and evaluation of strain-gauge measurements. Another promising approach is the use of optical measuring methods, such as electronic speckle pattern interferometry [8]. One less investigated approach is the utilisation of relatively widespread 3D-DIC systems for residual stress analysis [9, 10]. A possible experimental setup is presented in Fig. 1. The multi-camera system with the lighting unit and the 3D-DIC system is mounted on a frame-shaped device to this end, together with a high-speed drilling turbine (approximately 300,000 rpm). In a future setup, this device, with the hole-drilling and 3D-DIC unit, is to be positioned at the respective measuring or hole-drilling point using an industrial robot. In this case, the measuring points will usually be located in an area of no relevance for the function of the measured component. For fundamental investigations, the measuring device described in Fig. 1 has been configured differently, with the workpiece being moved to the measuring and drilling position with the aid of a linear axis.

2 3D-DIC Optical Residual Stress Measuring System

In the existing approaches, the hole-drilling device is either positioned between two fixed cameras with a fixed specimen [11] or the hole drill is retracted from the field of view after each depth increment before the image is taken [12]. In this new approach,

however, the hole-drilling device and the cameras are fixed. Either the specimen or the complete measuring device thus has to be moved for the incremental measurement procedure. The procedural benefit derived from this setup is the use of ideal camera calibration, respectively, the angle between the cameras and the specimen, leading to an optimal depth of field with a wide-range measuring surface around the drill hole. The use of a 3D-DIC camera setup, in particular, makes it possible to measure tubular specimens, for example.

The design of the optical residual stress measuring system is illustrated in Fig. 1 (*l*). The measuring device is designed as solid as possible to provide high stiffness and avoid vibrations. The linear guide's carriage is fixed with clamps at the outer end to achieve high-repeat accuracy. It is made of a GOM ARAMIS 5 M to capture the images. This is calibrated to an area of 15 mm × 13 mm. The workpiece is illuminated by two 16 W LED lamps. The captured images are processed by GOM ARAMIS 2017 software. For the hole-drilling process, the high-speed air turbine of the Vishay RS 200 is mounted on the measuring system. Inverted-cone drills of 1.6 mm diameter are used as described in ASTM E837-13a [5].

The measuring process is illustrated in Fig. 1 (*r*). Starting in the image acquisition position, the reference stage images are taken (a), then the specimen is moved on the linear guide (b) to the hole-drilling position (c), where a hole increment is drilled, and afterwards, the specimen is moved back (d) to the initial position where the residual strains of the hole-drilling step are measured (e). For further increments, the process restarts with step (b). The strain measurements can be processed full-field or over a defined area like a strain-gauge grid geometry.

The accuracy of the measuring procedure described is proved by solely moving the specimen between the image processing position and the drilling position without drilling. The procedure is completed after a repetition of eight times after capturing the reference stage images. The strains are expected to be zero. The mean deviation of the measured strains ε_1 is 0 µm/m, and ε_3 is 2 µm/m (*cf.* Fig. 2). The average measured displacement of the specimen u is 1 µm. The standard deviations are indicated in the columns of Fig. 2. These results confirm that it is possible to conduct measurements with this new approach for 3D-DIC optical residual stress analysis.

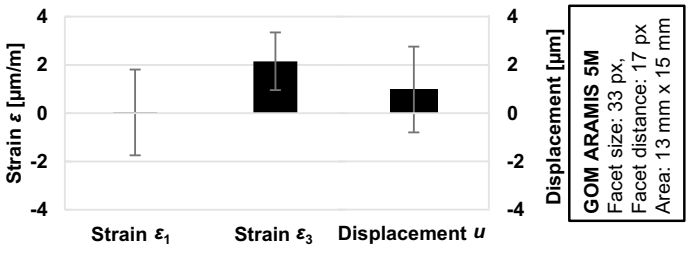

Fig. 2 Averaged deviation of the measured strains ε and displacement u of the specimen

3 Experimental Investigations

This chapter describes the experimental investigations on the accuracy of the 3D-DIC optical residual stress measuring system. Based on these investigations, adjustments are made to the measuring system. The workpieces (the tubular part with a flange) are manufactured using EN AW 6060 (3.3206) tubular profiles with a friction-spinning machine based on Leifeld Metal Spinning GmbH PLB400. Specimens for optical measurements are coated with a speckle pattern by spraying a white acryl-based spray coating layer and black speckles with an airbrush system, leading to better adhesion of the speckles, even when compressed air and fine wipers are used to remove chips and dust. To validate the 3D-DIC optical residual stress measurements, use is made of CEA-13-062UM-120 strain-gauge rosettes and CEA-13-062UW-120 strain gauges, which are soldered to a three-wire half-bridge circuit with a 120-Ω precision resistor and processed with a universal measuring amplifier HBM MX 440. This is also used for processing the type k thermocouple temperature measurements. The strains of the 3D-DIC optical residual stress measurements are always averaged over the same geometry (area, direction, and distances) as those of the used strain gauges. As the measuring area is 0.77 mm distant from the borehole, its speckle pattern is not influenced by the hole drilling operation.

3.1 Optical Micro-Strain Measurements

Initially, the accuracy of the 3D-DIC GOM ARAMIS 5 M system used is investigated by measuring micro strains. Small loads are applied to an aluminium EN AW 6060 (3.3206) specimen of $t = 2$ mm thickness by a Zwick Z100 testing machine. For the optical strain measurements, 15 images are taken for each stage with a frequency of 2 Hz. Preliminary investigations have shown that an optimum facet size and distance can be determined for each application, depending on various factors. These include the size of the calibrated area in relation to the characteristics of the speckle pattern and the character of the strain to be measured, for example, its potential variation within one facet. The resulting computing time must also be considered in the process of selection. Alternatively, a good approximate solution can be determined iteratively based on the manufacturer's specifications, starting with a facet size of 19 px and a facet distance of 15 px. In this case, the facet size is set to 21 px and the facet distance to 11 px. The influence on accuracy is negligible if a minimum facet size is achieved, which in this case means that the facets must be larger than 9 px. The two 16 W LED lamps were only turned on during the 7 s of image acquisition for an individual stage. This reduces the heat induction to the specimen. Figure 3 shows a comparison of the measured 3D-DIC strains with the strains calculated by Hooke's law. The applied load stages are 0 N, 100 N, 0 N, 200 N, 0 N, and 300 N. The strains of the 3D-DIC optical strain measurements are averaged over the same geometry (area, direction, and distances) as those of the used CEA-13-062UM-120

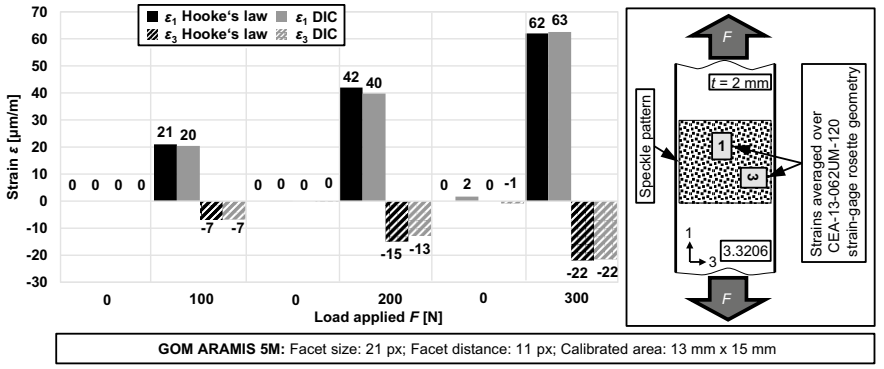

Fig. 3 Comparison of the calculated strains (Hooke's law) with the measured 3D-DIC strain values. Loads applied by Zwick Z100

strain-gauge rosette. The measured strains are averaged over two measurement procedures. The highest deviation of the measured DIC strains from the calculated strains is 2 µm/m. The deviation is not a function of the value of the strain, hence zero can be reliably measured. These results prove that this method meets the required accuracy for the measurement of micro strains and that it is possible to apply 3D-DIC optical residual stress analysis.

In the next step, the accuracy of the 3D-DIC method is investigated concerning the hole-drilling method. The same specimen as described above is set up with a CEA-13-062UM-120 strain-gauge rosette on the front and a speckle pattern on the back. A 1 mm deep hole is drilled on both sides with an RS-200 and a 1.6 mm diameter inverted cone driller (*cf.* Figure 4, left side). The distance between the two holes is 30 mm. The specimen is set up for the Zwick Z100 after a resting time of four hours following the hole drilling. Thus, all the thermal influence of the hole-drilling process can be excluded. The applied loads are 100 N, 200 N, and

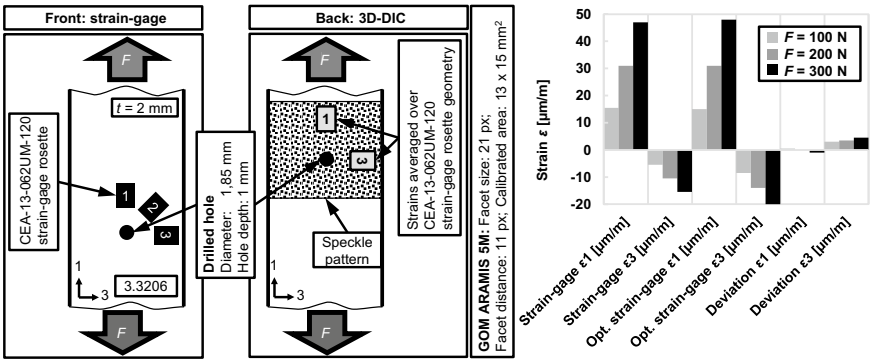

Fig. 4 Comparison of strain-gauge and 3D-DIC strain measurements with drilled holes. Loads applied by Zwick Z100

300 N. The strains of the 3D-DIC optical residual stress measurements are averaged over the same geometry (area, direction, and distances) as those of the used CEA-13-062UM-120 strain-gauge rosette. The measured strains are averaged over two measurement procedures. The 3D-DIC measurement is performed as described above. In Fig. 4 (right side) it is shown that the deviation of the two strain measurement methods has a magnitude of 5 μm/m, and the deviation is higher in direction 3 (ε_3), in particular. The deviation in direction 3 can be explained by the lower depth of field in the marginal area, which is compensated with a closed aperture ($f/16$). The results show that this 3D-DIC method has an acceptable level of accuracy for the application of the hole-drilling method.

3.2 Influence of Air Flow and Vibrations

For the 3D-DIC system, air flow and vibrations can be critical in measuring micro-scale strains. The measurement is affected, for example, by air flow and vibrations due to people talking or moving close to the measuring system so that a shattering live-view image can be observed. This is caused by the oscillation of the air between the cameras and the specimen. Air flow can also be caused by unadapted mounted blowers in the workshop, for example. Even a person speaking at a distance of 500 mm from the cameras can cause shattering live-view images. The air flow initiated by a talking person is considered to have a flow rate of approx. 2 l/s [13]. This reveals a high sensitivity to external influences. In the worst case, it leads to the speckle pattern not being recognised at all or only in part, with the result that a measurement cannot be performed. Consequently, any air flow and vibrations must be prevented during the measuring process. Therefore, the measuring system is designed to be very stiff to avoid vibrations, and a cover is mounted to prevent air flow.

3.3 Influence of the Speckle Pattern Coating

When it comes to incremental hole-drilling measurements, it can be observed that the measured strains vary with the time after a drilling step is performed, which has also been investigated by other scholars [14]. Figure 5 shows the time-dependence of a 3D-DIC optical hole-drilling measurement. The strains of the 3D-DIC optical residual stress measurements are averaged over the geometry (area, direction, and distances) of a CEA-13-062UM-120 strain-gauge rosette. This phenomenon was observed in measurement at a hole depth of 0.7 mm. The first drilling steps were operated continuously. Then the 0.7 mm depth stage is set as a reference stage for illustration purposes. The next 0.1 mm hole-drilling step to 0.8 mm is performed, and strains are measured after 4, 40, and 80 min. The results indicate that the measured absolute value of the residual strain increases with the time after hole

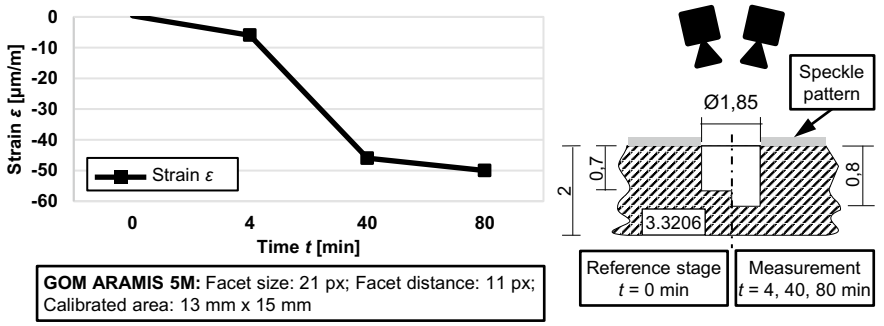

Fig. 5 Time-dependence of a 3D-DIC optical hole-drilling-method measurement

drilling. In this way, it was deduced that the release of the residual strains takes up to 80 min, contradicting the strain-gauge measurements. A different interpretation is that heat is emitted, leading to a decreasing thermal strain until thermal equilibrium is reached. Furthermore, the influence of the speckle pattern layer could influence the heat conduction. Therefore, the phenomenon described must be investigated further, especially regarding the unknown influence of the speckle pattern coating.

4 Temperature Compensation of Optical Residual Stress Measurements

The need for a temperature compensation method for optical residual stress measurements results from the fact that optical residual stress measurements are not temperature-compensated like strain-gauge measurements. Thermal strains induced by the illumination of the specimen or room temperature changes cannot be distinguished from load-induced strains. Additionally, with the high thermal expansion coefficient α_T of aluminium ($23.1 \cdot 10^{-6} \cdot K^{-1}$), for example, small temperature changes lead to significant errors in optical residual stress measurements. Temperature compensation should work as intrinsically as the self-temperature compensation in strain gauges. Numerous possibilities for measuring temperatures on surfaces exist, but there are also limitations to keeping the financial and time deficit as low as possible while retaining high accuracy. It is also desirable to process the temperature measurement values directly with the DIC system. Temperature measurements can be performed with a type k or PT1000 thermocouple, which can be clamped onto the surface. To eliminate the influence of thermal strains on the optical residual stress measurement, use is made of the formula for total strain ε consisting of the elastic strain ε_E and the thermal strain ε_T:

$$\varepsilon = \varepsilon_E + \varepsilon_{T.} \tag{1}$$

This formula is adapted to calculate the thermally corrected residual strains $\varepsilon_{\mathrm{RS}}$ consisting of the strain measured by the DIC method $\varepsilon_{\mathrm{DIC}}$ and the thermal strain ε_{T} by:

$$\varepsilon_{\mathrm{RS}} = \varepsilon_{\mathrm{DIC}} - \varepsilon_{\mathrm{T}} = \varepsilon_{\mathrm{DIC}} - \Delta T * \alpha_{\mathrm{T.}} \tag{2}$$

It is sensible to implement a correction factor k when the measured temperature cannot fully reproduce the thermal strain deviation:

$$\varepsilon_{\mathrm{RS}} = \varepsilon_{\mathrm{DIC}} - \varepsilon_{\mathrm{T}} = \varepsilon_{\mathrm{DIC}} - k(\Delta T) - \Delta T * \alpha_{\mathrm{T.}} \tag{3}$$

The correction factor k can be described by a linear or a polynomial function depending on the remaining thermal strain difference after dividing the calculated thermal strain measured by a thermocouple.

4.1 Validation of the Temperature Compensation Method

The temperature compensation method described above is investigated by comparing the temperature compensated 3D-DIC optical measurements with self-temperature-compensated strain-gauge (CEA-13-062UW-120) measurements in a single test setup on one specimen. Only the illumination heat affects the specimen, where the strain gauge is expected to measure zero strain and the optical strain measurement is expected to measure a strain equal to the temperature delta multiplied by the thermal expansion coefficient α_{T} ($23{,}1 \cdot 10^{-6} \cdot \mathrm{K}^{-1}$) of the aluminium specimen (3.3206). The heat is induced by two 16 W LED lamps on the 3D-DIC system, as in an ordinary. 3D-DIC measurement means that the lamps are not switched off between two measurements. The temperature is measured by a type k thermocouple on the specimen surface. The thermocouple braids are clamped on the specimen, as illustrated in Fig. 6. The optical strain measurements are performed in eight stages in the manner described in Chap. 3. The strains of the 3D-DIC optical strain measurements are averaged over the same geometry (area, direction, and distances) as those of the used CEA-13-062UW-120 strain gauges. The temperature and the strain-gauge measurements are linked to and averaged out over the period of the optical strain measurements. No correction factor is used. Figure 6 shows the averaged optical strain measurement error $\varepsilon_{\mathrm{DIC,err}}$, the averaged compensated optical strain measurement $\varepsilon_{\mathrm{comp}}$, the averaged strain-gauge measurement error, and$\varepsilon_{\mathrm{strain\text{-}gauge}}$ with their standard deviations. The optical strain measurements are described as optical strain measurement errors because the measured strains are induced by the measuring system itself, and the strains to be measured are zero. The compensated optical strains $\varepsilon_{\mathrm{comp}}$ are calculated by:

$$\varepsilon_{comp} = \varepsilon_{\mathrm{DIC,err}} - \varepsilon_{T} = \varepsilon_{\mathrm{DIC,err}} - \Delta T_{therm} * \alpha_{\mathrm{T}}, \tag{4}$$

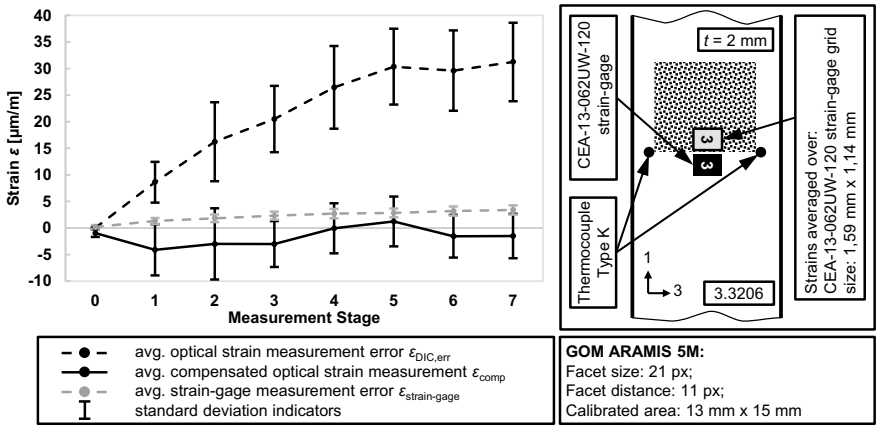

Fig. 6 Temperature compensation of 3D-DIC measurements compared with self-temperature-compensated strain-gauge measurements. Heat is induced by the illumination of the specimen. Loads are not applied

with the temperature difference ΔT_{therm} measured by a type k thermocouple and the thermal expansion coefficient α_T of aluminium ($23{,}1 \cdot 10^{-6} \cdot K^{-1}$). The averaged strain-gauge measurement error $\varepsilon_{\text{strain-gauge}}$ increases continuously to a maximum deviation of 3.4 µm/m from zero. This is due to the fact that the self-temperature compensation for materials with a thermal expansion coefficient of 20 to $23.4 \cdot 10^{-6} \cdot K^{-1}$ is used. The averaged optical strain measurement error $\varepsilon_{\text{DIC,err,}}$ increases significantly more steeply than the strain-gauge measurement to a maximum of 31 µm/m. The averaged compensated optical strain measurement $\varepsilon_{\text{comp}}$ tends towards zero between −4 µm/m and 1 µm/m. This shows that the influence of temperature changes on 3D-DIC optical strain measurements can be reduced
significantly by this method. Finally, the influence and measurability of the hole-drilling heat still have to be investigated and considered in this temperature compensation method. The thermal influence of the coating layer will also have to be investigated in this context.

5 Conclusion

In this paper, a new approach to optical residual stress measurements was proposed and investigated. Systematic errors are identified, and countermeasures are outlined. In particular, a new temperature compensation method for reducing the thermally induced errors is investigated and validated. The experimental investigations prove the required accuracy of the proposed method regarding the measurement of micro strains and, therefore, the possibility of its application in 3D-DIC residual stress

analysis. It is shown that 3D-DIC residual stress measurements (in terms of micro-scale strain measurements) are inaccurate if the specimen temperature is not monitored or if a constant specimen temperature is not ensured through laboratory conditions that maintain a constant room temperature and eliminate air flow and vibrations. In future investigations, the influence of the time-dependent behaviour of the speckle pattern coating must be considered.

Formation of Residual Stresses in Austenitic Stainless Steels by Infeed and Recess Rotary Swaging

Holger Hoche, Fabian Jaeger, Alessandro Franceschi, Matthias Oechsner, and Peter Groche

Abstract The austenitic stainless steels 1.4307 and 1.4404 significantly benefit from cold forming, due to their high work hardening capability. Great potential to improve the component's fatigue properties is expected by optimizing the forming process chain such that specific residual stresses are induced in critical component areas. In this work, an analysis of the formation of residual stresses during rotary swaging is carried out. Through this incremental forming process, high strain hardening and a complex material flow history are induced in the workpieces. Therefore, measuring strategies for the residual stress measurement of cold deformed austenitic steels by X-ray diffraction, using the $\sin^2\Psi$-method, were developed. Here, especially the 1.4307 is a challenging material due to cold forming-induced martensite formation. Despite phase changes, both cold-formed materials exhibit anisotropic microstructures as well as coarse-grained areas. Moreover, particular notched geometries are produced on the workpieces by rotary swaging. The measuring techniques are further developed for these complex geometries and the residual stresses are investigated.

1 Introduction

Rotary swaging is a well-established forming technology in the automotive and aerospace manufacturing industries for the forming of axial symmetric bars and tubes [1]. According to the German standard DIN 8583, it belongs to the open die forming processes [2]. The advantages of this incremental process lie, in particular, in its high flexibility combined with low investment and tooling cost, due to the

relatively low forming forces needed [3]. Moreover, rotary swaging offers some important advantages on the product side. Very hard materials can be worked and the final parts exhibit high static and cyclic strength due to strain hardening [4]. Two main process variations can be distinguished: the infeed and the recess rotary swaging. These variants differ for the direction of the feed motion, as schematically represented in Fig. 1. The infeed rotary swaging process feeds the workpiece with an axial motion into the machine. The working tools oscillate radially and reduce the diameter of the workpiece along the whole feed length. By recess rotary swaging, the workpiece has no axial motion. In this process, the forming is performed by the radial movement of the working tools, which is superposed to their oscillation. In this way, a localized reduction of the workpiece occurs according to the tool geometry. Infeed and recess rotary swaging can also be combined to obtain geometries that are more complex.

Decisive product qualities for cold-formed components are the residual stresses, especially in the near-surface area. However, in the literature, incremental processes are not analysed to the same extent as conventional continuous technologies. Investigations of residual stresses in rotary swaged products are mainly related to the forming of tubes [1, 5].

The researched materials are the austenitic stainless steels 1.4404 (X2CrNiMo17-12–2, AISI 316L) and 1.4307 (X2CrNi18-9, AISI 304L). Due to their high chrome and nickel content, the materials exhibit good resistance against both oxidation and electrochemical corrosion [6]. Stainless austenitic steels have a great flow behaviour, which makes them extremely suitable for cold working processes [7]. The high deformability is coupled with strain hardening during the deformation, leading to localized enhanced mechanical properties. The challenge with strain hardening is the formation of residual stresses, which have not been extensively researched yet. Especially, the targeted employment of compressive stresses by cold forming could be beneficial for the component lifetime and safety. Both 1.4404 and 1.4307 are used in the food industry due to their great corrosion resistance.

There exist several challenging factors when performing residual stress measurements of austenitic stainless steels. Due to the cold forming process, they reveal a texture, which depends on the local degree of deformation. Moreover, coarse grains make it difficult to measure a sufficient number of grains to achieve results with good statistics. The texture complicates the measurement further since it leads to a shift of the reflex width based on orientation as well as the interference lines. Therefore,

$d(\sin^2\psi)$ plots are not linear, if the sample is textured [8], making the analysis more elaborate. Another challenge is the sample geometry. Since rotary swaging usually produces cylindrical workpieces, there are no flat surfaces, where X-ray diffractometry can be performed easily. Additionally, recess rotary swaging forms notches, which are difficult to examine due to shadowing effects.

The present paper investigates the formation of residual stresses in rotary swaged parts of the materials 1.4307 and 1.4404. Measurements of residual stresses in these rotary swaged parts are challenging due to local non-isotropic strain hardening and texture formation. Especially the 1.4307 makes the matter more complex due to cold forming induced martensite formation. Moreover, the literature provides sparely information about the stress state of rotary swaged components. The task is to provide a better description of the residual stress generation in rotary swaged parts.

2 Materials and Methods

Samples of the materials 1.4307 (0.024 C, 0.275 Si, 2.01 Mn, 0.033 P, 0.034 S, 18.16 Cr, 0.295 Mo 8.00 Ni, 0.07 N) and 1.4404 (0.022 C, 0.413 Si, 1.35 Mn, 0.031 P, 0.027 S, 17.72 Cr, 2.01 Mo, 9.90 Ni, 0.04 N) were milled from billets belonging to the same batch of raw material, to ensure identical material properties. Cylinders, respectively, 14.5 mm and 10.78 mm in diameter, were realized for infeed and recess rotary swaging. These parts were then solution annealed in a preheated vacuum oven for 15 min at 1050 C and cooled in air. Prior to the cold deformation, a lubricant was applied to the samples surfaces. The parameters used for infeed and recess rotary swaging are summarized in Table 1.

In Fig. 2, the tools used for the experiments are shown. For infeed rotary swaging, the diameter of the workpiece is reduced with an entry angle of 4°. The length of the forming and calibrating zones is 50 mm each. With the second tool (Fig. 2b), two

Table 1 Parameters used during the rotary swaging

Parameter	Infeed rotary swaging	Recess rotary swaging
Rotational speed [rot/min]	50	
Feeding velocity [mm/min]	100	–
Hub [mm]	0.7	
Frequency of hub [Hz]	29	
Radial velocity [mm/min]	–	50
Final diameter [mm]	10.9	10.38

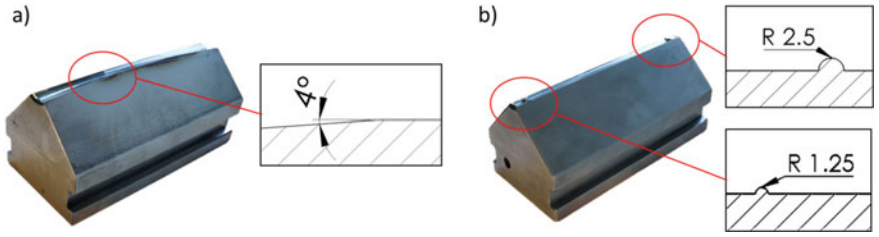

Fig. 2 Forming tools used for infeed (**a**) and recess (**b**) rotary swaging. (Color figure online)

different notched geometries can be manufactured on the samples through recess rotary swaging. The radii of these notches are 1.25 and 2.5 mm, respectively.

The residual stresses were determined by X-ray diffraction (XRD) according to DIN EN 15,305 using the $\sin^2\Psi$-method. Therefore, a diffractometer made by Stresstech, model XStress G3R in a modified Ψ-arrangement was used. The residual stresses were calculated from 7 equidistant Ψ angles from 0° to +45° and from 0° to −45°, respectively. Mn Kα radiation was used for the measurement of the austenitic residual stresses since it yields better results for austenitic steels than Cr Kα. With Mn Kα radiation the reflex (311) can be measured, which exhibits double the multiplicity of the (220) reflex, which is measured with Cr Kα radiation [8]. The measurements in the martensitic phase as well as the determination of the martensite content were performed with Cr Kα radiation. The cylindrical samples produced by the rotary swaging process have a diameter of approximately 1 cm. Since the maximum aperture for this kind of measurement should not exceed a tenth of the diameter of curvature of the sample, according to DIN EN 15,305, the aperture was set to a diameter of 1 mm. The X-ray elastic constant used to calculate the residual stress values was $½S2\,\{311\} = 7.57 \times 10^{-6}$ mm^2/N for austenite and $½S2\,\{211\} = 5.82 \times 10^{-6}$ mm^2/N for martensite [9].

To measure residual stress depth profiles of the material 1.4404, an electropolishing machine type Struers Movipol-3 was employed. The polishing process was stopped at 0.125, 0.25, 0.5, and 1.0 mm to perform residual stress measurements.

In addition, microspecimens were prepared and examined by optical microscopy to reveal the influence of the rotary swaging process on the material microstructures. Also, microhardness depth profiles were conducted at the microspecimens. In addition, hardness measurements were also performed on the surfaces of the specimens.

3 Results

The analysis of the initial state of the samples was already performed in [7]. After the solution annealing of the machined samples, the metallographic examinations of both materials showed a purely austenitic microstructure without deformation-induced defects. With a Vickers hardness of 151.4 HV 0.3 for 1.4307 and 143.3 HV 0.3 for 1.4404, the hardness values are in the characteristic range of solution annealed microstructures of the respective materials. Significant differences between the two materials were observed in the grain sizes. The grain size of 1.4307 was determined to G = 4, which, according to Table C1 of DIN EN ISO 643, corresponds to an average of about 128 grains/mm^2. With a grain size of G = 5.5, the microstructure of 1.4404 is significantly finer, revealing an average of 384 grains/mm^2. The X-ray measurements showed for both materials these samples are close to a residual stress-free state.

The residual stresses on the samples manufactured through infeed rotary swaging were analysed along the path shown in Fig. 3. Along this path, three regions can be distinguished:

- Section 1 goes from 0 to 50 mm. Here the sample has been fully deformed and calibrated by the working tools.
- Section 2, from 50 to 100 mm, the sample has been reduced to its final geometry, but it is still inside the calibration zone at the end of the process
- From 100 to 120 mm, the sample is still in the forming zone and has not reached its final diameter, which can be inferred from its curvature.

Measurements through X-ray diffraction were performed both in axial and tangential direction on the components' surface (Fig. 4). The results of the surface residual stress measurements after the infeed rotary swaging are displayed in Fig. 5.

In all the measured points, these samples are characterized by compressive residual stresses on the surface. In general, the quality of the $\sin^2\Psi$ plots is very good and complies with the criteria to assess the measurement quality of cold deformed parts in [7]. The axial compressive stresses are both, in Sects. 1 and 2, significantly higher than the tangential stresses. In particular in Sect. 1, the axial as well as the tangential stresses of both materials are in good compliance with each other, showing a quite constant behaviour. This means that the calibration process had the desired effect of producing a defined residual stress state. Some differences can be observed

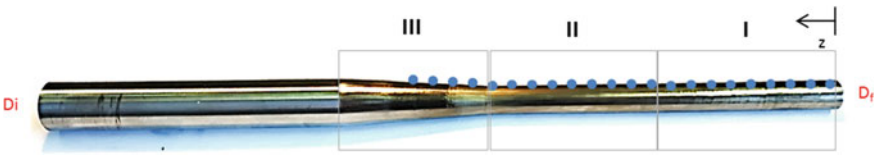

Fig. 3 Position of the measurements of the residual stresses through X-rays on the samples produced by infeed rotary swaging. (Color figure online)

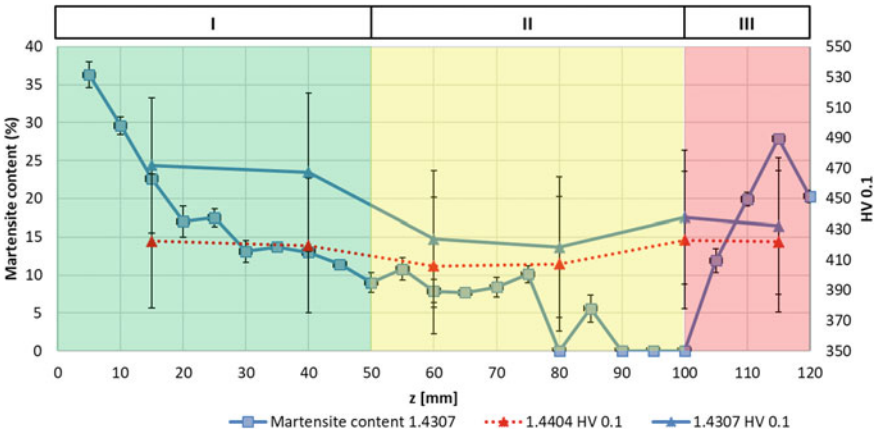

Fig. 4 Martensite content of 1.4307 and result of the hardness measurements on the samples manufactured through infeed rotary swaging. The Martensite content of 1.4404 was measured as well but was not present in a detectable quantity. For this reason, it is not reported in the diagram. (Color figure online)

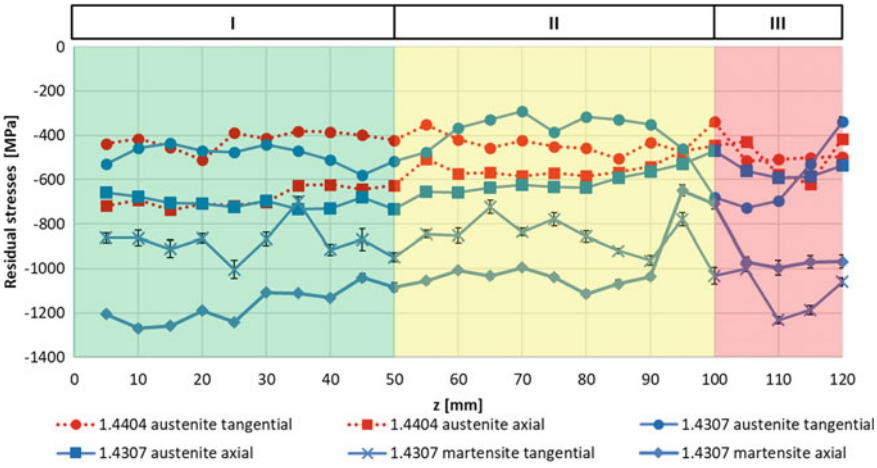

Fig. 5 X-ray residual stress measurements on the samples manufactured through infeed rotary swaging. The martensite phases of 1.4404 were not measured, since the percentage of it is below the detection limit. (Color figure online)

between the behaviour of the axial and tangential stresses in the second section. In the axial direction, the compressive residual stresses tend to increase along the formed section. In the tangential direction instead, the residual stresses fluctuate stronger than in Sect. 1, but there is no definite trend identifiable. In Sect. 2, the axial compressive residual stresses of 1.4404 exhibit higher values than 1.4307, which is interesting it signifies a change to the behaviour in Sect. 1. Nevertheless, the measured residual stresses of Sects. 1 and 2 do not show significant differences, which could be

correlated with the material microstructure, in particular, the martensite formation in 1.4307. In Sect. 3, the size of the fluctuations in residual stresses is very pronounced in 1.4404 for the tangential stresses. At the beginning of Sect. 3, there is a sudden increase in the compressive residual stresses in comparison with the previous section. The material 1.4307, on the other hand, does not show this effect. The martensite content of 1.4307 can be seen in Fig. 4. In Sect. 1, it is higher the closer the measured point, which is to the tip of the sample. Between the middle of Sect. 1 and the middle of Sect. 2, the martensite content does not change. At the end of Sect. 2, the martensite content is zero. However, in Sect. 3, the martensite content is again relevant. The martensite content of 1.4404 was measured as well, but was under the detection limit.

In Sect. 1, the hardness exhibits the highest values for 1.4307 due to the highest degree of deformation achieved by forming as well as calibration. This correlates with the evolution of the compressive residual stresses, which exhibit higher values in Sect. 1 due to the calibration process. Additionally, 1.4307 exhibits higher hardness values than 1.4404, which could be an effect caused by martensite formation. In Sect. 2, the hardness of 1.4307 slightly drops. The decrease in hardness of 1.4307 is approximately 50 HV 0.1. In Sect. 3, the surface hardness of 1.4307 increases again, which could be an effect of the high degree of cold deformation even in this section. The hardness of 1.4404, however, is homogeneous over the length of the sample. The higher hardness of 1.4307 can be explained by the formation of deformation martensite. The reason for the deviating hardness values appears to be that the different points of this section have undergone different stages of calibration.

For the material 1.4404, the tangential residual stresses are nearly identical in Sects. 1 and 2 and only slightly differ in Sect. 3. For material 1.4307 instead, there is a sudden decrease of the austenitic compressive residual stresses in comparison with the previous section. In Sect. 3, the data show even bigger fluctuations, which could be due to inhomogeneous deformation in the section. In the martensitic phase, the axial stresses are bigger than the tangential ones, mirroring the austenitic behaviour. The martensitic compressive stresses are higher than the austenitic ones. Since the forming of martensite is caused by deformations, it is plausible that zones with higher deformation would both have greater stresses and more martensite formation. The relatively low stresses at 905 and 100 mm are measurement artefacts caused by the low martensite content in those points leading to a bad signal to noise ratio.

In Fig. 6, the different microstructures in the infeed rotary swaged samples are exemplarily shown for Sects. 1 and 3. In comparison to the annealed state, the grains are refined by the rotary swaging process. Unfortunately, due to the texture, the grain size according to DIN EN 643–1 cannot be assessed. In general, the microstructure of 1.4404 is finer than of 1.4307, which also corresponds to the differences in grain sizes in the solution annealed state. In both, Sects. 1 and 3, the microstructures are uniform up to a depth of approximately 4 mm from the surface. 1.4404 exhibits deformation structures like slip bands, which are more pronounced in Sect. 1 due to the higher degree of cold deformation. The microstructure of 1.4307 also indicated the formation of deformation-induced martensite, which could be proved by a noticeable magnetism of this material. In the case of 1.4404, the magnetism is negligible.

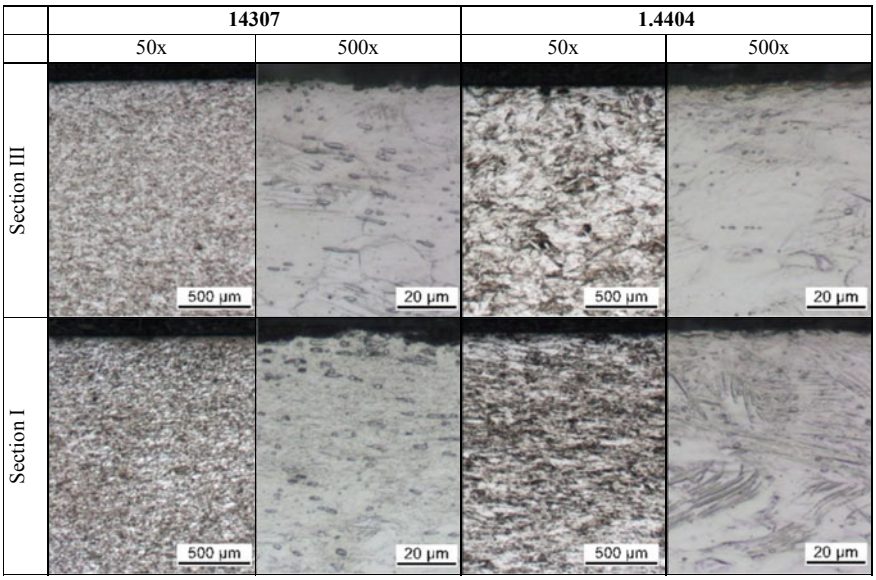

Fig. 6 Microstructure analysis by optical microscopy of Sects. 1 and 3, V2A-etchant. The initial micrographs can be seen in [7]. (Color figure online)

Figure 7 shows an axial cross-section of Sect. 3 of 1.4404. It is visible that the surface of the sample has cracked, which released residual stresses. Processes like this are one of the reasons for the unsteadiness of residual stress measurements.

Through recess rotary swaging, notches with radius 1.25 and 2.5 mm, respectively, were produced on the solution-annealed samples. A distance of 15 mm was maintained among the notches to avoid mutual influence on the stress state. The process was performed with the parameters shown in Table 1. After reaching the final radial position, the tools were kept oscillating in position for 2 seconds for calibrating the

(Color figure online)

samples. Then the residual stresses were measured on the bottom of each cavity in eight different points. In Fig. 8, the position of these X-ray measurements along the circumference of the samples is clarified.

Figure 9 shows the residual stresses measured on both 1.4307 and 1.4044 in the 1.25 mm and 2.5 mm notches for the austenitic (left) and martensitic (middle) phases as well as the martensite content (right). Although the notches complicate the measurements, there are only small errors and the criteria of [7] are fulfilled. Although the measurements scatter within the six measurements in the 90° section, some trends are still identifiable. In the 2.5 mm notches of 1.4307, the highest axial austenitic compressive stresses can be observed. Depending on the angle, the stress values fluctuate between −260 MPa and −500 MPa without any dependency on their circumferential position. The compressive stresses inside the 1.25 mm notch of 1.4307 are systematically on a lower level and vary from −160 MPa at 0° to −250 MPa. Only at the 90° position, a value of only −60 MPa was measured, which may be caused by microstructural artefacts, e.g. by material overlapping.

The axial stresses in the 2.5 mm notch of 1.4404 exhibit a graded increase from −240 MPa at 0° to −530 MPa at 90°. While the residual stresses for the materials 1.4404 and 1.4307 show a quite good agreement for the 2.5 mm notch, the behaviour

of the 1.25 mm notch is different. Unlike the 1.4307 sample, the 1.25 mm notch of 1.4404 reveals considerably higher compressive stresses with values between −190 MPa and −450 MPa. In general, it can be stated that the axial stress values for the 2.5 mm notches fluctuate more than for the 1.25 mm ones.

In general, the tangential residual stresses comply with the axial stresses. The compliance is more pronounced for the 1.25 mm notch, while the scatter of the values is again significantly higher for the 2.5 mm notch. In particular, the 2.5 mm notch of 1.4404 has the most notable scatter in residual stresses. For all orientations and materials, the largest compressive stress is bigger for the notch produced with the 2.5 mm tool. The reason for this is the higher deformed area when using a bigger tool, which results in a greater degree of deformation. This is concurrent with the results of the samples produced through infeed rotary swaging, where the stresses were highest in the zone with the most deformation as well (see Fig. 5).

The stresses of the martensitic phases show greater compressive stresses and a bigger isotropic effect. For the 1.4404 sample, the axial stresses of the 2.5 mm notch (between −500 and −830 MPa) and the 1.25 notch (between −470 and −660 MPa) are bigger than the tangential stresses, which range from −380 to −630 MPa and from −270 to −520 MPa respectively. The 1.4307 sample exhibits a larger difference between the notches. In the 2.5 mm notch, the axial stresses from −280 to −780 MPa are generally larger than the tangential ones from −390 to −680 MPa. This behaviour is reversed in the 1.25 notch with smaller stresses in the axial direction from −170 to −460 MPa compared with tangential stresses from −390 to −530 MPa. However, all martensitic graphs fluctuate stronger than the austenitic ones. This can be explained by the stronger deformation processes in the martensitic phases leading to a bigger spread in compressive stresses. The martensite content itself does not change much with the position at which it is measured. It can be seen that 1.4307 is more disposed towards forming martensite than 1.4404.

For better understanding, Fig. 10 shows the different microstructures of the notches produced by recess rotary swaging. In all of them, the notch area itself exhibits deformation structures due to strain hardening that happened during the recess rotary swaging process. Here, 1.4307 and 1.4404 reveal a nearly similar degree of highly deformed microstructures. For 1.4307, there is also evidence for the presence of cold deformation-induced martensite. An interesting outcome is that the degree of deformation of the microstructure is lower for the 2.5 mm notch. The smaller 1.25 mm tool is causing a higher degree of deformation than the broader 2.5 mm tool. For the material 1.4404, this observation is in accordance with the results on the residual stress measurements. For 1.4307, the 1.25 mm notch reveals lower stresses than the less deformed 2.5 mm notch. A reason, therefore, could not be stated yet, but it is likely, that the formation of deformation-induced martensite could change the residual stress state.

Figure 11 shows the comparison of residual stress measurements on the same notch at angles of 0, 90, 180, and 270°, respectively. The goal is to verify the theory that the residual stress state follows the fourfold symmetry of the tools for the recess rotary swaging. For the 2.5 mm notch in 1.4307, the residual stresses in axial as well as tangential direction are clustered between −250 and −350 MPa with the

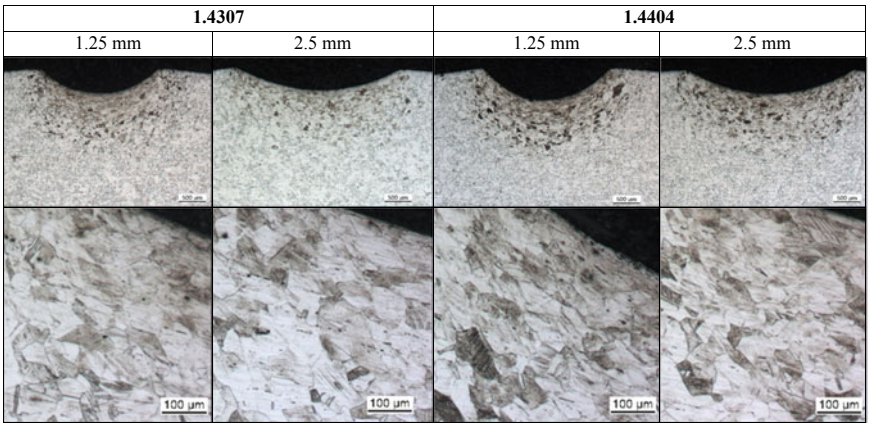

Fig. 10 Microstructure of the notches, produced by recess rotary swaging, V2A-etchant. (Color figure online)

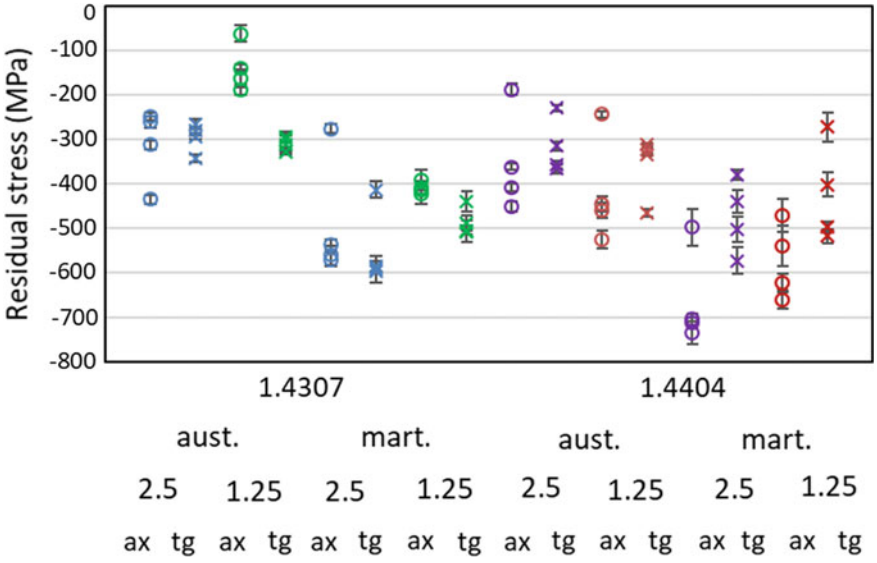

Fig. 11 Comparison of residual stresses for 0, 90, 180, and 270° in all notches. (Color figure online)

exception of a single value of −440 MPa. The residual stresses in axial direction for the 1.25 mm notch of 1.4307 are lowest in comparison to all other parameters, which complies with the circumferential measurements shown in Fig. 8. For the tangential direction of both notches in 1.4307, all the residual stresses are in great accordance with each other and show a low scatter. The martensitic stresses in 1.4307 are generally higher. Similar to the austenitic phase, the stresses in the 1.25 mm notch are clustered closer together. For 1.4404, both, the axial and the tangential notches

reveal a remarkable scatter between the angles. This is especially the case for the axial direction. The 2.5 mm notch shows values between −240 and −530 MPa and the 1.25 mm one between −190 and −450 MPa. Meanwhile, the tangential stresses are in good accordance with each other for three out of four data points, while the fourth point diverges. The martensitic stresses are higher in 1.4404 as well. The spread of the stresses is comparable to the austenitic case.

When looking at all the data points, it can be seen that the tangential stresses are generally closer to each other than the axial stresses. This is plausible, since, for the recess swaged specimens, the stresses in tangential are pointing in the direction of the material flow. The same effect can be seen in Fig. 5, where the material flow is in the axial direction and axial stresses fluctuate less than the tangential ones. However, the theory of the existence of a fourfold symmetry of the stress state caused by the fourfold symmetry of the forming process could not be proven due to large scatter at the measured points.

By examination of the microspecimens, some material overlaps due to the rotary swaging process are present at each specimen (Fig. 12). The length of these overlaps could be up to several 100 μm, while their depth is maximum, some 10 μm. At these sites, there is no homogenous residual stress state, since the stresses are relaxed in the overlap. The overlaps are most pronounced in the bottom of the notches, where the material flow is highest. This also complies with the XRD measurement positions. From the $\sin^2\Psi$-plot, the overlaps cannot be assessed definitely. The overlaps cause non-isotropic stress states and, therefore, contribute to the scatter in the measurements. Moreover, these overlaps affect the cyclic properties, thus compensating for the beneficial effect of the compressive residual stresses.

To further comprehend the changes going on in the material upon deformation, hardness depth profiles were recorded (Fig. 13). Although an influence of the notch

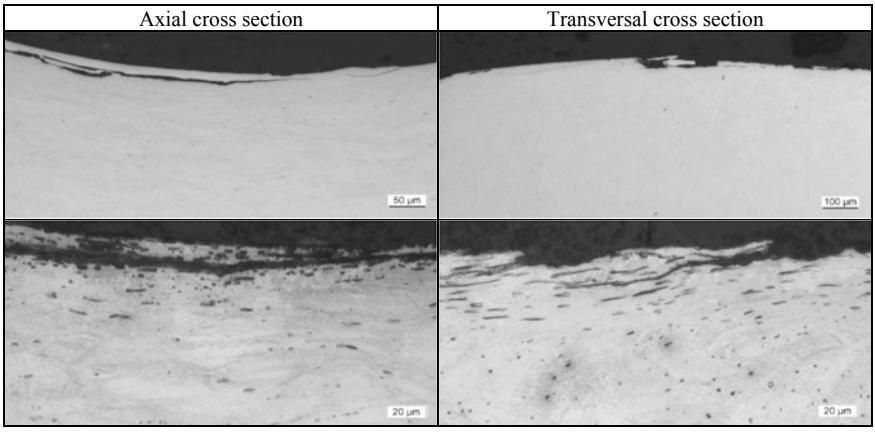

Fig. 12 Microscopic pictures of the 1.25 mm notch of 1.4404 with material overlaps. The microsections are oriented axially (left-hand side) as well as transversal (right-hand side). (Color figure online)

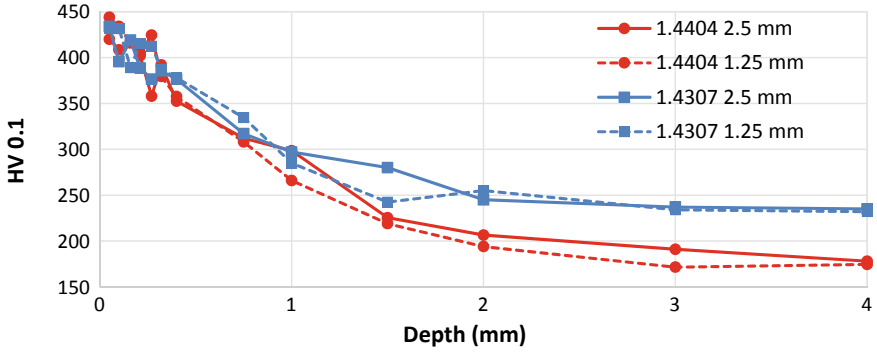

Fig. 13 Result of the hardness measurements (HV 0.1) on both materials in two notches per sample. The hardness values are connected to achieve better visualisation of the results. (Color figure online)

size on the compressive residual stresses was proven, no significant influence, neither of the notch nor the material, could be validated from the hardness depth profiles. In particular, at the surface all values scatter in a narrow range, thus indicating an identical degree of the strain hardening. With progressing depth, the hardness decreases as the effect of strain hardening lessen. Up to a depth of 0.3 mm, the hardness only slightly decreases. Even at a surface distance of more than 2.5 mm, the hardness of the solution annealed state is not reached. However, 1.4404 exhibits lower values of approximately 180 HV0.1 than 1.4307 with approximately 230 HV 0.1. This coincides with the literature values of 151.4 HV 0.3 for 1.4307 and 143.3 HV 0.3 for 1.4404 in the annealed state [7]. It is of note that the decay of the hardness is roughly exponential.

This behaviour can be compared with the depth profiles of the residual stresses of 1.4404 of the 2.5 mm notch, shown in Fig. 14. There, the residual stress is −200 and

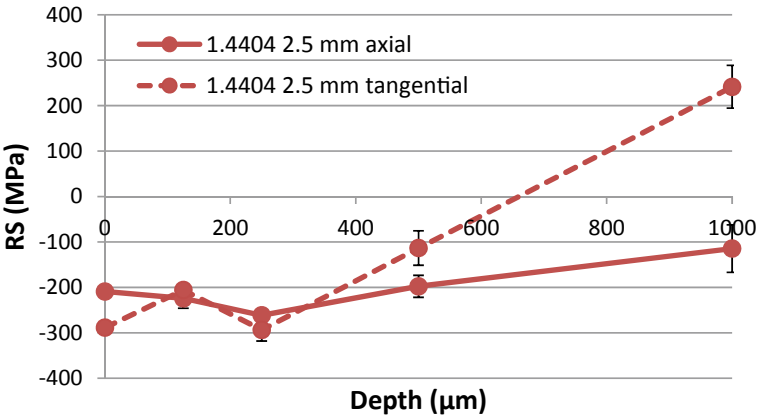

Fig. 14 Depth profile of the residual stresses in austenite for 1.4404. (Color figure online)

−390 MPa at the surface, respectively. The maximum of the compressive residual stresses is in a depth of about 0.25 mm. Exceeding this depth, both, the axial and the tangential compressive stresses decrease, where the tangential ones become tensile stresses in approximately 0.7 mm depth and the axial stresses remain compressive even at 1 mm distance from the surface. The residual stress depth profile complies with the hardness measurements, where the drop in hardness is only slightly up to 0.3 mm, which corresponds to the maximum of the compressive residual stresses.

4 Conclusions

The effect of infeed and recess rotary swaging techniques on the austenitic stainless steels 1.4307 and 1.4404 on the formation of the residual stresses, the changes in microstructure and the work deformation hardening were analysed. Due to rotary swaging, a grain refinement of the initially coarse-grained austenitic microstructure was achieved. Both processes could induce compressive residual stresses at the surface in both, axial and tangential direction. In general, the distribution of the residual stresses exhibits less scattering in the direction of the maximum material flow, i.e. the axial direction for infeed and the tangential direction for recess rotary swaging. It was shown that rotary swaging techniques induced strain hardening and the formation of deformation structures, with both effects being more pronounced on the surface. Overall, the residual stresses comply with the degree of deformation of the microstructures. Additionally, in 1.4307 also, cold deformation martensite has been formed.

Unfortunately, the rotary swaging produced several material overlaps at the surface, which could be some 100 μm in length. At these sites, the residual stresses are inhomogeneous, since the stresses are relaxed by the overlap. Therefore, these surface artefacts are likely to contribute to the scatter in the measured residual stresses. Moreover, these overlaps affect the cyclic properties, thus compensating for the beneficial effect of compressive residual stresses.

Influence of Material Delivery Condition on Residual Stresses and Part Properties During Forward Rod Extrusion

Andreas Jobst and Marion Merklein

Abstract During the manufacturing of semi-finished products, the material is subjected to various forming steps to achieve the final geometry. In order to reduce the work hardening introduced and to ensure a good formability, it is annealed before component manufacturing. Forming technologies like forward rod extrusion are well-established methods for the efficient production of resilient components. In this process, however, an inhomogeneous pre-strengthening of the material influences the stress distribution during forming and therefore the mechanical properties and the residual stresses in the component. Since they affect the parts' operating behaviour, knowledge of the influence of the delivery condition of the material is necessary. The aim of this paper is to derive dependencies between material properties and the resulting residual stresses and work hardening in the component. Due to the increasing application, ferritic stainless steel *X6Cr17* in the skin passed (+LC) and soft annealed (+A) states are used. Residual stresses, microstructure, and microhardness distribution of both material states are compared regarding the rods and extruded parts. The effects of the delivery condition are evaluated by comparing process and component properties.

work hardening [1]. However, in the manufactured components, residual stresses are generated due to inhomogeneous forming, which influence the parts' operating behaviour. Tensile residual stresses generally have negative effects as they inhibit crack initiation and propagation and thus reduce fatigue strength [2]. To ensure a long part service life, they must either be relieved by energy-intensive annealing after component manufacturing or taken into account when designing the part. For the prediction of the component properties after forming, knowledge of influencing variables on the component residual stresses is, therefore, necessary. So far, only little data are available about the use of pre-strengthened material. Therefore, in this paper, the influences of the material delivery condition on the properties of the forming process and the produced part are researched.

Since ferritic stainless steels are usually used in the annealed condition [3], the soft annealed state serves as a reference. The skin passed state is used to represent an insufficiently annealed material in which single areas still show a strengthening. The objectives pursued and the approach are shown schematically in Fig. 1.

To characterize the initial state, the material parameters of the non-deformed material are identified in the two investigated states "annealed" (+A) and "skin passed" (+LC). The influence of the material condition on the resulting part properties is determined by the comparison of the initial material and the manufactured components. In addition to near-surface residual stresses, microhardness and grain size distributions are investigated, since they influence the cyclic strength [4] and a depth-dependent residual stress measurement is difficult due to the corrosion resistance of the material. The effects of the material delivery condition on the forming process are identified by the determination of the process forces necessary for forming and ejection. In order to check for thermal effects on the residual stresses, the temperature in the formed part section is also measured after ejection. By comparing billets and components, correlations between material condition and the resulting process and component

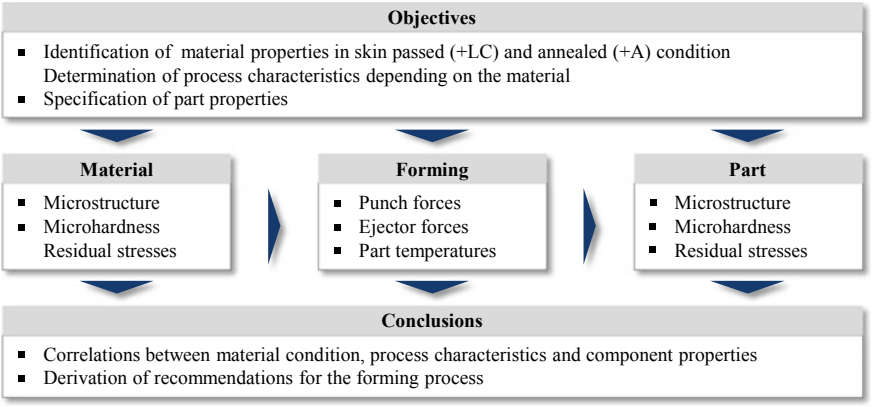

Fig. 1 Objectives and approach. (Color figure online)

properties are determined. On this basis, recommendations for the forming process are derived in order to ensure efficient component production.

2 State of the Art

During the production of steel rods, various rolling steps are carried out after the casting of the slabs in order to achieve the target geometry of the semi-finished product. This involves either rolling in the hot state in order to keep the process forces low or in the cold state, which results in a finer structure and a better surface, but a strong hardening. In forward rod extrusion, stainless steels are usually used in the annealed condition to ensure a good formability. Before part production, the semi-finished product is annealed and pickled in order to remove the scale layer [5]. Ferritic stainless steels usually are soft annealed [3], where the respective delivery condition of the semi-finished product is designated as $+A$ according to [6]. If a high geometric accuracy of the semi-finished product is required, a final drawing operation with low diameter reduction will be performed. This not only achieves a high accuracy of the nominal diameter but also introduces residual stresses and a slight hardening on the surface [7]. This condition is defined as *skin passed* and is abbreviated as $+LC$ according to [6].

In forward rod extrusion, the billet is pressed into the die and formed in the die shoulder area. The inhomogeneous deformation results in residual stresses in the component. After forming, tensile residual stresses are present at the surface [8], which are in equilibrium with compressive residual stresses in the core [9]. After achieving the specified geometry, the component is ejected in reverse to the punch direction. In this step, a change of the residual stress state in the formed section may occur due to the elastic springback of the die [10]. For the chosen component material and process configuration, a reduction of the near-surface tensile residual stresses by the ejection step is shown in [11].

For the determination of the residual stresses, several methods exist. One of the most common techniques is the hole-drilling method, where a change of the stress state is measured, while a small hole is being drilled into the part's surface. It allows depth-dependent residual stress profiles to be determined with little effort, but it is destructive, which means that residual stress mapping with smaller point distances is not possible [12]. As a non-destructive method, radiation diffraction is used. X-ray or neutron radiation is emitted onto the material area to be analysed and the angle and intensity of the beam reflected at the material lattice are determined. The measured angle of reflection is used to calculate the lattice spacing, which changes when residual or load stresses are present [13]. In addition to the residual stresses, the full width at half maximum (FWHM) of the recorded intensity curves can be determined and used as an indicator for the deformation introduced [14].

3 Experimental Setup

The single-phase ferritic stainless steel *X6Cr17* (DIN *1.4016*, AISI *430*) is used as the component material. Due to its classification in corrosion protection class I according to [15], it is used for components in food industry and in medical technology. The soft annealed condition (+A) is selected as reference, since it ensures good formability. The skin passed state (+LC), which is often chosen due to the higher surface quality, is examined as a comparison case. A forward rod extrusion process is used for the forming of the billets. The process for component manufacturing is shown in Fig. 2.

The billets (a) are manufactured from bar-shaped material by cutting and plane-parallel grinding of the end faces. They are coated with a lubrication system consisting of iron-III-oxalate as a carrier layer and a MoS_2-based lubricant. The forming of the components takes place on a hydraulic press *Lasco TZP 400* with the tool system shown in (b). In a one-step process, the components are formed and then ejected in opposite direction to the punch movement. The die (c) is designed and manufactured according to usual design guidelines with a shoulder opening angle of $2\alpha = 90°$. The formed part (d) consists of a non-deformed area, the transition area, which represents the shoulder geometry, and a deformed shaft. The deformation from diameter 25 mm to 15 mm results in an equivalent plastic strain of $\overline{\varepsilon} = 1.02$.

The influences of the material condition on the component properties are determined by material characterization before and after forming. For this purpose, the near-surface residual stresses in the axial and tangential directions in both the non-deformed and the formed section of the component are determined by X-ray diffractometry. The measurements are performed with the 8-axis *Seifert XRD 3003* X-ray diffractometer. Cr-Kα radiation with a wavelength of $\lambda = 0.2291$ nm is used for the measurement since it is within the range of the lattice constant of 0.286 nm of unstressed α-iron. The measuring spot diameter is approximately 0.8 mm with a maximum penetration depth of 5.8 µm. The measurement is carried out on the {2 1 1} lattice plane using the χ-method according to [16] with 13 ψ-tilts from $-50°$ to $+50°$, subdivided for constant $\sin^2\psi$. The reflected beam is detected with a line detector. The angle positions of the recorded intensity curves are determined by fitting with a pseudo-Voigt function. For the evaluation, the $K\alpha_1$ peak is used, which is gained by subtracting the $K\alpha_2$ peak from the measured intensity distributions. The calculation of the present stress state is done by the software *Rayflex Analyze*

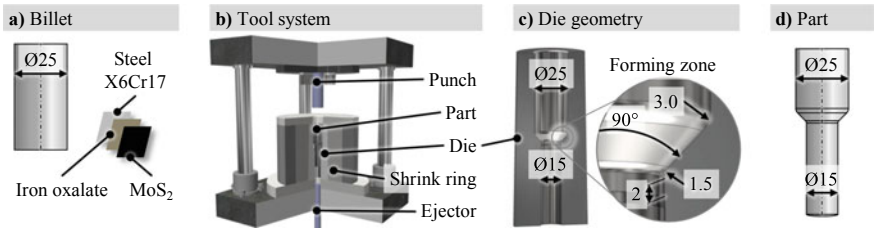

Fig. 2 Experimental setup for part production. (Color figure online)

with the $\sin^2\psi$ method. In addition to the residual stresses, the FWHM values of the recorded peaks are determined, allowing conclusions to be drawn about the induced deformation [17].

The determination of depth-dependent residual stress profiles is difficult due to the corrosion resistance of the material. In order to determine the properties in the interior of the component, the microstructure and the microhardness are, therefore, investigated in the longitudinal section. The samples are embedded and severed by sawing. The preparation of the surface to be examined is carried out by grinding up to a grit size of 15 µm and final polishing with diamond paste with 6, 3, and 1 µm grain size. The grain structure of the material is made visible by etching with an etchant consisting of water, hydrochloric acid, and nitric acid. The aim of the microstructural investigations is to determine the changes in the grain structure during the forming process, depending on the condition of the material used.

To quantify the mechanical properties of the material, the indentation hardness in the initial and formed state is measured. For this purpose, microhardness measurements according to [18] are carried out on longitudinal sections. The Vickers hardness is determined with the *Fischerscope HM2000* microhardness tester in an air-conditioned measuring room. During this test, a tungsten carbide pyramid penetrates the material. The time required to apply and relieve the testing force on the component is 20 s. When the test load of 1 N is reached, a creep time of 5 s is maintained. The hardness is determined from the measured penetration depth. To reduce the required measuring time, the spot distances in the component areas are varied. In the non-deformed area, measurements are taken in lines with a distance of approximately 5 mm and a radial spot distance of approximately 0.8 mm. In the area of the shoulder, a spot distance of 0.3 mm in axial and radial direction is used to achieve a high resolution. In the formed shaft and the tip, the point spacings are 0.8 mm radially and 1.2 mm axially.

4 Results and Discussion

In order to determine the influence of the initial material state, material, process, and part properties are determined. The results are shown and discussed in the following section. Regarding the process properties, maximum forces and part temperatures are taken into account, since these allow drawing conclusions about the die load. As part properties, residual stresses, microstructure, and microhardness distribution are considered, which influence the operational behaviour of the produced component.

4.1 Forming Process Properties

During the extrusion of the components, the process forces required for forming and ejection were determined. Their maxima are shown in Fig. 3. Additionally, the

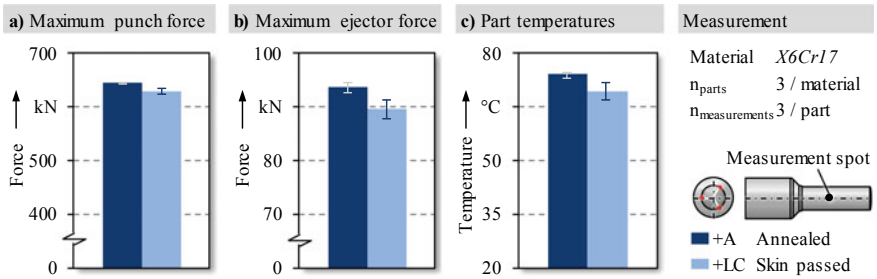

Fig. 3 Process forces and part temperatures. (Color figure online)

component temperatures—measured after ejection and removal from the tool—are displayed.

If annealed material (+A) is used, a punch force of 644 ± 2 kN and an ejector force of 94 ± 1 kN are required for the production of the parts. Due to the deformation of the material and friction between the part and the die, the component heats up to a temperature of 74 ± 1 °C. Using skin passed (+LC) material, however, slightly lower process forces of 628 ± 5 kN are measured at the punch and 90 ± 2 kN at the ejector. This is also mirrored in the part temperature, where only 69 ± 2 °C is reached. Tribology provides an explanation for these differences. Since the skin passed material has a smoother surface than the annealed one, influences on the resulting friction forces are possible here, which correlates with the resulting component temperatures.

4.2 Residual Stresses

To determine the influence of the material condition on the component residual stresses, X-ray stress measurements were performed on the surface of the manufactured components. Since only around 50% of the billet volume is deformed during component manufacture, measurements were carried out both on the non-deformed and on the deformed area of the specimens. In the non-deformed area, an oscillation in the axial direction was necessary during the measurement due to the small measuring point size, resulting in a linear measuring range. In addition to the residual stresses, the FWHM values of the peaks were determined in order to derive qualitative information on the forming history. The results are shown in Fig. 4.

In the non-deformed section, the residual stresses shown in Fig. 4a are present. The surface of the annealed material (+A) shows compressive residual stresses of −49 ± 5 MPa in the axial and −61 ± 14 MPa in the tangential direction. These stresses result from the cooling of the material after soft annealing, since the core will cool after the surface. Thus, thermal shrinkage induces compressive residual stresses in the surface tensile stresses in the core [19]. In the skin passed material (+LC), there are low tensile residual stresses of +44 ± 18 MPa in the axial direction, which are

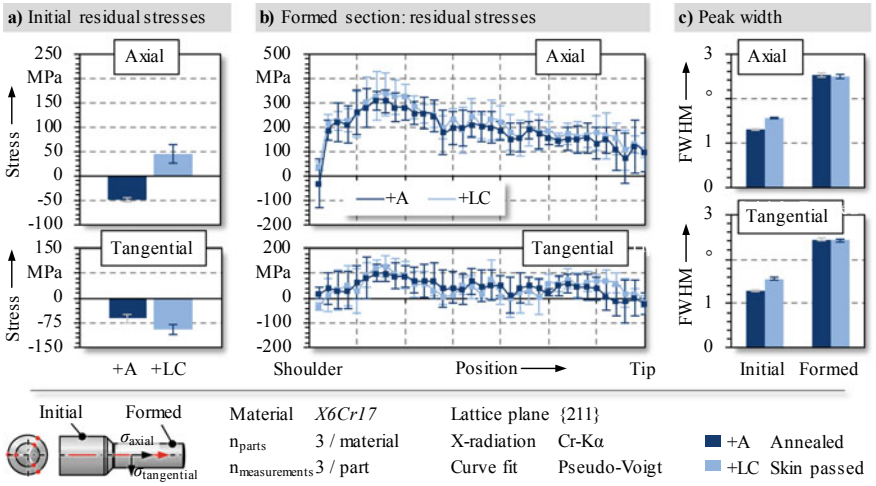

Fig. 4 Residual stresses in formed parts and full width at half maximum (FWHM) values of the measured peaks. (Color figure online)

caused by the cold drawing process [20]. In circumferential direction, compressive stresses with a value of -96 ± 15 MPa are higher than in the annealed material. This residual stress condition is due to the surface load during the cold drawing [21].

The residual stresses on the formed shaft of the components are shown in Fig. 4b. In both main stress directions—axial and tangential—similar curves are present. There are small residual stresses near the shoulder, which change into distinct tensile stresses with increasing distance. Maximum residual stresses are present at a distance of 8 mm from the shoulder with about +310 MPa in axial and about +100 MPa in tangential direction. The residual stresses decrease towards the tip. This stress state can be explained by the inhomogeneous deformation during the flow through the forming zone [9]. It coincides with results from the literature [22]. Despite the different initial conditions, no significant differences can be identified in the formed state between the annealed and the drawn material. One explanation for this is that during the forming of the components, a much higher degree of deformation occurs than during cold drawing of the material. This is backed up by the FWHM values as shown in Fig. 4c. While significant differences can be seen in the initial state due to the different deformation history, the FWHM values in the manufactured components are at the same level.

4.3 Microstructure

However, X-ray diffractometer measurements only map the residual stress state on the component's surface. Since a depth-dependent stress measurement is difficult

to perform due to the corrosion resistance, the hardness and the microstructure are investigated to depict the component properties inside the part. In these investigations, the comparison between the original state and the formed material properties is performed on a longitudinal section. Figure 5 shows the material flow and the microstructure of the manufactured components.

With regard to the material flow, different areas can be identified in the formed specimens in Fig. 5a. The material is not deformed during part production in the area of the initial material. Here, the linear structure of the material with parallel lines in the axial direction may be recognized. The forming takes place in the transition zone in the area of the die shoulder. In this region, the material flows to the centre and in the axial direction. This results in a structure with increasingly elongated grains. In the approximately 36 mm long area "formed material", there is a homogeneous structure in axial direction with strongly elongated parallel grains. In the "tip" area, inhomogeneous flow lines can be seen, which end in the edge area, since this is the place, where the end face of the billet and its edge area is located.

A detailed view of the grains in the core and the edge is shown in Fig. 5b for the component areas "initial material" and "formed material". The initial material has a linear structure with slightly elongated grains. In the annealed condition (+A), the core and edge areas show a homogeneous grain distribution with grain sizes of about 24 µm in the radial direction. In the skin passed condition (+LC), a similar structure is present in the core. In the edge area, however, slightly narrower and longer grains with grain sizes of 20 µm are present, which can be explained by the forming of the material during cold drawing of the semi-finished product.

In the deformed area, there are strongly elongated grains in both material states. In the edge area, with a size of 9 µm, there are thinner grains than with 12 µm in the core, which can be explained by the deformation when passing the die shoulder. While the core area is only axially stretched, the edge area is stretched in axial direction and additionally compressed in the radial direction. There are no significant differences between the annealed and skin passed material. This shows that the deformation during extrusion is so high that the influence on the surface caused by the cold drawing of the bars is negligible.

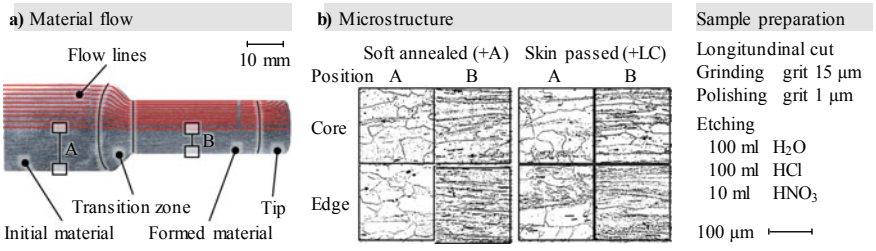

Fig. 5 Material flow and microstructure of formed parts. (Color figure online)

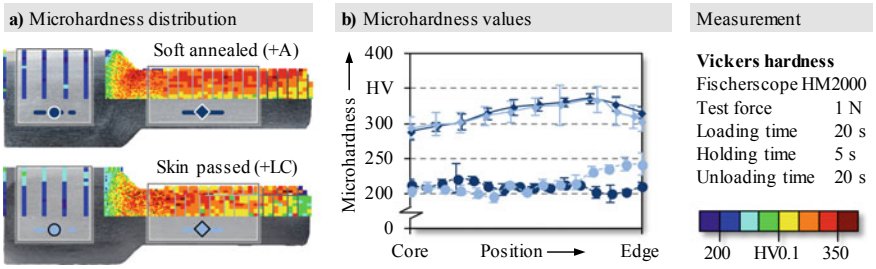

Fig. 6 Microhardness distribution of formed parts. (Color figure online)

4.4 Microhardness

To analyse the mechanical properties of the parts, the microhardness is used, as it provides a measure of the work hardening induced to the material. The hardness distribution in the longitudinal section of the extruded components is shown in Fig. 6.

In the initial state, the annealed material (+A) shows a homogeneous hardness distribution in the axial and radial directions with values of about 210 HV0.1. In the forming zone in the shoulder area, the material hardness increases due to work hardening. In the formed area, there is a homogeneous hardness distribution in the axial direction. In the radial direction, the lowest hardness values of about 290 HV0.1 are located in the area of the symmetry axis. The hardness increases in the direction of the component surface, with the maximum of 335 HV0.1 being approximately 1.5 mm below the surface. The hardness at the tip of the component is lower due to the lower deformation-induced.

In the skin passed (+LC) material, however, there is a hardness gradient in the radial direction in the initial state. With a value of 208 HV0.1, the hardness in the core is similar to that in the annealed material. The surface is strengthened to a depth of approximately 3 mm and has a significantly higher hardness of 230…240 HV0.1. In the transition area, the formed area and the component tip, similar hardness distributions can be found compared with the soft annealed material.

In the formed components, there are comparable microhardness distributions for both material states. Since there is no significant change in the microhardness despite the different levels of pre-hardening in the surface layer, it can be assumed that the low level of deformation during the cold drawing of the semi-finished product has no influence on the forming result.

5 Conclusions and Recommendations

A forward rod extrusion process was performed with a ferritic stainless steel in the delivery conditions “soft annealed” (+A) and “skin passed” (+LC). For the determination of the influence of the material delivery condition, the properties of the

forming process and the initial and the formed material were identified. With the findings shown in this paper, the following conclusions can be drawn.

- The delivery condition affects the material properties
  The cold drawing during the production of skin passed (+LC) material does not only change the appearance of the surface of the material. On the surface, residual stresses are induced. In the near-surface material volume, the microhardness is increased due to work hardening. The microstructure is affected only slightly.
- The material condition slightly affects the process properties
  When skin passed material is used, slightly lower maximum forces are required for forming and ejection. This reduces the tool load, which may result in higher tool life. As a side effect, slightly lower component temperatures are achieved, which improves component handling.
- Skin passing does not affect the parts' microhardness and residual stresses

During the forming of the material with a comparatively high degree of deformation carried out within the scope of this article, no influences of the material condition on the target variables "residual stresses", "grain size" and "work hardening" are detectable. The induced residual stresses and the hardening of the material due to the skin pass process do not cause any significant difference in the target values in the formed component.

For this reason, the following recommendations for process design are derived. The use of skin passed material is recommended if a high accuracy of the billet diameter is required in the process. Furthermore, it is recommended when cost-intensive forming dies are used, as the lower maximum process forces can be expected to increase the tool life. However, if there is, for example due to previous process steps, a certain hardening in the material, which is comparable to the "skin passed" state, it can be tolerated, if the deformation during component production is much higher. In this case, it is advisable from an economic and ecological point of view to avoid heat treatment, as this eliminates the need for a cost-intensive and energy-intensive annealing step. In addition, there is no necessity for pickling with hazardous acids to remove scale after annealing.

6 Summary and Outlook

Semi-finished products for cold extrusion are produced by various rolling, annealing and drawing operations. At the end of this process chain, ferritic stainless steels are soft annealed with final pickling to remove scale and an optional drawing step to achieve a small diameter tolerance. The aim of the paper was to investigate the influence of the material condition on the resulting process properties and component residual stresses and material properties for forward rod extrusion. To determine the process properties, billets made of ferritic stainless steel *X6Cr17* (DIN *1.4016*, AISI *430*) in the soft annealed (+A) and skin passed (+LC) condition were extruded and maximum process forces and part temperatures were determined. The residual

stresses were determined both in the initial and in the formed state on manufactured components. To analyse the material properties inside the component, grain sizes and microhardness distribution in the longitudinal section were identified. The results showed that slightly lower process forces are required for forming and ejection when using skin passed material. Due to the lower part temperatures, tribological influences were identified as the cause. Despite different residual stresses in the initial material, a similar near-surface residual stress condition was measured in the formed components. Differences in grain size and microhardness distribution in the initial material also did not cause any significant change in the formed components. This was attributed to the comparatively large deformation during forming compared to the cold drawing (skin pass) during the manufacturing of semi-finished products. These results led to the conclusion that a low pre-strengthening in the material does not cause any changes in the process and component properties, if the deformation in the forming process is comparatively high. The recommendation was derived from this, that soft annealing can be omitted for semi-finished products with low hardening if a significantly larger forming operation is carried out in the main forming operation.

These findings form the basis for further investigations to ensure reliable handling of residual stresses during cold extrusion. Due to increasing demands on corrosion resistance, the applicability of the findings to materials with a more complex structure, such as duplex steels, will have to be investigated. In order to include the residual stresses in the calculation of the component operating behaviour, the stability of the residual stresses under typical operating loads is to be researched.

Acknowledgments The research activities are funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) within the scope of the priority programme SPP2013—Targeted Use of Forming Induced Residual Stresses in Metal Components in the subproject P10 (project number: 374688875).

Experimental and Numerical Investigations on the Development and Stability of Residual Stresses Arising from Hot Forming Processes

Bernd-Arno Behrens, Jörg Schröder, Hendrik Wester, Dominik Brands, Sonja Uebing, and Christoph Kock

Abstract Residual stresses are an important issue as they affect both the manufacturing process as well as the performance of the final parts. Taking the whole process chain of hot forming into account, the integrated heat treatment provided by a defined temperature profile during cooling of the parts offers a great potential for the targeted adjustment of the desired residual stress state. The aim of this work is the investigation of technological reproducibility and stability of residual stresses arising from the thermomechanical forming process. For this purpose, a long-term study of residual stresses on hot-formed components is conducted. In order to develop finite element models for hot forming, a comprehensive thermomechanical material characterisation with special focus on phase transformation effects is performed. The numerical model is validated by means of a comparison between residual stress states determined with X-ray diffraction on experimentally processed components and predicted residual stresses from the simulations.

Keywords Forming process · Finite element analysis · Residual stress stability · X-ray diffraction

1 Introduction

In metal forming, the arising residual stresses influence the material behaviour during manufacturing as well as the performance of the final component [1]. In the past, the focus of forming process design was on minimising or eliminating residual stresses. However, residual stresses can also serve to improve the properties of the components through targeted use, for example with regard to distortions or wear behaviour

[2]. This requires the residual stresses to be applied technologically in a reproducible manner and to remain stable over longer periods of time. In this context, reproducibility and stability of residual stresses particularly resulting from the four process types “peening and related surface treatments”, “cold expansion of holes”, “welding”, and “machining” have been investigated by many authors, such as [3]. It is noticeable that most authors examine the development and stability of residual stresses in a strictly defined manner for a specific application. Depending on the type of process and the choice of material, which is linked to the process type, characteristic residual stress profiles are generated. For example, a typical feature of the surface treatment “shot peening” is a highly negative residual stress on the components surface, which decreases significantly towards the inside of the component [4]. Furthermore, it is known that relaxation and redistribution of residual stresses occur due to static or dynamic mechanical loads and thermal exposure. Static relaxation of residual stresses was for example investigated by [5] and [6] on components treated by shot peening. It should be noted that relaxation and redistribution of the local residual stresses occur when the accumulated residual stresses and the applied stresses due to subsequent mechanical loading exceed the yield state of the material. An important issue for many mechanical components is the potential effect of cyclic mechanical loads on the relaxation and redistribution of residual stress, even if the individual mechanical load cycles do not cause macroscopic plastic deformation. For example [5] and [7] investigated the stability of the peening residual stresses. It turned out that the residual stress relaxation is more significant for larger cyclic stress or strain. Little or no relaxation of peening residual stresses occurs, especially for small fatigue stress amplitudes [8]. Furthermore, e.g., in [9], the hole expansion process has shown that thermal exposure also leads to stress relaxation. In this case, the stress relaxation in aluminium samples was investigated at temperatures around 100 °C. After 250 h of thermal exposure they noticed a low relaxation (5 to 15%) and relatively small changes in fatigue life.

Until now, little attention has been paid to the stability as well as the calculation of residual stresses resulting from hot forming processes. The cost-efficient virtual process design of individual process steps or even an entire process chain is gaining in importance due to economic globalisation, continuously rising energy costs and growing competition in the manufacturing industry. Especially in the field of hot forming, process design in trial and error approaches represents a substantial cost and time expenditure [10]. At the same time, hot forming offers great potential for energy-efficient production of components by integrated heat treatment in the cooling phase after forming. Due to the numerous process parameters during forming, such as forming speed, and plastic strains as well as the temperature profile in the subsequent cooling process, there are numerous control parameters influencing the residual stresses. Nevertheless, the finite element (FE) simulation-supported design of hot forming processes using polymorphic steels is very challenging. As shown in Fig. 1a, numerous influencing parameters from thermal, metallurgical, and mechanical fields exist, which affect each other in complex interactions [11, 12]. For realistic process simulation, an appropriate mathematical model capable of consistently describing the polymorphic material behaviour is required. For this purpose, fully

coupled thermomechanical-metallurgical FE simulations based on the theory of additive strain decomposition method are often used in literature [13, 14]. The resulting strain components are structured in Fig. 1b according to their physical origin.

This article presents the material modelling of two typical hot forming steels with the aim of calculating the residual stresses arising from the thermomechanical process. An experimental hot forming process is carried out and the resulting residual stresses are investigated in a long-term study with respect to their stability. Furthermore, an FE model is created and validated on the basis of the comprehensive experimental data. The FE-model validated in this work is intended to serve in future work as a virtual tool, enabling the determination of process parameters for inducing favourable residual stresses in hot-formed components. As an example, with the help of FE-based process design residual compressive stresses should be generated in components such as crankshafts or gears to increase the product lifetime.

2 Material Characterisation of Hot Forming Steels

For the investigations in this work, the typical hot forming steels with the material numbers 1.3505 (AISI 52,100) and 1.7225 (AISI 4140) according to German standards were used. The chemical composition of the two materials is listed in Table 1.

Table 1 Chemical composition of steel alloys 1.7225 and 1.3505 according to international standards [16] and [17]

[wt%]	C	Si	Mn	P	S	Cr	Mo	Fe
1.3505	0.99	0.25	0.35	0.025	0.015	1.475	0.10	Balance
1.7225	0.42	0.25	0.75	0.025	0.035	1.10	0.22	Balance

As outlined in the introduction, a comprehensive material characterisation is required to model the numerous thermal, metallurgical, and mechanical material phenomena arising from the thermomechanical process. To simulate the plastic deformation behaviour during hot forming, compression tests were performed on the Gleeble 3800-GTC physical forming simulator with cylindrical samples of 10 mm diameter and 15 mm length. The flow curves were determined in the relevant temperature range (T = 900, 1000, 1100, and 1200 °C). In addition, the tests were carried out at the corresponding temperatures with the equivalent plastic strain rates of $\dot{\varepsilon}_{eq}$ = 10 s^{-1} and 50 s^{-1}. Figure 2 shows the experimentally determined flow curves exemplarily for material 1.3505 at different temperatures and the strain rate $\dot{\varepsilon}_{eq}$ = 1 s^{-1} as well as for T = 1000 °C and different strain rates. A strict temperature and strain rate dependence of the strain hardening behaviour could be observed for both materials.

In order to ensure a continuous description of the flow behaviour for the process simulation as a function of the equivalent plastic strain, the equivalent plastic strain rate and the temperature, the analytical approach of the so-called GMT model [19] for calculating the yield stress was calibrated. Equation 1 shows the calculation approach whereas the determined coefficients c_1, c_2, n_1, n_2, l_1, l_2, m_1, and m_2 of the analytical approach for both materials are listed in Table 2.

$$k_f = c_1 e^{c_2 T} \varphi^{n_1 T + n_2} e^{\frac{l_1 T + l_2}{\varphi}} \dot{\varphi}^{m_1 T + m_2} \tag{1}$$

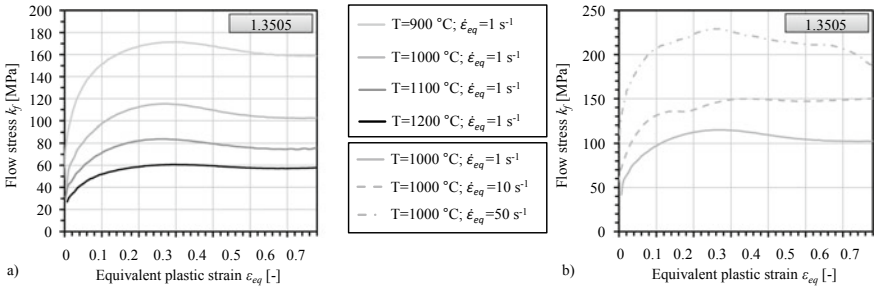

Fig. 2 Flow curves of 1.3505 for different temperatures T (**a**) and different strain rates $\dot{\varepsilon}_{eq}$ (**b**) determined in upsetting tests at the Gleeble 3800-GTC [18]

Table 2 Fitted GMT model parameters for 1.3505 and 1.7225

Material	c_1 [MPa s]	c_2 [°C^{-1}]	n_1 [°C^{-1}]	n_2 [−]	l_1 [°C^{-1}]	l_2 [−]	m_1 [°C^{-1}]	m_2 [−]

1.7225	6054.21	−0.0039	−3.0846 * 10^{-5}	0.3000	1.8926 * 10^{-5}	−0.03548	−9.4422 * 10^{-5}	0.2484

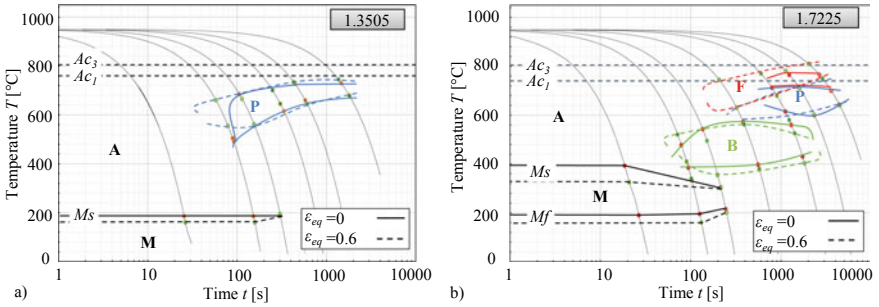

Fig. 3 Continuous cooling transformation diagrams for the materials 1.3505 (**a**) and 1.7225 (**b**) [20]. (Color figure online)

In order to model the phase transformation behaviour during cooling after the forming process, continuous cooling transformation diagrams (cct diagrams) have been determined in experimental studies. Thereby, the phase transformation behaviour was investigated both without and with a previous deformation of the fully austenitised material. These diagrams are shown in Fig. 3.

It can be clearly seen that a previous deformation influences the microstructural transformation behaviour of both materials investigated significantly. For example, a reduction in the martensite start temperature Ms was found in each case. From these cct diagrams, time temperature transformation diagrams (ttt diagrams) were determined and implemented in the Simufact.forming software. Further information on the investigation of phase transformation has already been published in [20] by the authors.

Besides the strains due to phase transformation, the transformation plastic strains (TRIP strains) were investigated by the authors in [21]. For this purpose, the phase transformation behaviour of the materials at a superimposed stress was investigated. The phase-specific TRIP coefficients listed in Table 3 were determined as characteristic material parameters.

In addition to the austenite flow curves, the ttt diagrams and the transformation plasticity coefficients, further phase-specific data are required for the correct modelling of the thermomechanical forming process. This comprises, for instance, characteristic data on specific heat capacity, latent heat, or phase-specific flow curves. In most cases, it is difficult to generate experimental material data for pure microstructural phases [22]. For this reason, supplementary material data have been generated with the thermodynamic simulation software JMatPro [23]. With the help of this

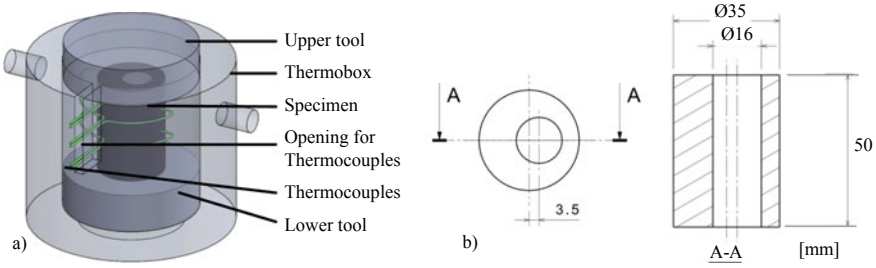
Table 3 The phase-specific coefficients of transformation plasticity for 1.3505 and 1.7225 [21]

	1.7225		1.3505
Phase	TRIP coefficient K_n [MPa^{-1}]	Phase	TRIP coefficient K_n [MPa^{-1}]
Martensite	1.54 * 10^{-4}	Martensite	4.85 * 10^{-5}
Bainite	1.01 * 10^{-4}	Pearlite	6.17 * 10^{-5}

software, it is possible to generate mechanical and thermal material data by means of thermo dynamic calculation approaches from [24] to [25] based on the chemical composition of the steel alloys. Further details on the material data used for simulation of the hot forming process can be found in [18].

3 Experimental and Numerical Procedure for Thermomechanical Processing of Cylindrical Specimen With Eccentric Holes

An experimental reference process was carried out to investigate the residual stress development in hot forming and to validate the material models created. The specimens were provided with thermocouples for a temperature-controlled process management. Subsequently, as shown in Fig. 4a, the specimens were placed in a thermobox to ensure a quasi-isothermal test procedure during the forming phase. Within the thermobox the specimens were heated up to 1000 °C in a furnace. A ten-minute holding time was applied to ensure complete austenitisation. Afterwards, the thermobox with the specimen was transferred from the furnace to the servo hydraulic forming simulator VHS8800 (Instron GmbH). The specimens were upset at a punch speed of 200 mm/s to a final height of 28 mm from the initial height of 50 mm. The untreated specimen is shown schematically in Fig. 5a whereas the deformed specimen is shown in Fig. 5b in the cross-sectional view. Immediately after the forming process, the specimen was removed from the thermobox and cooled down to room temperature either in ambient air or in water. Due to the different cooling routes, different phase transformation phenomena are expected in the material, which lead to different residual stress profiles. In these tests cylindrical specimens with eccentric holes as shown in Fig. 4b were used. Due to the asymmetrical hole, an inhomogeneous development of the residual stresses is expected in the material. For a statistical verification of the residual stress measurements, five identical tests were performed for each cooling medium and material. The experimental test procedure is described in detail in [18].



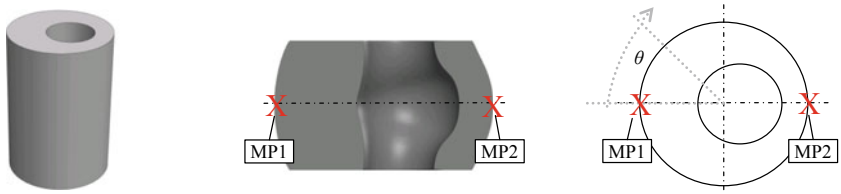


Fig. 4 Schematic representation of the specimen prepared with thermocouples in a thermobox (**a**) and shape of the investigated specimen with dimensions in mm (**b**). (Color figure online)

a) Untreated specimen

b) Measuring points (MP) on the mid-height of the specimen

c) MP on the circumferential surface indicated by the angle θ

Fig. 5 Illustration of the untreated specimen (**a**), the measuring points MP1 and MP2 at the mid-height of the specimen (**b**) as well as the angle θ on the circumference of the specimen. (Color figure online)

X-ray diffraction is used for residual stress analysis. The respective measuring point was initially polished electrolytically in order to avoid influences on the analyses from the scale layer of scale arising in the hot forming process. Subsequently, the tangential residual stresses were determined with the X-ray diffractometer X3000G2 (Stresstech GmbH) employing Cr-Kα radiation according to the corresponding DIN standard [26]. The measuring point was defined by a collimator with a diameter of 2 mm. Nine tilting positions of the measuring device were used per measuring point for stress evaluation. Afterwards, the measurements were evaluated with the software XTronic (Stresstech GmbH) by means of the $\sin^2$ method. The values for the X-ray elasticity constant $½s_2 = 5.81 * 10^{-6}$ mm^{2}N^{-1} and the reference values for the unstressed material ($d_{211} = 1.1703$ Å, $2\theta_{Cr} = 156.084°$) were taken from the tabular data collection of [27]. These data of X-ray elasticity constants were calculated as mean values from the so-called Voigt [28] and Reuß [29] approaches for the pure alpha iron lattice.

The measuring points were placed at the mid-height of the specimen (cf. Fig. 5b). Comprehensive residual stress measurements were carried out the following days after the thermomechanical treatment. The tangential residual stresses on the surfaces of the specimen were determined as shown in Fig. 5b on the thick-walled side, measuring point 1 (MP1) and on the thin-walled side (MP2) of the specimen. In addition, further measurements along the circumference of the specimen were taken at angles $\theta = 45°, 90°, 135°$ according to Fig. 5c. The X-ray measurement was additionally repeated several times per measuring point, to minimise the instrumental error, adjustment of the measurement system, and effect of specimen curvature on the results. The investigation of the specimen, which has undergone the same experimental procedure each, is intended to make a statement about the technological reproducibility of the residual stresses. Additionally, subsequent to the immediate X-ray measurements, the measurements on MP1 and MP2 were repeated after six months and twelve months. In the meantime, the specimens were stored in a laboratory cabinet at a constant temperature of 20 °C. Thus, a statement on the stability of the residual stresses generated by the thermomechanical treatment can be made.

The experimental reference process described above was modelled with the commercial FE software Simufact.forming based on MSC.Marc solver. For this purpose, the comprehensive material data presented in Sect. 2 were implemented

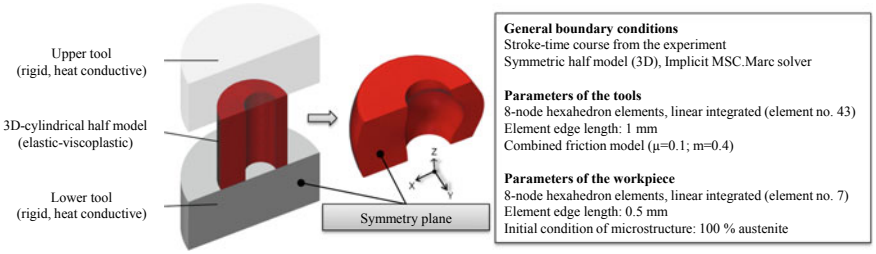

Fig. 6 Design of the investigated FE simulation model with the boundary conditions. (Color figure online)

in the software. In the simulation the heating process was modelled by a volume expansion of the specimen due to the austenitic phase transformation as well as the thermal expansion of the material.

At the beginning of the forming process a stress-free state in the specimen consisting of 100% austenitic sample is assumed. A schematic representation of the FE model and the boundary conditions is shown in Fig. 6.

The tools are considered as heat conducting rigid bodies and provided with a mesh of 1 mm element edge length. For the tools of the material 2.4668 (AISI: Inconel-718) constant values of the specific heat capacity $c_p = 435$ Jkg^{-1} K^{-1} and heat conductivity $\lambda = 11.4$ Wm^{-1} K^{-1} were taken from the data of the supplier [30]. The workpiece is assigned with an adaptive hexagonal mesh with the minimum element edge length of 0.5 mm, determined in a mesh sensitivity analysis.

4 Results of Long-term X-ray Analysis and FE Model Validation

The tangential residual stresses calculated in the simulations and the results of the experimental long-term X-ray analyses are shown in Fig. 7. Considering the results of the residual stress measurements immediately after the hot forming tests, it is noticeable that the residual stresses due to rapid cooling in water are higher than those after cooling in air. After cooling in water, for the material 1.3505 residual stresses of $\sigma_t = 216$ MPa at MP1 and $\sigma_t = 138$ MPa at MP2 are determined, for the material 1.7225 $\sigma_t = 212$ MPa at MP1 and $\sigma_t = 192$ MPa at MP2. After cooling in air, however, significantly lower stresses of $\sigma_t = -83$ MPa at MP1, $\sigma_t = -52$ MPa at MP2 for 1.3505 and $\sigma_t = 27$ MPa at MP1, $\sigma_t = 19$ MPa at MP2 for 1.7225 are measured. At high cooling rates, a diffusion-free transformation of the austenitic into the martensitic phase takes place in the material, which leads to severe stresses in the crystal lattice. During diffusion-controlled phase transformation, which occurs while cooling in air, comparatively lower residual stresses in the range of zero can be observed.

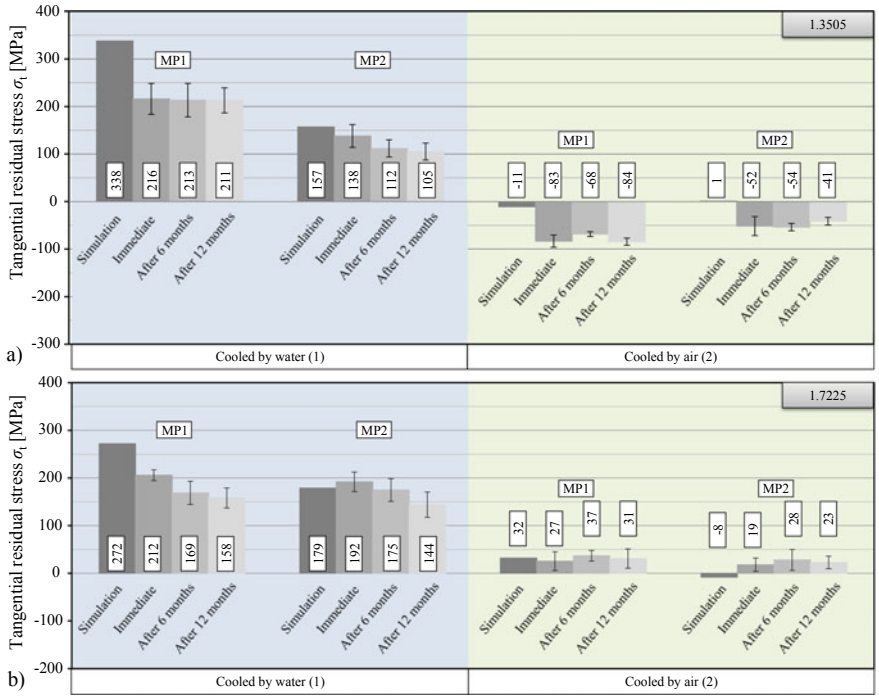

Fig. 7 Calculated tangential residual stresses σ_t in comparison with the results of the experimental long-term residual stress analyses. (Color figure online)

It is noted that cooling of the specimens in water causes positive residual stresses in both materials. Furthermore, cooling of the specimens made of 1.7225 in air lead to positive residual stresses as well. Negative residual stresses are only measured for the air-cooled specimens of material 1.3505. This is primarily due to the changed phase transformation behaviour of 1.3505 during slow cooling. At rapid cooling in water, a martensitic phase transformation occurs for both materials first in the specimen surface and afterwards in the specimen core. Each time this phase transformation is associated with volume expansion due to the larger lattice constants of the martensitic phase compared to the austenitic phase. Since the volume expansion occurs last in the specimen core, a strain gradient is created in the material, which leads to positive stresses at the specimen surface and negative residual stresses in the specimen core. When the specimens from 1.3505 are cooled in air, the volume expansion during the transformation of the austenitic to the pearlitic phase is significantly smaller. In addition, the transformation already takes place at high temperatures between 700 °C and 600 °C (cf. Fig. 3a). Following the pearlitic phase transformation, the specimen is further cooled down from about 600 °C to room temperature. Due to free convection, the specimen surface cools down faster than the specimen core. Once the surface temperature of the sample reaches room temperature, thermal shrinkage of the core continues. In contrast to the water-quenched specimens, where a volume

expansion due to the martensitic transformation occurs in the end of cooling in the core, a thermal shrinkage of the core appears here. This leads to a strain gradient between the specimen surface and the specimen core, which results in negative residual stresses on the specimen surface and positive residual stresses in the core. The effect of the bainitic phase transformation in the material 1.7225 compared to the pearlitic phase transformation in the material 1.3505 starts much later in the temperature range from 400 °C to 600 °C (cf. Fig. 3b). The volume expansion as a result of the bainitic phase transformation and the thermal shrinkage compensate each other so that only low positive stresses up to a maximum of 37 MPa are measured.

Furthermore, it is observed that the amount of residual stresses on the thick-walled side (MP1) of the specimen cooled by water are always higher than on the thin-walled side (MP2). According to the asymmetrical geometry of the specimen, an inhomogeneous residual stress profile is generated on the circumference of the specimen.

The residual stresses were applied reproducibly in each case with an absolute standard deviation of less than 30 MPa by the experimental setup described in Sect. 3. Accordingly, it can be assumed that technologically reproducible residual stresses can also be generated targeted to components in further hot forming processes.

The comparison of the experimentally measured residual stresses and the values obtained from simulations shows that the developed FE model is suitable for a good prediction accuracy of the residual stresses. In particular, the differences in the amount of residual stresses during cooling in water between the thick-walled side (MP1) and the thin-walled side (MP2) of the specimen are calculated properly in the simulations.

Repeating measurements after six months and twelve months shows that the residual stresses generated remain essentially stable in the material. In particular, at MP1 on the specimen of the material 1.3505 which were cooled in water, hardly show any changes in residual stresses with respect to time. In contrast, at the measuring points on the specimens of the material 1.7225 cooled by water, a slight decrease in the tangential residual stresses is observed over time. Despite storage at the constantly low temperature of 20 °C, stress relaxation has occurred. In contrast, the measured values of the stresses on the specimen cooled in air show generally lower initial residual stresses and barely changes in the stresses during the long-term investigations.

It should be noted that the residual stresses arising from the thermomechanical process are significantly influenced by the phase transformations. These transformations take place on the atomic level. With the X-ray method, the residual stresses on a macroscopic level can be measured exclusively. The complex interrelations between the residual stresses of the second and third type on the microscopic scale and their influence on the stability of the residual stresses of the first type on the macroscopic scale can therefore not be measured experimentally. For this reason, a working group of the authors is simultaneously engaged in modelling the effects of the microscopic processes using FE^2 simulations based on the macroscopic calculations from this work [31]. With such multiphase approaches, an improved numerically supported statement on the stability of the residual stresses should be possible in the future.

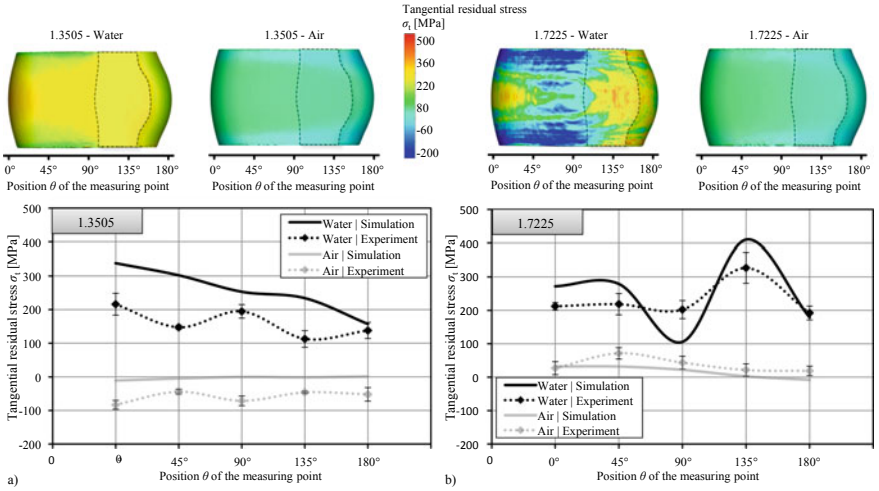

Fig. 8 Contour plots of the tangential residual stress σ_t from the simulations (top) as well as comparison with experimental results on the specimens' circumferential surface (bottom) with respect to the measuring position θ for the materials 1.3505 (**a**) and 1.7225 (**b**). (Color figure online)

For an advanced model validation, the measurements of residual stresses on the circumference of the specimen surface at different angles θ corresponding to Fig. 5c were also evaluated. Figure 8 shows a comparison of the calculated and experimentally determined residual stress values.

In addition, the contour plots for the distribution of the tangential residual stresses on the specimen surface of each case are shown in the top of Fig. 8. The simulations reveal that a homogeneous distribution of the equivalent plastic strain occurs on the surface of the specimens. Equivalent plastic strain values of $\varepsilon_{eq} = 0.46$ at MP1 and $\varepsilon_{eq} = 0.47$ at MP2 for the material 1.3505 as well as $\varepsilon_{eq} = 0.52$ at MP1 and $\varepsilon_{eq} = 0.5$ at MP2 for the material 1.7225 are calculated. The comparison of results for both materials in Fig. 8 shows that the residual stress profile can also be predicted with good quality over the course of the circumference. On the specimens out of 1.3505 cooled in water, a slightly decreasing stress curve can be observed from MP1 ($\theta = 0°$) to MP2 ($\theta = 180°$). In contrast, the stress profile of the specimens made of 1.7225 shows slight oscillations with a minimum at $\theta = 90°$ and a maximum at $\theta = 135°$. The residual stresses of specimens cooled in air are constantly low for both materials. In this way, the developed FE simulation model could be validated for different cooling conditions at different measuring points of the specimen with eccentric hole.

5 Summary and Outlook

In the scope of this work, a material model for the simulation of the interrelated thermal, metallurgical, and mechanical interactions during hot forming was created with the aim of residual stress prediction for the materials 1.3505 and 1.7225. Furthermore, a reference process of hot forming was investigated using cylindrical specimen with eccentric holes regarding the residual stresses resulting from two different cooling procedures (cooling medium water or air) by X-ray diffraction. It was found that the residual stresses can be generated by the hot forming process in a technologically replicable manner. A long-term study showed that the residual stresses are mostly stable over time, whereby slight stress relaxation was observed. Based on the extensive experimental results, the developed FE model of the hot forming process could finally be validated.

In a next step, the stability of the residual stresses resulting from the hot forming processes should be investigated under cyclic mechanical and thermal loads. Besides, the validated numerical model can be used to predict residual stresses in complex industrial processes. The overall objective of the work is the FE-based process design for targeted application of residual stresses to improve the properties of hot-formed components.

Analysis of Cylindrically and Spherically Embossed Flux Barriers in Non-oriented Electrical Steel

Ines Gilch, Simon Vogt, Tobias Neuwirth, Benedikt Schauerte, Kay Hameyer, Michael Schulz, Alex Gustschin, Wolfram Volk, and Hannes Alois Weiss

Abstract In reluctance and permanent magnet synchronous machines, flux barriers are crucial for magnetic flux guidance. Designed as cutouts, flux barriers reduce the mechanical strength of the rotor construction. To operate these electric drives at higher rotational speed, an alternative flux barrier design is required. Since residual stress influences the magnetic properties of soft magnetic materials, this paper deals with embossing induced residual stress as flux barriers in non-oriented electrical steel with 2.4 wt% silicon and a sheet thickness of 0.35 mm. The investigated flux

barriers were fabricated with a cylindrical or spherical punch at two different penetration depths and were compared to a flux barrier fabricated as cutout. A residual stress analysis using finite element analysis helps understanding the mechanism of embossed flux barriers. Additionally, the influence of induced residual stress on the magnetic material behavior is measured using standardized single sheet tests and neutron grating interferometry measurements. This investigation aimed at a better understanding of the flux barrier design by local induction of residual stress.

1 Introduction

With politics emphasizing energy change, the significance of energy efficiency is increasing. One factor to enhance the energy efficiency of electric drives, especially of reluctance and permanent magnet synchronous machines, is optimizing the magnetic flux guidance in the electrical steel that form the motor core. Conventionally, cutouts are inserted in electrical steel sheets for magnetic flux guidance. Coincidentally, they deteriorate the mechanical strength of the rotor construction. Hence, the maximum rotational speed of the motor is limited. The following investigation focuses on an alternative strategy of magnetic flux guidance in electrical steel to enable higher rotational speed and to increase the power density of electric drives.

Prior studies revealed that mechanical stress has a negative effect on the magnetic properties of non-oriented electrical steel [1]. The inverse magnetostrictive effect describes the correlation between mechanical stress and magnetic material behavior. These studies focused on the effect of mechanical stress caused by dynamic loads, like centrifugal forces [2], or of processing induced residual stress, e.g., by blanking [3], on the magnetic properties of non-oriented electrical steel. Their target was the decrease of the magnetic deterioration by reduction of mechanical stress. It is determined that compressive residual stress has a higher impact on the magnetic material behavior than tensile residual stress [1, 4].

In contrast, the following work aims to enhance the properties of electric drives by focused application of the inverse magnetostrictive effect. As residual stress deteriorates the magnetic material behavior, the local induction of residual stress reduces the magnetic permeability in the affected volume, hence the magnetic flux. As shown in [5] this phenomenon allows a magnetic flux guidance.

Different to [5], the relation between residual stress distribution and magnetic material behavior is analyzed in detail. Furthermore, the influence of cylindrical and spherical embossing geometries and of different penetration depths is examined. To evaluate the relation of embossing and magnetic properties, it is crucial to quantify the distribution of residual stress with a Finite Element Analysis (FEA) of the embossing process. The magnetic material behavior of the specimen is analyzed with

neutron grating interferometry (nGI) [6] and single sheet tests [7]. Additionally, the functionality of the embossed flux barrier is demonstrated by comparing it to a flux barrier fabricated as cutout. This investigation is necessary to show the applicability of the new flux barrier design for electric drives.

2 Methods

2.1 Specimen Manufacturing Process

The specimens were fabricated from a non-oriented electrical steel with a silicon content of 2.4 wt% and a sheet thickness of 0.35 mm, comparable to [5]. The size of 10 mm × 60 mm has been maintained, because it is suitable for both magnetic measurement methods. The strategy of specimen manufacturing is illustrated in Fig. 1. In the first step, locating holes are cut in the specimen and the flux barrier is embossed. Secondly, the final specimen geometry is wire-cut. To finish the specimen manufacturing, the final specimen geometry is measured optically.

To begin, two locating holes are cut in the specimen with the same punching tool used for embossing (Fig. 1b). The locating holes are mandatory to ensure a reproducible position of the embossing in the specimen's center.

Subsequent, the specimens are positioned with the locating holes and the magnetic flux barriers are embossed with a cylindrical or spherical punch (Fig. 1c). The two exemplary punch geometries were selected, because of strongly varying deformations and residual stress distributions. The tool, which is schematically shown in Fig. 2, is designed like a shear cutting tool. The main components are embossing punch, die, and blank holder. The blank holder ensures that the blank keeps its position during embossing. For the embossing, two different punches were selected. One embossing

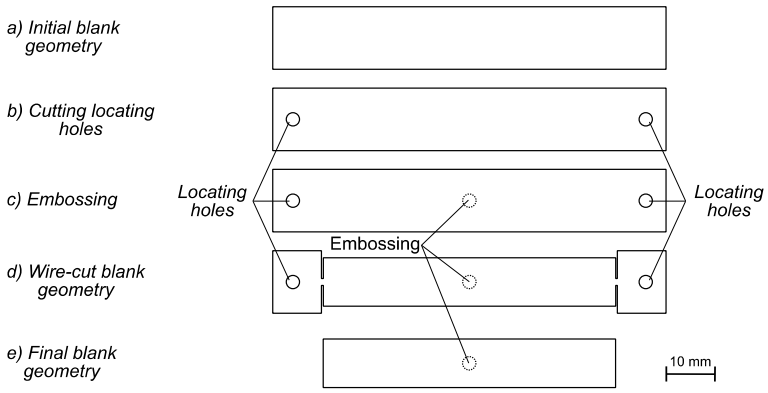

Fig. 1 Schematic illustration of specimen manufacturing: **a** initial blank geometry, **b** cutting of locating holes, **c** embossing of flux barrier, **d** wire-cutting and **e** final blank geometry

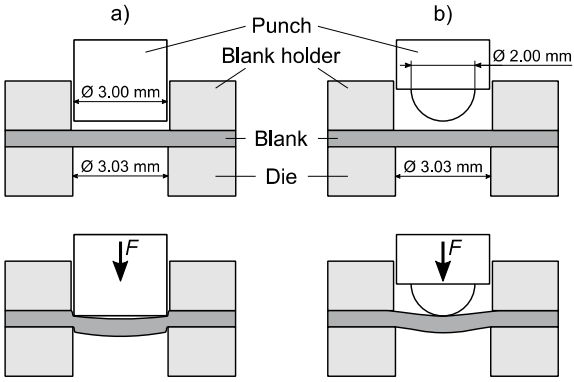

Fig. 2 Schematic illustration of the embossing tool and the embossing of the blank with **a** cylindrical punch and **b** spherical punch

punch has a spherical tip with a diameter of 2.00 mm, while the second embossing punch has a cylindrical tip similar to a punch used for shear cutting with a diameter of 3.00 mm. The cylindrical die remains unchanged for all experiments and has a diameter of 3.03 mm. The tool was utilized on a servo press with a velocity of 30 strokes per minute. The tool concept and the deformation of the blank caused by the punch force F is illustrated in Fig. 2.

The embossing depth, i.e. the way the punch penetrates below the initial upper surface of the blank, is adjustable. This allows a variation of the deformation grade between different embossings, which is for the executed experiments between 36 µm and 240 µm. With the cylindrical embossing punch and a sufficient penetration depth, the electrical steel sheet can be shear cut to produce a specimen with cutout as flux barrier.

Succeeding, the final specimen geometry is produced (Fig. 1d). The contour, shown in Fig. 1, is wire-cut. This cutting method ensures a negligible influence of the cut edges on the magnetic properties of the specimen [8]. Hence the cutting of the specimen doesn't need to be considered for the simulation of residual stress. During the wire-cutting, the specimens are positioned and fixed over the locating holes. Finally, the additional parts on both sides of the specimens are removed (Fig. 1e).

To finish the specimen production, the obtained embossing geometry is analyzed. A 3D-scan of the specimen's surface was executed with a confocal laser scanning microscope to analyze the final deformation and the penetration depth.

The specimen names are combined of the used punch, *Cyl* for cylindrical and *Sph* for spherical punch, and the penetration depth, *PD 1* for a small penetration depth and *PD 2* for a higher penetration depth. The sample names and the resulting depth of embossing are listed in Table 1.

Table 1 Measured final depth of deformation between initial blank surface and center of deformation as well as corresponding simulated penetration depths

Specimen	Punch	Resulting embossing depth (mm)	Simulated penetration depth (mm)
Cyl—PD 1	Cylindrical	0.031	0.036
Cyl—PD 2	Cylindrical	0.235	0.240
Sph—PD 1	Spherical	0.073	0.079
Sph—PD 2	Spherical	0.225	0.230

2.2 Finite Element Analysis

The embossing process is computed to analyze the relation between residual stress distribution in the specimen and its magnetic material behavior. The flux barrier caused by a cutout is not accounted in the Finite Element Analysis (FEA) as Weiss et al. [9] analyzed the effect of cutting in greater depth. With the FEA, a three-dimensional numerical model calculates the embossing related deformation and mechanical stress in the specimen. The embossing process is structured in three steps: clamping the blank with blank holder, embossing with cylindrical or spherical punch and removing external forces on the specimen to allow a springback movement.

To clamp the blank, a blank holder force of 25.5 kN is applied. Next, the punch penetrated the electrical steel. The depth varies because of different final depths of the specimens' embossings, which are listed in Table 1. Completing the numerical analysis, the springback of the blank is simulated: all external forces on the specimen are removed concurrent with punch, blank holder and die. The final geometry after step three is compared to the optically measured specimen profile to iteratively adapt the penetration depth. Thus obtaining a model close to reality. The computed stress without influence of external mechanical forces results in the required residual stress distribution.

The geometric parameters of the numerical model are approximately the same as in the experimental setup, see Chap. 2. The edge radius of the die and the cylindrical punch are set to 0.05 mm.

The non-oriented electrical steel is an approximately homogenous material with slightly different properties in and transverse to rolling direction. Considering the small anisotropy and the symmetry of the embossing process, calculating a quarter of the model is sufficient and reduces the computation time. The deformation of the tools is neglected due to modeling them as rigid bodies.

The material model is built on the measurement of material properties in [9]. The edge lengths of the elements, which are used for the discretization of the blank, are between 0.0017 mm in areas with high deformations and 2.58 mm in areas with small deformations. The mesh consists of 37,870 8-node linear brick C3D8R elements for the embossing simulation with cylindrical punch and 46,823 elements for the model with spherical embossing geometry.

As tensile and compressive residual stress have a different influence on the magnetic properties of electrical steel, von Mises equivalent stress criterion is not applicable for the analysis. A distinction of tensile and compressive residual stress is realized by the analysis of local maximum absolute principle stress $\sigma_{\mathrm{max,principle,abs}}$.

The stress values are evaluated along lines intersecting the specimen perpendicular to the blank surface. For each line 350 stress values are analyzed over the sheet thickness and separated in tensile and compressive stress. Subsequent, the mean tensile and compressive stress is computed for the line. The evaluation lines are arranged in a distance of 5 µm along five cross sections intersecting the center of embossing. Each cross section is rotated in an angle of 22.5°. The residual stress distributions of the cross sections were averaged to a single residual stress distribution plotted to the distance x from the center of embossing. Because of symmetry constraints, the residual stress distribution in and transverse to rolling direction are included with weighting factor 0.5 to the mean residual stress distribution.

2.3 Experimental Methods

2.3.1 Neutron Grating Interferometry

The imaging method neutron grating interferometry (nGI) analyzes the absorption, phase shift and ultra-small-angle neutron scattering (USANS) of a neutron beam passing through the specimen. [10] Neutrons do not interact with the electron hull, but the atomic core. This allows for a high penetration in most metals, i.e. electrical steel. Due to their spin, neutrons also interact with magnetic fields. In the case of a magnetic domain structure, as found in electrical steels, the scattering of the neutrons is in the USANS regime. These two factors cause nGI to be the prime technique to analyze local magnetic properties in bulk samples.

The image containing information about USANS is called the dark field image (DFI). Encoded in the DFI is information about the local magnetic domain structure, which in turn is linked to the residual stress distribution in the evaluated volume [6].

The neutron grating interferometer used for this study is a Talbot-Lau interferometer for neutrons [11]. A detailed explanation of the components and principle of a neutron grating interferometer may be found in [11, 12].

The measurements were performed at the neutron imaging beamline ANTARES at the FRM II [13, 14]. As experimental setting, a correlation length of 1.865 µm was selected. The exposure time of 10 s and an amount of 30 images per sample resulted in a total exposure time of 300 s per nGI-scan. The used detector has a field of view of 70.3 mm × 83.3 mm. The pixel size is 32.5 µm × 32.5 µm and the achieved resolution is roughly 90 µm.

The measurement of the specimens was conducted under the influence of different magnetic fields to analyze the effect of magnetization on the behavior of magnetic flux barriers. The yoke, described in [15] induces the magnetic field in the specimens,

Table 2 Magnetization of specimen in nGI-measurements: applied electric currents I and resulting magnetic field strength H

Applied current I (A)	0.00	0.47	1.34	2.00	3.00	4.00	5.00	6.67
Magnetic field strength H (A/m)	0.00	780	2230	3330	4955	6660	8325	11,105

which is generated by an electric current in the coils. In Table 2, the applied electrical currents I and resulting magnetic field strengths H are listed.

For evaluation of the DFI-signal, the measurement results were normalized to the DFI-signal of a virgin reference specimen. A scaled DFI-signal lower than 1 signifies a higher magnetic domain density and a value higher than 1 a lower magnetic domain density, compared to the reference. To analyze the progression of the magnetic domain structure, the scaled DFI-signal of all pixels at discrete distances of the embossing's center was radially averaged.

The magnetic domain structure of a specimen is highly affected by the residual stress. Additionally, the local magnetic domain structure gives an idea of the movement of magnetic domains under magnetization. The movability and magnetizability of magnetic domains are fundamental for the global magnetic properties.

2.3.2 Single Sheet Tests

Single sheet measurements are used for magnetic property characterization of electrical steel averaged across the entire volume of specimens. The measurement system utilized for this work is a double yoke 60 mm × 60 mm single sheet tester (SST). The specimen is clamped in between two yokes which close the magnetic circuit. The influence of the reluctance return path for the flux in the yokes can be neglected because of the considerably larger cross section of the yoke when compared to the specimen. The specimen is surrounded by two windings. The primary winding applies the magnetic field strength. The secondary winding induces the measurement voltage and thus the magnetic flux density in the specimen. The electrical currents in the primary windings are controlled in such a way, to cause sinusoidal magnetic flux density waveforms with a predefined amplitude B_m at a magnetization frequency f. In this way, the specimen can be compared in terms of characteristic properties such as iron loss, magnetic permeability and hysteresis loop shape [16].

For the selected measurement system, a specimen's geometry of 60 mm × 60 mm is optimal. Its size is reduced to 60 mm × 10 mm for this study, to measure the identical specimen as analyzed in the nGI. The specimen is clamped centrally between the yokes. The magnetic field and the resulting flux density are measured simultaneously and recorded, when a sinusoidal magnetic flux density waveform is set up in the investigated volume. For the measurements, a magnetization frequency f of 50 Hz was selected. The magnetic flux density is the average of the measured magnetic flux across the specimen's cross section. The magnetic field can be calculated by

the known magnetic path length, number of turns of the primary winding and the electrical current in the excitation coil.

A magnetic flux density exists between the yokes even without specimen due to the permeability of the vacuum μ_0, the so-called air flux. It is considered by air flux compensation to solely measure the magnetic flux in the specimen.

By principle, the single sheet tests only enable a conclusion on the global magnetic material behavior without insights on the local distribution of the magnetic flux. The combination of nGI and SST is necessary to analyze the magnetic material behavior of the embossed flux barriers. The connection of global magnetic properties and numerically analyzed local residual stress is shown in [17] by analyzing electrical steel in a tensile test.

3 Results

3.1 Numerical Analysis of Residual Stress

The following part depicts and discusses the FEA results of the embossing process. In Fig. 3, the simulated residual stress distributions distinguished into tensile and compressive stress are displayed. The vertical line at distance $x = 1.5$ mm represents the position of die diameter equal to the edge of embossing.

For the cylindrically embossed flux barriers, the maximal tensile and compressive residual stress values appear at a distance close to 1.5 mm. A higher penetration depth

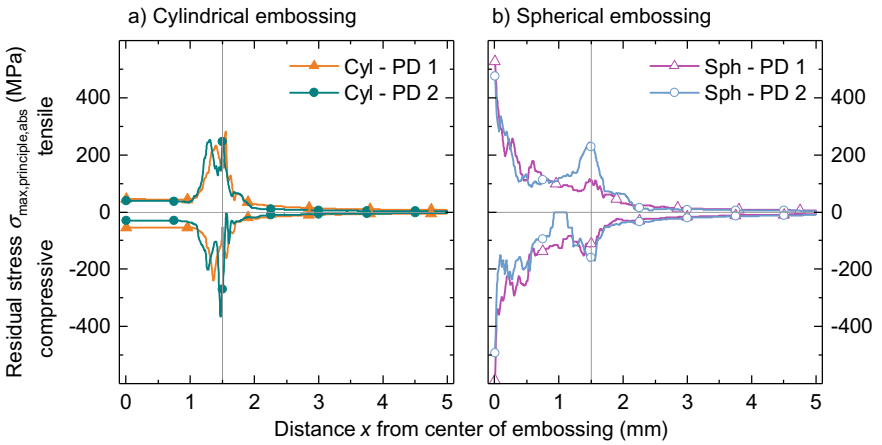

Fig. 3 Numerically analyzed distribution of tensile and compressive residual stress $\sigma_{max,principle,abs}$ plotted to the distance x from center of embossing for **a** the cylindrically embossed specimens and **b** the spherically embossed specimens. (Color figure online)

leads to a larger maximum of compressive residual stress at punch and die diameter and to a lower tensile and compressive stress level in- and outside of the embossing.

The simulated residual stress distributions of the spherically embossed flux barriers show global tensile and compressive stress maxima in the center of the embossing and local maxima at distance $x = 1.5$ mm. The local compressive stress maxima are significantly smaller than the global ones of the cylindrically embossed specimen. For Sph—PD 2, the local maximum of the tensile stress is two times the one of Sph—PD 1 and has a similar magnitude as the global tensile stress maxima of the cylindrical embossings. The residual stress outside the spherical embossings are increased in relation to the cylindrical embossings.

In summary, a higher total residual stress amount is induced using the spherical punch. The maxima of the spherical embossing are higher than the ones of the cylindrically embossed specimens. Additionally, the residual stress outside and inside the spherical embossing is more increased compared to the cylindrically embossed flux barrier.

3.2 Local Magnetic Material Behavior

The effect of residual stress on the local magnetic domain structure of the specimens was determined using neutron grating interferometry. The scaled DFI of the cylindrically and spherically embossed specimens are displayed in Fig. 4. They were fabricated with high penetration depth and measured with an applied magnetic field strength H of 780 A/m. The results of the embossed flux barriers are compared to the specimen with a flux barrier fabricated as cutout (Fig. 4c). The lowest scaled DFI-signals are measured at the edge of the cylindrical, in the center of the spherical embossing and on the right and left side of the cutout. The scaled DFI-signal is strongly increased above and below the cylindrical embossing and the cutout. This effect slightly occurs in the spherically embossed specimen.

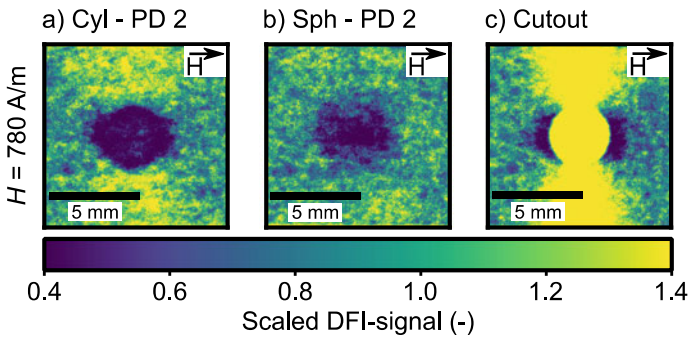

Fig. 4 Scaled DFI of **a** Cyl—PD 2 and **b** Sph—PD 2, with applied magnetic field strength H of 780 A/m. (Color figure online)

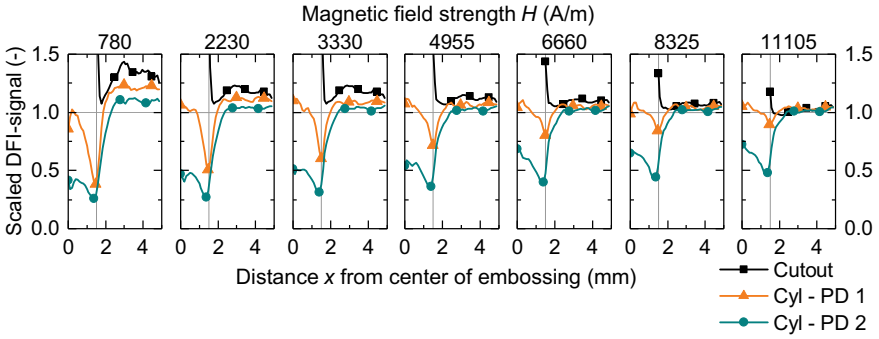

Fig. 5 Scaled DFI-signal of the cylindrically embossed specimens at two different penetration depths compared to a specimen with a cutout (diameter 3.00 mm) as flux barrier measured at different magnetic field strengths H. (Color figure online)

For further evaluation, the scaled DFI-signal progression of the cylindrically embossed specimen is compared to the specimen with cutout (Fig. 5). Close to the cutting line, the magnetic material behavior of this specimen is affected by shear cutting [15]. This causes an increased amount of magnetic domains close to the cutout. For the cutout flux barrier, the magnetic domain density in the remaining material is slightly decreased when compared to the reference material because the same magnetic flux is concentrated to a smaller cross section. Hence, the applied magnetic field strength has a higher impact on the remaining material.

The cylindrically embossed flux barriers show a scaled DFI-signal slightly higher than 1 outside of the embossing, similar to the cutout. At the edge of the embossing, the scaled DFI-signal is characterized by a minimum, which is lower for higher penetration depths. Embossing Cyl—PD 1 has a scaled DFI-signal above 1 in the center of embossing. In contrast, the scaled DFI-signal of embossing Cyl—PD 2 is only slightly increased from the edge to the center of embossing. The difference of minimal value of the scaled DFI-signal from small to high magnetization is approximately 0.5 for Cyl—PD 1 and lower than 0.25 for embossing Cyl—PD 2. Thus, the embossed flux barrier Cyl—PD 2 is more stable and has still an effect of flux guidance at high magnetic field strengths. Deductively, the cylindrically embossed flux barrier has a higher impact on the magnetic domain density in the center of the embossing, if the grade of deformation is sufficient. This is achieved with embossing Cyl—PD 2.

The minimal scaled DFI-signal of the spherically embossed specimen is located in the embossing's center and increases up to a distance of 3 mm, see Fig. 6. The scaled DFI-signals for the whole distance from the center of embossing is lower than 1, consequently more magnetic domains are measured in the evaluated volume than in the reference specimen, except of the measurement results at a magnetic field strength of 780 A/m. Therefore, the magnetic material behavior of the spherically embossed specimen is degraded in the full evaluated volume. The scaled DFI-signal is slightly lower for the specimen fabricated with higher penetration depth. The minimal

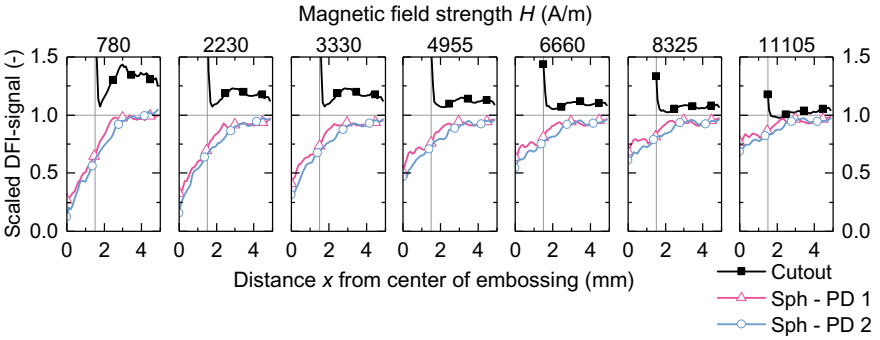

Fig. 6 Scaled DFI-signal of the spherically embossed specimens at two different penetration depths compared to a specimen with a cutout (diameter 3.00 mm) as flux barrier measured at different magnetic field strengths H. (Color figure online)

scaled DFI-signal at the highest magnetization compared to the lowest magnetization increases by 0.5. Due to that, the influence of spherical embossings on the magnetic domain structure is more dependent on the magnetization compared to Cyl—PD 2.

In summary, the difference between Sph—PD 1 and Sph—PD 2 is far smaller than between the cylindrical embossings. The spherically embossed specimens have the highest amount of magnetic domains in the embossing's center. For cylindrical embossings the minimal scaled DFI-signal is located at distance 1.5 mm. The magnetic material behavior of the spherically embossed specimens is additively deteriorated outside the embossed part. The effect on the magnetic domain structure decreases for higher magnetizations. For the two penetration depths, the difference of the scaled DFI-signal progression is small. A concentrated effect on the magnetic material behavior in the area of embossing is detected for the cylindrically embossed flux barriers. Outside the embossing less magnetic domains are measured compared to the reference. At increased magnetic field strength, the effect of the embossing Cyl—PD 2 on the magnetic domain structure is still considerably high in contrast to the other specimens.

3.3 Global Magnetic Material Behavior

The global magnetic properties, iron loss, magnetic permeability and hysteresis loop shape, of the embossed specimen and the reference material were analyzed with single sheet tests. Because the embossing has the highest impact on the permeability, this is the eligible parameter to illustrate the effect of embossed magnetic flux barriers. The comparison to the reference material shows the deterioration of the magnetic properties by the embossings.

In Fig. 7, the magnetic permeabilities of the embossed specimens fabricated with small penetration depth are compared to a higher penetration depth. The embossing

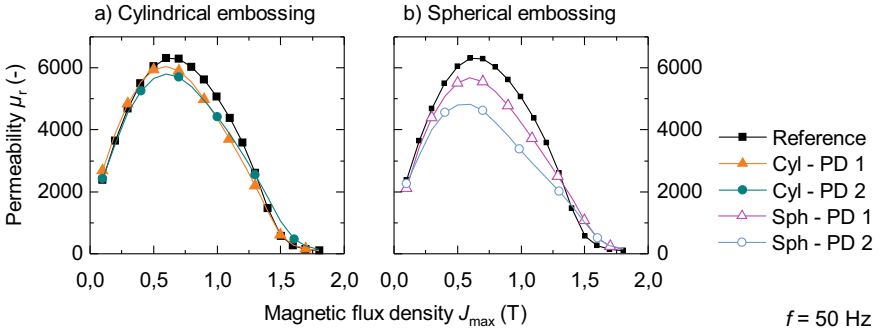

Fig. 7 Magnetic permeability μ_r for **a** cylindrically embossed and **b** spherically embossed specimen, fabricated with two different penetration depths compared to a reference material. (Color figure online)

of flux barriers reduces the permeability of electrical steel compared to the reference material. A cylindrical embossing with a penetration depth of 36 µm has a slightly smaller magnetic material deterioration compared to the penetration depth of 240 µm for magnetic flux densities lower than 1 T. For a magnetic flux density above 1.3 T, the permeability of Cyl—PD 2 is higher than the one of the reference material. Above 1.4 T, the permeability of Cyl—PD 1 and the reference material are approximately the same.

The permeability of spherically embossed specimens is further reduced for higher penetration depth. For magnetic flux densities above 1.3 T, the magnetic permeability of the spherically embossed electrical steel results in values higher than the ones of the reference. This effect only occurs in a comparatively small scope of magnetic flux densities but has to be analyzed in further studies.

The permeabilities of spherically and cylindrically embossed specimen are compared in Fig. 8a and Fig. 8b. For small penetration depths and low magnetization, the permeability of the spherical embossing is further reduced. At high magnetic flux densities, the cylindrically embossed specimen shows weakly increased magnetic deterioration. Figure 8b distinguishes the permeability of the different embossing geometries at penetration depth 2. Sph—PD 2 has a reduced permeability compared to the cylindrically embossed specimen.

To show the effect of embossed flux barriers, the results of Cyl—PD 2 and Sph—PD 2 are compared to a flux barrier fabricated as cutout (Fig. 8c). The permeability of Sph—PD 2 is up to 1.3 T strongly reduced compared to the specimen with cutout. Up to a magnetic flux density of 0.7 T, the permeability of the specimen with the cutout is slightly higher than the one of Cyl—PD 2. As shown in Fig. 5, the magnetic domain density of Cyl—PD 2 at the edge of embossing is higher than the one of the specimens with cutout. Hence, the embossing magnetically deteriorates an enlarged volume. For magnetic flux densities above 0.7 T, the permeability of Cyl—PD 2 is increased compared to the specimen with cutout, because the magnetic flux can partially pass the embossed flux barrier and has therefore a larger cross section. In summary, the cylindrically embossed flux barrier Cyl—PD 2 has almost the same

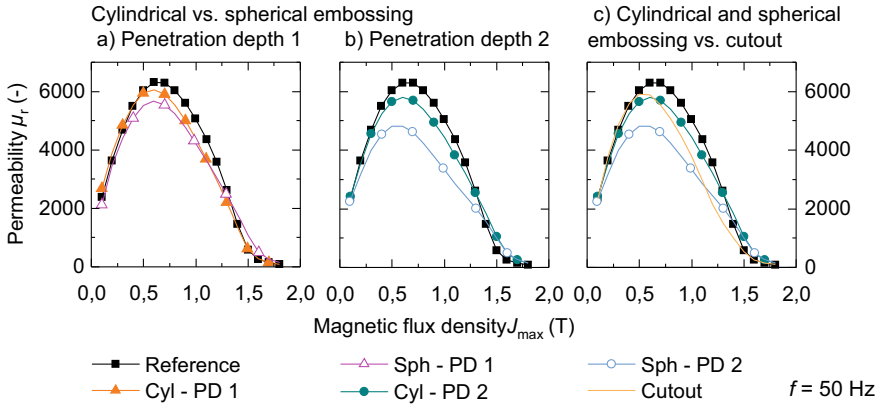

Fig. 8 Magnetic permeability μ_r of cylindrically and spherically embossed specimen fabricated with **a** penetration depth 1 and **b** with penetration depth 2 compared to reference material and **c** comparison of reference material, cylindrically embossed specimen with a penetration depth of 240 μm, spherically embossed specimen with a penetration depth of 230 μm and flux barrier manufactured as cutout. (Color figure online)

influence on the permeability of the specimen like a cutout with similar geometry, if the magnetic flux density is lower than 0.7 T.

4 Discussion

Connecting the numerical analysis with the magnetic measurements, a causal relationship between residual stress distribution and magnetic properties is apparent. For the interpretation of the averaged residual stress distribution, the knowledge of an higher impact on the magnetic material deterioration of compressive stress compared to tensile stress is essential [1]. To illustrate the relation of residual stress distribution and magnetic domain structure, the results are combined in Fig. 9. The diagrams of the nGI were measured with a magnetic field strength of 4955 A/m.

The stress peaks at distance 1.5 mm of the cylindrical embossings lead to an increased magnetic domain density (Fig. 9a). Despite small residual stress inside the embossings, the magnetic domain density is still at an increased level. The cylindrical flux barrier design results in a flux barrier shaped as circle, which adds up to a reduced magnetic flux inside the embossed circle. Inducing lower tensile residual stress (Cyl—PD 1) weakly affects the magnetic domain structure inside the embossing, especially at high magnetic flux densities. As the residual stress in- and outside of Cyl—PD 1 are a bit higher than the stress values of Cyl—PD 2, the magnetic permeability is further reduced (Fig. 7a). To conclude, strongly increased compressive residual stress in a restricted material volume has a higher impact on the magnetic

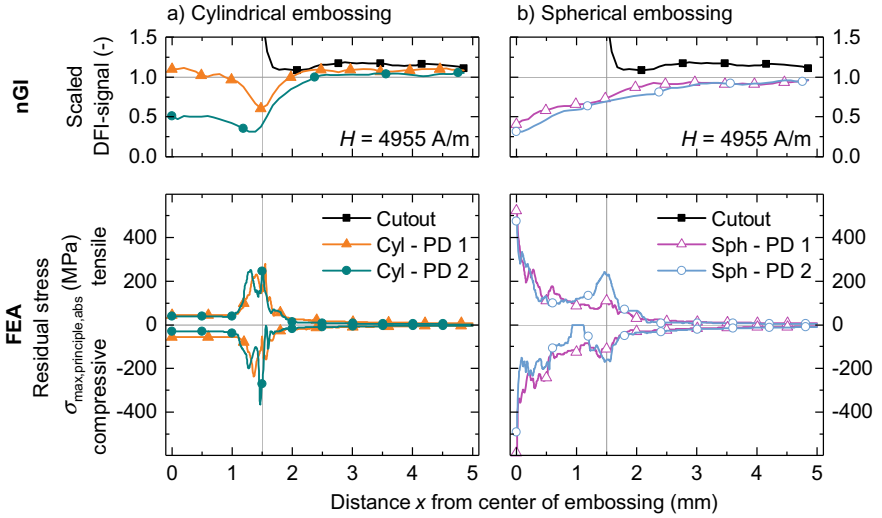

Fig. 9 Comparison of scaled DFI-signal at a magnetic field strength H of 4955 A/m and numerically analyzed residual stress distributions $\sigma_{max,principle,abs}$ of **a** cylindrical and **b** spherical embossings. (Color figure online)

flux guidance than peaks of tensile residual stress, even on the material volume in the embossing, which only has slightly increased residual stress.

In the center of the spherical embossing, the highest stress values and a maximum amount of magnetic domains arise (Fig. 9b). The residual stress outside the embossing as well as the amount of magnetic domains is increased in relation to the cylindrically embossed specimens. Hence, a larger volume is mechanically and magnetically deteriorated. Comparing both spherical embossings, the mean stress is similar (Fig. 3). The slightly increased magnetic domain density approves the reduced permeability of Sph—PD 2 (Figs. 6 and 7).

To compare the cylindrical and spherical embossings, the focus is set on penetration depth 2, because the embossings Cyl—PD 1 and Sph—PD 1 are fabricated with strongly deviating penetration depths. The residual stress and the magnetic domain density outside of the embossed geometry are increased for Sph—PD 2 (Fig. 9). The magnetic domain density in embossing Cyl—PD 2 is slightly smaller than the maximal density of Sph—PD 2 but affects a larger volume and has a stronger effect at higher magnetic field strength. Thus the embossing Sph—PD 2 has locally a higher impact on the magnetic properties but weakly influences the material outside the center of embossing. The spherical embossing deteriorates the magnetic properties up to a distance of 5 mm. These results substantiate the decreased permeability of Sph—PD 2 (Fig. 8).

Finally, Cyl—PD 2 and Sph—PD 2 are compared to a specimen with a cutout (diameter 3 mm) to analyze its effect as flux barrier Fig. 8c. The spherically embossed specimen has a considerably reduced permeability compared to the specimen with

cutout. At low magnetizations, the permeability of the cylindrically embossed specimen is slightly smaller than the permeability of the specimen with cutout. At higher magnetic flux densities, the permeability is above the one of the specimen with cutout (Fig. 8). High magnetizations allow the magnetic flux to partially pass the embossed flux barrier, which is not possible for the cutout, and the permeability is increased. In summary, focused induced residual stress has the potential to guide magnetic flux, especially at magnetic flux densities below 0.7 T for the investigated embossed specimen.

5 Conclusions

This work studied the effect of focused induced residual stress by cylindrical and spherical embossing on the magnetic flux guidance in electrical steel. With the FEA, the residual stress distribution in the specimen was numerically computed. The magnetic properties were evaluated locally by neutron grating interferometry and globally by single sheet tests. The magnetic domain structure and the resulting magnetic permeabilities were approved by the computed residual stress distribution. A large amount of compressive residual stress (Cyl—PD 2) has a sustainable effect on the magnetic domain structure in the embossed geometry. This is achieved by cylindrical embossing. The spherical embossing led to a stress maximum in the embossing's center and higher residual stress up to a distance of 5 mm. The spherical flux barrier has no determined boundaries like the cylindrical embossing. Hence, the global magnetic properties of the spherically embossed specimen are more deteriorated than the ones of the cylindrical embossing.

Summarizing, the magnetic flux guidance by locally induced residual stress was approved, especially by the comparison to a flux barrier fabricated as cutout. Further investigations have to define optimal residual stress distributions and suitable embossing geometries for the application of focused induced residual stress as flux barrier. Furthermore, the increased permeabilities of the embossed specimen compared to the virgin reference material measured at magnetic flux densities above 1.3 T have to be analyzed.

Analysis of Influencing Factors on the Achievability of Bistable Fully Closed Shells by Semi-Analytical Modeling

Pavlo Pavliuchenko, Marco Teller, and Gerhard Hirt

Abstract Bistable fully closed shells can serve as long supporting structures that can be folded into a compact transport geometry and unfolded at the construction place. Bistability is achieved by introducing a specific distribution of residual stresses through the thickness of the shell, e.g., by incremental die-bending. In order to find a suitable bending radii combination a semi-analytical model was developed and experimentally validated for the steel 1.1274 in previous research. Nevertheless, minor deviations have occurred in the prediction of final curvatures of the different stable geometries and it is still unclear to what extent other influencing variables such as shell thickness or material properties influence the achievability of fully closed bistable shells. Therefore, in this paper, an enhancement and generalization of the existing semi-analytical model for different steels is described and the extended model is used for a comprehensive analysis of the influence of different variables on bistability and final shell geometries.

Keywords Bistability · Residual stress · Sheet metal

1 Introduction

Deployable structures can be defined as structures that have two main stable states, namely, a compact and a deployed geometry [1]. The compact state is mainly used for transportation and therefore should occupy the smallest possible volume. Additionally, a housing is necessary to keep the structure in the compact state. In contrast, bistable structures are deployable structures that have stable geometries in both states [1]. Such structures could be produced from metallic thin shells with high yield strength by introducing a specific residual stress distribution over the shell thickness [2]. The general production route of bistable metallic shells was described in [3] and consists of two sequential plastic bending steps in opposite directions, along two orthogonal axes (see Fig. 1). The particular residual stress distribution over the

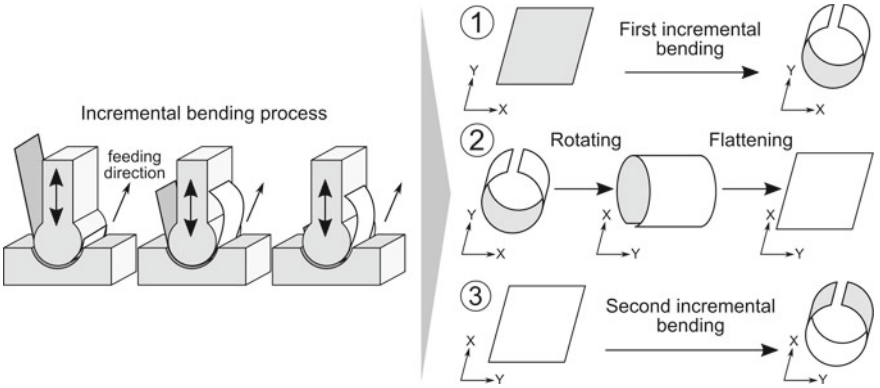

Fig. 1 Scheme of the production process of bistable shells [3]

shell thickness, introduced during the bending process, provides two stable states, as shown in Fig. 2, where X- and Y-axis represent the longitudinal and transverse directions. The Z-axis represents the thickness of the shell and is not shown in the figure, since due to the small thickness the stresses in this direction are not considered.

The analytical models for determining the effect of bistability of such structures are given by Galletly and Guest using beam [4] and shell [5] models and He [6], respectively. In [7], a semi-analytical model for the rapid determination of possible bending radius combinations was developed. This model works with some simplifications and assumptions, which are only valid for the steel 1.1274 used in [7]. In order to enable the investigation of various influencing factors and to allow for a general investigation on the influences on bistability, the model is firstly extended in this paper. Afterward, a comprehensive study of a wide range of parameters is presented. This large number of simulations can only be performed due to the fast computing time (less than 3 s per simulation) of the semi-analytical model.

2 Semi-Analytical Model

2.1 Model Extension and Generalization

The semi-analytical model for investigation of the influence of production process parameters on bistable shells for the steel 1.1274 was introduced in [3]. The production process described by this model could be represented by the sequence of following steps: first bending of the shell along X-axis; flattening of the shell; second bending of the shell along Y-axis in opposite direction; springback to the first stable state; flattening of the shell and slight bending of it along X-axis in order to check second stable state.

As already mentioned, some assumptions were made specifically for the material 1.1274 used. A main assumption is that during the first bending process only kinematic hardening and during the second bending only isotropic hardening occurs, respectively. A general combined hardening approach, where both, kinematic and isotropic hardening, contribute to the plastic behavior of the material, seems to be suitable. Hence, a combined isotropic/kinematic hardening behavior during first and second bending was introduced into the new model.

In the original model, the thickness of the shell was divided into an elastic part, where only elastic deformation occurs, and a plastic part, where plastic hardening takes place. Both parts were afterward divided into an equal number of layers. This approach could lead to different layer thickness in elastic and plastic parts of shell, which may affect the accuracy of calculations. Also, the initial division of the shell on elastic and plastic regions leads to difficulties in calculation the second bending step, where the ratio of these regions may differ in comparison with the first bending. To avoid complications, in the new model the shell thickness is initially dived into 100 layers with equal thickness and then stresses are calculated for each layer. An initial splitting into elastic and plastic areas no longer takes place.

2.2 Extended Semi-Analytical Model

Based on the semi-analytical model described in [7] several changes were made. A combined isotropic/kinematic hardening model was introduced. During plastic deformation the yield locus translates (kinematic part) as well as increases in size (isotropic part). The ratio of kinematic and isotropic hardening on the total hardening of the shell is assumed to be 0.5 [8]. Also, the shell thickness is divided by 100 layers with equal size.

In order to avoid unnecessary repetition of the work in [7], here only the most important equations and changes compared to the former model will be described.

The strain along the bending direction is described by the multiplication of shell curvature k and layer thickness z and provided in Eq. (1):

$$\varepsilon = k \cdot z \tag{1}$$

The elastic stress calculation is presented in Eq. (2):

$$\sigma = E\varepsilon_e = E\big(\varepsilon - \varepsilon_p\big), \tag{2}$$

where E is the Young's modulus of the material.

The elastic stress increment is shown in Eq. (3):

$$d\sigma = Cd\varepsilon_e, \tag{3}$$

where C is the stiffness matrix defined as

$$C = \frac{E}{1-v^2}\begin{bmatrix} 1 & v \\ v & 1 \end{bmatrix}, \tag{4}$$

where v is Poisson's ratio.

The equivalent stress is presented in Eq. (5):

$$\sigma_e = \frac{1}{\sqrt{2}}\sqrt{(\sigma - X)^T A(\sigma - X)}, \tag{5}$$

where X is the so-called back stress, and its increment could be calculated by Eq. (6):

$$dX = \frac{c}{\sigma_{y0}}(\sigma - X)dp - \gamma X dp. \tag{6}$$

The isotropic hardening plastic stress increment is calculated via Eq. (7):

$$d\sigma = C\left(I - \frac{a \cdot Ca}{a \cdot Ca + bQe^{-bp}}\right)d\varepsilon \tag{7}$$

and the kinematic hardening plastic stress increment is presented in Eq. (8):

$$d\sigma = C\left(I - \frac{a \cdot Ca}{a \cdot Ca - \left(\gamma + \frac{c}{\sigma_{y0}}\right)a \cdot X + \frac{c}{\sigma_{y0}}\sigma \cdot a}\right)d\varepsilon, \tag{8}$$

where a is the normal to the yield locus, I is identity matrix and γ, c, b, Q are material flow curve constants. The weighting of the two hardening mechanisms is determined by the parameter m. The combined strain rate is presented in Eq. (9) [8]:

$$\dot{\varepsilon}_p = \dot{\varepsilon}_{pi} + \dot{\varepsilon}_{pk} = m\dot{\varepsilon}_p + (1-m)\dot{\varepsilon}_p \tag{9}$$

Combining Eqs. (7) and (8) the plastic stress increment for the combined hardening model is given by Eq. (10):

$$d\sigma = C\left(I - \frac{a \cdot Ca}{a \cdot Ca - (1-m)\left(\left(\gamma + \frac{c}{\sigma_e}\right)a \cdot X - \frac{c}{\sigma_e}\sigma \cdot a\right) + mbQe^{-mbp}}\right)d\varepsilon, \tag{10}$$

where at parameter $m = 0$ pure kinematic hardening and at $m = 1$ pure isotropic hardening occurs during the plastic deformation of the material.

When considering the stability of shell geometry after springback, it is assumed that the resulting bending moment inside the shell is equal to zero. Due to the symmetry about the mid-surface, the integrated, applied bending moment through the thickness can be calculated as

$$M = 2\int_0^{T/2} \sigma(z) z dz, \tag{11}$$

where T is the thickness of shell.

The shell geometry is considered stable if the resulting bending moment per unit length for the required axis is close to zero. Based on the study [9], the applied bending moment per unit length (M) and curvature (k) has a linear relationship during elastic unloading. The slope of this elastic recovery is given by Eq. (12):

$$\frac{M}{k} = \frac{2}{3}\frac{E(T/2)^3}{(1-\nu^2)} \tag{12}$$

As the bending moment after spring back should be zero, then the curvature after spring back, k_{sp}, can be derived from Eq. (12) as

$$k_{sp} = k_x - \frac{3(1-\nu^2)M}{2E(T/2)^3} \tag{13}$$

where k_x is the first bending curvature.

3 Materials

For the parameter studies the steels 1.1274 and 1.4310 were used. The main difference between these materials is the yield strength. The stress–strain curves and material constants are provided in Fig. 3 and Table 1, respectively. The shell thickness is 0.2 mm for both materials.

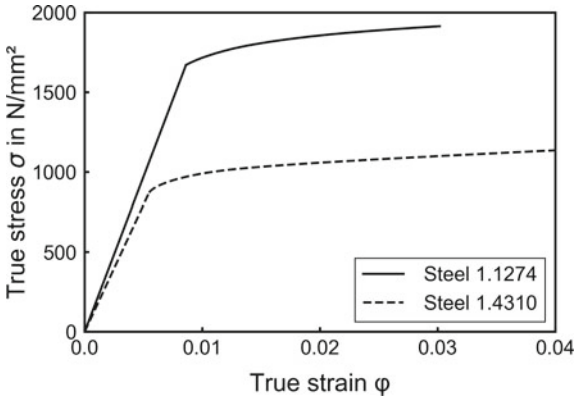

Fig. 3 Stress–strain curves of steels 1.1274 and 1.4310

Table 1 Material property constants

Steel	σ	E	c	γ	b	Q
1.1274	1690 MPa	189,450 MPa	33,933	152.576	152.576	222.403
1.4310	918 MPa	158,920 MPa	30,520	194.284	194.284	157.089

3.1 Choosing Appropriate m-value

In order to find the appropriate ratio between kinematic and isotropic parts of combined hardening the evaluation of experimental data was done. For this reason, the comparison between experimentally obtained springback shell radii after first second bending for the steel 1.1274 was carried out and the results are given in Fig. 4. It can be seen from the graph, that, for all bending radii R_{bend}, shell radius after elastic springback after second bending (bending of pre-bent shell) is always smaller than shell radius after first bending of the flat shell.

To determine which *m*-value should be used during parameter study, the comparison of springback shell radii for different *m*-value after first and second bending using semi-analytical model was carried out. The results are presented in Fig. 5. For a bend radius R_{bend} of 10 mm, the results are not presented, because a stable geometry after the second bending was not achieved. As can be seen, with increasing the isotropic part in the combined hardening (*m* approaches 1), the calculated shell radius after second springback became greater than after first bending. This difference is minimal when the pure kinematic hardening is considered during plastic deformation. It should be mentioned that even for the pure kinematic hardening the calculated shell radius after second springback is not always greater than after first bending. Therefore, the pure kinematic hardening ($m = 0$) was chosen to perform the parameter study with the help of semi-analytical model.

4 Investigation of Bistability Using the Extended Semi-Analytical Model

4.1 Influence of Bending Radii Combinations for Measured Material Properties

The influence of bending radii combination on the bistability of metallic shells is investigated for the different materials presented in Chap. 3. The shell thickness is equal to 0.2 mm. For steel 1.1274 the study was done using bending radii from 4 to 12 mm with a step size of 0.1 mm. The results are depicted in Fig. 6. For steel 1.4310 the study was done using bending radii from 4 to 17 mm with a step size of 0.1 mm. The results are depicted in Fig. 7. As can be seen, with decreasing yield strength of the material, the range of radii combinations that lead to bistability increases.

4.2 Influence of Yield Stress Disturbances on Bistability

In addition to the calculations with the material values actually measured, parameter studies were also carried out for individually varied characteristic values.

The dependency of stable geometry radii regarding fluctuations of yield strength ($\pm$ 200 MPa) of the shell is presented in Figs. 8 and 9 for the materials 1.1274 and 1.4310, respectively. The analysis was done for the bending radii combinations 6–6 mm, 7–7 mm, 8–8 mm, 9–9 mm, and 10–10 mm for steel 1.1274 and 8–8 mm, 9–9 mm, 10–10 mm, 11–11 mm, 12–12 mm for steel 1.4310, respectively.

It can be seen for both materials that with increasing bending radii the influence of yield strength fluctuation increases rapidly. This can be explained by the fact that

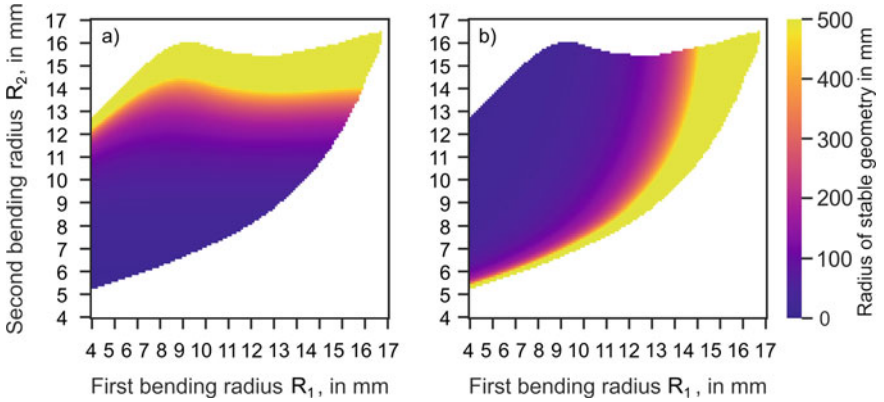

Fig. 7 Bistability and radii of **a** first and **b** second stable geometry for steel 1.4310 depending on different bending radii combinations. (Color figure online)

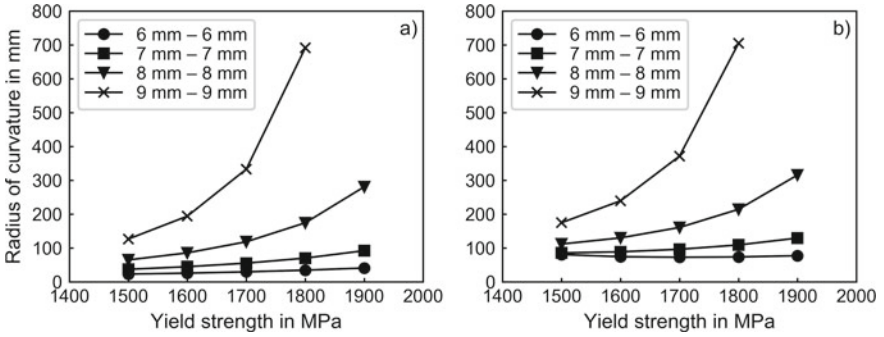

Fig. 8 Dependence of **a** first and **b** second stable state geometries on yield strength fluctuations for steel 1.1274

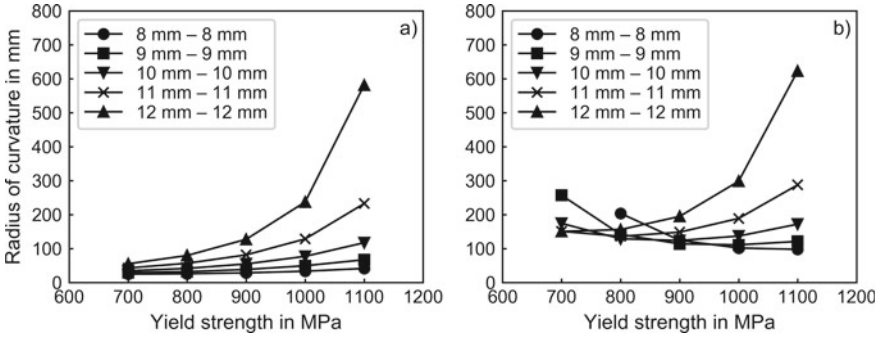

Fig. 9 Dependence of **a** first and **b** second stable state geometries on yield strength fluctuations for steel 1.4310

larger bending radius introduces smaller residual stresses in the shell, and even small changes of the yield strength lead to high deviations of stable geometry radii.

4.3 Influence of Shell Thickness Disturbances on Bistability

The dependency of stable geometry radii regarding fluctuations of the shell thickness (± 0.01 mm) is presented in Figs. 10 and 11 for the materials 1.1274 and 1.4310, respectively. The analysis was done for the same bending radii as in Chap. 4.2. The properties of the materials were taken from Table 1.

As in Chap. 4.2 it can be stated for both materials that with increasing bending radii the influence of shell thickness fluctuations increases significantly. The shell thickness has influence on the residual stress distribution as well as on the global stiffness of the shell and by that on the springback behavior.

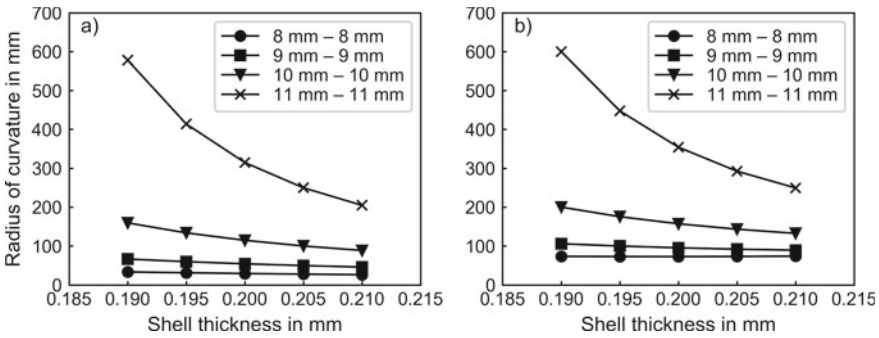

Fig. 10 Dependence of **a** first and **b** second stable state geometries on shell thickness fluctuations for steel 1.1274

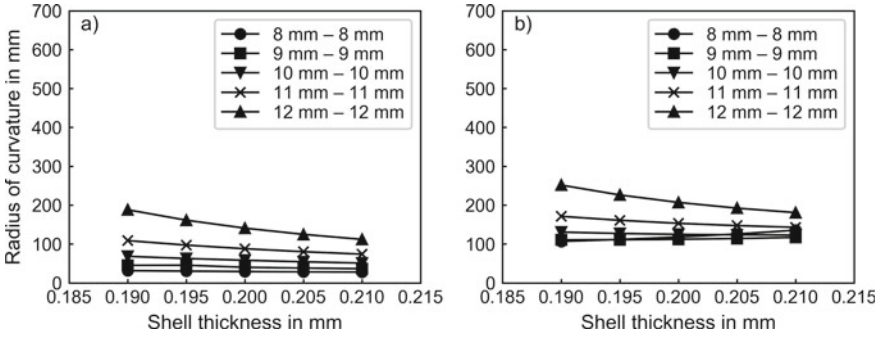

Fig. 11 Dependence of **a** first and **b** second stable state geometries on shell thickness fluctuations for steel 1.4310

5 Conclusions

The analysis of influences of production parameters as well as fluctuation of material properties on bistability of metallic shells was performed via a combined isotropic/kinematic hardening model.

The following conclusions can be made for the variation of the bending radii combination:

- Increasing of the first bending radius at a constant second bending radius leads to an increasing first stable geometry radius as well as a decreasing second stable geometry radius.
- Increasing of the second bending radius at constant first one has the opposite effect.
- Reducing the yield strength of the material increases the number of possible bending radii combinations that lead to bistability.
- Also smaller yield strength of the material allows for obtaining the bistable properties of the metallic shell by bending around higher bending radii, which reduces the number of required incremental bending operations.

  The analysis of the influence of the yield strength fluctuations provides the following conclusions:
- Increasing of the yield stress of the shell while keeping other parameters constant (Young's modulus, shell thickness, bending radii combination) leads to an increase of the radii of both stable geometries for steel 1.1274.
- Nevertheless, the influence of the yield strength fluctuation on the second stable geometry is not so pronounced for steel 1.4310. For small bending radii (8 mm – 8 mm and 9 mm – 9 mm) the second stable geometry decreases with increase of yield strength. For higher bending radii combinations the radius of second stable geometry increases with an increase of the yield strength.
- Nonetheless, the influence of yield strength fluctuation is significantly higher with increase of the bending radii value. The larger the bending radius, the greater the deviation of the stable geometry.

  From the investigation of the shell thickness fluctuations the following conclusions are made:
- The increase of the shell thickness while keeping constant other parameters (Young's modulus, yield strength, bending radii combination) leads to a decrease of the radii of the first and second stable geometry for steel 1.1274.
- Nevertheless, for steel 1.4310 the effect of thickness fluctuations on the radius of second stable geometry is not so straightforward. For the small bending radii (8 mm – 8 mm and 9 mm – 9 mm) the second stable geometry increases with higher thickness. For higher bending radii combinations, the second stable geometry radius starts to decrease with increase of the shell thickness.
- The fluctuation of the shell thickness has much more noticeable effect on the stable state geometries at higher bending radii combinations.

Overall, the new model allows the estimation and calculation of the influence of different sheel and material properties. This allows even tighter requirements to be placed on the semi-finished product used and deviations between experiments (as shown in [3, 4]) and the simulations can be better isolated. This enables the reliable production of bistable shells.

Influence of Shear Cutting Process Parameters on the Residual Stress State and the Fatigue Strength of Gears

Daniel Müller, Jens Stahl, Isabella Pätzold, Roland Golle, Thomas Tobie, Wolfram Volk, and Karsten Stahl

Abstract Shear cutting is used for manufacturing various parts ranging from, e.g. simple washers to complex gears. The latter are typically subjected to cyclic loading and fail foremost due to fatigue damages. Hereby, the part's lifetime is mainly determined by the geometry, the applied load, the material, the hardness, the roughness, and the residual stress state. While numerous research works deal with the influence of the process parameters on the hardness and the part's geometry, the influence of the process parameters on the residual stress state and on the resulting fatigue strength has not been investigated in detail, yet. In an earlier publication, suitable shear cutting techniques, which allow achieving a high amount of clean cut and a favorable residual stress state were compared. In this paper, the influence of the process parameters on the residual stress state and the resulting bending fatigue strength are addressed. To simulate the bending stress occurring in the tooth root, C-shaped specimens were manufactured by different blanking techniques. The die clearance and punch and die edge radii were varied with these blanking techniques. After measuring the cut-surface geometry, the hardness distribution, and the surface roughness, the fatigue strength was determined in a pulsating test rig. By carrying out residual stress measurements using X-ray diffraction and simulating the material flow behavior using the Finite-Element Method, basic mechanisms, which are influencing the residual stress state and the resulting bending fatigue strength, were identified and will be presented and discussed in the paper.

1 Introduction

Shear cutting is one of the most important manufacturing techniques in sheet metal processing [5]. Due to this high industrial relevance, shear cutting is also an active topic in the research community. Especially, the geometry of the shear cut edge has been of interest [12]. According to [16], the die clearance, the clearance between punch and die, is an important process parameter affecting the cut-surface geometry. It is often given as the relative die clearance u_r which can be calculated by dividing the size of the clearance by the sheet metal thickness [2]. As shown by [16], a smaller die clearance leads to a higher amount of clean cut. The preparation of the punch and die edge significantly affects the cut-surface geometry. An increased burr height and a decreased clean-cut height were observed for simultaneously increased punch and die edge radii in [15]. According to [6], either the punch or the die edge should be rounded when a high amount of clean cut is desired.

In many applications where the manufactured part is subjected to cyclic loading, the fatigue strength of the shear-cut edge is of importance. The investigations by Meuerling et al. showed that edges manufactured by shear cutting with a die clearance of 6 % show a lower fatigue strength than laser-cut edges [10]. Lara et al. found that specimens manufactured with a die clearance of 6 % and sharp cutting edges show a higher fatigue strength than specimens manufactured with a bigger die clearance of 10 % with rounded cutting edges [7]. Maronne et al. found that a too big die clearance significantly reduces the fatigue strength of the shear cut edge [9]. Here, a die clearance range from 5 to 30 % was examined. A similar tendency for small die clearances can be found in [6]. Again, a smaller die clearance increased the fatigue strength of the parts manufactured of thick sheets (thickness 14mm). A beneficial effect of a v-ring was found in this publication as well.

Factors that are known to affect the fatigue strength are, among others, the material and its microstructure, the hardness [11], the part's geometry [1], the roughness [8], and the residual stresses [17]. Thus, the fatigue strength can be increased by a higher hardness, a lower roughness, and compressive residual stresses. Compressive residual stresses are utilized to improve the fatigue strength in many applications, for example, in shot-peened gears [4]. Still, the targeted use of residual stresses is scarce in shear cutting, although it has been published for additional process steps like coining [18].

With Near-Net-Shape Blanking processes (NNSBPs), a high amount of clean cut and thus a large load-bearing surface can be achieved. With these different blanking processes, different residual stresses can be induced, which was addressed in [14]. It was discovered that the sheet metal strip is commonly subjected to a compressive stress state while the blank shows a tensile stress state for most NNSBPs. This work was extended by the effect of the residual stresses on the fatigue behavior of parts manufactured by NNSBPs in [13]. Besides the beneficial effect of compressive residual stresses, the part bending during the cutting process was identified as a major influence parameter on the bending fatigue strength. While the influence of the chosen NNSBP on the residual stress state and the fatigue behavior has been discussed in these earlier works, this research focuses on the influence of the process

parameters such as punch and die edge radius as well as die clearance on the residual stress state and the resulting fatigue behavior.

The aim of this research is to increase the fatigue strength of shear cut edges by using the effect of the residual stresses induced by NNSBPs. The correlation of the part's residual stress state and the chosen NNSBP with its process parameters is investigated and discussed.

2 Experimental Setup and Test Equipment

2.1 Shear Cutting Setup

Five different Near-Net-Shape Blanking Processes are investigated: Fineblanking (FB), blanking with small die clearance and v-ring (BV), precision blanking without blank holder (PBwBH), precision blanking with blank holder (PB), and blanking with small die clearance (B). They are illustrated in Fig. 1. When changing from one NNSBP to another, only one active element is changed which allows drawing conclusions on the effect of this active element on the residual stress state of the manufactured part.

For FB and B, three different relative die clearances u_r were investigated. A die clearance of 0.5 % (30 µm) was used for all NNSBPs, as it allows to produce cut surfaces without a fracture zone. Thus, the effect of the process-induced residual stresses can be investigated without major geometry changes of the shear cut edge. Clearances smaller than 30 µm are challenging to manufacture, especially for complex industry-relevant cutting line geometries, and are therefore not investigated. To examine the influence of the formation of a fracture zone, two additional bigger die clearances of 1 % (60 µm), and 3 % (180 µm) were chosen. Two different cutting edge strategies were chosen: One with a punch edge radius of $r_S = 200\,\mu m$ and a sharp die edge $r_M < 20\,\mu m$ and one with a sharp punch edge $r_S < 20\,\mu m$ and a rounded die edge $r_M = 200\,\mu m$. The cutting edge radii were measured with a tactile surface measurement device (see Sect. 2.3) on at least four positions of each punch and die. The results are listed in Table 1.

< 20 µm	9 ± 3	12 ± 2	9 ± 1	11 ± 5	11 ± 2

The punch velocity was set to 50 mm s^{-1}, as this is a velocity typically used in industrial fineblanking and as it allows to compare the results to previous publications. A detailed description of the used tool can be found in [14]. The experiments were carried out on a Feintool HFA 3200 plus fineblanking press with a nominal press force of 3200 kN. Here, the v-ring force of 450 kN was set for the NNSBPs involving a v-ring, otherwise a blank holder force of 200 kN was chosen. The counter punch force was set to 200 kN.

2.2 Materials and Specimen Geometry

The fine-grain, hot rolled, microalloyed structural steel S355MC with a thickness of 6 mm was chosen as it is a typical steel used in fineblanking. Its chemical composition, measured with an optical emission spectrometer, is listed in Table 2.

Microsections of the investigated steel after the heat treatment are displayed in Fig. 2. Measured mechanical properties can be found in [14]. A flow curve for specimen taking out of the sheet in 0° and 90° to the rolling direction can be found together with the used extrapolation in Fig. 3a. After milling the contour illustrated

Table 2 Measured chemical composition of the sheet metal material S355MC in percentage by mass.

Alloying element	C	Mn	Si	P	S	Al_{Ges}	Nb	V	Ti

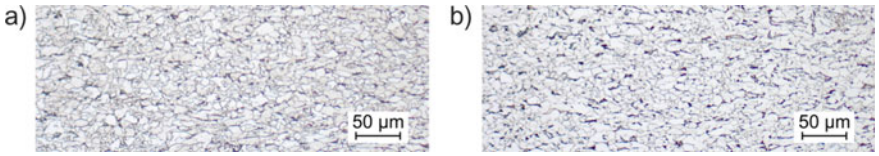

Fig. 2 Microsections of the investigated structural steel S355MC after the stress relief heat treatment taken out in (**a**) and perpendicular to the rolling direction (**b**). (Color figure online)

in Fig. 3c), the specimens were subjected to a stress relief heat treatment. This heat treatment was performed by heating up the specimens with 150 °C h^{-1}, holding the temperature at 540 °C for 15 min according to [3], followed by cooling with less than 50 °C h^{-1}. Afterwards, a hole with a diameter of 60 mm was cut by the different NNSBPs, followed by abrasive cutting to get the final geometry used for fatigue testing as shown in Fig. 1.

2.3 Measurement Techniques

Factors that are known to affect the fatigue strength are the geometry and roughness of the manufactured edge [1, 8]. Additionally, the part bending was identified as a major factor influencing the fatigue behavior in [13]. Accordingly, these part properties were measured. Finally, the fatigue testing setup is explained.

The cut surface characteristics were measured with a tactile surface measurement device with a resolution of 0.5 µm for the used arm length. The part bending was measured optically on the burr side of the part and is given as the deviation from a mean plane. Further information on the measurement methods and devices can be found in [13, 14].

The roughness of the clean cut and the fracture zone was measured using a laser scanning microscope VHK-150 manufactured by Keyence Corporation, Osaka (Japan). The part bending measurement procedure is explained in [13]. The HV 0.2 hardness distribution was examined using a LECO AMH-43 microhardness testing device. The Residual stresses were measured by X-ray diffraction with a Seifert XRD 3003 PTS System and evaluated with the $sin^2\psi$-method. A 1 mm collimator was used and is positioned in the middle of the sheet thickness with a 10 mm distance between collimator and specimen surface. For parts that show a significant fracture zone, three positions were evaluated: in the middle of the sheet thickness and additionally in the middle of the clean cut and in the middle of the fracture zone. Further information on the setup and method can be found in [14].

For the fatigue testing, a servo-hydraulic pulsating test rig was used with a special specimen holder. The C-profiles were loaded with tensile swelling loads at a test frequency of 50 Hz. The fatigue strength was determined on two different load stages, 19 kN and 16 kN, in the limited lifetime range. The lower load limit of the pulsating load is always zero (R = 0).

2.4 Finite-Element Model

A finite-element (FE) model of the NNSBPs was built in Simulia Abaqus 2018 as illustrated in Fig. 3b. This explicit, rotationally symmetric model uses CAX4R elements for all the deformable bodies (punch, die, sheet metal) while the counter punch and the blank holder were modeled as rigid bodies. The mesh in the shearing

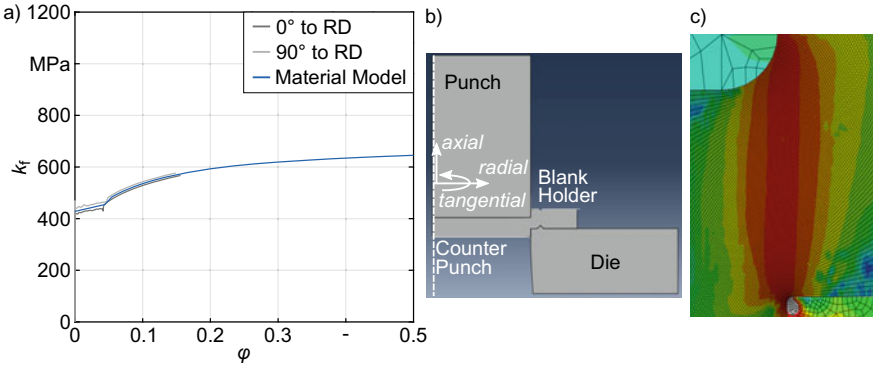

Fig. 3 Stress strain curves of the material together with the flow curve extrapolation (**a**), the simulation setup of the fineblanking process (**b**), and the mesh in the shearing zone shortly before fracture (**c**). (Color figure online)

zone shows elements with a width of 5 µm and a height of 55 µm. This high initial aspect ratio leads to almost quadratic elements shortly before fracture, as illustrated in Fig. 3. Together with the use of ALE, this helps to cope with the severe mesh distortion during the shear cutting process. Mass scaling is used to reduce the long calculation time.

3 Results and Discussion

3.1 Cut-Surface Characteristics and Part Bending

The clean-cut height and the fracture zone height are given in percent of the sheet metal thickness in Table 3. For $u_r = 0.5\,\%$ and $1\,\%$, the configuration with the sharp punch leads to a slightly higher amount of clean cut, except for FB where similar values were measured. For $u_r = 3\,\%$ this tendency changes and a much lower clean-cut height is observed for this configuration. While the specimens show no fracture zone for the small die clearance, a small amount of fracture can be observed for $u_r = 1\,\%$, and a significant amount of fracture of up to 42.3 % of the sheet thickness is observed for $u_r = 3\,\%$.

The roughness of the clean cut ranges from $Ra = 0.61\,\mu m$ to $2.1\,\mu m$. The fracture zone shows a significantly higher roughness ranging from $Ra = 6.3\,\mu m$ to $8.7\,\mu m$. As stated in [13], no correlation between roughness and the used NNSBPs with its process parameters was found.

An overview of the influence of the chosen NNSBP on the microhardness distribution was given in [13]. Thus, the influence of the die clearance and the active element edge radii on the microhardness distribution is investigated on the example

Table 3 Clean-cut height and fracture zone height (in brackets) in percent of the sheet metal thickness together with the values published in [14]

NNSBP	FB	FB	FB	BV	PBwBH	PB	B	B	B
u_r	3 %	1 %	0.5 %	0.5 %	0.5 %	0.5 %	0.5 %	1 %	3 %
$r_S =$ 200 µm; $r_M <$ 20 µm	81.3 (14.8)	93.7 (3.2)	97.6	97.0	90.3	93.2	93.7	87.7 (5.7)	63.8 (29.2)
$r_S <$ 20 µm; $r_M =$ 200 µm	67.7 (29.5)	95.2 (2.3)	97.5	97.9	91.6	94.6	94.2	90.9 (3.7)	51.9 (42.3)

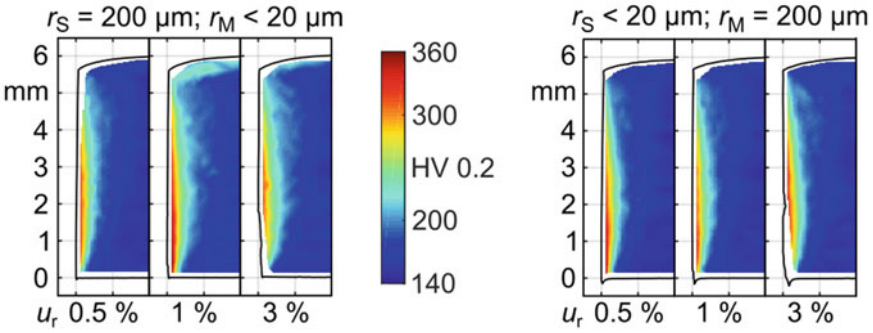

Fig. 4 Microhardness distribution of the specimens manufactured by B together with the result published in [14]. (Color figure online)

of blanking in the following. These results are displayed in Fig. 4. For all variants, a significant hardness increase toward the clean cut can be observed. This is interrupted by the fracture zone for the variants manufactured with $u_r = 3\,\%$.

The part bending is displayed in Fig. 6b. It can be observed that the parts manufactured by PBwBH show the biggest bending, followed by those manufactured by PB and B. A higher deviation is visible for the parts manufactured with $r_S = 200\,\mu m$, especially for PBwBH although this tendency can be observed for PB and B as well. For B, a bigger die clearance leads to a smaller bending. For the processes with a v-ring, i.e. FB and BV, is it so small that a comparison is not possible.

3.2 Residual Stresses

The axial and tangential residual stresses were measured at the shear cut surface of the specimen geometry respective to the coordinate system shown in Fig. 3b. The measured residual stresses for the five NNSBPs, the two different active element edge

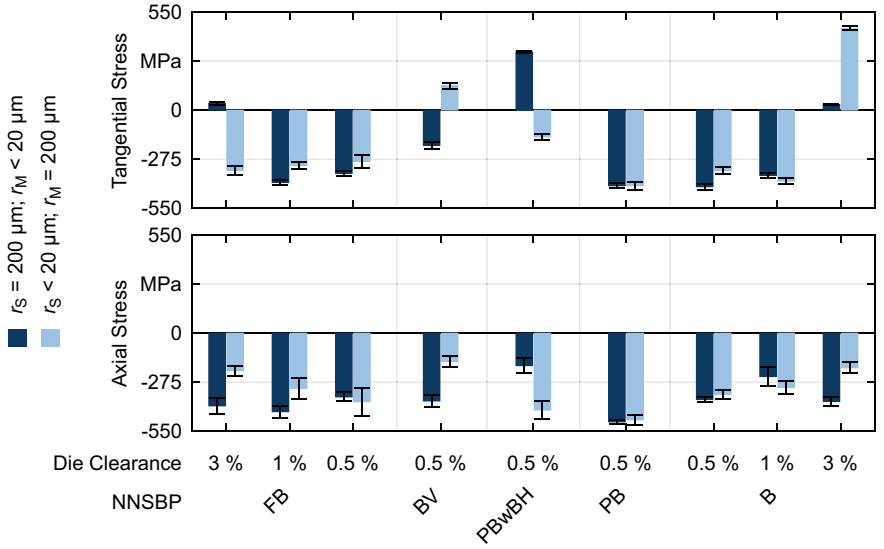

Fig. 5 Residual stresses in tangential and axial directions measured in the middle of the sheet thickness for the five NNSBPs with different die clearances and active element edge radii together with the results published in [14]. (Color figure online)

preparations, and the three die clearances are displayed in Fig. 5. For $u_r = 0.5\,\%$ and $1\,\%$, the parts manufactured by FB, PB, and B show compressive residual stresses in a tangential direction independent of the used active element edge preparation. Only BV and PBwBH show tensile stresses at $u_r = 0.5\,\%$, in the case of BV for the configuration with the sharp punch edge and for PBwBH for the configuration with the rounded punch edge. For the small die clearance of $0.5\,\%$, the configuration with the rounded punch leads to higher compressive residual stresses in the tangential direction compared to the configuration with the sharp punch edge for all the parts except those manufactured by PBwBH. For FB, $u_r = 1\,\%$ leads to higher compressive stresses for both edge preparations. For a die clearance of $3\,\%$, only the configuration with the sharp punch edge leads the even higher compressive residual stresses while the rounded punch edge leads to tensile stresses. When changing u_r from $0.5\,\%$ to $1\,\%$ for B, only the sharp punch edge leads to increased compressive residual stresses. For $u_r = 3\,\%$, the parts manufactured by B show tensile stresses in the tangential direction which are not as high for the configuration with the rounded punch.

All the produced parts show compressive residual stresses in the axial direction. These are higher for the configuration with the rounded punch edge, except for those manufactured by FB and PB with $u_r = 0.5\,\%$ where similar values were measured and for those manufactured by PBwBH and B with $u_r = 1\,\%$. For FB and the configuration with the rounded punch edge, a bigger die clearance leads to increased compressive stresses compared to the configuration with $u_r = 0.5\,\%$ while an opposing trend is observed for the configuration with the sharp punch edge. For B with a sharp punch

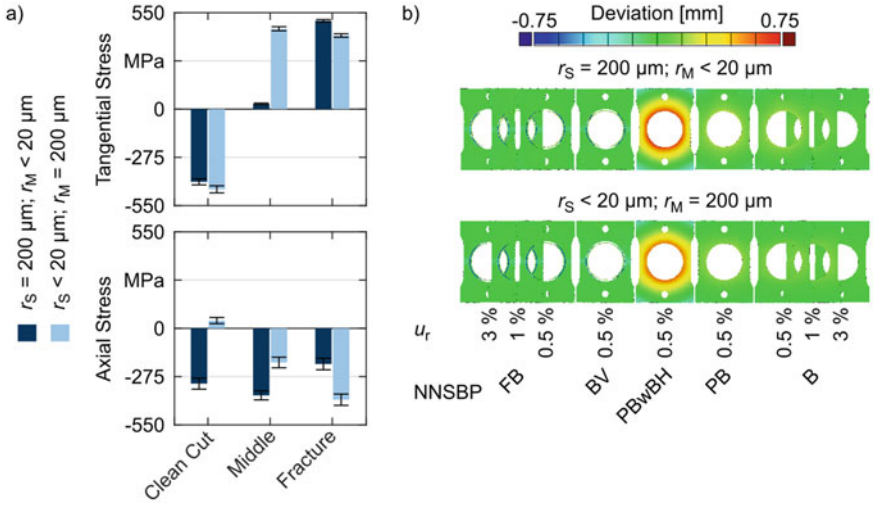

Fig. 6 Residual stresses in tangential and axial directions measured on three positions of specimen manufactured by Blanking (B) with a die clearance of 3 % with two different active element edge radii (**a**), and the surface deviation of the produced sheet metal strips together with the result published in [13] (**b**). (Color figure online)

edge, the same tendency can be observed while the configuration with the rounded punch edge shows no clear trend.

To address the influence of a fracture zone on the residual stress state, additional measurements were carried out on the strips produced by B with a die clearance of 3 % for both active element edge preparations. The first measurement position is in the middle of the clean cut, the second in the middle of the sheet thickness, and the third in the fracture zone. The results are displayed in Fig. 6a. It is visible that the fracture zone is subjected to significant tensile residual stresses. As the fracture zone reaches till the middle of the sheet thickness for the variant with the sharp punch, high tensile stresses are measured there as well.

3.3 Finite-Element Analysis

A comparison of the stresses in the tangential direction after the cutting operation but before springback calculated with the FE model is illustrated for FB in Fig. 7. It can be observed that the variant with the rounded punch edge leads to higher stresses in the sheet metal strip.

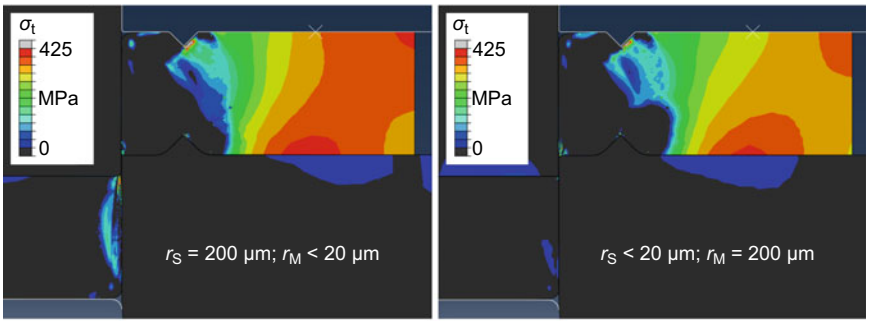

Fig. 7 Tangential stress after the fineblanking operation (but before springback) with a die clearance of 0.5 % for $r_S = 200\,\mu m$ and $r_M < 20\,\mu m$ on the left, and $r_S < 20\,\mu m$ and $r_M = 200\,\mu m$ on the right. (Color figure online)

3.4 Fatigue Behavior

The fatigue behavior of the parts is illustrated in Fig. 8. The fatigue tests are described in [13]. In Fig. 8a, a decreased number of cycles to failure is observed for all the parts manufactured with $r_S < 20\,\mu m$ compared to those manufactured with $r_S = 200\,\mu m$. Only those manufactured by PBwBH stand out. The results for the bigger die clearance of 1 %, illustrated in Fig. 8b, also show this tendency. Figure 8c shows the influence of the die clearance on the fatigue strength. Here, a bigger die clearance causes a lower number of cycles to failure. To further identify the effect of the residual stress, state parts manufactured by BV and FB were subjected to a stress relief heat treatment after the blanking operation. A comparison of those with specimens manufactured by BV without this additional stress relief heat treatment is given in Fig. 8d). This heat treatment causes a significantly lower number of cycles to failure for the high test load for the specimens manufactured by BV. It can be observed that the specimens manufactured by BV+SR and FB+SR show an almost identical fatigue strength.

3.5 Discussion of Parameters Influencing the Residual Stress State and Effect on the Fatigue Strength

3.5.1 Influence of Punch and Die Edge Radius

A rounded punch leads to material flow toward sheet metal strip which leads to higher stresses in the strip in the tangential direction, as shown by the FE model. After springback, these result in higher compressive residual stresses. This is not strictly true for variants with a fracture zone as the earlier fracture changes the material flow behavior. Also, this effect cannot be observed for PBwBH. Due to the

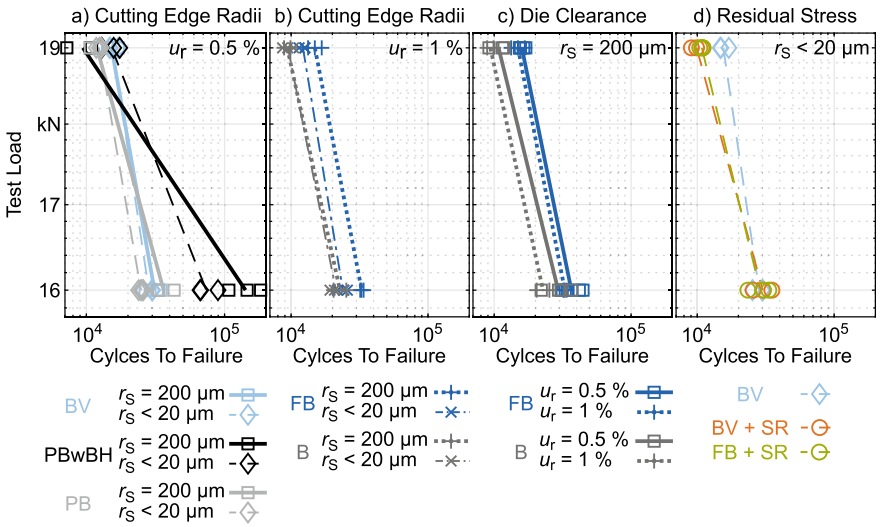

Fig. 8 Influence of the two different active element edge radii combinations ($r_S = 200\,\mu m$; $r_M < 20\,\mu m$ and $r_S < 20\,\mu m$; $r_M = 200\,\mu m$) on the fatigue strength for $u_r = 0.5\,\%$ (**a**), and $u_r = 1\,\%$ (**b**). Influence of the die clearance on the fatigue strength (**c**), and influence of a subsequent stress relief heat treatment (SR) together with the data published in [13]. (Color figure online)

heavy bending of the part, the tangential stress is overlayed by an additional stress from the bending springback. As the bending springback is opposed to the parts' initial bending direction, this leads to tensile stresses on the die-roll side of the sheet metal strip and to compressive stresses on the burr side. As the bending of the part manufactured with a sharp punch is lower compared to the part manufactured with the rounded punch, this effect is most likely responsible for the tensile tangential residual stresses of the PBwBH configuration with the rounded punch.

Axial compressive residual stresses are measured for all the configurations in the middle of the sheet independent of the process parameters. As the material is drawn in the axial direction, which is necessary for the formation of a die roll, axial tensile stresses occur during blanking. After springback, these lead to compressive residual stresses. For $u_r = 0.5\,\%$, the axial stresses are not very sensitive regarding the active element edge preparation for FB, PB, and B. Only BV and PBwBH show different values for different edge preparations. For PBwBH, this is most likely caused by the early fracture of the blank (see [14]) which reduces axial stresses and causes smaller residual stresses after springback. The same behavior may be responsible for the differences between the parts manufactured with a rounded punch and a sharp punch for the die clearances bigger than 0.5 %.

For $u_r = 0.5\,\%$, the fatigue behavior shows the expected result: As the parts manufactured with a sharp die edge show smaller compressive residual stresses, these show a lower number of cycles to failure. The effect is also visible for the specimens subjected to a stress relief heat treatment after the blanking operation even though

the overall stress state (mean from tangential and axial stresses) is comparably low. Again, the parts manufactured by PBwBH stand out. Their behavior confirms the theory on the influence of the part bending on the fatigue behavior given in [13], which is the dominant mechanism in this case.

For u_r =1 % and 3 %, the effect of residual stresses is overlayed by the additional notch caused by the fracture zone. It should be noted that for FB with u_r = 1 % the configuration with the round punch edge still shows a higher number of cycles to failure than the one manufactured with a sharp punch edge although the fracture zone is bigger. This is caused by the significant higher residual stresses in both directions for the rounded punch edge.

3.5.2 Influence of the Die Clearance

For FB, when u_r is changed from 0.5 % to 1 %, higher compressive residual stresses are observed in tangential direction for both active element edge preparations. For B, this effect can only be observed for the configuration with the sharp punch edge while an opposing trend is observed for the rounded variant. Again, the stresses caused by the radial springback are overlayed by those caused by the bending springback. As the bending is small for the parts manufactured by FB, the radial springback mode dominates in this case. For B, the parts show a visible bending accompanied by differences in bending regarding the die clearance and the active element edge preparation. This bending seems to be responsible for this behavior of the residual stress state. Due to the occurrence of a significant amount of fracture zone, the results for a die clearance of 3 % are challenging to interpret. Still, the results from FB with u_r = 3 % show that the fracture zone is subjected to significant tensile residual stresses in the tangential direction.

Even for the bigger die clearances, the axial residual stresses are negative in the middle of the sheet. For the variant with the sharp punch edge, the residual stresses get smaller when a bigger die clearance is chosen. However, the variant with the round punch edge does not strictly show that behavior. This is most likely caused by a different material flow behavior caused by the combination die clearance and active element edge condition in the middle of the sheet. Again, the results for u_r = 3 % are challenging to interpret due to the big fracture zone.

The comparison between the parts manufactured with a u_r = 0.5 % and 1 % show the effect of the residual stresses on the fatigue strength: While the difference is small for FB, the negative effect of the fracture zone can be partly compensated by the higher compressive stresses, the parts manufactured by B show a significantly lower number of cycles to failure for u_r = 1 % as a fracture zone, and a smaller compressive stress state reduces the fatigue strength.

4 Conclusion

A rounded punch edge in combination with a sharp die edge leads to higher compressive residual stresses in the tangential direction compared to parts manufactured with a sharp punch edge and a rounded die edge. Due to the rounded punch, material flow is more likely toward the sheet metal strip, which leads to higher elastic stresses that cause higher residual stresses after springback. This is only valid for configurations without a fracture zone, i.e. for the small die clearance of 0.5 %, and without a significant part bending, i.e. all the processes except PBwBH. The influence of the active element edge radii on the residual stress state is small compared to the influence of the chosen NNSBP.

A fracture zone should be avoided as the rough fracture does not only lead to stress concentrations but also shows significant tensile residual stresses. These effects significantly reduce the parts' fatigue strength. Therefore, a die clearance of 0.5 % should be chosen instead of a die clearance of 1 % or 3 %.

The results lead to the conclusion that the residual stress state of the manufactured parts can be explained by a bending springback, a radial springback, and an axial springback. Furthermore, the residual stresses can be adjusted by the process parameters and may be used for an improved fatigue behavior. As the fatigue strength is caused by a combination of the material properties, the surface geometry and the residual stress state, all of these factors should be considered to achieve a long part life under cyclic loading.

Residual Stresses in Hot Bulk Formed Parts—A Phenomenological Approach for the Austenite-to-Martensite Phase Transformation

S. Uebing, D. Brands, L. Scheunemann, C. Kock, H. Wester, B.-A. Behrens, and J. Schröder

Abstract In production engineering, current research focuses on the induction of targeted residual stress states in components in order to improve their properties rather than follow the usual path of minimizing residual stresses to prevent failure. In this contribution, a focus is laid on the investigation of the subsequent cooling process of hot bulk formed parts. Such cooling of a component leads to a microscopic phase transformation, which has to be considered in order to compute residual stresses inside the material. A numerical approach based on a phenomenological macroscopic material model is presented to depict the related stress evolution.

1 Introduction

The adjustment of targeted residual stress states in component production has become more and more the focus of research in recent years. After being considered unfavorable for a long time, residual stresses shall now be used to positively influence component properties such as wear resistance or strength. In general, residual stresses are defined as stresses, which exist in closed systems in the absence of outer forces or moments and fulfill mechanical equilibrium. Often a classification is made following [1–4], i.e., residual stresses are differentiated according to the scale on which they act. Residual stress of the first type, which are also called macroscopic, refer to a certain macroscopic section of the component as average over some grains. They are most important with respect to the final component properties. Residual stresses of the second and third types, respectively, which are also called microscopic, refer to residual stresses in a grain or a number of atoms. Thus, they influence residual stresses of first type.

Residual stresses can be caused by, e.g., phase transformation due to cooling. Considering austenite-to-martensite phase transformation, transformation induced plasticity (TRIP) has a decisive influence on the material response. It describes the occurrence of irreversible plastic deformation although the yield stress is not exceeded. Instead, these deformations are caused by changes in the atomic lattice, which may be associated with a change in volume, which was first observed by [5]. The classical numerical approach to model TRIP in steels is presented in [6], which has been extended to more than one product phase by [7].

Phenomenological material models are one possibility of numerical representation of TRIP, which directly describe the observed phenomena without taking into account their point of origin, e.g., effects occurring at a lower scale. The scientific works [8–14] deal with the interaction of TRIP with microstructural phase transformations considering mechanical, chemical, and/or thermal aspects. Thermomechanical models with a more differentiated view of different contributions, e.g., thermal, metallurgical, and applications to further inelastic simulations are presented in [15–17]. For instance, considerations on lower scales are shown in [18, 19]. Examples for experiments concerning TRIP are given in [20–22].

In this contribution, previous models, which concern the cooling of a cylindrical specimen with eccentric hole, see [23, 24], are extended by the TRIP effect based on the phenomenological material model in [8]. Therefore, this work is organized as follows. In Sect. 2, the underlying experimental process is explained and important parameters for the numerical simulation are derived. The numerical material model including TRIP effects is presented in Sect. 3. It is used to compute the residual stresses inside the component which are then compared to a previously published multiscale simulation done with a two-scale approach without TRIP [24]; see Sect. 4. A conclusion is given in Sect. 5.

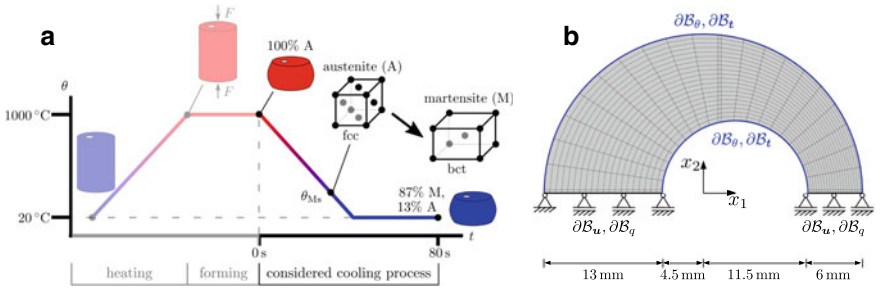

Fig. 1 **a** Schematic representation of the considered cooling process after heating and forming with austenite-to-martensite phase transformation. The considered austenite-to-martensite phase transformation goes along with a lattice shearing. **b** Geometry of 2D horizontal cross section of the cylindrical specimen with boundary definitions for finite element simulation, adopted from [23]. (Color figure online)

2 Setup of Boundary Value Problem

The cooling process of a 2D horizontal cross section taken from a cylindrical specimen with eccentric hole made from Cr-alloyed steel 100Cr6 is analyzed. Details on the experimental setup and macroscopic material simulations, which are carried out at the Institute of Forming Technology and Machines (IFUM), Leibniz University Hannover, are given in [23–26] and the process is illustrated in Fig. 1a.

The specimen is heated to above 1000 °C, then upset, and subsequently cooled in water down to room temperature. Due to the choice of material, it is purely austenitic after heating. The cooling in water results in a diffusionless phase transformation from austenite to martensite (martensitic start temperature $\theta_{\mathrm{Ms}} = 185\,^{\circ}\mathrm{C}$). At the end of the cooling process, the final volume fractions obtained from macroscopic simulations are 87% martensite and 13% austenite.

A 2D horizontal cross section of the experimentally investigated cylindrical specimen is taken into account for numerical modeling, where plane strain condition is assumed. Due to the symmetry with respect to the x_1-axis, we consider only a half of the cylindrical section; see Fig. 1b. Thus, it holds for the displacement $u_{x_2} = 0$ on $\partial\mathcal{B}_{\boldsymbol{u}}$ and for the heat flux $q_0 = 0$ on $\partial\mathcal{B}_{\boldsymbol{q}}$. Furthermore, for the traction vector $\boldsymbol{t}$, it holds $\boldsymbol{t} = \boldsymbol{0}$ on $\partial\mathcal{B}_{\boldsymbol{t}}$. On the lateral surface of the considered geometry, the temperature profile during cooling is applied as boundary condition θ on $\partial\mathcal{B}_{\theta}$. The cooling route is taken from the macroscopic simulations and is illustrated as a function of the process time in Fig. 2. There, the austenitic and martensitic volume fractions are plotted in dependence of the temperature, respectively. The actual volume fraction of martensite c^{M} is computed with the temperature-dependent Koistinen-Marburger equation $c^{\mathrm{M}}(\theta) = 1 - \exp\left(-(\theta_{\mathrm{Ms}} - \theta)/\theta_{\mathrm{M0}}\right)$ with θ_{M0} as temperature-independent material parameter; see [27–29].

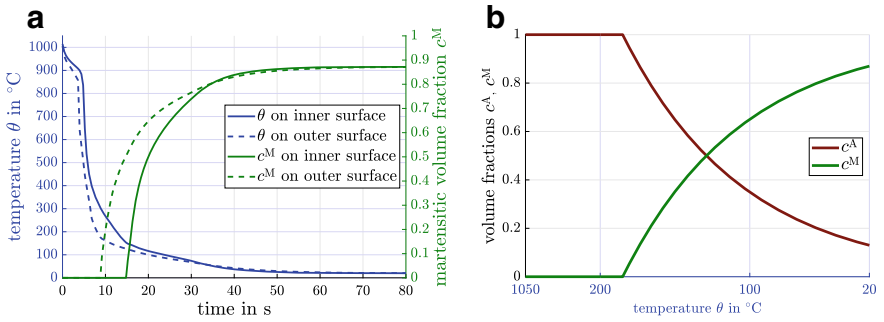

Fig. 2 **a** Temperature θ of outer and inner lateral surfaces of the cylinder over cooling time t, adopted from [24] and **b** related increase of martensitic volume fraction c^{M} and decrease of austenitc volume fraction c^{A} in consequence of the cooling, adopted from [23]. (Color figure online)

3 Phenomenological Material Modeling

In order to depict the microscopic phase transformation, in this section, a phenomenological material model is presented which bases on the work of [8]. Therein, a macroscopic model for the representation of the austenite-to-martensite phase transformation is proposed, which incorporates classical as well as transformation induced plastic effects.

3.1 Constitutive Equations

Following [8], the proposed phenomenological material model for austenite-to-martensite phase transformation bases on an additive decomposition of the total strains $\boldsymbol{\varepsilon}$ into five parts. It takes into account thermal strains $\boldsymbol{\varepsilon}^{\theta}$ and elastic strains $\boldsymbol{\varepsilon}^{\mathrm{e}}$. They are combined together with the plastic strains $\boldsymbol{\varepsilon}^{\mathrm{p}}$, transformation induced plasticity strains $\boldsymbol{\varepsilon}^{\mathrm{trip}}$, and transformation volumetric strains $\boldsymbol{\varepsilon}^{\mathrm{tv}}$, i.e., $\boldsymbol{\varepsilon} = \boldsymbol{\varepsilon}^{\mathrm{e}} + \boldsymbol{\varepsilon}^{\theta} + \boldsymbol{\varepsilon}^{\mathrm{p}} + \boldsymbol{\varepsilon}^{\mathrm{trip}} + \boldsymbol{\varepsilon}^{\mathrm{tv}}$. With material parameter K_{tv}, which describes the volumetric expansion of the atomic lattice during austenite-to-martensite phase transformation, initial and actual temperatures θ_0 and θ, respectively, and heat expansion coefficient α_{T}, the transformation volumetric strains, and thermal strains are defined as

$$\boldsymbol{\varepsilon}^{\mathrm{tv}} = \frac{1}{3} K_{\mathrm{tv}} \mathbf{1}\,, \quad \boldsymbol{\varepsilon}^{\theta} = \alpha_{\mathrm{T}}(\theta - \theta_0)\mathbf{1}\,, \tag{1}$$

respectively. Considering thermo-elasto-plasticity, the free energy function ψ is defined in dependence of the thermal-elastic strains $\boldsymbol{\varepsilon}^{\mathrm{te}} = \boldsymbol{\varepsilon}^{\mathrm{e}} + \boldsymbol{\varepsilon}^{\theta}$, the temperature θ and the strain-like internal variable e as

$$\psi(\boldsymbol{\varepsilon}^{\mathrm{te}}, \theta, e) = \frac{1}{2}\kappa\,(\mathrm{tr}\,\boldsymbol{\varepsilon}^{\mathrm{te}})^2 + \mu\|\,\mathrm{dev}\,\boldsymbol{\varepsilon}^{\mathrm{te}}\|^2 - c_\rho(\theta\ln\frac{\theta}{\theta_0} - \theta + \theta_0) - 3\alpha_{\mathrm{T}}\kappa(\theta-\theta_0)\,\mathrm{tr}\,\boldsymbol{\varepsilon}^{\mathrm{te}} + \frac{1}{2}h\,e^2 \tag{2}$$

with bulk modulus κ, shear modulus μ, and linear hardening parameter h. The abbreviation c_ρ describes the product of specific heat capacity and density. Finally, the differential equations to be solved, neglecting body forces and heat sources, are the balance of momentum $\mathrm{div}\,\boldsymbol{\sigma} = \mathbf{0}$ and the balance of energy $\rho(\dot{\psi} + \dot{\theta}\eta + \theta\dot{\eta}) - \boldsymbol{\sigma} : \dot{\boldsymbol{\varepsilon}} + \mathrm{div}\,\boldsymbol{q} = 0$. Therein, η denotes the entropy and $\boldsymbol{q}$ is the heat flux vector. Evaluating the entropy inequality $-\rho\dot{\theta} + \rho\theta\dot{\eta} + \boldsymbol{\sigma} : \dot{\boldsymbol{\varepsilon}} - \frac{1}{\theta}\,\boldsymbol{q}\cdot\mathrm{grad}\,\theta \geq 0$ yields the well-known constitutive relation for the stresses $\boldsymbol{\sigma} = \frac{\partial\psi}{\partial\boldsymbol{\varepsilon}^{\mathrm{te}}}$. With $k > 0$ as heat conduction coefficient, we assume $\boldsymbol{q} = -k\,\mathrm{grad}\,\theta$. The yield criterion following [30] is given as $\phi = \sqrt{\frac{3}{2}}\|\,\mathrm{dev}\,\boldsymbol{\sigma}\| - h\,e - Q_0(1-\exp(-\delta e)) - Y$. Therein, Q_0, δ, and Y denote a material parameter, the exponential hardening parameter, and the yield strength, respectively. The flow rules for the plastic strains and the strain-like internal variable are derived, and the flow rule for the transformation induced plasticity strains are given according to [6]

$$\dot{\boldsymbol{\varepsilon}}^{\mathrm{p}} = \sqrt{\frac{3}{2}}\,\dot{\lambda}\,\boldsymbol{n}\,, \quad \dot{e} = \dot{\lambda}\,, \quad \dot{\boldsymbol{\varepsilon}}^{\mathrm{trip}} = \frac{3}{2}K_{\mathrm{tp}}\,\mathrm{dev}\,\boldsymbol{\sigma}\,f'(c^{\mathrm{M}})\dot{c^{\mathrm{M}}} \tag{3}$$

with plastic multiplier λ, outer normal $\boldsymbol{n}$, TRIP coefficient K_{tp}, the deviatorical part of the stresses $\mathrm{dev}\,\boldsymbol{\sigma} = \boldsymbol{\sigma} - \frac{1}{3}\,\mathrm{tr}\,\boldsymbol{\sigma}\,\mathbf{1}$, and saturation function $f(c^{\mathrm{M}}) = (2-c^{\mathrm{M}})c^{\mathrm{M}}$ with $f'(c^{\mathrm{M}}) = 2(1-c^{\mathrm{M}})$.

3.2 Material Parameters and Numerical Implementation

To solve the balance laws, thermal and mechanical material parameters have to be determined. Therefore, experimental and simulative data is provided by the Institute of Forming Technologies and Machines (IFUM) at Leibniz University Hannover. A first data set gives information regarding thermal and elastic parameters, namely κ, μ, k, c_ρ, α_{T}, for each phase at certain temperatures. For the numerical simulation, a linear interpolation scheme is applied based on the actual temperature; see [23, 24]. For the plastic regime, the material parameters Y, Q_0, δ, and h are fitted to another data set. This set contains data of isothermal yield functions of each considered phase. Based on these sample points, a least-square fit using Mathematica (version 12.0), see [31], has been performed.

For the numerical simulation, the Finite Element Analysis Program (FEAP) in version 8.2, see [32], in combination with the Pardiso Solver, see [33], provided by the Intel Math Kernel Library in version 10.1.3.027 is used. The required numerical implementation of the material model bases on an integration scheme, which solves the plastic evolution equations given in Eq. (3). The quantities $\boldsymbol{\varepsilon}^{\mathrm{p}}_{n+1}$ and α_{n+1} as well as

(I) Get temperature θ_n and total strains $\boldsymbol{\varepsilon}_{n+1}$

(II) Compute martensitic volume fraction

$$c^{\mathrm{M}}_{n+1}(\theta_n) = \begin{cases} 1 - \exp\left(-\frac{\theta_{\mathrm{Ms}} - \theta_n}{\theta_{\mathrm{M0}}}\right) & \text{for } \theta_n \leq \theta_{\mathrm{Ms}} \\ 0 & \text{else} \end{cases}$$

and saturation function $f_{n+1}(c^{\mathrm{M}}_{n+1}) = (2 - c^{\mathrm{M}}_{n+1})c^{\mathrm{M}}_{n+1}$ with $f'_{n+1}(c^{\mathrm{M}}_{n+1}) = 2(1 - c^{\mathrm{M}}_{n+1})$.

For all phases, here austenite and martensite, do:

(III) Get history variable e_n, $\boldsymbol{\varepsilon}^{\mathrm{p}}_n$ and $\boldsymbol{\varepsilon}^{\mathrm{trip}}_n$

(IV) Interpolate material parameters κ, μ, k, c_ρ, α_{T}, h, δ, Y, Q_0, K_{tp}, K_{tv}, see Sec. 3.2

(V) Compute $\boldsymbol{\varepsilon}^{\mathrm{tv}}_{n+1} = \frac{1}{3}K_{\mathrm{tv}}\mathbf{1}$, $\quad \boldsymbol{\varepsilon}^{\theta}_n = \alpha_{\mathrm{T}}(\theta_n - \theta_0)\mathbf{1}$

(VI) Compute elastic trial strains $\boldsymbol{\varepsilon}^{\mathrm{e,trial}}_{n+1} = \boldsymbol{\varepsilon}_{n+1} - \boldsymbol{\varepsilon}^{\theta}_n - \boldsymbol{\varepsilon}^{\mathrm{p}}_n - \boldsymbol{\varepsilon}^{\mathrm{trip}}_n - \boldsymbol{\varepsilon}^{\mathrm{tv}}_{n+1}$
and deviatorical trial stresses $\operatorname{dev}\boldsymbol{\sigma}^{\mathrm{trial}}_{n+1} = 2\mu \operatorname{dev}\boldsymbol{\varepsilon}^{\mathrm{e,trial}}_{n+1}$
and deviatorical trial tangent $\mathbb{C}^{\mathrm{iso,trial}}_{n+1} = \frac{2\mu}{\beta}\mathbb{P}$ with $\mathbb{P} = \mathbb{I} - \frac{1}{3}\mathbf{1}\otimes\mathbf{1}$
with $\beta = 1 + 3\mu\, K_{\mathrm{tp}} f'(c^{\mathrm{M}}_{n+1})\Delta c^{\mathrm{M}}_{n+1}$

(VII) Compute yield criterion $\phi^{\mathrm{trial}}_{n+1} = \sqrt{\frac{3}{2}}\,\|\operatorname{dev}\boldsymbol{\sigma}^{\mathrm{trial}}_{n+1}\| - h\, e_n - Q_0(1 - \exp(-\delta e_n)) - Y$
if $\phi^{\mathrm{trial}}_{n+1} \leq 0$ then
$e_{n+1} = e_n$, $\boldsymbol{\varepsilon}^{\mathrm{p}}_{n+1} = \boldsymbol{\varepsilon}^{\mathrm{p}}_n$, $\boldsymbol{\varepsilon}^{\mathrm{p}}_{n+1} = \boldsymbol{\varepsilon}^{\mathrm{p}}_n$
$\operatorname{dev}\boldsymbol{\sigma}_{n+1} = \operatorname{dev}\boldsymbol{\sigma}^{\mathrm{trial}}_{n+1}$, $\mathbb{C}^{\mathrm{iso}}_{n+1} = \mathbb{C}^{\mathrm{iso,trial}}_{n+1}$, go to (VIII)
else Radial Return Algorithm

(i) Solve residuum function

$$r(\Delta\lambda) = \sqrt{\tfrac{3}{2}}\,\frac{\|\operatorname{dev}\boldsymbol{\sigma}^{\mathrm{trial}}_{n+1}\| - 2\mu\sqrt{\frac{3}{2}}\Delta\lambda}{\beta} = 0$$

(ii) Update $e_{n+1} = e_n + \Delta\lambda_{n+1}$, $\boldsymbol{\varepsilon}^{\mathrm{p}}_{n+1} = \boldsymbol{\varepsilon}^{\mathrm{p}}_n + \sqrt{\frac{3}{2}}\Delta\lambda_{n+1}\boldsymbol{n}_{n+1}$

(iii) Update stresses $\operatorname{dev}\boldsymbol{\sigma}_{n+1} = \frac{1}{\beta}\left(\operatorname{dev}\boldsymbol{\sigma}^{\mathrm{trial}}_{n+1} - 2\mu\sqrt{\frac{3}{2}}\Delta\lambda_{n+1}\boldsymbol{n}_{n+1}\right)$

(iv) Compute moduli $\mathbb{C}^{\mathrm{iso}}_{n+1} = \frac{2\mu}{\beta}\mathbb{P} - \sqrt{\frac{3}{2}}\Delta\lambda\frac{(2\mu)^2}{\beta}\frac{1}{\|\operatorname{dev}\boldsymbol{\sigma}^{\mathrm{trial}}_{n+1}\|}(\mathbb{P} - \boldsymbol{n}_{n+1}\otimes\boldsymbol{n}_{n+1})$
$+\frac{3}{2}\left(\frac{2\mu}{\beta}\right)^2\frac{1}{f}\boldsymbol{n}_{n+1}\otimes\boldsymbol{n}_{n+1}$ with Jacobian $J(\Delta\lambda) = \partial r(\Delta\lambda)/\partial\Delta\lambda$

(VIII) Update TRIP strains $\boldsymbol{\varepsilon}^{\mathrm{trip}}_{n+1} = \boldsymbol{\varepsilon}^{\mathrm{trip}}_n + \frac{3}{2}K_{\mathrm{tp}}\operatorname{dev}\boldsymbol{\sigma}_{n+1}f'_{n+1}(c^{\mathrm{M}}_{n+1})\Delta c^{\mathrm{M}}_{n+1}$

(IX) Add volumetric stresses $\boldsymbol{\sigma}_{n+1} = \operatorname{dev}\boldsymbol{\sigma}_{n+1} + \kappa\,\mathrm{tr}\,\boldsymbol{\varepsilon}^{\mathrm{e}}_{n+1}\mathbf{1}$
and volumetric tangent $\mathbb{C}_{n+1} = \mathbb{C}^{\mathrm{iso}}_{n+1} + \kappa\mathbf{1}\otimes\mathbf{1}$

(X) Average stresses, tangent moduli and material parameter
$\bullet_{n+1} = (1 - c^{\mathrm{M}}_{n+1})\,\bullet^{\mathrm{A}}_{n+1} + c^{\mathrm{M}}_{n+1}\,\bullet^{\mathrm{M}}_{n+1}$ for $\bullet \in \{\boldsymbol{\sigma}, \mathbb{C}, \kappa, k, c_\rho, \alpha_{\mathrm{T}}\}$

a consistent tangent moduli $\mathbb{C}_{n+1}$ and the stresses $\boldsymbol{\sigma}_{n+1}$ are computed using a classical radial return mapping algorithm; see [30]. The individual steps are summarized in Table 1. This procedure is done for each phase, i.e., austenite and martensite, in each finite element integration point and, afterwards, the volume average of necessary quantities is computed based on the martensite volume fraction; see Equation (X) in Table 1.

4 Comparison of Tangential Stress Distribution

Macroscopic tangential residual stresses σ_{tang} with respect to the outer lateral surface are most important with respect to wear resistance or lifetime. Due to the absence of outer forces during cooling of the investigated section of the cylindrical specimen, see Fig. 1b, the occurring stresses are interpreted as residual stresses. In addition to the overall tangential stresses, phase-specific stresses can be analyzed, which are computed implicitly in the material model. Moreover, the results from the above-proposed material model are compared to the two-scale finite element simulations presented in [24]. Therein, on the microscale a randomized representation of the microstructure consisting of austenite and martensite is used. The resulting total and phase specific tangential residual stresses of both simulation models are shown in Fig. 3. In each upper row the phenomenological material model is evaluated, and in the lower rows results of the FE^2 calculation are shown. Regions in which martensite has not yet formed are not taken into account in the illustration of martensitic stresses.

Here, three prominent points of the phase transformation during cooling are investigated. After nine seconds, the phase transformation has just started on the outer lateral surface; see Fig. 3a. After 15 seconds, martensite is also formed on the inner lateral surface and in the bulk of the thin side, cf. Fig. 3b. In the bulk of the thick side, martensite is initiated last. The final state is reached after 80 seconds; see Fig. 3c.

One can see that both models yield qualitatively similar total tangential stress distributions. At first, the total tangential stresses show tensile stresses σ_{tang} due to thermal contraction. With the onset of phase transformation, these stresses are superimposed with compressive stresses due to lattice shearing from austenite to martensite. Only when the phase transformation occurs in the bulk, this changes. The evoked compressive stresses in the bulk cause tensile stresses at the outer and inner lateral surfaces. Quantitatively, it can be said that the phenomenological material model generally calculates slightly higher stress values.

The results of the phase-specific residual stresses of both models also show qualitative agreement, but differ considerably quantitatively. First, we want to consider the martensitic stresses $\sigma^{\text{M}}_{\text{tang}}$ over time. Compared to the austenitic atomic lattice, martensite exhibits a volumetric expansion of 2%. Thus, compressive stresses form in martensite with the onset of phase transformation. The largest absolute values occur in the region of the component where the phase transformation begins. After phase transformation, at the end of the cooling process, the stress distribution is almost homogeneous; see Fig. 3c. The absolute stress values of the phenomenological model presented here are several times higher than the ones computed with the two-scale approach. In the austenitic phase, after $t = 9\,\text{s}$, compressive stresses near the outer lateral surface result in the austenitic phase-specific tangential stresses $\sigma^{\text{A}}_{\text{tang}}$. This is caused by the heat flux into the bulk of the component and the associated thermal contraction. Thus, with ongoing cooling, more and more of the body shows increasing tensile stresses. Finally, the stress distribution is nearly homogeneous, whereas the values of the two-scale computation are lower, as observed in martensite.

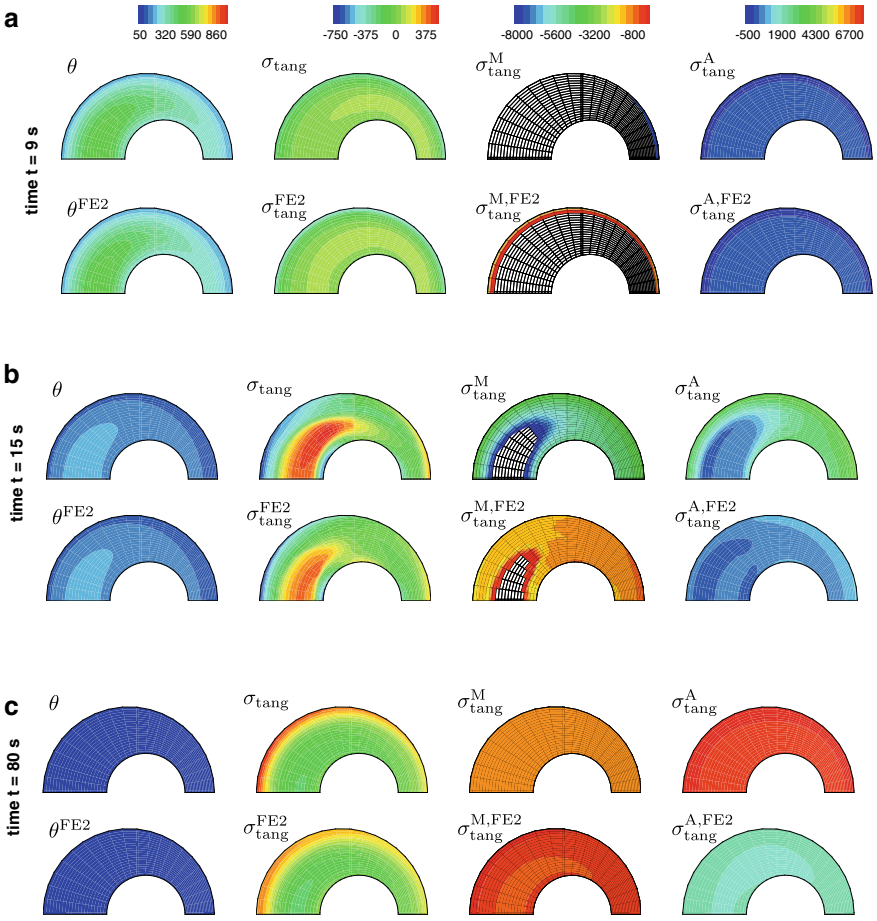

Fig. 3 Temperature distribution θ and tangential stress distribution σ_{tang} and phase-specific tangential stresses in austenite and martensite $\sigma^{\text{A}}_{\text{tang}}$, $\sigma^{\text{M}}_{\text{tang}}$, in MPa, for both computational approaches, after a) $t = 9$ s, b) $t = 15$ s, and c) $t = 80$ s. (Color figure online)

The comparison shows that the phenomenological material model is well suited to qualitatively as well as quantitatively determine the total tangential residual stress as a result of phase transformation. However, this model is not suitable for making statements about phase-specific stress distributions, which seem strongly overestimated.

By setting $K_{\text{tp}} = 0$ in the phenomenological model, one does not consider TRIP effects, as is the case in the two-scale approach. Figure 4 shows the total tangential stresses at time $t = 12$ s with and without TRIP in comparison to the FE^2 computation. It can be seen that the resulting stress values without TRIP are larger than that with TRIP, which exceed the stresses computed with the two-scale approach. In the future, validation with experiments must be done in order to assess the results.

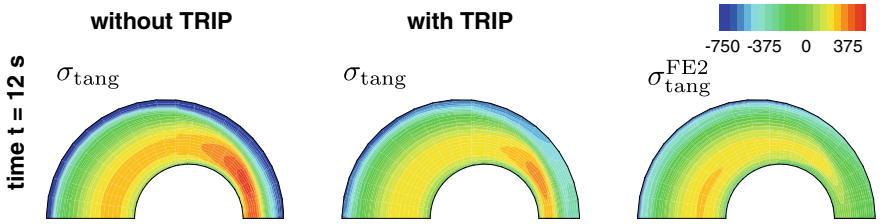

Fig. 4 Tangential stress distribution σ_{tang} computed with the phenomenological model with and without TRIP effects and tangential stresses computed with the two-scale approach $\sigma_{\mathrm{tang}}^{\mathrm{FE2}}$ in MPa after $t = 12\,\mathrm{s}$. (Color figure online)

5 Summary and Outlook

In this contribution, a phenomenological material model has been presented to numerically analyze the cooling process of a cylindrical specimen. Several physical effects such as plasticity or TRIP have been considered in order to illustrate the occurring austenite-to-martensite phase transformation which is associated with the cooling process. The results have been compared to a two-scale finite element simulation of a previous publication, see [24], which does not take into account transformation induced plasticity. It has been observed that the phenomenological approach without TRIP effects yields higher stresses than when TRIP is taken into account. However, these stresses are also higher than the tangential stresses calculated by the FE^2 approach. It is seen that microscopic stresses are strongly overestimated with the phenomenological model, such that it is inevitable to incorporate the TRIP effect in the two-scale approach to make a statement about the influence of TRIP on the phase-specific stresses. Thus, as a next step, a combination of both models should be aimed at, i.e., a two-scale finite element simulation considering also the TRIP effect.

Local Creation of Uniform Residual Stresses Into Sheet Metal Components by Means of Multiple One-Side Embossing

Stefan Walzer, Nicola Simon, Mathias Liewald, and Jens Gibmeier

Abstract In sheet metal forming, embossing provides a process for targeted improvement of the mechanical properties of sheet metal materials. The local property modification is thereby achieved by uniform residual stresses induced as a result of the one-side embossing process. For example, such a targeted induction of the residual stresses can significantly increase the fatigue strength of sheet metal components. In order to ensure this kind of component optimization in continuous operation, the induced stresses have to be uniform. In the study presented in this paper, duplex stainless steel (X2CrNiN23—4) specimens having a thickness of 1.5 mm were unilaterally embossed in order to investigate the effects of the embossing process on the component properties. The primary objective of this investigation was to find a suitable embossing strategy for generating preferably uniform stress distributions into sheet metal blanks.

Keywords Residual stresses · Sheet metal · Embossing

1 Introduction

In recent years, both industry and institutional research have been endeavoring to reduce weight and thus material demand of sheet metal products in order to save energy and resources on the one hand and to meet increasing lightweight construction requirements on the other hand. As a consequence, a huge amount of sheet metal materials conventionally used in automotive engineering nowadays

are replaced by high strength steel materials having comparatively thin sheet thicknesses [7]. However, a reduction in sheet metal thickness also leads to a reduction in fatigue strength and stiffness of the sheet metal components [1]. A common approach for extending the fatigue life of technical components is a post processing surface treatment, such as shot peening or deep rolling. It was found that in most cases, thereby induced compressive residual stresses (RS) in the surface layer counteract with external applied tensile loads in service and therefore are found beneficial with regard to the fatigue performance [2]. Regarding metal sheet components, local embossing enables an alternative approach for targeted induction of residual stresses. The embossing structure can be considered, e.g., in the shape of the deep drawing punch or die geometry, which allows for an integrated manufacturing process regarding both, the components shape and the local RS development. In this case, application of time consuming post surface treatments can be omitted.

For this reason, specific induction of RS into sheet metal components during manufacturing is the declared objective of various current research projects. The surface layer represents the most highly stressed component area for varying stress conditions. This especially applies to quasi-static inhomogeneous stresses due to torsion, bending, or notching as well as to homogeneous or inhomogeneous oscillating stresses [2].

Liewald et al. [8] investigated the effects of strain and stress dependent material properties on the formability of sheet metals and showed that most of the mechanical sheet metal properties are not constant values but should be rather considered as process parameters with dependency on effective strain or strain rate, for example. Thus, sheet metal components can be locally reinforced by inducing residual compressive stresses and hardening conditions via mechanical surface treatment processes such as shot peening or deep rolling [9]. This local increase in strength by RS offers great potential for lightweight construction in order to realize weight-optimized overall structures with simultaneously increased local load-bearing capacity.

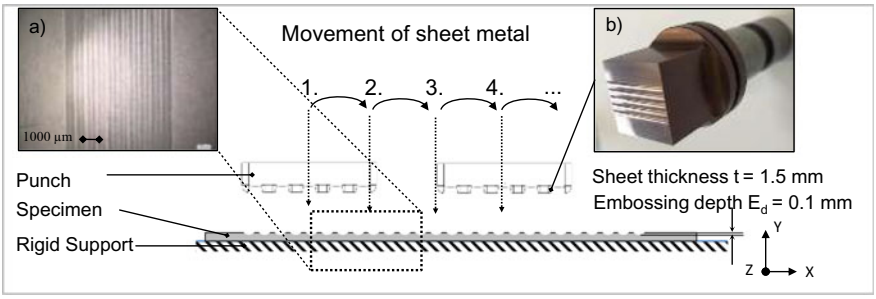

Fig. 2 Schematic embossing process showing repeated relative movement of the sheet metal stripe after each embossing step of 0.1 mm in x-direction; **a** surface structure after multiple one-side-embossing, **b** embossing punch. (Color figure online)

Sheet metal profiles as shown in Fig. 1 (left) are used in many technical applications in order to absorb forces and torques. In electro-driven vehicles, for example, such profiles are responsible for carrying and securing heavy battery packs and are constantly exposed to static and dynamic loads [3]. These superimposed static and dynamic loads may lead to reduced fatigue life of the sheet metal component. One approach to this problem consists in local embossing of the components and thus in the induction of compressive residual stresses into those areas where tensile loading stresses dominate during operation. Thereby, the tensile stresses counteract with compressive residual stresses and delay premature failure of the component. In this respect, finite-element (FE) simulations of the fatigue life of the sheet metal specimen depicted in Fig. 1 have shown that the fatigue life of the component can be extended by inducing residual compressive stresses. Figure 1 (right) shows extended fatigue life of the specimen without and with acting residual compressive stresses in the failure-critical zone of the punch radius B (see Fig. 1, left).

In the study presented in this paper, one-side embossing technology (see Fig. 2) was put forward as an alternative sheet forming manufacturing method with integrated surface treatment with respect of inducing favorable residual stresses. In order to gain more deeper knowledge of the effect and interaction of induced residual stresses, their homogeneity as well as amount of stresses, simulative, and experimental investigations were carried out on a flat sheet metal specimen.

2 Material and Experimental Embossing Method

The embossing experiments presented in this paper were performed with cold rolled duplex stainless steel sheets X2CrNiN23—4 having a sheet thickness of 1.5 mm. This duplex steel consists of ferritic (α) and austenititc phases (γ) in equal volume fraction. The materials' chemical composition is given in Table 1.

Table 1 Chemical composition of X2CrNiN23—4 in weight—% [10]

C	Cr	Ni	Mn	Co	Si	Mo	N	Fe
0.034	23.91	4.74	1.326	0.104	0.38	0.37	0.13	Balance

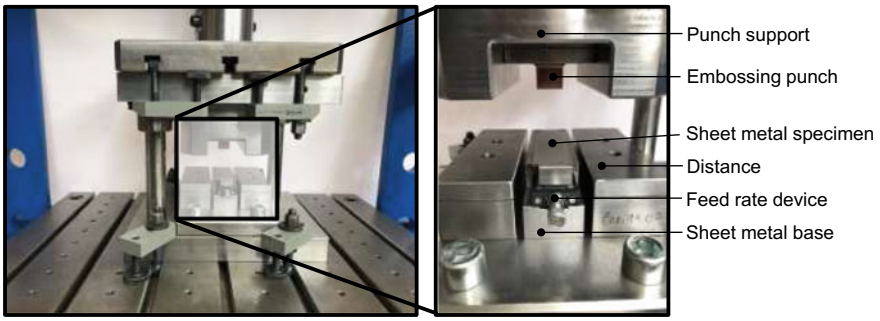

Fig. 3 Embossing tool with detailed components. (Color figure online)

The embossing experiments were carried out using a conventional hydraulic press "Metallkraft WPP 60 MVZ" and a manufactured embossing tool (see Fig. 3) under dry condition, i.e., without lubricant. The sheet metal specimens used were cut from stainless steel blanks and had a size of 100 × 30 × 1.5 mm. The punch force was set to $P_f = 25$ kN to ensure a uniform embossing depth of 0.1 mm even with multiple embossing and thus partially strain-hardened material states. The embossing depth was verified by topography measurements of the embossed structure using the confocal surface microscope "μsurf" subsequent after the embossing process.

For embossing, the sheet metal specimen is placed on the laser hardened (62 HRC) rigid sheet metal base (see Fig. 3). Afterward, the first indentation of the embossing process was performed by indenting the punch geometry (see Fig. 2b) into the sheet metal specimen via vertical movement of ram. The maximum embossing depth of 0.1 mm is limited by the punch geometry and by flat-grinded distances on both sides of the specimen support. After the first stroke, the sheet metal specimen was moved forward horizontally by a defined distance (e.g., 0.25 mm) using a precision linear feed rate device. Subsequently, the embossing process was repeated. After 8 consecutive indentations and equidistant unidirectional specimen movements, a characteristic embossed structure (see Fig. 2a) was created.

3 Experimental Residual Stress Analysis

The residual stress distribution, which was induced into the specimen's surface by the embossing process described above, has subsequently been analyzed by means of X-ray diffraction (XRD) according to the well-known $sin^2\psi$-method. Thereby,

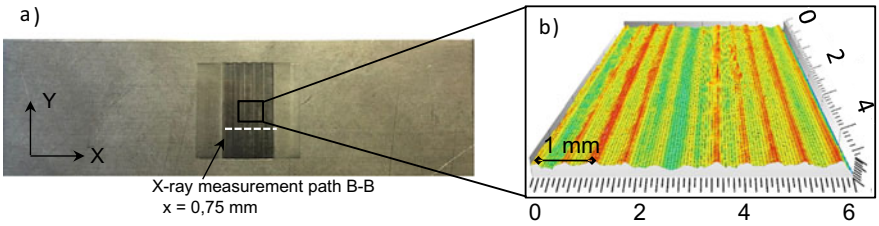

Fig. 4 **a** Measurement path B-B for X-ray residual stress analysis; **b** resulting surface roughness of the embossed area. (Color figure online)

Table 2 X-ray elastic constants for austenite {220} and ferrite {211}, based on single crystal and Eshelby-Kröner model [6]

	$s_1\{hkl\}$	$1/2s_2\{hkl\}$
Austenite {220}	−1.46 E-6 MPa^{-1}	6.16 E-6 MPa^{-1}
Ferrite {211}	−1.27 E-6 MPa^{-1}	5.82 E-6 MPa^{-1}

phase-specific residual stress components in direction X and Y have been determined for both the austenite and the ferrite phase at 12 overlapping measurement points along the measurement path given in Fig. 4.

Measurements were performed using an X-ray diffractometer with vanadium filtered Cr-Kα radiation, which allowed the analysis of {211}-ferrite and {220}-austenite diffraction lines. The spot size was defined by a pinhole collimator having a nominal diameter of 1 mm as primary aperture. On the secondary side, a 2 mm single slit and a 4 mm symmetrization slit were used for analysis of the austenite phase and the ferrite phase, respectively.

An increased number of 21 ψ-tilts from −60° to 60° was used for considering non-linear 2θ-$sin^2\psi$ distributions, as recommended for slightly textured materials. The interference lines 2θ were then determined from the measurement data using Pearson VII peak-fitting after backround subtraction. For residual stress evaluation, X-ray elastic constants have been used for austenite and ferrite, as given in Table 2.

Subsequently, the macro-residual stresses σ^I were calculated according to [4] for each measurement point, assuming a ferrite phase fraction q of 50 vol.%. In addition, the phase-specific micro-residual stresses $<\sigma^{II}>_{\alpha,\gamma}$ were determined, as given in the following equations.

$$\sigma^I = q < \sigma >_\alpha + (1-q) < \sigma >_\gamma \tag{1}$$

$$< \sigma^{II} >_{\alpha,\gamma} = < \sigma >_{\alpha,\gamma} - \sigma^I \tag{2}$$

4 Numerical Method

As already shown in Fig. 1, the embossing process examined consists of several indentions, while the sheet specimen is moved continuously below the embossing punch. These multiple and partly overlapping indentations lead to a homogeneous compressive residual stress distribution in the embossed area. In both the numerical and experimental investigations, the stress distributions after one punch indentation and after 7 steps of movements by 0.25 mm, i.e., after 8 indentations, were investigated (Table 3).

The numerical simulation of the embossing process was performed by using finite-element method. The model surfaces and the tool were designed in the CAD-System CATIA and subsequently imported into the commercial FE-software STAMPACK V7.2.2 (Fig. 5). For simulation objectives, an element number of 5 along the blank thickness of $s_0 = 1.5$ mm was chosen. The simulation model was set up with hexahedral fully integrated solid elements with size of 0.2 mm × 0.2 mm and a height of 0.3 mm to discretize the blank. In contrast, rigid shell elements were used to discretize the tools. No mass scaling was used in simulation. The anisotropic behavior of the material was taken into account according to Hill yield criterion [5] by the implementation of r-values estimated by uniaxial tensile tests. The contact modeling between the blank and tool surfaces was implemented with the Coulomb friction coefficient of $\mu = 0.12$. Explicit dynamic algorithm was used to emboss the blanks and implicit algorithm to simulate springback. Especially for the calculation of stress and strain conditions during the process and after springback, flow curves had to be specified up to the maximum strain occurring. The macroscopic flow resistance of the sheet metal material was modeled by using a stress—strain model that was analytically

Table 3 Parameter of investigated embossing configurations

Configuration	No. of indentations	Distance of indentions	Indention depth	Indention force
1	1	–	0.100 mm	250 kN
2	7	0.25 mm	0.100 mm	250 kN

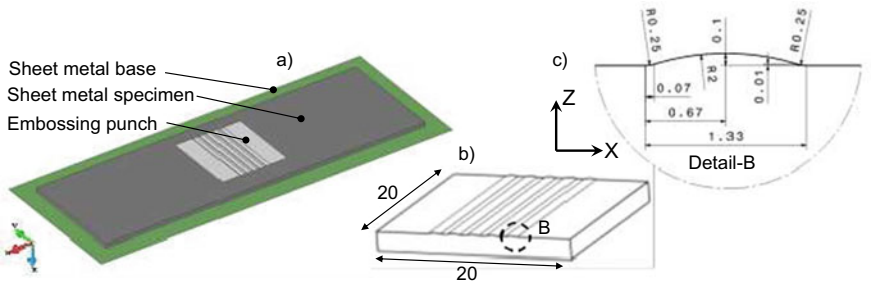

Fig. 5 **a** Fe-model, **b** geometry of embossing punch, **c** enlarged geometry of the indentation beads manufactured onto punch surface. (Color figure online)

approximated using the extrapolation method according to Ludwik-Hollomon. The material parameters used in the model were as follows: Young's modulus of 196 GPa, Poisson's ratio of 0.33, mass density of 7.850 kg/m^3, yield stress of 568 MPa, and tensile stress of 732 MPa. The stress–strain curve determined by tensile test was implemented into the model point by point without using a curve fit equation.

5 Results and Discussion

Figure 6a, b is showing the plastic strain distribution in the direction of sheet metal thickness for the configuration 1 and configuration 2. It can be seen that the plastic deformation due to the embossing process takes place in the upper half of the sheet metal blank and is almost zero on the opposite, unembossed side.

The numerically calculated surface residual stress distribution after a single indentation (see configuration 1 in Table 2) is shown in Fig. 7 on the left-hand side. Here, the upper figure presents the residual stress component σ_{xx} transverse to the orientation of the indentation lines. The lower figure illustrates the stress component σ_{yy} in direction along the indentation lines. For both stress components, negative residual stresses can be observed in the embossed area, whereas compensating tensile stresses are located in the surrounding area. For evaluation of the local surface residual stress states, σ_{xx}- and σ_{yy} are shown in increased depiction in detail for the given section A-A across the embossed area on the right-hand side of Fig. 7.

The calculated residual stress distribution shown in Fig. 7 indicates a periodic lateral RS gradient across the 5 indentation lines having maximum and minimum peaks in compressive residual stress. RS component σ_{xx} contains maxima of approx. −460 MPa, which are located in between the embossed lines. The minima within the

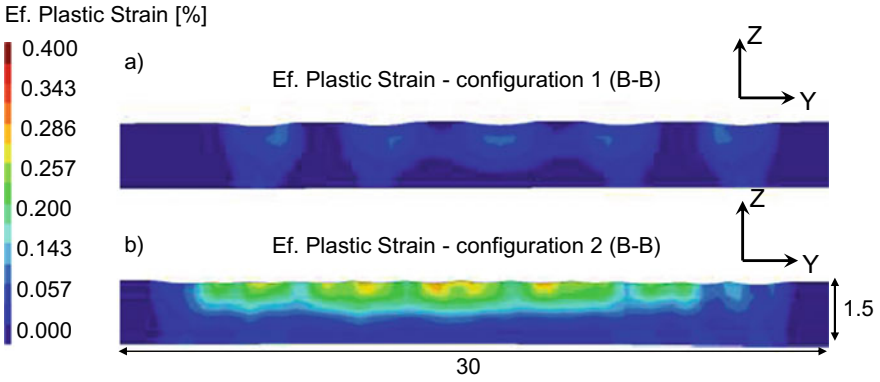

Fig. 6 **a** Effective plastic strain distribution in direction of sheet thickness of configuration 1, **b** Effective plastic strain distribution in direction of sheet thickness of configuration 2. (Color figure online)

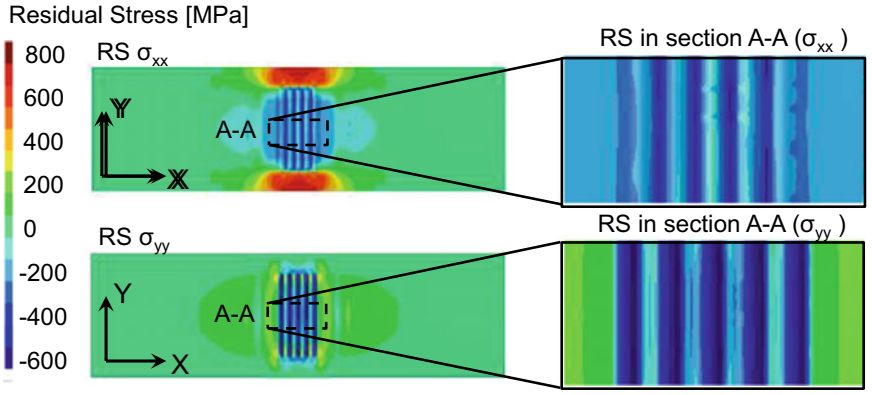

Fig. 7 Residual stresses in section A-A with embossing configuration 1 (Table 2) in σ_{xx}- and σ_{yy}-direction. (Color figure online)

embossed area of approx. −170 MPa are located at the maximum depths of the five-line indentations. This periodic residual stress distribution is even more pronounced for the stress component σ_{yy}, with maximum and minimum compressive residual stresses of −680 MPa and 0 MPa, respectively. For this stress component, however, it should be noted that the periodic residual stress distribution is inverted, since the maximum values are located at the indented lines and the minimum values at the positions in between. Hence, the simulation results obtained for configuration 1 reveal that the used embossing geometry with five linear rounded structures enables plastic material flow in direction X and hinders plastic flow in direction Y. This indicates a complex multiaxial stress state during embossing, which induces the above shown residual stress distribution after unloading.

Figure 8 shows the residual stress distribution in σ_{xx}- and σ_{yy}-direction after 7 subsequent punch indentations and equidistant, linear specimen movements (see configuration 2 in Table 2). Again, the surface residual stresses are depicted in stress mappings on the left-hand side of the Fig. 8, and its distribution in section A-A on the right hand.

After multiple embossing, an asymmetrical surface residual stress gradient has formed along path A-A in contrast to the periodic and symmetrical residual stress distribution in σ_{xx}-direction of the single indentation. In sheet movement direction, the maximum compressive residual stress values increase from approx. −460 MPa to about −550 MPa, whereas the minimum compressive residual stresses remain at about −80 MPa. Although the mean compressive residual stress value in section A-A decreases and a lateral gradient is caused by the unidirectional specimen movements, a more homogenous residual stress distribution can be achieved by the multiple embossing technique for the stress component σ_{xx} than by single embossing. This applies almost equally to the stress component σ_{yy}. Here, the highest values of compressive residual stresses in σ_{yy}-direction remain nearly unchanged at about −680 MPa. But in contrast, the minimum compressive

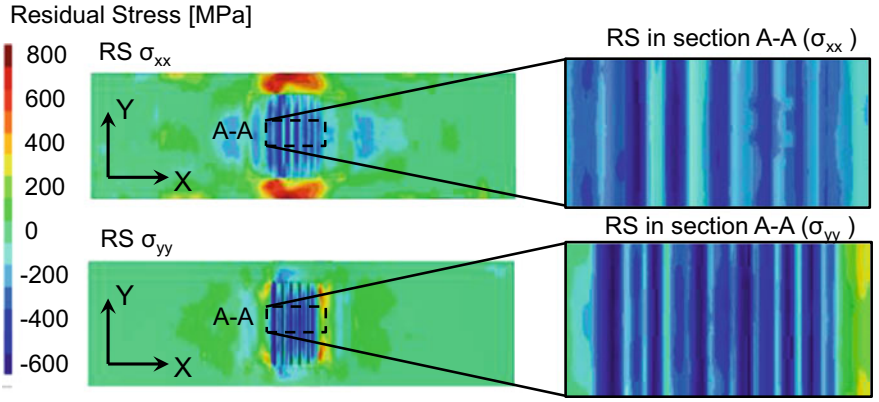

Fig. 8 Residual stresses in section A-A with embossing configuration 2 (Table 2) in σ_{xx}- and σ_{yy}-direction. (Color figure online)

residual stress values predominantly increase to −25 MPa. Consequently, in this case, multiple embossing leads to a more homogenous residual stress distribution and to higher mean compressive residual stresses compared to single embossing. Outside the embossed areas, however, concentrated tensile stresses can be seen which establish a stress balance with regard to the induced residual compressive stresses. Since such concentrated tensile stresses can impair the fatigue strength of the embossed sheet metal components, current research work is concerned with relocating these stresses to non-critical component areas.

After the numerical investigations, the simulation results of the multiple embossing were compared to the results of the experimental residual stress analysis performed by XRD. Here, phase-specific residual stresses were determined for 14 measurement points along a surface path (Fig. 4, B-B) for ferrite and austenite phase. The measuring results for residual stress component in σ_{xx}-direction and σ_{yy}-direction compared to the numerical results are shown in Fig. 9. A comparison of the numerical and experimental results requires the consideration of the measurement volume that contributes to the measured data in the diffraction experiment. Therefore, the numerically determined residual stress distribution is integrated according to size, geometry, and position of the experimental measurement points.

Figure 9 show that the XRD-measurements confirm the induction of predominantly compressive residual stresses in the embossed area for both stress directions. The phase-specific residual stresses in Fig. 10, measured for ferrite and austenite only differ of about 80 MPa in the center of the embossed area. Due to the equal volume fraction of both phases, the macro-residual stress is given by the mean value of both phase-specific stresses in each measurement point. The integrated simulation results show good conformity with the XRD results in σ_{xx}-direction and σ_{yy}-direction. The slightly decreasing trend (Fig. 9, left) of σ_{xx} in sheet movement direction already discussed above is reflected by the experimental results, as can be seen in Fig. 8 (from right to left). Nevertheless, the experimental results reveal that the numerical

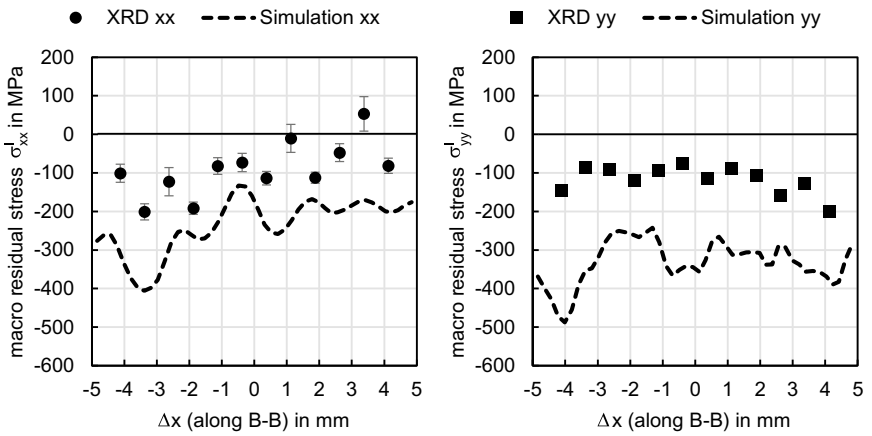

Fig. 9 Left: numerical results of macro-residual stress component σ_{xx} compared to XRD, right: numerical results of macro-residual stress component σ_{yy} compared to XRD

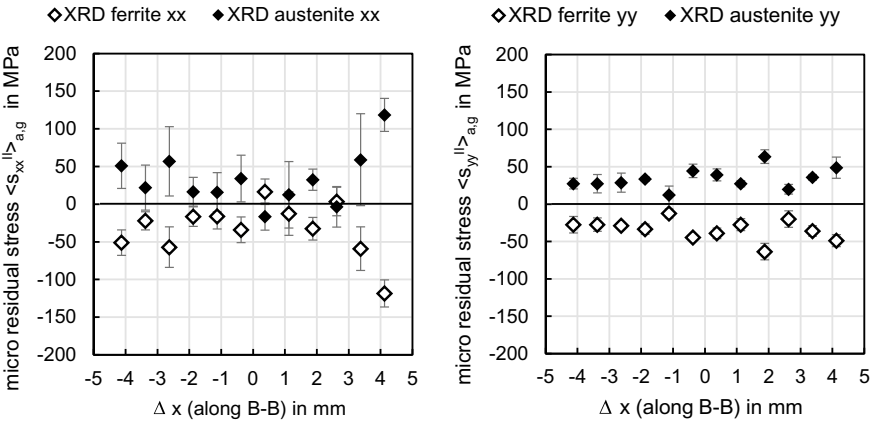

Fig. 10 Experimentally determined phase-specific micro-residual stresses along path B-B for ferrite $<\sigma^{II}>_{\alpha}$ and austenite $<\sigma^{II}>_{\gamma}$ left: micro-residual stresses $<\sigma^{II}{}_{yy}>_{\alpha,\gamma}$ in direction xx, right: micro-residual stresses $<\sigma^{II}{}_{yy}>_{\alpha,\gamma}$ in direction yy

simulation overestimates the true compressive residual stress state for σ_{xx}-direction and σ_{yy}-direction up to 200 MPa and 300 MPa, respectively. The quantitative deviation between numerical and experimental results can be explained by the used material model, since the strain rate of the real embossing process is 5 times lower compared to the tensile tests from which the plastic material behavior is approximated for the simulation. This leads to significantly higher strain hardening effects in the simulation, presumably resulting in the overestimation of the residual stresses after unloading.

In Fig. 10, the phase-specific micro-residual stresses are depicted for ferrite and austenite along the measurement path B-B. Direction xx can be referred to the rolling direction of the initial blank, which is for the given crystal structures commonly more sensitive to residual stress measurement errors in application of the $\sin^2\psi$-method. Apart from one measurement point, which is located close to the border of the embossed area, only small phase-specific micro-residual stresses of less than 60 MPa have been evaluated for both directions, xx and yy. The impact of induced micro-residual stresses on the mechanical behavior of a likewise manufactured sheet component requires further investigation.

6 Conclusion

In the study presented in this paper, the effects of a multiple one-sided embossing process on the local creation of residual stresses in stainless steel sheet material (X2CrNiN23—4) with a thickness of 1.5 mm were investigated. Therefore, a flat embossing punch having five parallel convex line structures of 0.1 mm height was used. Numerical simulation has been shown that by a single indentation, residual compressive stress maxima of up 460 MPa in σ_{xx}- and around 680 MPa in σ_{yy}-direction occur. The areas between the 5 indentation lines of the punch that have not been plastically deformed create areas in which the residual stresses remain at amounts of 0 MPa, which results in an inhomogeneous periodic stress distribution. For this reason, the strategy was pursued to move the sheet unidirectional under the punch in order to generate a high degree of overlap and homogenize the stress distribution.

After 7 subsequent indentations with step wise unidirectional movements of the specimen transverse to the line axis, an overlapping of the indentation lines was achieved. According to the numerical results, the multiple indentations lead to a reduction in the amplitude of the lateral periodic residual stress gradient and a more homogenous compressive residual stress distribution compared to the single indentation. Furthermore, it was found that the unidirectional movement results in a slightly asymmetric residual stress distribution with a decrease of the maximum compressive residual stress in sheet movement direction.

Finally, experimental residual stress analysis was performed for several measurement points along a measurement path within the embossed area by means of XRD. The experimental results not only confirmed the qualitative course of the numerical results, but also revealed that the compressive residual stress values are overestimated by the simulation. Numerical simulation has been shown that after 7 subsequent indentations, residual compressive stress maxima of up to 400 MPa in σ_{xx}- and around 500 MPa in σ_{yy}-direction occur. For this reason, future research work on the simulation of the embossing process will particularly take into account the strain rate dependency of the duplex stainless steel considered.

Rolling

Hot Ring Rolling and Cold Expanding Strengthening of Mn18Cr18N Thick-Wall Hollow Ingots

Huiqin Chen, Huihua Wen, Jinliang Wang, Fei Li, and Wenwu He

Abstract A short route manufacturing process of retaining rings was put forward, which was composed of hollow ingots manufacturing by Electro-Slag Re-melting (ESR), hot ring rolling and cold expanding strengthening. And microstructure mechanisms, deformation characteristics, and process parameters during both of hot ring rolling and cold hydraulic expanding strengthening were investigated. The results show that the multi-pass flow stresses decreased with increase of interval time. During multi-pass compression, grain refined at lower temperature of 1050 °C by static recrystallization, then grain refined at higher temperature of 1150 °C by both of dynamic and static recrystallization. Based on the influence of the contact arc length ratio on strain penetration in the wall deformation zone, the driving roller radius of 500 mm and the pressure roller radius of 130 mm were determined for the ring rolling process of φ712 mm/308 mm × 902 mm thick-wall hollow ingot. The optimum rotate velocity of the driving roller should be 0.8 rad/s. And the feeding velocity of the pressure roller should to be 1 mm/s for matching. During cold deformation, planar slip and twinning predominated at small and large deformation, respectively, to increase strength. For the hydraulic expanding process of ϕ937/672 × 1034 mm hollow forging, the optimum matching of 60° punch angle and 5 mm contact seal height can be adopted for obtaining well-shaped strengthening forgings.

Keywords Mn18Cr18N steel · Microstructure evolution · Hot ring rolling · Strain penetration · Cold expanding strengthening

1 Introduction

Mn18Cr18N, a high-nitrogen austenitic stainless steel, is widely used to manufacture retaining rings of generators due to its distinctive advantages such as high strength and toughness, non-magnetic property and excellent stress corrosion resistance [1]. The retaining ring of generators is a thick-wall heavy cylindrical forging. Its traditional manufacturing process is a typical free forging process followed by solid-solution and cold deformation strengthening [2]. The free forging process of the ring forgings consists of ingots logging, upsetting and punching, drawing and expanding with mandrels, which is a complex multiple heating deformation process for controlling. And hot cracking often occurs during the free forging process, size mixed grains often appear in forgings. A short process consisting of ESR hollow ingot manufacturing, expanding and extruding combined forming, cold expanding strengthening has been reported and investigated [3]. However, it was found that the process needs large forming loads due to extrusion deformation manner in the final forming stage. And it was also found that it is not convenient to de-mould after forming. In this paper, a simple manufacturing process of retaining rings was put forward, which is composed of hollow ingot manufacturing, hot ring rolling, and cold deformation strengthening. High-quality hollow ingots can be made by a special metallurgical technique of Electro-Slag Remelting (ESR) [4, 5], which are pure, compact, and coarse column grain structure dominated. Therefore, the hot ring rolling of ESR hollow ingots has to transfer coarse column grains into uniform refined grains by dynamic and static recrystallizaion during hot deformation [6, 7], which is followed by cold deformation for strengthening [8].

2 The Hot Ring Rolling Process of Hollow Ingots

2.1 Flow Stresses and Microstructures During Multi-pass Hot Compression of Mn18Cr18N

The multi- pass hot compression experiments with $\phi 8 \times 12$ mm samples at different pass-reduction rates and holding time were carried out on a Gleeble-1500D thermal modelling simulator for modelling the microstructure evolution during hot ring rolling of Mn18Cr18N. Figures 1 and 2 show the stress–strain curves and microstructures of single-pass and six-pass compressed samples with 60% total reduction rates at the initial heating temperature of 1150 °C and the final rolling temperature of 1050 °C and 1 s^{-1} strain rate. In the six-pass hot deformation experiments, 10, 11.1,

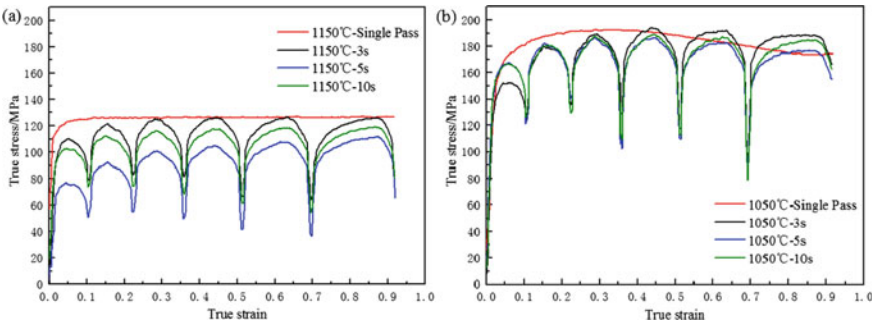

Fig. 1 The single-pass and six-pass compressive stress–strain curves at 1 s^{-1} **a** 1150 °C **b** 1050 °C. (Color figure online)

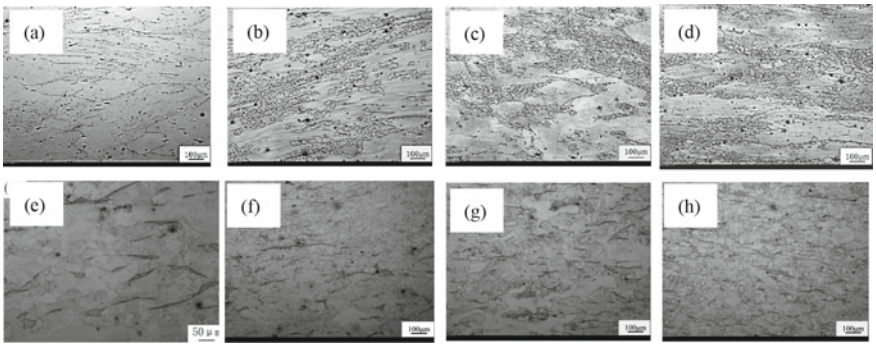

Fig. 2 Microstructures in the six-pass compressed samples at 1 s^{-1} **a** 1050 °C, 0 s **b** 1050 °C, 3 s **c** 1050 °C, 5 s **d** 1050 °C, 10 s **e** 1150 °C, 0 s **f** 1150 °C, 3 s **g** 1150 °C, 5 s **h** 1150 °C, 10 s. (Color figure online)

12.5, 14.3, 16.7, and 20% pass-reduction rates was designed to modelling the gradually increasing radial deformation at constant radial feeding velocity during ring rolling. It can be seen that the multi-pass compression flow stresses increased from 120 MPa of 1150 °C (Fig. 1a) to 180 MPa of 1050 °C (Fig. 1b) at the strain rate of 1 s^{-1}. The multi-pass compression flow stresses of Mn18Cr18N ESR ingot sample coincide with that of the single-pass flow stresses at short interval time of 3 s. It also can be seen that the multi-pass flow stresses decreased with increase of interval time. However, the lowest multi-pass flow stresses were arrived at the 5 s interval time, which may be the result of grain refinement and coarsening competition.

The corresponding microstructures of Fig. 1 were shown in Fig. 2. It can be seen that recrystallization occurred during six-pass compression. It was hardly to observe dynamic recrystallized grains in the sample compressed up to 60% total reduction rate at 1050 °C by single-pass compression (Fig. 2a). However, as shown in Fig. 2b–d, recrystallised grains can be observed, and recrystallized fraction increased slightly with increase of interval time. It suggests that static recrystallization occurred at

1050 °C during six-pass compression. On the contrary, dynamic recrystallization occurred at 1150 °C in the sample compressed up to 60% total reduction rate by single-pass compression (Fig. 2e). And that recrystallized fraction increased with increase of interval time (Fig. 2f–h). Also Grain boundary high temperature ferrite δ disappeared and dispersed distributed gradually with increase of interval time. Therefore, both of dynamic and static recrystallization occurred at 1150 °C during six-pass compression. The above microstructure evolution suggests that the rolling velocity should be slower for the thick-wall rings than that of conventional rings for obtaining the refined and uniform recrystallised grain structure.

2.2 *Strain Penetration During Ring Rolling Forming*

Strain penetration is an important issue for thick-wall ring rolling process design. When the radial reduction is too small, strain could not penetrate the ring wall, the pressure roller could be slip, which could cause that the hollow ingot could not bite into the rollers at the beginning of rolling, or the non-uniform deformation defect of fish tail occurs. The conventional strain penetration model of ring rolling is based on the finite height block drawing theory (Fig. 3a), which can be expressed as follows deduced by slip line field theory [9].

$$\frac{L}{h_a} \geq \frac{1}{8.74} \tag{1}$$

where L is the contact arc length; h_a is the average wall thickness of rings.

Figure 3b was the simulation result of Fig. 3a with the contact arc length ratio of 1, in which the symmetrical distribution of strain in the wall thickness of the ring is clearly shown as shown in the finite height block drawing model (Fig. 3a). However, the contact arc lengths of driving rollers and pressure rollers during ring rolling

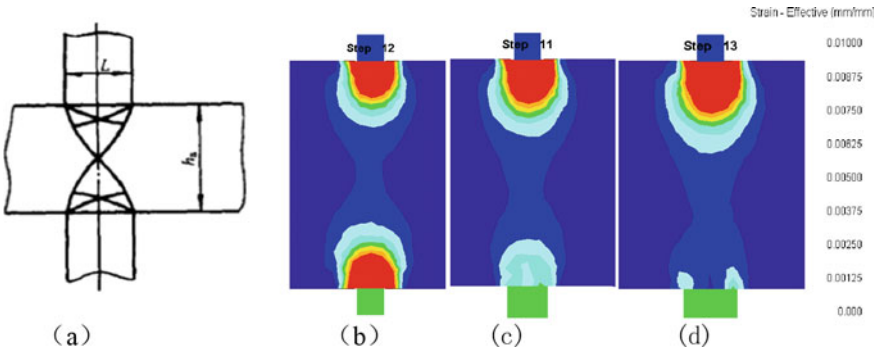

Fig. 3 Strain distribution in the rolled ring wall with different contact arc length ratio **a**, **b** the finite height block drawing model with the contact arc length ratio of 1 **c** the contact arc length ratio of 1.5 **d** the contact arc length ratio of 2. (Color figure online)

process with thick-wall hollow ingot are usually asymmetrical, in which the contact arc length ratio usually does not equal to 1. Figure 3c–d shows strain distributions in the ring wall with different contact arc length ratios. It can be seen that strain distributions are asymmetrical. And the simulation results also show that the strain penetration reduction with different contact arc lengths should be greater than that with the same contact arc length.

2.3 The Ring Rolling Forming Process with Mn18Cr18N Thick-Wall Hollow Ingot

Based on the above analysis, the ring rolling process of φ712 mm/308 mm × 902 mm thick-wall hollow ingot was analysed by numerical simulation method. First, the influence of the driving roller size and the pressure roller size on strain distribution in the deformation zone was analysed. The results show that the pressure roller size has a remarkable influence on strain distribution rather than that of the driving roller size. As shown in Fig. 4, the symmetry centre of strain distributions in the deformation zone along wall thickness varied with the pressure roller size for the constant driving roller with 500 mm radius. The symmetry centre of strain distribution coincided with that of the wall thickness only when the pressure roller radius was 130 mm. The symmetry centre of strain distribution moved towards the pressure roller with increase or decrease of the pressure roller size. The minimum contact arc length ratio also can be reached when the pressure roller radius is 130 mm, as shown in Fig. 4c. The corresponding minimum radial reduction should be 3 mm.

The rotate velocity of driving rollers and the feeding velocity of the pressure rollers also have an important impact on rolling stability and ring forgings. The greater both of the rotate velocity of driving rollers and the feeding velocity of the pressure rollers are, the greater the radial reduction of each pass is. The ring could be deformed to distort. Considering both of rolling efficiency and microstructure improvement of hollow forgings according to microstructure evolution during multi-pass compression as stated in 2.1, the optimum rotate velocity of the driving roller should be 0.8 rad/s, which corresponding the interval time was 7.85 s during rolling

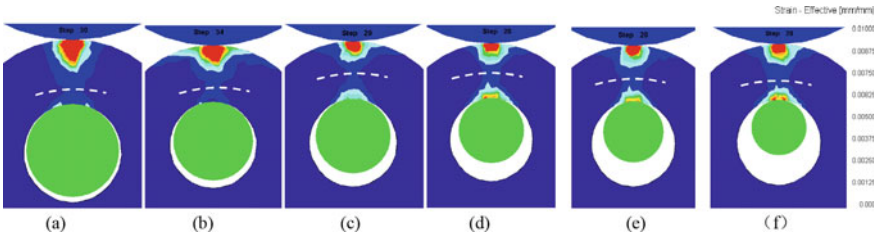

Fig. 4 Strain distributions in the strain penetration region under different radius of pressure rollers **a** 145 mm **b** 140 mm **c** 130 mm **d** 120 mm **e** 110 mm **f** 100 mm. (Color figure online)

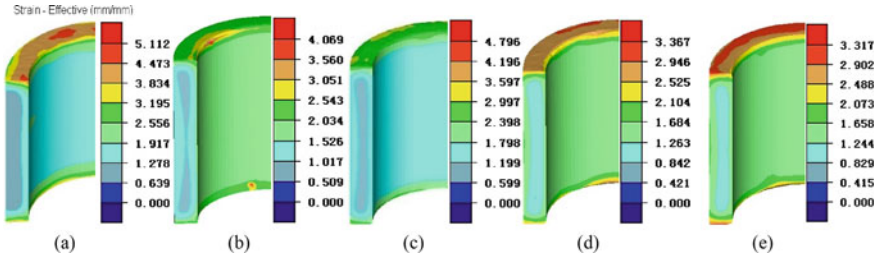

Fig. 5 Strain distribution after rolling at different feeding velocities of the pressure roll (rotation speed = 0.8 rad/s) **a** 0.5 mm/s **b** 0.7 mm/s **c** 1 mm/s **d** 1.3 mm/s **e** 1.5 mm/s. (Color figure online)

of the hollow ingot. And the feeding velocity of the pressure roller had to be 1 mm/s for matching the driving roller (Fig. 5c). Then ring forgings could be has refined uniform microstructure and well shaped.

3 The Cold Hydraulic Expanding Strengthening of Thick-Wall Hollow Forgings

3.1 The Cold Deformation Characteristics of Mn18Cr18N with High Nitrogen

Mn18Cr18N is an austenitic stainless steel without phase transformation during cooling. Strain strengthening becomes the only way to increase its strength. The steel is an f.c.c crystal structure with low stacking fault energy [10]. The deformation mechanisms at room temperature is slipping and twinning mainly. In the early stage of deformation near the yield strain of 0.04 (Fig. 6a), planar slip was predominate. With further deformation, slip is hindered by dislocation tangles, pile-ups and stacking faults, deformation resistance increases, and slip at other directions occur

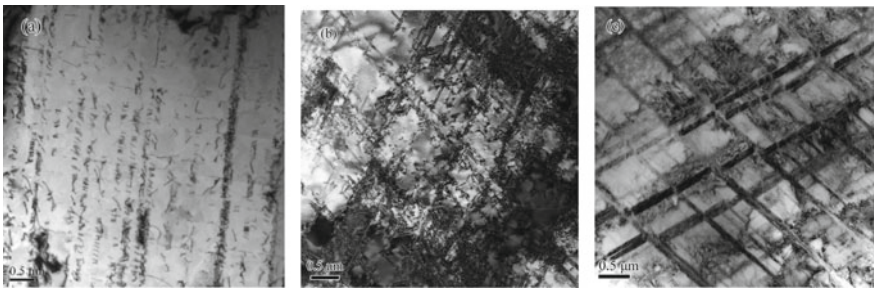

Fig. 6 TEM micrographs of samples compressed up to different reduction rates **a** 4% **b** 15% **c** 35%

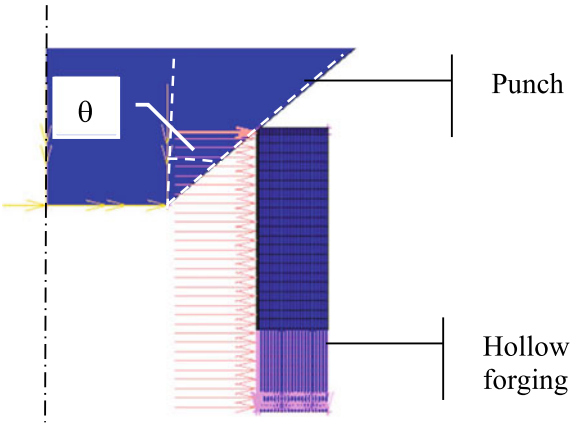

Fig. 7 The hydro-expanding FEM model. (Color figure online)

(Fig. 6b). At large deformation, twinning is activated (Fig. 6c). Although the appearance of deformation twins played an important role in deformation coordination, twin boundary was still a great hindrance for dislocation movement. Therefore, the strength of the steel could be increased with increase of deformation.

3.2 The Hydraulic Expanding Strengthening Process of Mn18Cr18N Hollow Forgings

As shown in Fig. 7, Mn18Cr18N hollow forgings can be strengthened by ultra-high pressure hydraulic expanding process, in which the hollow forgings expand along the radial direction gradually under the action of ultra-high hydraulic pressure. The punch serves only as a seal by contacting the ends of the hollow forgings. During hydraulic expanding process, the punch angle of θ and the contact state between the punch and the hollow forging have a great influence on the expanding manner.

The hydraulic expanding process of ϕ937/672 × 1034 mm hollow forging was analysed. Figure 8 shows the influence of punch angles on expanding manner at constant contact state (the contact seal height of 5 mm) between the punch and the hollow forging with mechanical seal coefficient of 1.2. It can be seen that there was an optimum punch angle in the vicinity of 60° for obtaining well-shaped strengthened forgings (Fig. 8c). When the punch angle is less than 60°, the ends of expanded forgings will be funnel shaped. On the contrary, the expanded forging will be drum-shaped, when the punch angle is greater than 60°.

Figure 9 shows that the influence of the contact seal height (h in Fig. 7a) on expanding manner at constant punch angle of 60° with mechanical seal coefficient of 1.2. It can be found that there was also an optimum contact seal height of 5 mm for obtaining well-shaped strengthened forgings (Fig. 9b). When the contact seal height is less than 5 mm, the ends of expanded forgings will be funnel shaped. On

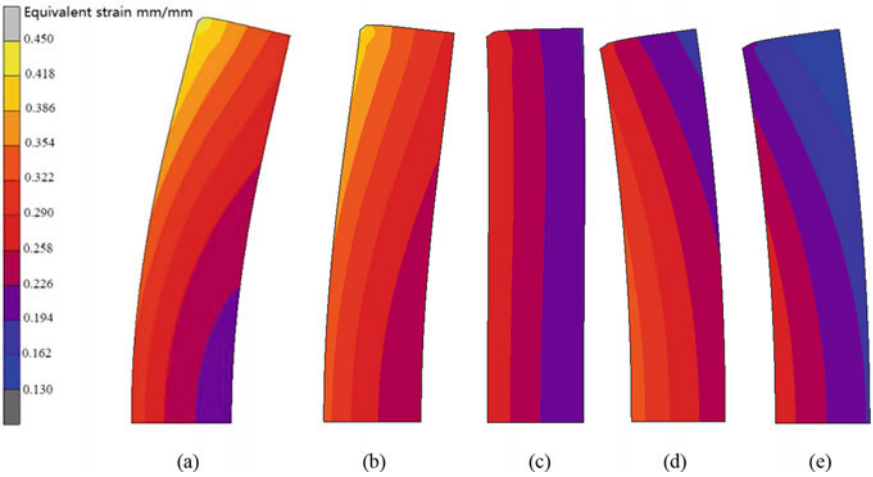

Fig. 8 The influence of punch angles on expanding manner with mechanical seal coefficient of 1.2 **a** 50° **b** 55° **c** 60° **d** 65° **e** 70°. (Color figure online)

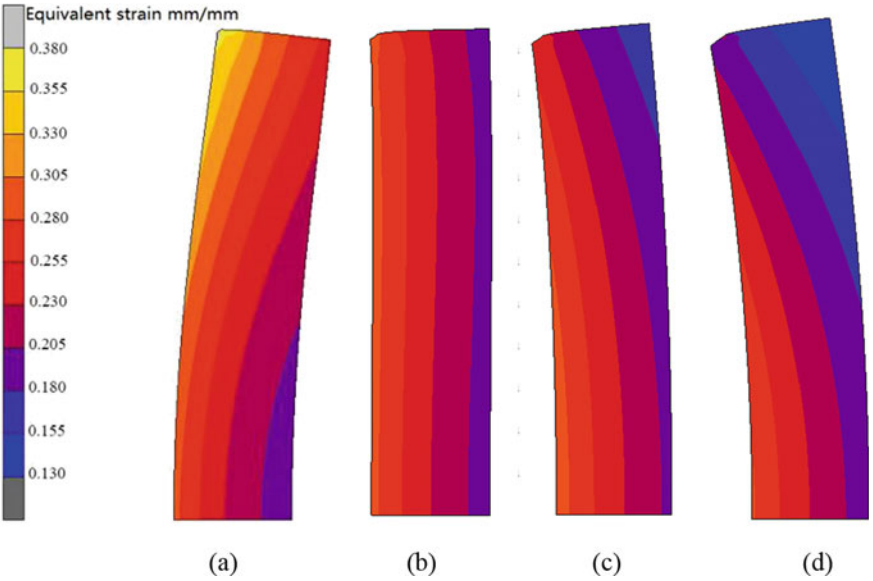

Fig. 9 The influence of the contact seal height on expanding manner with mechanical seal coefficient of 1.2 **a** 2.5 mm **b** 5 mm **c** 7.5 mm **d** 10 mm. (Color figure online)

the contrary, the expanded forging will be drum shaped, when the contact seal height is greater than 5 mm. Therefore, the contact seal height and the punch angle have to be matched to an optimum state for obtaining well-shaped hollow forgings.

4 Conclusions

In this paper, a short route manufacturing process of retaining rings was put forward, which was composed of hollow ingots manufacturing by ESR, hot ring rolling, and cold expanding strengthening. And microstructure mechanisms, deformation characteristics and process parameters during both of hot ring rolling and cold expanding strengthening were investigated. The conclusions can be drawn as follows:

(1) The multi-pass compression flow stresses of Mn18Cr18N ESR ingot sample coincide with that of the single-pass flow stresses at short interval time of 3 s. However, the multi-pass flow stresses decreased with increase of interval time. Grain was refined at lower temperature of 1050 °C by static recrystallization during multi-pass compression. Then, grain was refined at higher temperature of 1150 °C by both of dynamic and static recrystallization during multi-pass compression.

(2) For the thick-wall hollow ingots, strain penetration in the deformation zone must be considered the contact arc length ratio based on the conventional strain penetration model of ring rolling. Based on this, the driving roller radius of 500 mm and the pressure roller radius of 130 mm were determined for the ring rolling process ofφ712 mm/308 mm $\times$ 902 mm thick-wall hollow ingot. The optimum rotate velocity of the driving roller should be 0.8 rad/s. And the feeding velocity of the pressure roller had to be 1 mm/s for matching the driving roller.

(3) During cold deformation, planar slipping and twinning predominated at small and large deformation, respectively, which induce dislocation arrangement and grain boundaries as hindrance for dislocation movement to increase strength. For the hydraulic expanding process of ϕ937/672 $\times$ 1034 mm hollow forging, the optimum matching of 60° punch angle and 5 mm contact seal height can be adopted for obtaining well-shaped strengthened forgings.

Achieving an Interference Fit Between Two Rings During Composite Ring Rolling

Christopher J. Cleaver and Julian M. Allwood

Abstract Composite ring rolling could bring substantial material, cost, and energy savings and allow for lighter weight components, by joining concentric rings with different material properties. For there to be any possibility of achieving a material bond, an interference fit between the rings must be maintained. In this paper, a force equilibrium-based model is introduced to predict when such a fit is possible. This model, for radial composite rolling, predicts a limit to the flow stress of the inner ring relative to the outer ring, suggesting a maximum ratio of about 160%. It also shows that the inner tool's diameter must often be significantly smaller than the outer tool's. The model is tested in four composite ring rolling experiments with two grades of Aluminium alloy, 1050 and 6063, and different tool sizes. An interference fit was achieved in two cases: (1) when the inner ring is Al 1050 (flow stress 52% of the outer ring); and (2) when the two rings are both Al 6063 and the inner tool diameter was 39% of the outer tool. It was not achieved when (1) the materials were reversed nor when (2) the inner tool increased to 59% of the outer tool diameter. These outcomes were all predicted by the model, a potentially valuable new guide to designing composite ring rolling processes.

Keywords Ring rolling · Curvature · Joining

1 Introduction

Joining two rings together by ring rolling is an attractive proposition since it might be possible to tailor the material properties so that the ring is strong where it is needed, but expensive or heavy material is not wasted where it is not needed. Applications for such a process could include bearings, whose raceways are most heavily loaded—see Fig. 1a, and therefore increased hardness might be demanded on the outer and inner surfaces for the inner and outer raceways, respectively, regions I.

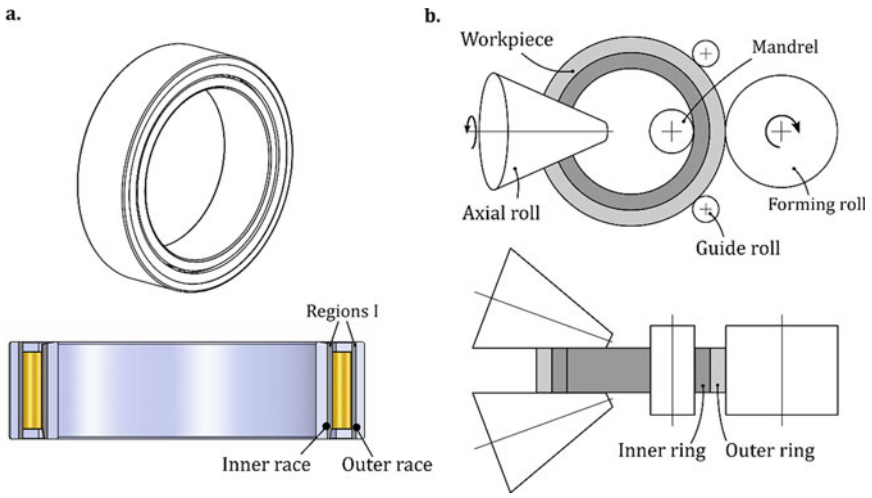

Fig. 1 **a** Possible application of composite ring rolling. **1b** Composite ring rolling machine setup. (Color figure online)

Rather than welding, or mechanically joining two rings of the correct 'final' size, better mechanical properties could be achieved by cold welding the workpieces in the process of expanding the stock material. Several previous studies have suggested this could be achieved by ring rolling two concentric blanks, as shown in Fig. 1b, a process labelled 'composite ring rolling'. Two rings of matching outer and inner radii are loaded together into a conventional radial-axial ring rolling machine. The radial and/or the axial roll gaps are closed as the workpiece rotates and the two rings ideally grow in diameter in tandem, maintaining an interference fit. Bonding occurs due to 'cold welding' in the solid state due to contact between the true surfaces of the metals in the exclusion of oxygen.

Achieving the interference fit throughout the composite ring rolling process is not trivial, and is the subject of this paper. As Fig. 2 demonstrates, a key hindrance is simply the fact that the outer ring is bigger than the inner one to start with; so if it experiences an equal strain, either in the radial or axial direction, it will 'naturally' get bigger by the same proportion, but by a larger *absolute* amount and so lose contact.

In radial rolling, there are two main ways to overcome this problem, i.e. to make it so that the inner ring 'wants' to grow faster than the outer ring. Firstly, the inner ring will want to grow faster if it is made from a softer material than the outer ring. By analogy to compressing two springs in series, the thickness reduction—and hence circumferential length increase—would tend to be larger for the softer inner ring than the harder outer ring. Alternatively, it might also be possible to achieve a faster growth rate by using a very small mandrel tool, even if the inner ring had an equal, or slightly larger, flow stress. By analogy to indentation with unequal indenters, the smallest indenter will tend to penetrate further, and so the inner ring deforms more.

Rather than rely on analogies or rules of thumb, it would be valuable to have a prediction for when an interference fit is possible: the topic of this paper.

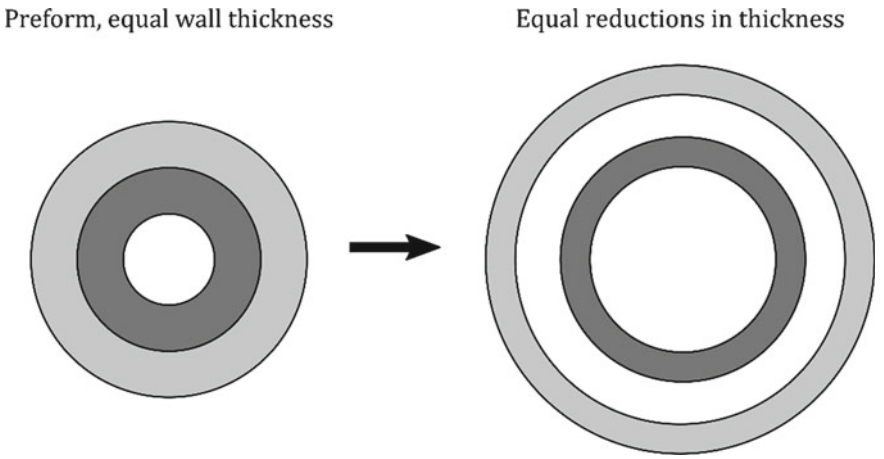

Fig. 2 **a** Tendency for outer ring to get bigger by a larger absolute amount

2 Literature Review

Previous efforts to achieve a 'composite ring rolling process' (Table 1) and past work on curvature change in ring rolling are briefly reviewed. The latter—the authors' recent model for curvature change in open-ended rings—is relevant to the interference fit prediction. Composite ring rolling is in some respects analogous to roll-bonding, which is a relatively well-established technique, both industrially and as a topic of scientific research (e.g. [1, 2]).

Table 1 Studies on joining two rings by ring rolling

Study	Inner ring material	Outer ring material	Flow stress ratio (Inner/Outer)	Description of study
Kluge et al. [3]	Duplex steel: X2CrNiMoN 22-5-3	Construction steel: StE 460	120%	Demonstration of feasibility
Seitz et al. [5]	Tempering steel: 13CrMo4-5	Stainless steel: X5CrNiMo17-12-2	50%	Achieving interference fit: effect of tool size
Kusters et al. [4]	Brass	Steel	Unknown	Cold composite rolling: working principle
Guenther et al. [6]	Tempering steel: 13CrMo4-5	Stainless steel: X5CrNiMo17-12-2	50%	Bonding: preform preparation, oxidation
Guenther et al. [7]	Tempering steel: 13CrMo4-5	Stainless steel: X5CrNiMo17-12-2	50%	Bonding: axial rolling strategies

One of the first studies on joining two rings by ring rolling was carried out in the 1990s by Kuesters et al. [3]. In this, a construction steel outer ring was bonded to a duplex steel inner ring. The two preforms were initially welded together in a conventional way, and then rolled at high temperature. In this case—unlike all other examples that follow—the inner ring was said to have a slightly larger flow stress (620 MPa vs. 520 MPa). The authors discuss the importance of ensuring the inner ring 'wants' to grow faster than the outer ring, however, they do not detail how this might be achieved more generally.

Guenther et al. [4] studied cold composite rolling, and showed that a softer material should be used for the inner ring to achieve an interference fit during the process, and enable bonding. Guenther et al. [5] investigated hot composite ring rolling of an inner ring of tempering steel, and an outer ring of stainless steel. The inner ring had a flow stress about 50% of the outer ring, and so 'wants' to grow at a faster rate. The study showed that in fact unless the mandrel size was increased to almost the same size as the inner diameter, the inner ring 'escaped' from the outer ring out of plane. Despite achieving an interference fit, there was no material bonding. Seitz et al. proposed the rule of thumb that to ensure process stability, the predicted contact length at the forming roll should be larger than that at the mandrel.

Li et al. [6, 7] studied bond formation in radial-axial composite ring rolling, using a tempering steel inner ring, and stainless steel outer ring. They highlighted two key measures to ensure material bonding. Firstly, care should be taken to ensure that no scale develops on the joint surfaces during heating—not trivial due to differing coefficients of thermal expansion. Secondly, that axial rolling tends to lead to debonding (possibly for the reasons given above), and therefore should be avoided early in the process.

The current study returns to the question of when an interference fit can be achieved, in light of the authors' recent work predicting curvature changes in ring rolling. In this, Cleaver and Allwood [8] studied curvature change in open-ended arcs in conditions analogous to ring rolling—a powered outer radial tool and idle inner radial tool, and no entry or exit tension. They developed an analytical model to predict how the roll size ratio—and reduction—influences curvature change. Predicted curvature changes from this model matched experimentally observations and numerical simulations, to within 7%. Could a similar approach be applied to predict when an interference fit is possible in composite ring rolling?

3 Prediction for When an Interference Fit Is Possible

This paper develops Cleaver and Allwood's model for free curvature change [8] to predict if an interference fit can be achieved in composite radial ring rolling. This requires a modification to account for materials of different flow stresses, and the criteria for achieving an interference fit. These are introduced in Sect. 3.1 and an exemplar prediction is then given in Sect. 3.2.

3.1 Force Equilibrium Model to Predict Radius Changes in Composite Radial Rolling

An interference fit requires the inner ring to extend proportionally more than the outer ring, which by volume conservation requires a greater reduction in thickness in the inner ring. Therefore, the first aim of the model is to predict—given a known total reduction in thickness ΔT—the notional reductions in thicknesses ΔT_1^* and ΔT_2^* for the inner and outer rings, respectively. These are notional in the sense that they assume each ring's radius growth is completely independent, i.e. they allow the inner ring to interfere with the outer ring. In reality, despite potentially having a greater 'tendency' to grow, the inner ring is of course constrained by the outer ring.

To predict ΔT_1^* and ΔT_2^*, two simplifications are made—firstly, that the composite rolling process is for two rings of equal thickness, secondly that the reductions ΔT_1^* and ΔT_2^* are exactly equal to the reductions in thickness at each roll ΔT_M and ΔT_F—see Fig. 3. As each reduction increases, the contact length and hence force on each roll will increase; and there will be one value of ΔT_M relative to ΔT_F that achieves force equilibrium in the y-direction.

The force in the y-direction at each roll is found by the well-established model introduced by Hawkyard et al. [9]:

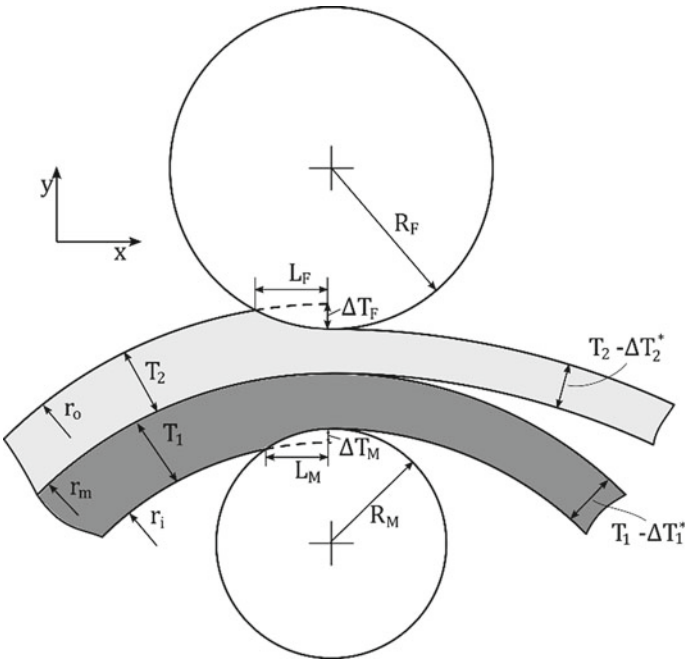

Fig. 3 Setup for composite rolling of two rings that are notionally free to interfere

$$F_M = \gamma_1 \overline{\sigma}_1 L_M \tag{1}$$

$$F_F = \gamma_2 \overline{\sigma}_2 L_F \tag{2}$$

where γ is the pressure factor, $\overline{\sigma}$ is the flow stress, and L is the projected contact length in the x-direction, and the subscripts denote inner and outer rings or rolling tools.

Since ΔT_1^* and ΔT_2^* are assumed to be equal to the equivalent reductions at the rolls ΔT_M and ΔT_F, then standard geometrical results give

$$L_M = \sqrt{\frac{\Delta T_1}{1/2R_M - 1/2r_i} - \Delta T_1^2} \tag{3}$$

$$L_F = \sqrt{\frac{\Delta T_2}{1/2R_F + 1/2r_o} - \Delta T_2^2} \tag{4}$$

where R_M and R_F are the mandrel and forming roll radii, respectively, and r_i and r_o are the composite ring's inner and outer radii.

The pressure factor approach introduced by Hawkyard et al. [9] is approximately

$$\gamma_1 \cong 0.8 + 0.2 * T/2L_M \text{ for } T > 2L_M \tag{5}$$

$$\gamma_2 \cong 0.8 + 0.2 * T/2L_F \text{ for } T > 2L_F \tag{6}$$

Finally, the flow stresses in each material are assumed to be given by

$$\overline{\sigma}_i = K_i \overline{\varepsilon}_i^{n_i} \tag{7}$$

Combining (3)–(7), the forces in Eqs. (1) and (2) are then balanced by a unique value of $\Delta T_1^*/\Delta T_2^*$ which can be found by numerical interpolation through the range $0 < \Delta T_1^*/\Delta T_2^* < 1$. If the effect of hardening can be ignored, then a closed form solution for this is possible, and is provided in Appendix.

Having found ΔT_1^* and ΔT_2^*, then the following condition is used to determine whether an interference fit is feasible. As illustrated in Fig. 2, the inner radius must 'want' to grow by more than the outer radius to account for it being initially smaller, and so we require

$$\Delta r_1^* > \Delta r_2^* + \Delta T/2 \tag{8}$$

where Δr_1^* and Δr_2^* are the notional increases in the inner and outer rings' mean radii, assuming that the rings are completely independent.

By volume conservation, assuming no axial spread we have

$$\Delta r_i^* = r_i \frac{\Delta T_i^*}{T_i} \tag{9}$$

So, the condition on ΔT_1^* to achieve an interference fit in composite ring rolling is

$$\Delta T_1^* > \frac{r_2 \Delta T_2^* + T\Delta T/2}{r_1} \tag{10}$$

3.2 *Predicted Operating Window for Composite Rolling*

Figure 4 sets out an operating window for the range of tool size ratios and ratio of flow stresses for which an interference fit is possible, as predicted by Eq. (10). The coloured lines represent the boundary between feasible and non-feasible operation, for different values of the ratio between the mean ring radius, r_m (of the composite ring) and the forming roll radius.

The model predicts that if the inner ring is softer than the outer ring, then it is always possible to achieve an interference fit. However, this also depends on having the right tool size ratio and the size of the ring relative to the forming tools. The smaller the mandrel is—or via effect 2 'appears' to be—the more likely an interference fit is predicted. Indeed, provided the mandrel is small enough an interference fit is predicted even if the flow stress is moderately higher in the outer ring.

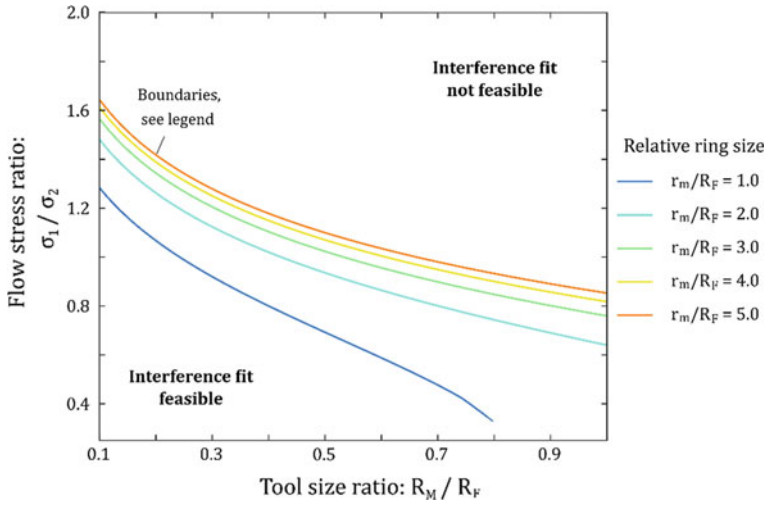

Fig. 4 Prediction for the range of ring size ratios and strength ratios for which an interference fit is possible for different relative ring radii. For $T/R_F = 0.17$, $\Delta T/T = 0.04$, $n = 0.14$. (Color figure online)

Although particular to the parameters listed in the caption, the prediction illustrated in Fig. 4 varies only by a small amount as these change within ranges reasonable to ring rolling.

4 Methodology: Composite Rolling Experiments

A set of four experimental trials was carried out to indicate whether the model could successfully predict if an interference fit is achievable in composite radial ring rolling. Tables 2 and 3 set out the experimental parameters used in the trials. There are four scenarios, labelled in Table 2. In the Soft inner ring trial and Soft outer ring trial, two different grades of aluminium were used with a large difference in flow stress at room temperature. In the Small and Big mandrel trials, the inner and outer ring are of the same material, and the mandrel varies by +30% and –13% from the mandrel size used in the first two trials, chosen because they lie on either side of the predicted feasibility boundary.

Flow stress curves for the two aluminium grades are given in Fig. 5, determined by compression tests on cylinders of diameter 15 mm and height 20 mm, carried out at room temperature. Teflon sheets were used as a lubricating medium. Three tests for each material were carried out and the dotted line represents an average fit to the Holloman model in Eq. (7).

Table 2 Four scenarios for composite radial ring rolling

Trial	Inner ring material	Outer ring material	Flow stress ratio $\overline{\sigma}_1 / \overline{\sigma}_2$	Mandrel size, R_M (mm)	Predicted outcome
Soft inner ring	Al-1050	Al-6063	0.52	45.0	Interference fit
Soft outer ring	Al-6063	Al-1050	1.89	45.0	No interference fit
Small mandrel	Al-6063	Al-6063	0.99	39.0	Interference fit
Big mandrel	Al-6063	Al-6063	0.99	58.9	No interference fit

Table 3 Constants

Variable	Value
Forming roll radius, R_F	100 mm
Ring average radius, r_m	200 mm
Inner ring wall thickness, $T1$	8.5 mm
Outer ring wall thickness, $T2$	8.5 mm
Height, H	18 mm
Nominal reduction in thickness per pass	4%

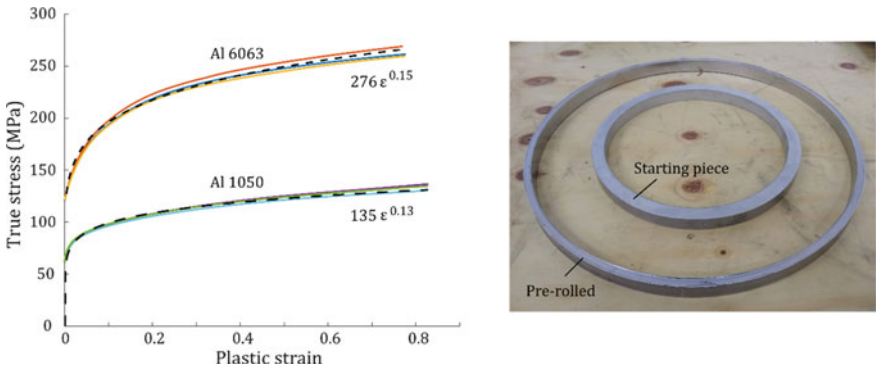

Fig. 5 **a** Flow stress curves for Al-6063 and Al-1050. **b** Pre-rolling. (Color figure online)

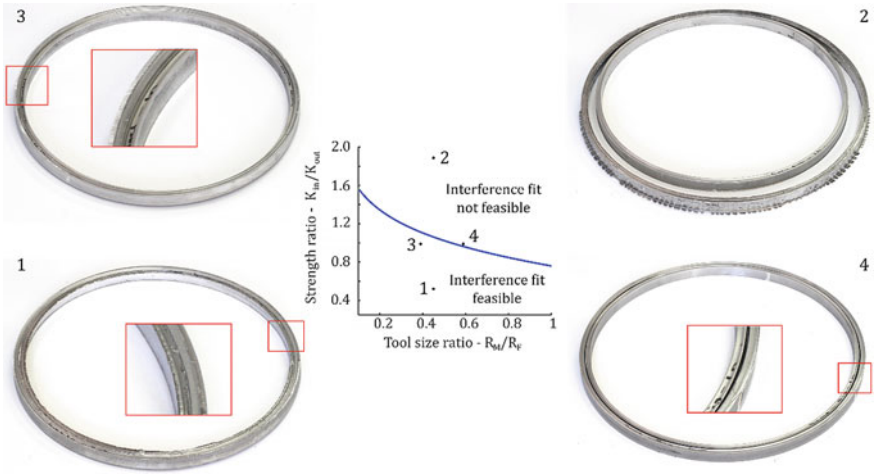

Fig. 6 Results of the four trials, compared to the prediction of Sect. 3. (Color figure online)

In order to prepare the rings for the test, the rings were first pre-rolled to the sizes specified in Table 3; the flow stress ratio quoted in Table 2 accounts for the work hardening due to pre-rolling. The composite rolling trials were carried out until it was clear whether an interference fit was achieved, for at least four revolutions in each case. Radial-only rolling was used, and the guide rolls—six in this case—applied a light force to stabilise the ring and prevent it from climbing out of plane.

5 Results

Figure 6 shows the results of the composite ring rolling trials and locates each on the axes used in Fig. 4. Figure 7 shows a series of images taken during the process.

An interference fit was achieved very rapidly in the Soft inner ring trial, and it was not in the Soft outer ring trial. This agrees with the prediction set out in Sect. 3, although intuition alone would probably also suggest that with such a large difference in flow stress the rings would behave as they did.

The Small mandrel and Big mandrel trials are a better test of the model, since it is *not* obvious a priori what mandrel size will and won't lead to an interference fit. An interference fit is achieved for the Small mandrel and not for the Big mandrel trial, in line with the prediction. It is notable that the clearance is much smaller for

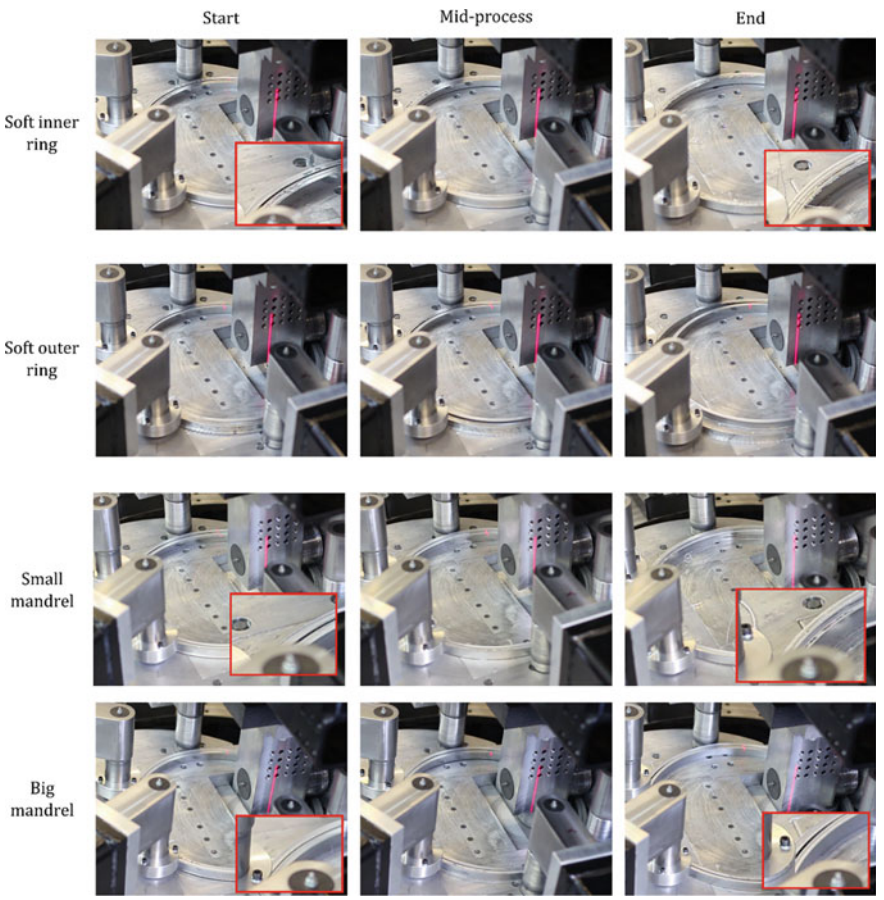

Fig. 7 Experiments on achieving an interference fit in composite ring rolling. (Color figure online)

the big mandrel trial compared to the Soft outer ring trial, which can be inferred by how close the experimental point is to the boundary on Fig. 7.

6 Discussion

This paper set out a way to predict if an interference fit is possible in composite radial ring rolling: a necessary but not sufficient condition for achieving a material bond. The prediction was successful in the four cases tested. Some caution is needed—for instance, the trials on the same material did not precisely establish the mandrel size where the feasibility line lies, simply that it is between 39.0 and 58.9 mm. The model could be anything from 0 to 20% wrong on this measure. Nevertheless, it does seem that Fig. 4 will provide a helpful guide to establishing whether a given composite rolling process is feasible.

A key finding from the operating window in Fig. 4 is the implied limit to the strength of the inner ring relative to the outer ring, at a ratio of somewhere between 125 and 160%. Composite rings with a much higher ratio are probably wanted; yet without further innovation, it seems impossible to produce them by composite radial ring rolling.

7 Conclusions

The following main conclusions are drawn from this work:

- The feasibility of achieving an interference fit in composite ring rolling primarily depends on the flow stress ratio, and on the tool sizes relative to each other and the ring.
- A model to predict if an interference fit is possible suggests the flow stress of the inner ring must be below about 1.6 times the flow stress of the outer ring.
- The model, based on force equilibrium, was tested under four different conditions and correctly predicted if an interference fit was possible in each, suggesting it is sufficiently accurate to *guide* process design
- For moderate values of the flow stress ratio in the region 0.8–1.4, the mandrel size can be adjusted to ensure an interference fit is achieved.

Appendix

Combining Eqs. (1)–(10), we have

$$(0.8 + 0.2T/L_1)K_1\left(\frac{2}{\sqrt{3}}\frac{\Delta T_1}{T/2}\right)^{n_1} L_1 = (0.8 + 0.2T/L_2)K_2\left(\frac{2}{\sqrt{3}}\frac{\Delta T_2}{T/2}\right)^{n_2} L_2 \tag{11}$$

Assuming ΔT_i^2 is small:

$$L_i = \sqrt{\frac{\Delta T_i}{A_i}} \text{ where } A_1 = \frac{1}{2R_M} - \frac{1}{2IR} \text{ and } A_2 = \frac{1}{2R_F} + \frac{1}{2OR} \tag{12}$$

Equation 11 can be rearranged in terms of L_1:

$$\widetilde{B}K_1(4L_1 + T)L_1^{2n_1} = \widetilde{C}K_2\left(4\sqrt{\frac{\Delta T - L_1^2 A_1}{A_2}} + T\right)\left(\Delta T - L_1^2 A_1\right)^{n_2} \tag{13}$$

Assuming no hardening ($n_1 = n_2 = 0$), then the force balance can be rearranged as follows:

$$4\left(K_1 L_1 - K_2\sqrt{\frac{\Delta T - L_1^2 A_1}{A_2}}\right) = T(K_2 - K_1) \tag{14}$$

The solution for L_1 is then

$$L_1 = \frac{\sqrt{16ab + 16ac^2 + bT^2\left(2c - 1 - c^2\right)} + cT(1 - c)}{4\left(b + c^2\right)} \tag{15}$$

where

$a = \frac{\Delta T}{A_2}$ $b = \frac{A_1}{A_2}$ $c = \frac{K_1}{K_2}$

The resulting prediction is compared to the numerically obtained predictions in Fig. 8.

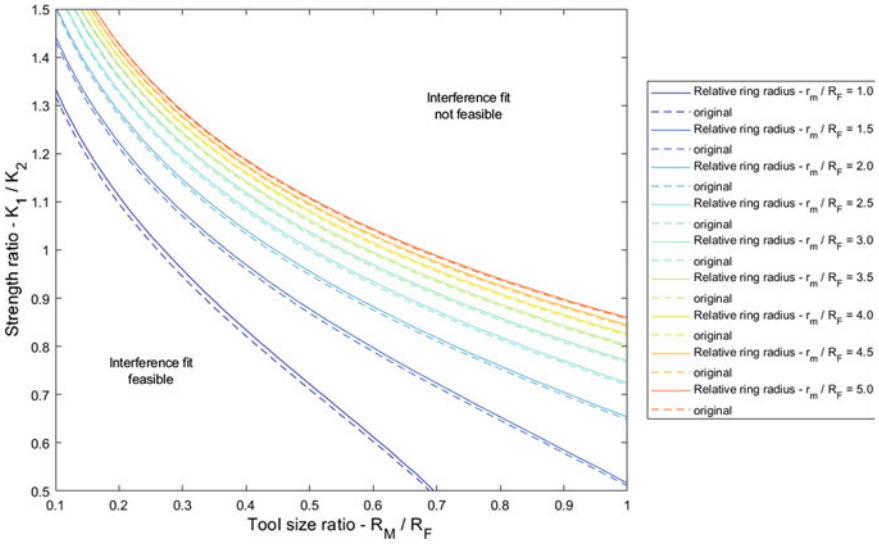

Fig. 8 Simplified closed form solution for the feasibility of composite ring rolling compared to the original numerically obtained solution. (Color figure online)

Advanced Design of Work Roll Contours for Different Roll Mill Types

Xiawei Feng, Xiaochen Wang, Quan Yang, and Zedong Wu

Abstract Steel producers are competing to roll non-grain oriented silicon (NGOS) strip with 1.25 m in width, 0.5–0.35 mm in thickness, and a profile deviation that is less than 5 micron-meters. Mathematical Models are indispensable tools to study the mechanism of work roll contours during rolling, but they require industrial tryouts to validate their effects on strip profile. Thus, this paper presents the effects of various work roll contours designed for (1) the 6th and 7th stand of a 4-high hot tandem rolling mill; (2) single stand 6-high reversing cold mill; (3) 1st to 3rd stands of a 6-high tandem cold mill. Results show that the NGOS strip profile hit rate of 5 micron-meters is increased by the implementations of advanced work roll contours.

Keywords Mathematical model · Edge drop control · Work roll contour

1 Introduction

Non-grain-oriented (NGO) silicon steel strip is an important soft magnetic material. In order to reduce eddy current loss, it is necessary to use hot and cold rolled laminates that are below 0.5 mm in thickness, and then stack them together. The phenomenon of edge drop (ED) defined in Eq. (1) is particularly detrimental to the lamination or stacking coefficient [1], shown in Fig. 1. Edge drop is the fundamental phenomenon during hot and cold rolling process resulting from wear and elastic deformation of work roll, the lateral flow of metal near the edge [2].

$$ED = \frac{1}{2}(h_{\text{eo1}} + h_{\text{ed1}} - h_{\text{ed2}} - h_{\text{eo1}}) \tag{1}$$

NGO strips are first hot rolled shown in Fig. 2, then if the thickness of the hot rolled strip is thicker than 2.2 mm thickness, it will be cold rolled by cold tandem

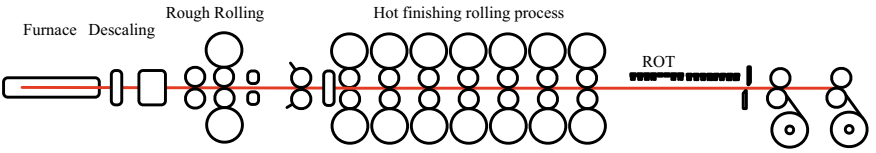

Fig. 2 Schematic illustration of hot rolling process. (Color figure online)

mills shown in Fig. 3, otherwise it will be cold rolled by cold reversing mills shown in Fig. 4. The reversing mill's work roll diameter is 240 mm, which is significantly smaller than cold tandem mills' 420 mm. Previous studies treat them separately: Ma et al. found that the implementation of work roll contours during reversal rolling process leads to flatness problem [3]. They further pointed out that for six-high reversible rolling process, the hot rolled profile has strong relationship with the cold rolled profile [4]. Wang et al. [5] proposed a concept of rectangular section control strategy for hot and cold tandem rolling process, experiments showed that a hot rolled strip with a stable crown and limited wedge, local spot, and single wave is

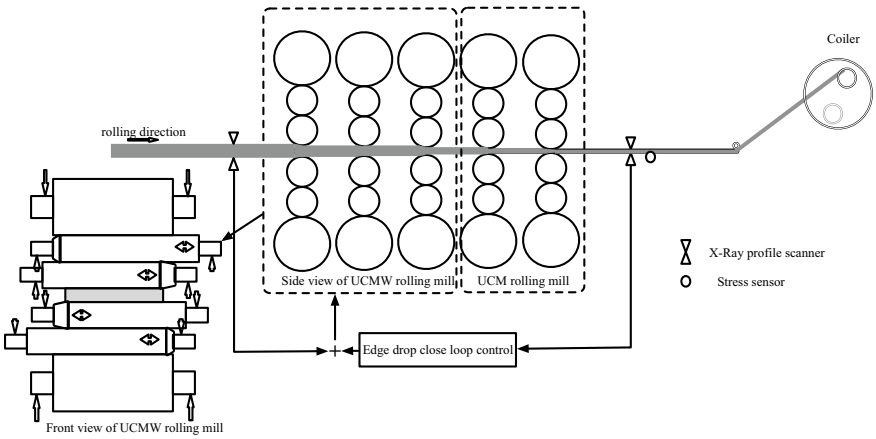

Fig. 3 Schematic illustration of 5-stand six-high cold rolling process

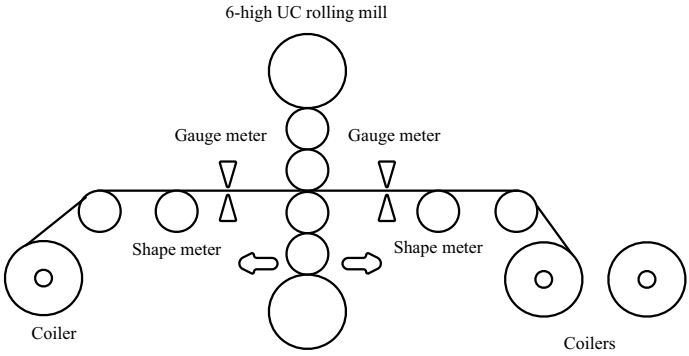

Fig. 4 Schematic illustration of six-high reversing cold rolling process

Table 1 Rolling parameters for 5-stand 6-high cold rolling mill

Stand No.	Back and front tension/MPa	Friction coefficient	Entry/exit thickness/mm
1st stand	15/135	0.085	2.5/1.8
2nd stand	135/140	0.075	1.8/1.18
3rd stand	140/145	0.06	1.18/0.8
4th stand	145/145	0.05	0.8/0.578
5th stand	145/55	0.045	0.578/0.5

recommended, and work roll contour is only needed at first and second stands of 5-stand cold tandem rolling process. The question is why is the work roll contour so different for these two mill types.

2 Industrial Setups of Hot and Cold Strip Rolling

One major difference between six-high reversing mill and cold tandem mill is that the front and back tensions of reversing mill at each pass can be separately set up, but the front tension of previous stand is the back tension for the next stand. The other is the diameter of work roll, as stated above. The rolling parameters of tandem cold rolling process are shown in Table 1 that of reversing mill are shown in Table 2.

3 Analytical Lateral Flow Model Based on FEM

Previous studies show that even though the majority part of strip width undergoes plain strain deformation, but the edge of strip deforms in 3D, that is to say the material of strip lateral flows to the edge. Lateral metal flow is one of the main contributions

Table 2 Rolling parameters for reversing cold mill

Pass No.	Back and front tension/MPa	Friction coefficient	Entry/exit thickness/mm
1st pass	20/118	0.075	2.2/1.36
2nd pass	87/150	0.06	1.36/0.87
3rd pass	88/150	0.05	0.87/0.566

5th pass	100/100	0.045	0.43/0.35

to edge drop, and a lateral flow model has been built to study the effects of rolling parameters on the width of lateral flow zone, and on the maximum value of lateral flow. Given the fact that the lateral flow during strip rolling is complicated, some simplification has to be made. In the previous study [6], the lateral flow G is defined as

$$G = -(1 + d\varepsilon_z/d\varepsilon_x) \tag{2}$$

where x, y, z is rolling, width and thickness direction respectively. Its distribution is simplified as

$$G(y) = \frac{G_{\max}}{(0.5B - y_0)^2}(y - y_0)^2, |y| \in [y_0, 0.5B] \tag{3}$$

where $G_{\max}$ is the maximum value of lateral flow, y_0 is the starting location of lateral flow, B is the strip width. They can be calculated as [6]

$$G_{\max} = 0.05 k_S k_\mu^{\max} k_\sigma^{\max} \tag{4}$$

where

$$\begin{cases} k_S = 0.009(Y_S - 100) + 1 \\ k_\mu^{\max} = 6(\mu - 0.05) + 1 \\ k_\sigma^{\max} = \left[0.0037\left(70 - \sigma_f\right) + 1\right][0.0051(50 - \sigma_b) + 1] \end{cases} \tag{5}$$

where Y_S is the yield limit of strip, μ the friction coefficient, σ_b and σ_f is the back and front tension stress. y_0 can be calculated as

$$y_0 = 0.5B - 30 k_h k_r k_\mu^{y0} \tag{6}$$

where

$$\begin{cases} k_h = 0.21\left(h_{\text{entry}} - 1.2\right) + 1 \\ k_r = 2(re - 5) + 1 \\ k_\mu^{y0} = 5.13(0.18 - \mu) + 1 \end{cases} \tag{7}$$

where h_{entry} is the entry thickness of strip, *re* is the reduction rate of the current pass. Considering the different work roll diameter and tension setups in reversing and tandem rolling process, the above lateral flow model has to include the effects of these parameters by FEM simulations.

As a general mathematic tool, FEM has been widely used to study the fundamentals of rolling process [7], it showed great precision in geometry calculation [8], and it has been used to study the mechanism in rolling process [9]. A 3D FEM model by Abaqus has been built to study the effects of different work roll diameter, back and front tension stress on the lateral flow factor *G,* i.e., $G_{\max}$ and y_0.

Figure 5 shows the effect of different back and front tension on the lateral flow factor. It can be seen that adding front tension has no significant effect on $G_{\max}$, but has some effect on y_0. On the other hand, back tension has great influence on both $G_{\max}$ and y_0. So that k_σ^{max} has to be revised and a k_σ^{y0} term has to be added to y_0:

$$k_\sigma^{\max} = 0.0051(80 - \sigma_b) + 1 \tag{8}$$

$$k_\sigma^{y0} = [0.00068(80 - \sigma_b) + 1]\left[0.00068\left(80 - \sigma_f\right) + 1\right] \tag{9}$$

Figure 6 shows the effect of different work roll diameter on the lateral flow factor. It can be seen that reducing work roll diameter significantly reduced $G_{\max}$ and the width of lateral flow area. So that a $k_D^{\max}$ has to be added to $G_{\max}$ and a k_D^{y0} term has to be added to y_0:

$$k_D^{\max} = -0.05(425 - D)/100 + 1 \tag{10}$$

$$k_D^{y0} = -0.1(425 - D)/100 + 1 \tag{11}$$

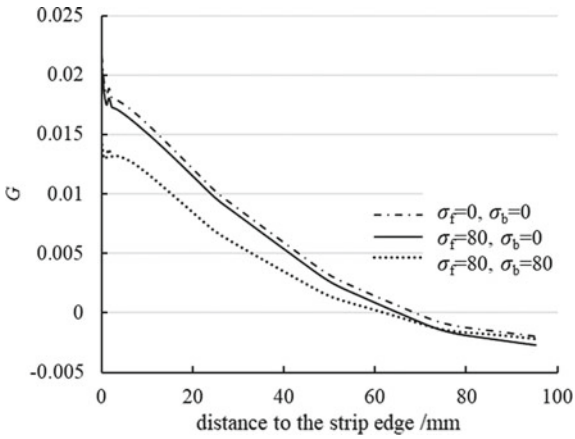

Fig. 5 Lateral flow factor *G* with different front and back tensions

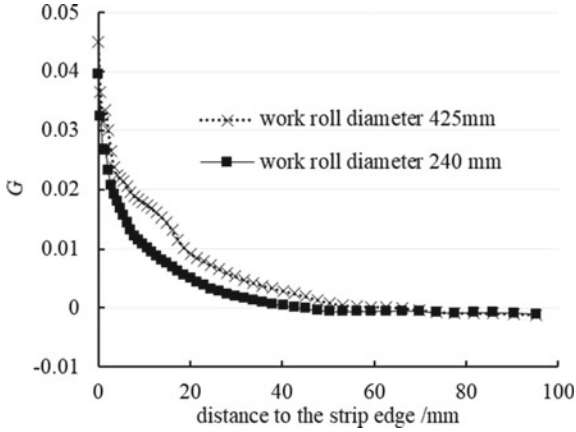

Fig. 6 Lateral flow factor G with different work roll diameters

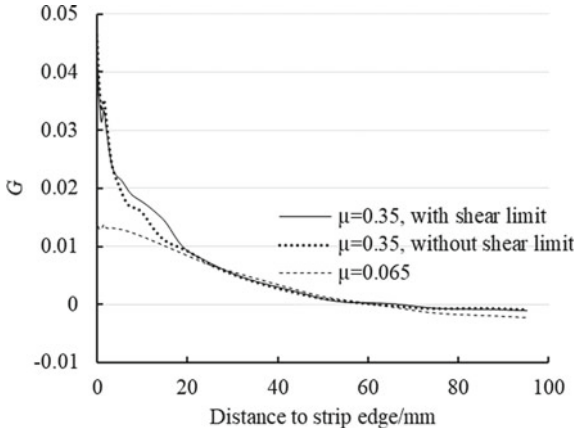

Fig. 7 Lateral flow factor G with different friction conditions

Figure 7 shows the effect of different friction conditions on the lateral flow factor. It can be seen that reducing friction coefficient greatly decreases the lateral flow factor $G_{\max}$, but has no effect on the lateral flow width y_0. So that the term k_{μ}^{y0} has to be taken out.

4 Model Results and Industrial Data

By using the analytical lateral flow model above, the calculated lateral flow factors are shown in Tables 3 and 4 for tandem and reversing cold mills, respectively. It can be seen that for the 1st pass of tandem rolling process, the maximum lateral flow factor $G_{\max}$ is significantly larger than the other 4 passes and also larger than that of reversing mill. It suggests that the taper of work roll contour for tandem mill has to

Table 3 Results of lateral flow model for tandem mill

Stand No.	G_{max}	$0.5B - y_0$
1st stand	0.32	60
2nd stand	0.17	48
3rd stand	0.16	42
4th stand	0.15	38
5th stand	0.15	30

Table 4 Results of lateral flow model for reversing mill

Pass No.	G_{max}	$0.5B - y_0$
1st pass	0.28	49
2nd pass	0.21	38
3rd pass	0.20	34
4th pass	0.19	27
5th pass	0.19	25

be larger than that of reversing mill. The G_{max} of the last 4 passes of tandem rolling process is smaller than that of 4-pass reversing mill; it suggests that there is no need of work roll contour on the last passes of tandem rolling process, and that the cold rolled profile of reversing mill has stronger similarity with hot rolled profile than tandem rolling mill. It also can be seen that the lateral flow width of reversing mill is smaller than tandem rolling. It suggests that in order to avoid flatness problem during reversing mill rolling it is necessary to reduce hot rolled strip edge drop.

A work roll contour has been grounded on the 6–7 stand of a 4-high hot tandem rolling process, shown in Fig. 8. The effect of work roll contour of hot rolling on the cold rolled product is shown in Table 5. It can be seen that the implementation of work roll contour on hot rolling mill makes a larger impact on the reversing mill. It is consistent with lateral flow model prediction.

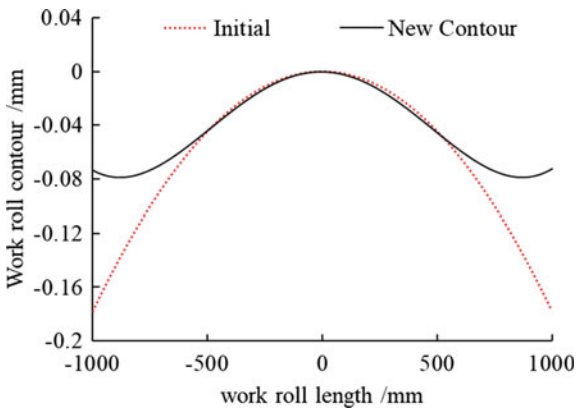

Fig. 8 Work roll contours for the last 2 stands of hot tandem rolling. (Color figure online)

Table 5 Effects of hot rolling work roll contour on cold rolled strip

Mill type	Edge drop (μm)	
	Before	After
Reversing mill	1.91	1.17
Tandem mill	2.61	2.32

	Before (%)	After (%)
Hit rate < 5 μm	19.5	35

A work roll contour has been grounded on the first stand of cold tandem rolling process, shown in Fig. 9. The effect of work roll contour on the cold rolled product is shown in Table 6. It can be seen that the cold rolled product hit rate can be improved by the work roll contour.

5 Conclusion

Finite element model reveals that work roll diameter has a significant effect on lateral flow during strip rolling process, back and front tension setups are different between tandem and reversing mill, and result in a significant difference in lateral flow model results. The results of lateral flow model and the industrial data are in good agreement. Improvement of hot rolled edge drop has larger effect on reversing mill than tandem rolling.

Study on the Transferability of Rolling with Ordered Texturing Roll

Yasuyuki Fujii, Yasushi Maeda, and Hiroshi Utsunomiya

Abstract Surface textured rolling is designed to transfer roughness onto the sheet from the surface of textured rolls. The authors investigated the influence of rolling conditions on transferability using an ordered texture roll experimentally. To understand such influence, we compared the rolled surface profiles during the experiments with those during Finite Element Analysis (FEA). However, at reductions greater than 5%, there is a discrepancy, which is believed to be caused by unknown restraint force. As it is difficult to estimate the restraint force with a 3D profile roll, we carried out experimental transformability tests with 3 simpler kinds of ordered texture rolls, namely, (1) RD, (2) TD, and (3) 45-degree groove rolls. In this paper, the apparent friction coefficients were evaluated experimentally with these rolls. The friction coefficients were found to be affected by several metal flows in the roll bite. In conclusion, it is still difficult to estimate the apparent friction coefficient because these metal flows affect each other.

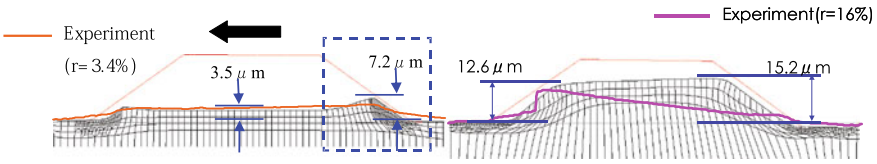
1 Introduction

The surface property of rolled strip is one of its most important characteristics. In texture rolling, the profile on the textured roll is transferred to that on the strip. In many previous studies, the character of the surface has employed the average roughness such as Ra [1]. Furthermore, numerous studies of skin-pass rolling with dull rolls have mainly discussed this under conditions where there was less than a 5% reduction. For example, Aoki et al. carried out rolling transcription experiments by changing the reduction, roll roughness, and inlet thickness. They reported that the transcribed average roughness on the sheet is dependent on the reduction, the surface pressure, and the shape factor. However, their results only looked at a low reduction region (<5%), and did not examine behavior at a higher reduction region [2]. Some studies have reported on numerical predictions of surface texture. For example, a rolling 2D-FEM simulation using a zooming method was studied by Yukawa et al. [3]. They showed the results of 2D-FEM at a relatively higher reduction region. However, there was no quantitative comparison with experimental results in their report. A simple compression simulation with a solid die using 2D-elastic-plastic FEM was studied by Ike [4]. In his conclusion, the frictional force and the angle of the die wedge were important for the surface profile. However, this model was a simple compression process. In the rolling process, there are relative vertical and horizontal velocities between the die and the material. In our previous research, we took into account the effect of both relative velocities in the rolling process, using the microscopic 3D deformation mode. In our present research, an ordered textured roll was used experimentally, and the profile of the rolled surface was measured as individual transcribed 3D profiles. To predict each individual profile, a 2-step FEA was established. In the first step, the relative velocity between the roll and the material in the roll bite was decided each time using 2D FEM for macroscopic analysis. In the second step, microscopic 3D FEA of the solid die and elastic–plastic material was applied, giving the relative velocity from macroscopic 2D FEA as the time step boundary conditions. Our results showed that, under lower reduction conditions, there was a high degree of agreement between the numerical predictions and the experimental results [5]. However, there was a discrepancy between them at higher reduction region (Fig. 1) [6]. We discovered that it was difficult to estimate the exact value of the material velocity on the microscopic 3D model from the results of 2D-FEM). It is believed that this affects an accurate estimation of the friction coefficient due to the formation of projections and the pattern itself on the roll.



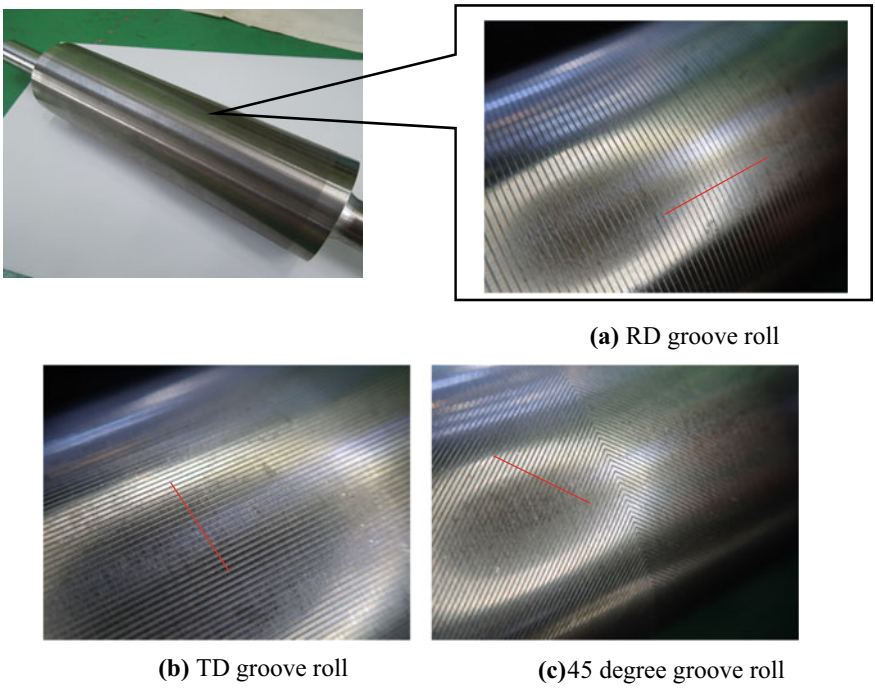


Fig. 1 3D-FEM simulation result (left: r = 3.4%, right: r = 16.0%). (Color figure online)

In this paper, we carried out experiments on transformability with 3 kinds of ordered texture rolls where: (1) the RD groove roll has the groove along the radial direction of the roll, (2) the TD groove roll has the groove along the axial direction of the roll, and (3) the 45-degree groove roll has the groove at an angle of 45° to the roll. We expected that an ordered 3D texture roll might be a mixture of these. These experiments showed that different rolls have different restraint force and friction coefficients.

2 Experimental Conditions

To simplify the discussion, three kinds of work roll with different ordered patterned surfaces were used, as shown in Fig. 2a–c. In Fig. 2a, the RD groove roll has the groove along the cylindrical direction of the roll surface. In Fig. 2b, the TD groove roll has the groove along the axial direction. In Fig. 2c, the 45-degree groove roll has the groove along different 45-degree directions against the center.

These grooves have the same profile as shown in Fig. 3. A 4-high rolling mill was used in the rolling test with these rolls as the work rolls. The back-up roll was 300 mm in diameter, and the work roll 55 mm. The patterned rolls were used as

(a) RD groove roll

(b) TD groove roll

(c)45 degree groove roll

Fig. 2 Roll appearance. (Color figure online)

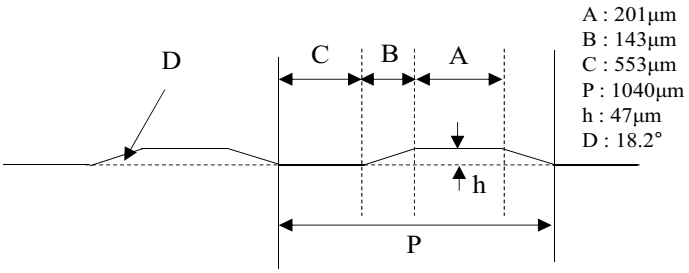

Fig. 3 Roll surface cross section

only the top work roll, and the bottom work roll was set to be a bright roll. The rolled material was pure titanium, 0.61 mm in thickness, 50 mm in width, and about 200 mm in length. The rolling reductions were changed from 5 to 25%. In addition, the 45-degree groove roll was asymmetrical with regard to the direction of rotation. We identified normal rotation and reverse rotation as shown in Fig. 4. A summary of the experimental conditions is shown in Table 1. After the rolling tests, the profiles transcribed onto the surface were measured using a laser microscope.

3 Experimental Results

3.1 Height of Transcribed Profile

In Fig. 5, the heights of the transcribed profile on the rolled sheets are shown as the relationship of the reductions from the experimental results. The height was strongly dependent on reduction under about 15% with any type of roll. On the other hand, at over 15%, it seems that the height is almost constant, and the values depend on the type of roll. Further, the height of the transcribed profile for each type of roll increases at higher reductions in the following order: TD groove roll, reverse rotation of 45-degree roll, normal rotation of 45-degree roll, RD groove roll. This order is understandable if the following mechanism is assumed, namely, that the height of the profile is formed by compressive metal flow on the surface of the roll bite. In general, material elongates along the rolling direction in the rolling process. In these experiments, surface elongation in the roll bite is resisted by the groove on the roll. The magnitude of such resistance depends on the direction of groove. The RD groove has the smallest resistance. Conversely, the TD grove has the largest one. The resistance of the 45-degree roll lies between the two. Imagining the surface resistance is useful in expecting the order of the type of roll.

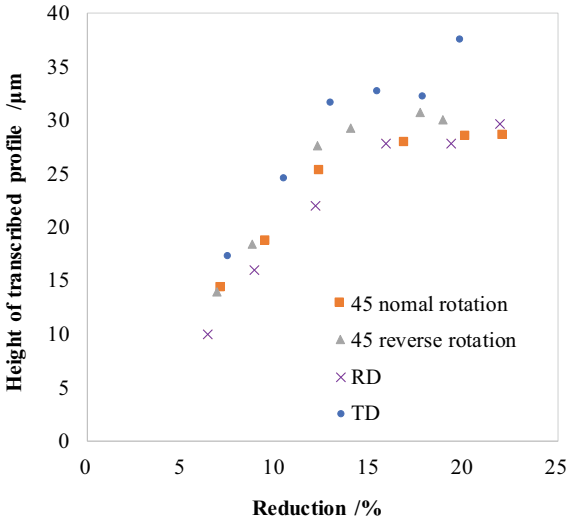

Fig. 5 Relation between rolling conditions and height of transcribed profile. (Color figure online)

3.2 *Estimation of Friction Coefficient*

The influence of the restraint force in the roll bite to be formed the projection height was suggested. To confirm the effect qualitatively, we estimated the friction coefficient during rolling on each roll as a macroscopic parameter. The method used to estimate the friction coefficient is described below. The sheet thickness on both the entry side and delivery side were measured under each condition.

Using the inverse equation of Hill's rolling load model, the estimated friction coefficient is shown in Eq. (1). However, flow stress k was estimated using Eq. (2). R' was calculated with Hitchcock's model using measured rolling load. Here, parameters A and n in Eq. (2) were determined using the fitting method taken from a great deal of experimental rolling data. As shown in Fig. 6, the estimated friction coefficients have strong dependency not only on reduction, but also on the type of roll. In general, the estimated friction coefficients increase as reduction increases. It is believed that there are two reasons for this increase. One is the new active surface, which is mainly formed by higher reduction. The other is the geometrical profile, which is shown in Fig. 3. It is difficult to explain these effects simply. We discuss this in detail in the following section.

$$\mu = \frac{\frac{P}{w\cdot\sqrt{R'\cdot(h1-h2)}\cdot(k-0.5\cdot(S1+S2))} + 1.02\cdot r - 1.08}{1.79\cdot r\cdot\sqrt{R'/h2}\cdot\sqrt{1-r}} \tag{1}$$

μ: friction coefficient P: rolling load w: width

R': flattening roll diameter $h1$: thickness of entry side $h2$: thickness of delivery side

$S1$: tension of entry side $S2$: tension of delivery side
r: reduction k: flow stress

$$k = A \cdot \varepsilon^n \tag{2}$$

A: statical flow stress (112.7 kgf/mm^2) ε: strain n: work-hardening exponent (0.122).

4 Estimated Friction Coefficient at Each Roll

4.1 Friction of TD Groove Roll

A significant characteristic of the TD groove roll is that the friction coefficient shows an increased jump at around 15% reduction. In the TD groove roll, the geometrical distance between neighboring grooves is shorter along the rolling direction. If there is only one groove in the roll bite, the effect of the groove is limited. However, if there is more than one groove, the forward groove is highly resistant to the 2nd one. In evaluating this phenomenon, the contact length between the roll and the sheet was compared with the geometrical groove pitch. The relation between the friction coefficient and the ratio of these is shown in Fig. 7. In this figure, a jump in the friction coefficient exists around 2.0. This means that the number of grooves in the roll bite is important, and more than 2 grooves in the roll bite induce increasing resistance.

Previously, we examined the effect of the number of grooves in a roll bite on the friction coefficient and the height of transcribed profile by using 2D-FEA. The

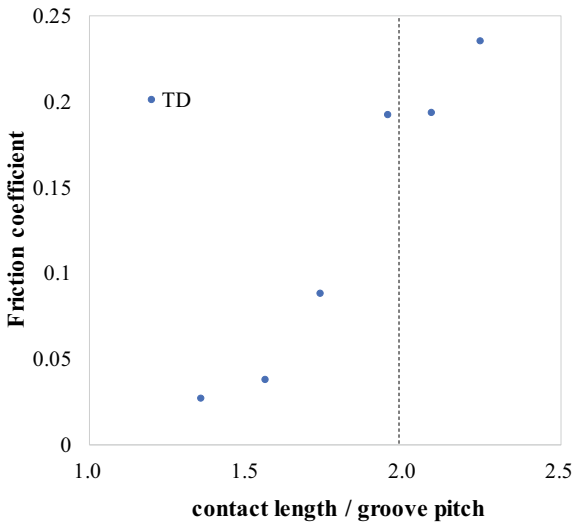

Fig. 7 Relation between rolling conditions and height of transcribed profile. (Color figure online)

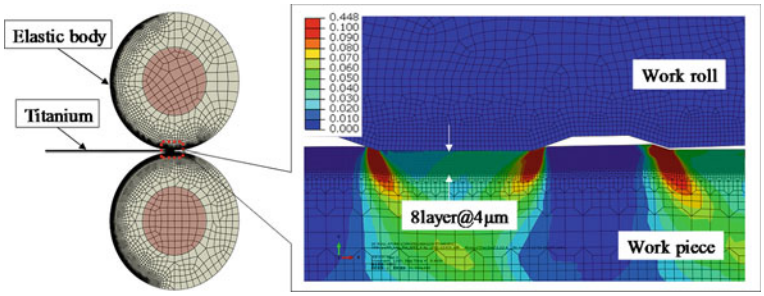

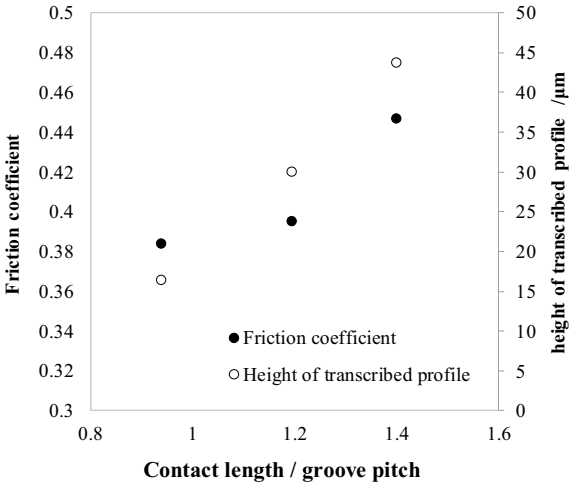

Fig. 8 2D-FEA model of rolling. (Color figure online)

Fig. 9 Relation between rolling conditions and friction coefficient and height of transcribed profile

"ABAQUS-standard" in 2D-FEA was used for the simulations of the rolling test. The rolling model of the 2D-FEA is shown in Fig. 8 [7]. Figure 9 shows the relation between number of contact grooves and the friction coefficient from the 2D-FEA. The friction coefficient in the figure was estimated from Eq. (1) using the rolling load obtained from the 2D-FEA. As a result, it was confirmed that the apparent friction coefficient (restraint force) increased as the number of grooves in the roll bite increased. Also, it was clarified that the height of transcribed profile increased with the increase in the friction coefficient.

4.2 Friction Coefficient of 45-Degree Groove Roll

In the case of a 45-degree groove roll, there is a difference in estimated friction coefficients between normal and reverse rotation. The friction coefficient of reverse

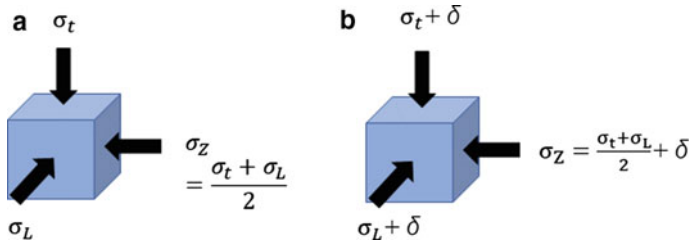

Fig. 10 Yield condition. **a** Plain strain. **b** Plain strain with additional stress δ. (Color figure online)

rotation is higher than in the case of normal rotation (Fig. 6). This difference is considered to be influenced by the lateral metal flow in the roll bite. In normal rotation, the metal flow along the rolling direction must be pushed outward from the center of the strip by the groove. On the other hand, in reverse rotation, the metal flow must be pushed toward the center from outside the groove.

These lateral metal flows along the width cause a compression stress along the width that is higher than in the case of normal rotation. Assuming Mises's yield criteria and associated flow rule, on the plane strain condition, yield condition is Eq. (3). σ_t is stress along the thickness, σ_L is stress along the rolling direction, σ_W is stress along the width direction and σ_{eq} is equivalent stress, as shown in Fig. 10a.

$$(\sigma_t - \sigma_L)^2 = \frac{2}{3}\sigma_{eq}^2 \tag{3}$$

If additional stress by constraint force along the width direction is assumed, the stress along the thickness is increased with compressive additional stress, and is decreased with stretch one as shown in Fig. 10b. As a result, the rolling load in reverse rotation is higher than in normal rotation. This is the reason why the estimated friction coefficient of reverse rotation is higher than in the other cases.

In addition, there is a jump phenomenon around 15%, as in the case of the TD groove roll. This jump might be the same phenomena as the TD groove roll. However, there is no jump in the case of a 45-degree normal rotation roll. This difference might come from the different axial metal flow between each other. In the case of reverse rotation, compressive flow along the width causes compressive stress along the rolling direction, too. On the other hand, in the case of normal rotation, the stretch flow along the width causes tensile stress along the rolling direction. This difference causes significant effect of the 2nd groove on the roll bit. In the case of normal rotation, the effect of the 2nd groove on the roll bite is very important, as it is in the case of the TD roll. However, in the case of normal rotation, the 2nd groove does not cause a strong compressive force, because of the axial metal flow from the center to the edge of the sheet. In Fig. 11, we show the heights of the transcribed projection at the center of the sheet and at the edge of the sheet with the 45-degree roll in both normal and reversed rotation. The height of the transcribed projections is higher in reverse than in normal rotation. Furthermore, this difference is quite large at the

Fig. 11 The height of the transcribed profile at the center of the sheet width and the edge. (Color figure online)

width edge portions in both normal and the reverse rotation. Since the free surface is formed at the width edge, the influence of the metal flow is large. It is presumed that the difference in compressive stress between normal rotation and reverse rotation appears in the height of the transcribed projection.

4.3 Relationship Between RD and TD Groove Roll

Figure 6 shows the estimated friction coefficients of the RD and the TD groove rolls with the reductions. As described above, the rapid increase in the friction coefficient at 15% or more with the TD groove roll is due to the resistance of the metal flow along the rolling direction. It is believed that the friction coefficient of the RD groove roll increases with higher reduction due to the formation of the new surface, which is in contact with the groove. Figure 12 shows the relationship between the friction coefficient and the contact area ratio of the protrusion and the roll bite length on the TD/RD rolls. In the RD roll, the contact area ratio is constant at any reduction. On the other hand, in the case of the TD roll, the contact area ratio increases with an increase in rolling reduction. The estimated friction coefficients are a kind of index of the resistance force along the rolling direction. Microscopic friction depends on the contact area ratio. If the microscopic friction is constant, the estimated friction is shown to relate to the contact area ratio in this figure. In particular, when more than two protrusions exist on the roll bite, it is believed that the restraining force in the rolling direction sharply increases and the friction coefficient jumps, as explained before.

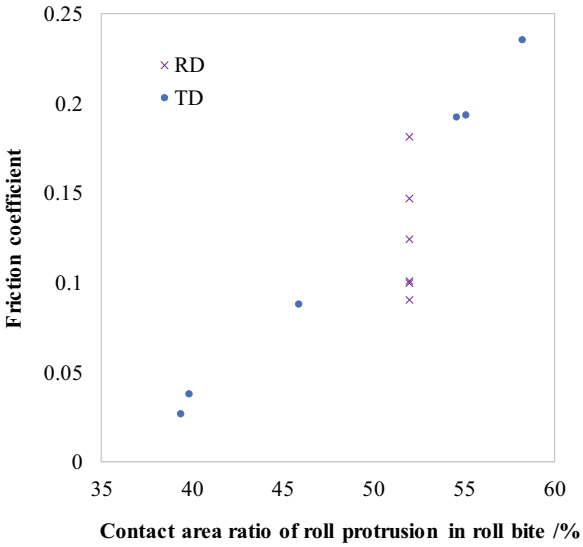

Fig. 12 Relationship between friction coefficient and contact ratio of roll protrusion. (Color figure online)

5 Relation Between Estimated Friction and Transcribed Profile

Figure 13 shows the relationship between the friction coefficient and the height of the projection for each roll.

In lower friction coefficients under 0.15, where the reduction is lower, it is difficult to understand the behavior of the friction coefficient because of the projection

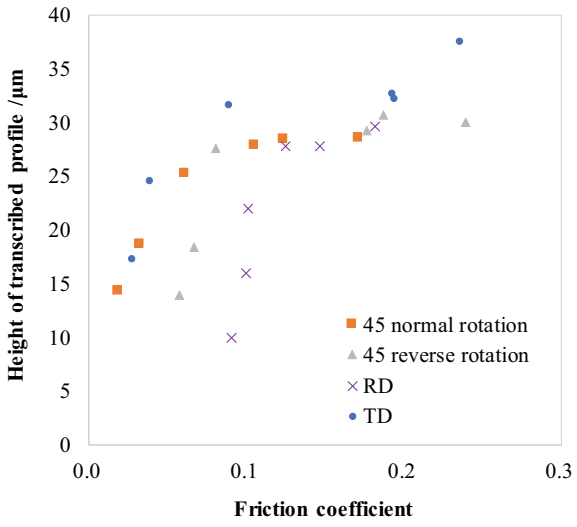

Fig. 13 Relationship between Height of transcribed profile and friction coefficient. (Color figure online)

formation process. In higher friction coefficients over 0.15, where the reduction is higher, higher friction causes higher projections with any of the rolls other than the 45-groove roll in reverse rotation. The compressive stress in the roll bite from the resistant force is helpful in forming the projection, as suggested other Refs. [8, 9]. In the case of the 45-degree groove roll in reverse rotation, an additional compressive stress along the width from the metal flow forces the formation of stronger flow stress on plan strain condition. This effect does not directly affect the resistant force. This might be the reason why a low projection height on the roll has a high friction coefficient.

6 Conclusion

To predict transferability on textured rolling, we have to decide on the adaptive boundary conditions, namely, the microscopic relative velocity between the material and the roll in the roll bite. Based on this idea, experimentally, we estimated the apparent friction coefficients of each roll (1) RD, (2) TD, and (3) the 45-degree groove roll. Based on our experiments, we confirmed that the influence of the following resistant forces exist in textured rolling.

1. Restraint force in the rolling direction due to the formation of protrusions
2. Restraint force in the rolling direction due to the presence of multiple roll grooves in the roll bite
3. Influence of flow stress due to metal flow in the width direction
4. Contact ratio of roll convex in the roll bite.

There is a relationship between the resistant force as the estimated friction coefficients and the projection height in the higher reduction area. However, the theoretical prediction itself of apparent friction coefficients is still difficult as there is an interaction between micro transferability and the resistant force. We conclude that it is important to estimate the apparent friction coefficient in predicting transferability.

Fundamentals of Continuous Helicoid Auger Flighting Rolling—Deformation Mechanics, Kinematics, and Applications

Ming He

Abstract An auger flighting is a helical-shaped circular product used to transfer bulk materials in broad applications. Continuous auger flightings are formed from straight steel strips by a specialty rolling mill. Because of the geometry and configuration of auger flightings, the rolling process is more complex than the ordinary longitudinal rolling. However, there is little published literature on the theoretical features of auger flighting rolling. In this article, the fundamental kinematics and mechanics of auger flighting rolling are mathematically developed. From these mathematical models, the contact area, rolling force, and torque are calculated and the affecting factors are evaluated. The slip characteristics between the strip and forming rolls and the effects of roll offset are studied. The article also provides design considerations, primarily for the main roll shafts and required rolling mill power. Finally, the application results are compared to the actual rolling readings and satisfactory agreement is obtained.

Keywords Auger flighting · Strip steel · Rolling · Plastic deformation · Mechanics · Kinematics · Mill design

1 Introduction

The helicoid auger flighting is the centerpiece of a helicoid auger or continuous screw conveyor, which is commonly used to transfer or propel loose materials in broad applications in the agriculture, food, mining, and construction industries. An auger assembly is composed of a helicoid flighting, outer pipe (container), and inner pipe (central shaft), as shown in Fig. 1. A continuous flighting is formed at room temperature from a straight carbon, alloy or stainless steel strip by a specialty rolling mill. Figure 2a shows the strip being uncoiled, straightened, and fed into the rolling mill. Figure 2b shows the rolled continuous auger flighting that is produced by the rolling mill.

(a) Feeding straightened strip into the rolling mill

(b) Rolled continuous auger flighting

Fig. 2 Continuous auger flighting rolling. (Color figure online)

Auger flighting rolling is a type of plastic deformation involving complex kinematics, elasticity, and plasticity, along with other important factors that extend from raw material properties to rolling mill operations. Flighting design and manufacturing, however, are mainly based on experience and trial and error because of the unavailability of systematic theories regarding the auger flighting rolling process. This article describes a few key auger flighting rolling features and common practices through theoretical and empirical equations.

2 Geometrical Features of Helicoid Auger Flighting

A rolled auger flighting has the following primary dimensions (Fig. 3): inner diameter d, outer diameter D, pitch P, inner edge thickness T_0, outer edge thickness T_1, and blade or strip width W. The selection of the inner diameter depends on a number of factors, including the size of the central shaft, outer diameter, pitch, and strip thickness. The geometrical relationships derived from a helix are applicable to flightings that are rolled under normal mill settings where the rolls are aligned without any skew, offset or misalignment. When the rolls are set up skewed (the roll axes are not parallel but cross at a small angle), offset (one roll is ahead of the other

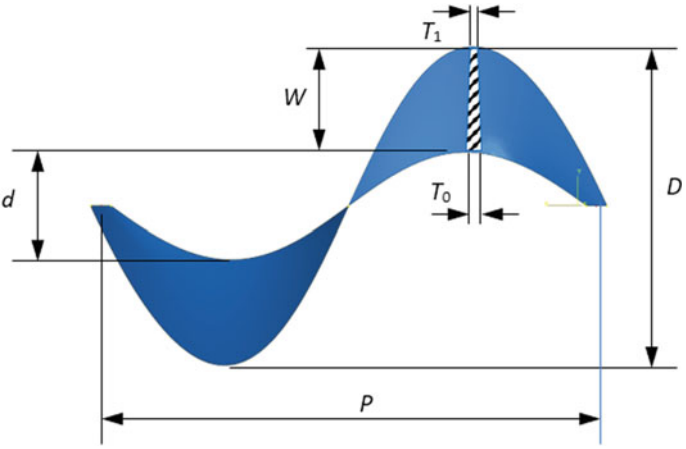

Fig. 3 Nomenclature of helicoid auger flighting. (Color figure online)

one) or misaligned (one roll is lower than the other one) or a combination of those conditions, the flighting's geometry becomes much more complex.

The inner length L_{in} and outer length L_{out} of one revolution of the flighting are calculated from

$$L_{\text{in}} = \sqrt{(\pi d)^2 + P^2} \text{ and } L_{\text{out}} = \sqrt{(\pi D)^2 + P^2} \tag{1}$$

If the initial thickness of the strip steel is T_0, based on the volume conservation rule, the theoretical outer edge thickness T_1 of the rolled flighting is

$$T_1 = \frac{L_{\text{in}}}{L_{\text{out}}} T_0 \tag{2}$$

When substituting Eq. (1) for L_{in} and L_{out} in Eq. (2), the relationship of the outer and inner edge thicknesses expressed by the pitch-to-outer diameter ratio P/D and inner diameter-to-outer diameter ratio d/D, shown in Fig. 4, is:

$$\frac{T_1}{T_0} = \sqrt{\frac{\left(\frac{d}{D}\right)^2 + \left(\frac{1}{\pi}\frac{P}{D}\right)^2}{1 + \left(\frac{1}{\pi}\frac{P}{D}\right)^2}} \tag{3}$$

The relationship in Eq. (3) indicates that the smaller these ratios, the more severe the thickness reduction at the outer diameter will be. Often this is driven by a demand for higher propelling productivity. Figure 4 shows that the thickness of the outer edge can be reduced to 20% of that of the initial strip when small ratios are selected. This requires good workability of the material to prevent the outer edge from cracking during rolling. When the thickness at the outer edge is significantly reduced, the

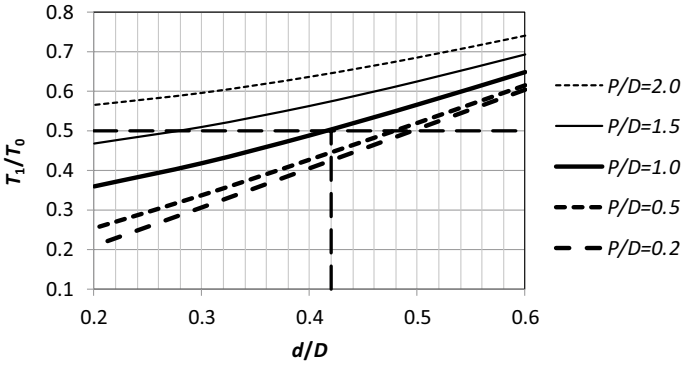

Fig. 4 The outer blade thickness affected by P/D and d/D ratios

service life of the flighting is compromised, since the outer edge is subject to greater wear as the result of its higher linear velocity relative to the inner edge.

To help maintain the minimum outer edge thickness, one can reduce the forming width to narrow the difference between the inner and outer diameters, or increase the pitch while keeping the outer diameter unchanged (Fig. 4). These two methods, however, are not always practical, since they are restricted by the auger flighting dimensional requirements specified by the customer. One might consider preventing a portion of the strip from undergoing any deformation at all by using a so-called "low-strip rolling" technique. Other options are to increase the outer edge thickness via a hard facing technique or to introduce a profile to the forming roll surface, as described in a number of patents [1–4].

"Low-strip rolling" means that a portion of the strip on the inner side is hanging outside the rolls, and therefore, is not rolled. Assume that the width of the hanging portion, or non-deformed zone, is Δ and the diameter at the location where the non-deformed zone ends and the deformed zone begins is d' (Fig. 5). The length of the one-revolution flighting at the diameter d' is:

$$L_{d'} = \sqrt{(\pi d')^2 + P^2}, \text{ where } d' = d + 2\Delta = D - 2(W - \Delta) \tag{4}$$

The outer thickness of the flighting will be

$$T_1^{'} = \frac{L_{d'}}{L_{\text{out}}} T_{d'} = \frac{L_{d'}}{L_{\text{out}}} T_0 \tag{5}$$

where T_0 is the initial thickness at the non-deformed zone.

To calculate how much the thickness of the outer edge increases as a result of this hanging portion, or "hangout," substituting Eq. (2) for T_0 in Eq. (5) leads to

$$\frac{T_1^{'}}{T_1} = \frac{L_{d'}}{L_{\text{in}}} \tag{6}$$

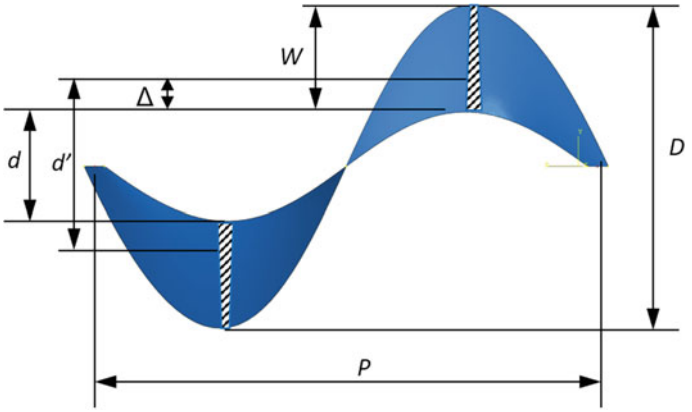

Fig. 5 Nomenclature of helicoid auger flighting in low-strip rolling. (Color figure online)

where T_1 is the thickness of the outer edge after regular rolling without the hangout.

By substituting Eq. (1) for L_{in}, Eq. (4) for $L_{d'}$ and d' in Eq. (6), the ratio between the outer edge thickness with hangout and thickness without hangout is

$$\frac{T_1'}{T_1} = \sqrt{1 + 4\pi^2 \frac{\frac{\Delta}{W}\left(\frac{d}{W} + \frac{\Delta}{W}\right)}{\pi^2\left(\frac{d}{W}\right)^2 + \left(\frac{P}{W}\right)^2}} \tag{7}$$

Because the right side of Eq. (7) is greater than 1 (see Fig. 6), the thickness of the outer edge of the flighting after low-strip rolling is larger than the thickness created by regular rolling. Thus, the flighting's wear life can be increased. The results show

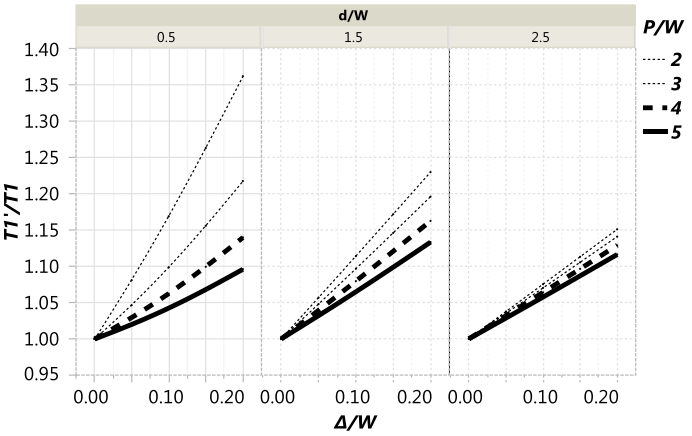

Fig. 6 Outer edge thickening resulting from the hangout after low-strip rolling. (Color figure online)

that the thickness of the outer edge increases with increasing hangout Δ in low-strip rolling. The influence of the hangout on the outer edge thickening is more significant when the d/W and P/W ratios are smaller.

It should be mentioned that applying low-strip rolling is not without potential risk. Notably, assuming that the length of the inner edge is the same as that of the strip with no hangout, the non-deformed hangout zone also causes thickening at the inner edge to occur. Based on the volume conservation rule, the inner edge thickness $T_0^{'}$ of the flighting after low-strip rolling now is

$$T_0^{'} = \frac{L_{d'}}{L_{\text{in}}} T_{d'} = \frac{L_{d'}}{L_{\text{in}}} T_0 \text{ or } \frac{T_0^{'}}{T_0} = \sqrt{1 + 4\pi^2 \frac{\Delta(d+\Delta)}{(\pi d)^2 + P^2}} \tag{8}$$

If the numerator and denominator of the second term on the right side of Eq. (8) are both divided by D^2, the equation becomes

$$\frac{T_0^{'}}{T_0} = \sqrt{1 + 4\pi^2 \frac{\frac{\Delta}{D}\left(\frac{d}{D} + \frac{\Delta}{D}\right)}{\pi^2 \left(\frac{d}{D}\right)^2 + \left(\frac{P}{D}\right)^2}} \tag{9}$$

Since the right side of the equation is greater than 1, $T_0^{'}$ will be larger than T_0 unless $\Delta = 0$. The relationship of Eq. (9) is also expressed in Fig. 7a. It is logical that the smaller the d/D and P/D ratios are, the more thickening will occur at the inner edge. Interestingly, if the numerator and denominator of the second term on the right side of Eq. (8) are both divided by P^2, the equation becomes Eq. (10), where it can be observed that maximum thickening happens when d/P is in the range of 0.2 to 0.3 (see Fig. 7b). Beyond this range, thickening actually decreases gradually.

$$\frac{T_0^{'}}{T_0} = \sqrt{1 + 4\pi^2 \frac{\frac{\Delta}{P}\left(\frac{d}{P} + \frac{\Delta}{P}\right)}{\pi^2 \left(\frac{d}{P}\right)^2 + 1}} \tag{10}$$

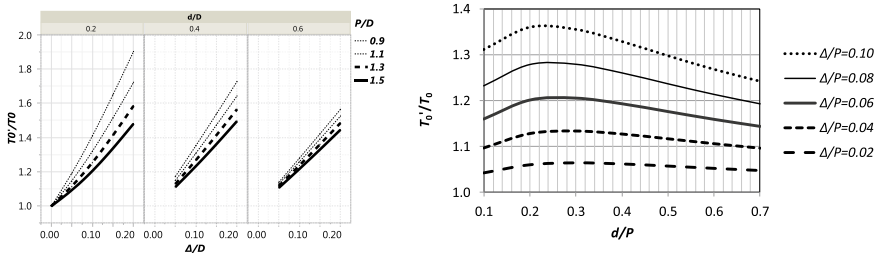

Fig. 7 Thickening of the inner edge after low-strip rolling. (Color figure online)

However, the amount of thickening in the non-deformed portion of the hangout is controlled not only by its geometry, but also by the strip's mechanical properties and the rolled flighting's dimensions. Even if the strip is very ductile, the thickening could be limited because the hangout region can buckle—an instability triggered by the slenderness ratio of the length of the hangout region to its thickness. The buckling pushes the material sideways to form a wavy or wrinkled inner edge, which can adversely affect product quality. That is why correctly selecting the ratios to achieve a balance between productivity and service life is of great importance in auger flighting design.

3 Mechanics of Auger Flighting Rolling

3.1 Stress-Strain Relationship of Auger Flighting Rolling

Auger flighting rolling can be categorized as a type of special longitudinal cold rolling. For this process, when elastic deformation is negligible compared to plastic deformation and the strip is assumed to be a *work-hardening* material with little strain rate sensitivity, the flow stress after yielding, expressed by the Johnson–Cook equation, is simplified into a power-law equation

$$\overline{\sigma} = K\overline{\varepsilon}^{n} \tag{11}$$

The material parameters K (the strength coefficient) and n (the strain-hardening exponent) are calculated from the true stress and true strain data points of a simple uniaxial tensile test of the subject strip. In auger flighting rolling, which is a plane-strain operation of a *work-hardening* strip steel, the von Mises yield criterion is

$$\sigma_1 - \sigma_3 = \frac{2}{\sqrt{3}}\overline{\sigma} = 1.155\overline{\sigma} = \overline{\sigma}_m \tag{12}$$

where $\overline{\sigma}_m = 1.155\overline{\sigma}$ is the effective plane-strain flow stress.

Substituting Eq. (11) for the flow stress $\overline{\sigma}$ in Eq. (12) results in a general effective stress–strain relationship for the work-hardening steel strip

$$\overline{\sigma}_m = 1.155\overline{\sigma} = 1.155K\overline{\varepsilon}^{n} \tag{13}$$

The effective strain in the plane-strain operation is expressed by

$$\overline{\varepsilon} = \left[\frac{2}{3}\left(\varepsilon_1^2 + \varepsilon_3^2\right)\right]^{\frac{1}{2}} \tag{14}$$

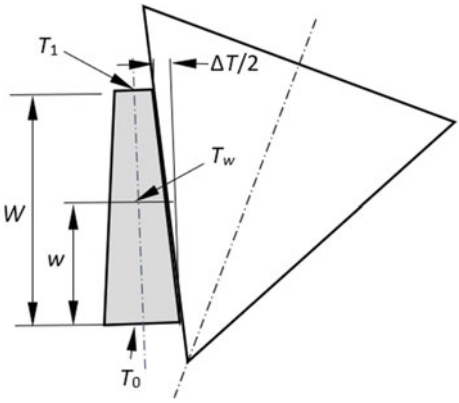

Fig. 8 Cross-section of a deformed flighting. (Color figure online)

In auger flighting rolling, the thickness along the width W of the strip varies (Fig. 8). If the total thickness reduction is $\Delta T = T_0 - T_1$, the strip thickness at the width w is:

$$T_w = T_0 - \frac{w}{W}\Delta T \tag{15}$$

The thickness strain at the width w is

$$\varepsilon_{1_w} = \varepsilon_{t_w} = \ln\left(\frac{T_0}{T_w}\right) = \ln\left(\frac{T_0}{T_0 - \frac{w}{W}\Delta T}\right) \tag{16}$$

where w is the strip width at the strip thickness T_w, measured from the inner edge of the strip, at which the strip has its initial thickness T_0. The longitudinal strain at the width w is

$$\varepsilon_{3_w} = -\varepsilon_{1_w} \tag{17}$$

Substitute Eqs. (16) and (17) for ε_1 and ε_3 in Eq. (14). The effective strain under the plane-strain condition at the width w becomes

$$\bar{\varepsilon}_w = \frac{2}{\sqrt{3}} \ln\left(\frac{T_0}{T_0 - \frac{w}{W}\Delta T}\right) \tag{18}$$

Equation (18) demonstrates that the effective strain increases with increasing strip thickness reduction. When the reduction is large, attention should be paid to ensure that the strip does not exceed its ultimate strength limit.

Substituting Eq. (18) for $\bar{\varepsilon}$ in Eq. (13), the effective plane-strain flow stress at the width w is

$$\overline{\sigma}_{m_w} = \frac{2}{\sqrt{3}} K \left[\frac{2}{\sqrt{3}} \ln\left(\frac{T_0}{T_0 - \frac{w}{W}\Delta T} \right) \right]^n \tag{19}$$

Equations (18) and (19) are closed-form equations that calculate the effective stress and strain at any width of a work-hardening steel strip at any moment during auger flighting rolling.

3.2 Rolling Contact Area

Because of the cone-shaped forming rolls and gradual thickness reduction in the strip from the inner edge to the outer edge, the contact area between a forming roll and the strip during plastic deformation has an irregular profile, as shown in Fig. 9. The following parameters are assigned for calculating the rolling contact area: A is the contact area, α is the included angle of a roll, c is the length of the truncated roll tip (the forming roll does not have a sharp tip), θ is the contact angle at the strip width w, s is the length of the contact arc at the strip width w, x is one-half of the thickness reduction at the strip width w, and r is the radius of the roll at the strip width w. From Fig. 9, the following relationships are established:

$$x = \frac{w}{W}\frac{\Delta T}{2}, r = (c + w)\sin\frac{\alpha}{2}$$

$$\cos\theta = 1 - \frac{x}{r} \text{and } s = r\theta \tag{20}$$

which lead to the extended formula expressed by Eq. (21).

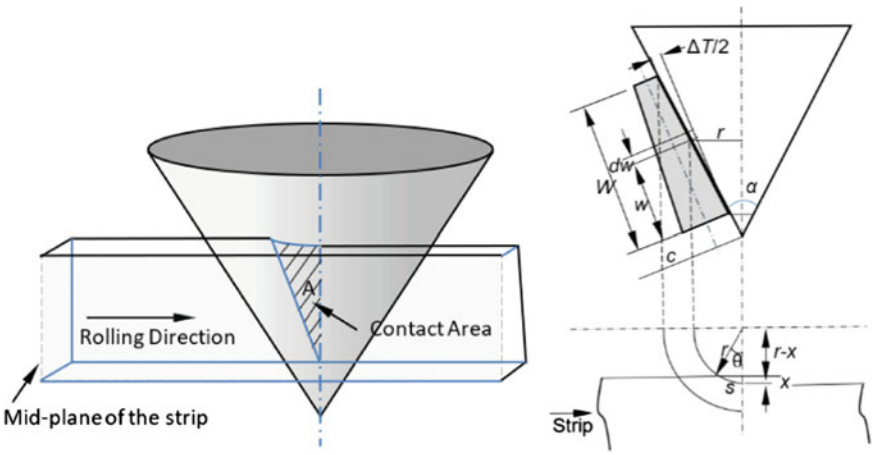

Fig. 9 Definition of the rolling contact area. (Color figure online)

$$\theta = \cos^{-1}\left[1 - \frac{x}{r}\right] = \cos^{-1}\left[1 - \frac{w\Delta T}{2(c+w)W\sin\frac{\alpha}{2}}\right] \tag{21}$$

The length of the contact arc s at the width w is

$$s = (c+w)\sin\frac{\alpha}{2}\cos^{-1}\left[1 - \frac{w\Delta T}{2(c+w)W\sin\frac{\alpha}{2}}\right] \tag{22}$$

The infinitesimal contact area at the width w is

$$dA = sdw|_W \tag{23}$$

where dA is an infinitesimal difference in the area and dw is an infinitesimal difference in the strip width.

After applying the definite integral to Eq. (23), the total contact area is

$$A = \int_0^W sdw = \int_0^W (c+w)\sin\frac{\alpha}{2}\cos^{-1}\left[1 - \frac{w\Delta T}{2(c+w)W\sin\frac{\alpha}{2}}\right]dw \tag{24}$$

3.3 Roll Separating Force

In its simplest form, the roll separating force or rolling force is a product of the rolling pressure from the rolls exerted to the workpiece (and vice versa) in the contact area:

$$F = \int_A pdA \tag{25}$$

where p is the rolling pressure in the roll-workpiece contact area. Because of the existent effect of the friction between the rolls and workpiece, the so-called *friction hill*, the calculation of the roll separating force historically has been very difficult and laborious. Many researchers in the last century presented experimental diagrams and various equations, either theoretical or empirical, to predict the roll separating force (primarily for longitudinal flat slab or plate rolling). All of these equations were proposed with assumptions and simplifications so that they could be used in practice.

3.3.1 Tselikov's Method [5]

Tselikov's method is one of the most famous and influential equations. Because the thickness reduction along the strip width varies, the calculation of the roll separation force is in the following form:

$$F = \int_0^W f(\overline{\sigma}, \overline{\varepsilon}) s dw = \int_0^W \frac{\overline{\sigma}_m (2 - \varepsilon_t)}{\varepsilon_t \delta} \left[\left(\frac{1}{1 - \varepsilon_t} \right)^{\frac{\delta}{2}} - 1 \right] s dw \tag{26}$$

The effective plane-strain flow stress $\overline{\sigma}_m$ is from Eq. (19) and the length of the contact arc s is from Eq. (22). The relative thickness reduction ε_t can be obtained by referring to Eq. (15).

$$\varepsilon_t = \frac{T_w}{T_0} = 1 - \frac{w \Delta T}{W T_0} \tag{27}$$

In addition, coefficient

$$\delta = \mu \sqrt{\frac{4r}{T_0 - T_w}} \tag{28}$$

Substituting Eq. (15) for T_w and Eq. (20) for r in Eq. (28) leads to an extended expression of δ:

$$\delta = 2\mu \sqrt{\frac{W(c + w) \sin \frac{\alpha}{2}}{w \Delta T}} \tag{29}$$

where μ is the coefficient of friction.

Substituting Eq. (19) for $\overline{\sigma}_m$ in Eq. (26), combining Eq. (24) with Eq. (26), and assuming that the total roll separating force acts at two-thirds of the total width W ($w = \frac{2}{3} W$) in the exponent δ, the total roll separating force is

$$F = \int_0^W (c + w) \sin \frac{\alpha}{2} \cos^{-1} \left[1 - \frac{w \Delta T}{2(c + w) W \sin \frac{\alpha}{2}} \right] \frac{2}{\sqrt{3}} K \left[\frac{2}{\sqrt{3}} \ln \left(\frac{T_0}{T_0 - \frac{w}{W} \Delta T} \right) \right]^n \frac{\left(1 + \frac{w \Delta T}{W T_0} \right)}{\left(1 - \frac{w \Delta T}{W T_0} \right) 2\mu \sqrt{\frac{W(c+w) \sin \frac{\alpha}{2}}{w \Delta T}}} \left[\left(\frac{1}{\frac{w \Delta T}{W T_0}} \right)^{\mu \sqrt{\frac{(3c+2W) \sin \frac{\alpha}{2}}{2 \Delta T}}} - 1 \right] dw \tag{30}$$

If the assumption that the total roll separating force acts at two-thirds of the total width W ($w = \frac{2}{3} W$) is applied to the entire Eq. (30), the calculation of the total roll separating force can be further simplified as

$$F = \frac{2}{\sqrt{3}} A \left[K \frac{2}{\sqrt{3}} \ln \left(\frac{T_0}{T_0 - \frac{2}{3} \Delta T} \right) \right]^n \frac{(3T_0 + 2\Delta T)}{(3T_0 - 2\Delta T) 2\mu \sqrt{\frac{(3c+2W) \sin \frac{\alpha}{2}}{2 \Delta T}}} \left[\left(\frac{1}{\frac{2 \Delta T}{3 T_0}} \right)^{\mu \sqrt{\frac{(3c+2W) \sin \frac{\alpha}{2}}{2 \Delta T}}} - 1 \right] \tag{31}$$

3.3.2 Homogeneous Plane-Strain Upsetting Method [6]

By assuming that the deformed zone can be approximated in the same way as homogeneous plane-strain upsetting, the roll separating force per unit width of the strip is given by

$$F = \int_0^W \frac{2\overline{\sigma}_m}{\sqrt{3}} \left(1 + \frac{ms}{4T_w}\right) s\,dw \tag{32}$$

where m is the shear coefficient of friction.

Substituting Eqs. (15), (19), and (22) in Eq. (32) for T_w, $\overline{\sigma}_m$ and s, respectively, gives

$$F = \int_0^W (c + w) \sin\frac{\alpha}{2} \cos^{-1}\left[1 - \frac{w\Delta T}{2(c + w)W \sin\frac{\alpha}{2}}\right] \frac{2}{\sqrt{3}} K \left[\frac{2}{\sqrt{3}} \ln\left(\frac{T_0}{T_0 - \frac{w}{W}\Delta T}\right)\right]^n \left[1 + \frac{mw}{4\left(T_0 - \frac{w}{W}\Delta T\right)}\right] dw \tag{33}$$

If the assumption that the total roll separating force acts at two-thirds of the total width W ($w = \frac{2}{3}W$) is applied to the entire Eq. (33), the calculation of the total roll separating force can be simplified as

$$F = \frac{2}{\sqrt{3}} A \left[K \frac{2}{\sqrt{3}} \ln\left(\frac{T_0}{T_0 - \frac{2}{3}\Delta T}\right)\right]^n \left[1 + \frac{mW}{6\left(T_0 - \frac{2}{3}\Delta T\right)}\right] \tag{34}$$

3.3.3 Example Calculations of Roll Separating Forces

Example calculations of the roll separating forces of an auger flighting using the closed-form equations described in Sects. 3.3.1 and 3.3.2 are shown below. The calculations are also compared with the results from finite element modeling performed with ABAQUS Unified FEA software. The following parameters were used. Strip dimensions: $T_0 = 5.08$ mm, $W = 152.4$ mm. Flighting dimensions: $D = 457.2$ mm, $d = 152.4$ mm, and $P = 660.0$ mm. Strip steel grade: $K = 551.6$ MPa and $n = 0.145$. Roll included angle: $\alpha = 90°$ or 65°. Coefficient of friction: μ or $m = 0.08$, 0.10 or 0.12 (Table 1).

Table 1 Calculated parameters varying with changing roll included angle

α, °	T_1, mm, Eq. (3)	c, mm	s, mm, Eq. (22)	A, mm^2, Eq. (24)
90	2.6232	10.3237	16.8284	1,320.6
65	2.6204	8.6555	14.6065	1,140.8

Table 2 Roll separating forces F in kN, with 90° roll included angle

μ or m	The Tselikov method, Eq. (30)	The simplified Tselikov method, Eq. (31)	The upsetting method, Eq. (33)	The simplified upsetting method, Eq. (34)	Average (Δ, % of average)	FEA
0.08	1,210	1,152	1,221	1,191	1,194 (5.8%)	1,218
0.10	1,351	1,257	1,342	1,301	1,313 (7.2%)	1,204
0.12	1,521	1,376	1,463	1,412	1,443 (10.0%)	1,260

μ or m	The Tselikov method, Eq. (30)	The simplified Tselikov method, Eq. (31)	The upsetting method, Eq. (33)	The simplified upsetting method, Eq. (34)	Average (Δ, % of average)	FEA
0.08	990	949	1,056	1,028	1,006 (10.6%)	1,056
0.10	1,085	1,023	1,161	1,124	1,098 (12.6%)	1,045
0.12	1,195	1,105	1,265	1,219	1,196 (13.4%)	1,103

The roll separating forces F with 90° and 65° roll included angles are given in Tables 2 and 3.

The simplified equations yield smaller forces than those produced by the initial equations. All four equations give similar force values. The difference Δ among all results is smaller in low-friction and larger in roll included angle conditions. The results from the closed-form equations are closer to the finite element results when the friction is low.

3.3.4 Factors Affecting the Roll Separating Force

The roll separating force in flighting rolling is affected by the dimensions of the flighting, roll included angle, lubrication conditions (frictions), skewed rolling (non-parallel roll axes), offset rolling (rolls misaligned in the rolling direction), misaligned rolling (rolls misaligned in the strip width direction), and strip hangout, as well as the carbon content of the steel.

The roll separating force increases with increased friction between the strip and rolls, as shown in Fig. 10. A larger roll included angle results in a higher rolling force, as shown in Fig. 11. The influence of the friction condition and the roll included angle on the roll separating force is more profound as the strip's width, outer diameter, and thickness increase. For simplicity, in these examples, the flighting's inner diameter and pitch are fixed.

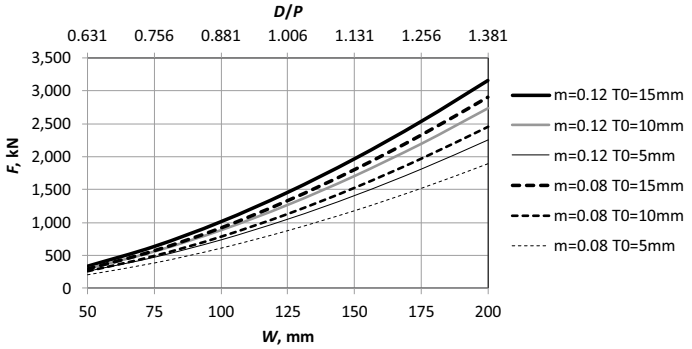

Fig. 10 Influence of friction condition, strip width and D/P ratio on the roll separating forces (90° roll included angle)

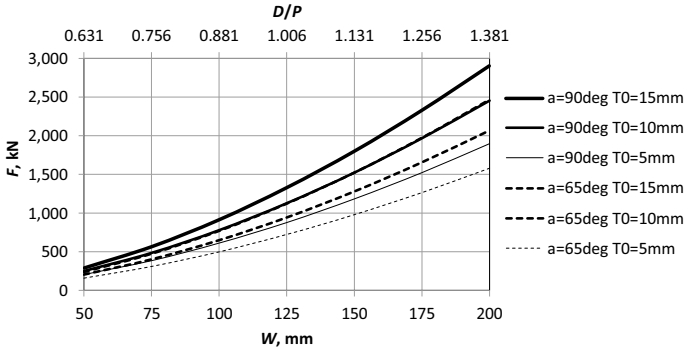

Fig. 11 Influence of roll included angle, strip width and D/P ratio on the roll separating forces ($\mu = 0.08$)

3.4 Rolling Torque on Main Roll Shafts

Because of the roll included angle α, the rolling torque acting on the two main roll shafts results solely from the component F_y of the roll separating force that is in the direction perpendicular to the axes of the main roll shafts (see Fig. 12). The component F_x of the roll separating force that is in the direction parallel to the axes of the main roll shafts will, however, exert a bending moment on the shafts.

The rolling torque T acting on one main roll shaft can be calculated by the following formula after applying the relationships described in Sect. 3.2.

$$T = F_y a = F \cos\frac{\alpha}{2} a = \cos\frac{\alpha}{2} \int_0^W f(\overline{\sigma}, \overline{\varepsilon}) s a d w \tag{35}$$

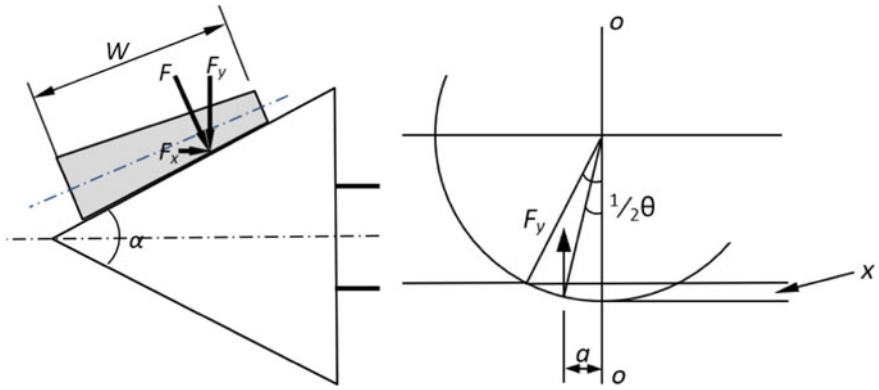

Fig. 12 Resultant torque from roll separating force and torque arm. (Color figure online)

where the torque arm a, assuming that the roll separating force is acting at one-half of the contact arc and is parallel to the rolling plane o-o, is expressed as

$$a = (c+w)\sin\frac{\alpha}{2}\sin\frac{\theta}{2} = (c+w)\sin\frac{\alpha}{2}\sin\left[\frac{1}{2}\cos^{-1}\left[1-\frac{w\Delta T}{2(c+w)W\sin\frac{\alpha}{2}}\right]\right] \tag{36}$$

When adopting Tselikov's method, the regular and simplified one-roll torques on the main shaft, respectively, are

$$T = \int_0^W (c+w)^2 \sin\left[\frac{1}{2}\cos^{-1}\left[1-\frac{w\Delta T}{2(c+w)W\sin\frac{\alpha}{2}}\right]\right]\cos^{-1}\left[1-\frac{w\Delta T}{2(c+w)W\sin\frac{\alpha}{2}}\right]$$
$$\frac{2}{\sqrt{3}}K\left[\frac{2}{\sqrt{3}}\ln\left(\frac{T_0}{T_0-\frac{w}{W}\Delta T}\right)\right]^n \frac{\left(1+\frac{w\Delta T}{WT_0}\right)}{\left(1-\frac{w\Delta T}{WT_0}\right)2\mu\sqrt{\frac{W(c+w)\sin\frac{\alpha}{2}}{w\Delta T}}}$$
$$\left[\left(\frac{1}{\frac{w\Delta T}{WT_0}}\right)^{\mu\sqrt{\frac{(3c+2W)\sin\frac{\alpha}{2}}{2\Delta T}}} - 1\right] dw\left(\sin\frac{\alpha}{2}\right)^2\cos\frac{\alpha}{2} \text{ and} \tag{37}$$

$$T = \left(c+\frac{2}{3}W\right)\sin\frac{\alpha}{2}\cos\frac{\alpha}{2}\sin\left[\frac{1}{2}\cos^{-1}\left[1-\frac{\Delta T}{(3c+2W)\sin\frac{\alpha}{2}}\right]\right]$$
$$\frac{2}{\sqrt{3}}KA\left[\frac{2}{\sqrt{3}}\ln\left(\frac{T_0}{T_0-\frac{2}{3}\Delta T}\right)\right]^n \frac{\left(1+\frac{2\Delta T}{3T_0}\right)}{\left(1-\frac{2\Delta T}{3T_0}\right)2\mu\sqrt{\frac{(3c+2W)\sin\frac{\alpha}{2}}{2\Delta T}}}\left[\left(\frac{1}{\frac{2\Delta T}{3T_0}}\right)^{\mu\sqrt{\frac{(3c+2W)\sin\frac{\alpha}{2}}{2\Delta T}}} - 1\right] \tag{38}$$

By following the same procedures, the regular and simplified one-roll torques calculated by the homogeneous plane-strain upsetting method, respectively, are

$$T = \int_0^W (c+w)^2 \sin\left[\frac{1}{2}\cos^{-1}\left[1-\frac{w\Delta T}{2(c+w)W\sin\frac{\alpha}{2}}\right]\right]\cos^{-1}\left[1-\frac{w\Delta T}{2(c+w)W\sin\frac{\alpha}{2}}\right]$$
$$\frac{2}{\sqrt{3}}K\left[\frac{2}{\sqrt{3}}\ln\left(\frac{T_0}{T_0-\frac{w}{W}\Delta T}\right)\right]^n\left[1+\frac{mw}{4\left(T_0-\frac{w}{W}\Delta T\right)}\right]dw\left(\sin\frac{\alpha}{2}\right)^2\cos\frac{\alpha}{2} \text{ and} \quad (39)$$

$$T = \left(c+\frac{2}{3}W\right)\sin\frac{\alpha}{2}\cos\frac{\alpha}{2}\sin\left[\frac{1}{2}\cos^{-1}\left[1-\frac{\Delta T}{(3c+2W)\sin\frac{\alpha}{2}}\right]\right]$$
$$\frac{2}{\sqrt{3}}KA\left[\frac{2}{\sqrt{3}}\ln\left(\frac{T_0}{T_0-\frac{2}{3}\Delta T}\right)\right]^n\left[1+\frac{mW}{2(3T_0-2\Delta T)}\right] \quad (40)$$

The two roll or total torque is $T_t = 2T$.

Calculations for the one-roll torques of one auger flighting using the above closed-form equations and the rolling parameters in Sect. 3.3.3 are given in Tables 4 and 5, respectively. The calculations are also compared to the results of finite element modeling using ABAQUS Unified FEA software. With influencing factors similar to those of the rolling force, the roll torque is affected more by the reduction ratio or larger *D/P* ratio, as shown in Figs. 13 and 14.

Table 4 One-roll torque T in kN-m, with 90° roll included angle

4 Kinematics of Auger Flighting Rolling

4.1 Strip Velocity in Forming Zone

When the strip enters the forming zone between the two rolls under the conditions that the two rolls have exactly the same rotational speed and the strip is deformed into an annular shape before it is bent into a helicoid auger flighting, the velocity of the strip along the width is not always the same as the tangential surface velocity of the rolls. From Fig. 15, it can be seen that the velocity at the inner edge of the rolled strip is higher than that of the rolls, while the velocity at the outer edge of the rolled strip is lower than that of the rolls because the strip and the rolls have different rotational centers. As a result, there must be a point, *e*, at which the velocities of the rolled strip and the roll surfaces are equal. This point *e* can be referred to as the neutral point.

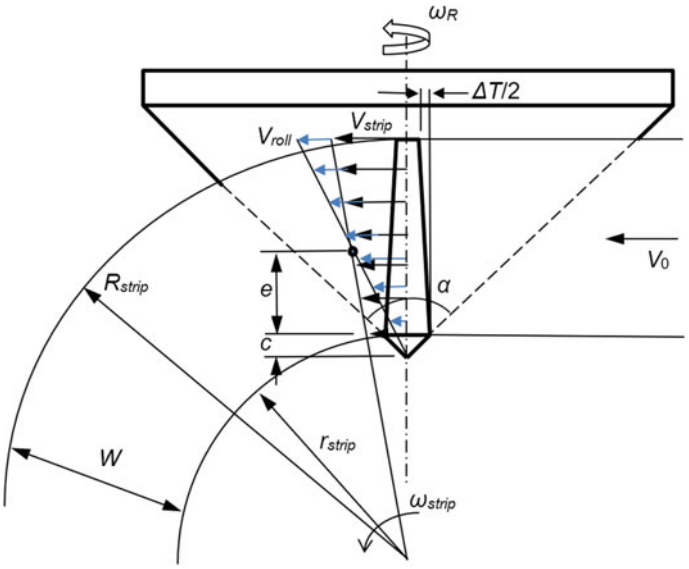

Fig. 15 Schematic of the velocity field in the forming zone. (Color figure online)

From the geometrical relationship, the tangential surface velocity of the rolls and the velocity of the rolled strip at point e are, respectively,

$$V_e = V_{\text{roll_}e} = (c+e)\sin\frac{\alpha}{2}\omega_R = V_{\text{strip_}e} = \left(r_{\text{strip}} + e\right)\omega_{\text{strip}} \tag{41}$$

By assuming that there is no thickening or thinning at the inner edge of the rolled strip in the forming zone, Eq. (2) holds and the following relationships $T_e L_e = T_{\text{inner}} L_{\text{inner}}$and $T_{\text{inner}} = T_0$ are obtained. Differentiating the L values with respect to time on both sides yields

$$T_e V_e = T_0 V_{\text{inner}} \text{or } V_{\text{inner}} = \frac{T_e}{T_0}(c+e)\sin\frac{\alpha}{2}\omega_R \tag{42}$$

where $T_e = T_0 - \frac{e}{W}\Delta T$, $\omega_R = \frac{\pi}{30} n_R$ and $V_{\text{inner}} = r_{\text{strip}}\omega_{\text{strip}} = r_{\text{strip}}\frac{V_e}{(r_{\text{strip}}+e)}$.

To solve for point e and other unknown parameters, the frictional forces from the velocity differential between the rolls and the rolled strip that act on both sides of the neutral point e must be in equilibrium about the point e (Fig. 16),

$$M_L = \int_0^e \mu f(\overline{\sigma}, \overline{\varepsilon}) s dw (e-w) \text{and } M_U = \int_e^W \mu f(\overline{\sigma}, \overline{\varepsilon}) s dw (w-e) \tag{43}$$

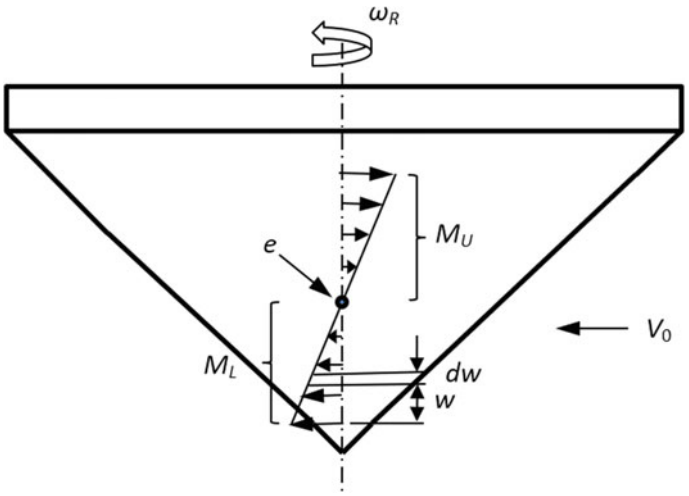

Fig. 16 Rotational frictional moment on roll surface. (Color figure online)

where μ is the coefficient of friction between the roll and strip, $f(\overline{\sigma}, \overline{\varepsilon})sdw$ are the infinitesimal friction forces in dw (Sect. 3.3.1), and $(e - w)$ or $(w - e)$ are moment arms.

Letting $M_L = M_U$ and solving the integration on both sides, the location of the neutral point e can be found, followed by obtaining other unknown kinematical parameters of the rolled strip and the rolls in Eqs. (41) and (42). Using the same dimensions of the example auger flighting shown in Sect. 3.3..3 and assuming that the given rotational speed of the rolls n_R is 9.355 rpm, the parameters calculated from the above closed-form equations are listed in Table 6.

The reason that point e locates more than 50% of the rolled strip width from the inner edge of the rolled strip is because there is more deformation and higher force toward the outer edge. With increasing friction between the rolls and strip, the

Table 6 Rolling velocity-related parameters

Parameters	90° roll angle			65° roll angle		
	$\mu = 0.08$	$\mu = 0.10$	$\mu = 0.12$	$\mu = 0.08$	$\mu = 0.10$	$\mu = 0.12$
Point e (% of the total width) from the inner edge of the rolled strip (mm)	94.89 (62.3%)	92.69 (60.8%)	90.15 (59.2%)	95.96 (63.0%)	94.21 (61.8%)	92.23 (60.5%)
V_e (mm/s)	72.88	71.36	69.60	55.06	54.14	53.11
V_{inner} (mm/s)	50.91	50.35	49.67	38.28	37.94	37.54
V_{outer} (mm/s)	98.70	97.60	96.28	74.21	73.55	72.78
r_{strip} (mm)	219.87	222.07	224.61	218.80	220.55	222.53

distance from the inner strip edge to point e slightly decreases and the velocities of the strip slightly decrease as well. The radius of the rolled strip r_{strip} increases because the upper moment M_U is larger when point e is closer to the inner strip edge. The rolls with a 65° angle, when compared to those with a 90° angle, result in a considerable decrease in the strip velocities owing to a much reduced roll surface linear speed.

The above calculations are based on assumption that sliding friction occurs in all contact zone between the strip and the rolls. In actual rolling, sticking zones can appear if the shear stress caused by the friction force is greater than the shear strength of the strip material. The higher the friction, the larger the sticking zone could be. If this happens, the surface of the rolled strip usually shows sticking marks, such as scratches, peeling, galling, or even some build-up.

With the setting depicted in Fig. 15, the rotational friction moment on the roll surface is in the clockwise direction, as shown in Fig. 16. The strip is, therefore, subject to a counter-clockwise rotational friction moment opposite to that on the roll surface. As a result, the section of the strip immediately prior to entering the rolling zone tends to be lifted upward. The lifting is larger when the rolling friction is higher. The lifting force is sometimes so high that the strip can come out of the lower row of guiding rollers, as shown in Fig. 17. Therefore, it is very important that the guiding mechanism be well designed to (1) provide sufficient retention of the strip to counter the lifting force acting on the strip, as well as maintaining the strip's position, and (2) protect the strip from any damage before it enters the rolling zone.

Fig. 17 Rotational friction moment causing the strip to derail from the guiding rollers. (Color figure online)

Table 7 Auger flighting rolling throughput and rate

Parameters	90° roll angle			65° roll angle		
	$\mu = 0.08$	$\mu = 0.10$	$\mu = 0.12$	$\mu = 0.08$	$\mu = 0.10$	$\mu = 0.12$
V_{auger} (m/min.)	2.473	2.445	2.412	1.859	1.843	1.823
$t_{\text{one-pitch}}$ (s)	16.02	16.20	16.42	21.30	21.49	21.72

4.2 Auger Flighting Forwarding Velocity and Throughput

By assuming that the velocity V_{inner} is equivalent to the total auger flighting velocity V, the forwarding velocity or the throughput of the auger flighting V_Z or V_{auger} in its axial direction during rolling is

$$V_{\text{auger}} = V_Z = \frac{V_{\text{inner}}}{L_{in}} P = \frac{P}{\sqrt{(\pi d)^2 + P^2}} \left(1 - \frac{e}{W} \frac{\Delta T}{T_{\text{inner}}}\right)(c + e) \sin\left(\frac{\alpha}{2}\right) \frac{\pi}{30} n_R \tag{44}$$

The time to roll the auger flighting in one revolution or one pitch is

$$t_{\text{one-pitch}} = \frac{L_{\text{in}}}{V_{\text{inner}}} = \frac{P}{V_{\text{auger}}} \tag{45}$$

If an auger flighting has n pitches, the time spent to roll that auger is

$$T_{n-\text{pitch}} = n t_{\text{one-pitch}} \tag{46}$$

Using the same auger flighting example, the throughput and rate calculated from Eqs. (44) and (45) are given in Table 7.

Auger flighting rolling throughput is slightly affected by rolling friction conditions, but it is considerably affected by the roll angle. As shown in this example, when the roll angle changes from 90° to 65°, under the same friction conditions the throughput of rolling the same auger flighting can decrease by more than 32%.

4.3 Strip Feeding (Bite) Condition

The strip feeding or "bite" condition describes the maximum thickness of a strip that the two rolls can pull into the roll gap under the specified friction and rolling conditions to initiate the rolling process. When the strip thickness exceeds the specified maximum value, the strip will slip over the roll surface and normal rolling cannot be established. The strip thickness that fails in one situation might be satisfactory in another situation once the friction or other rolling conditions are changed.

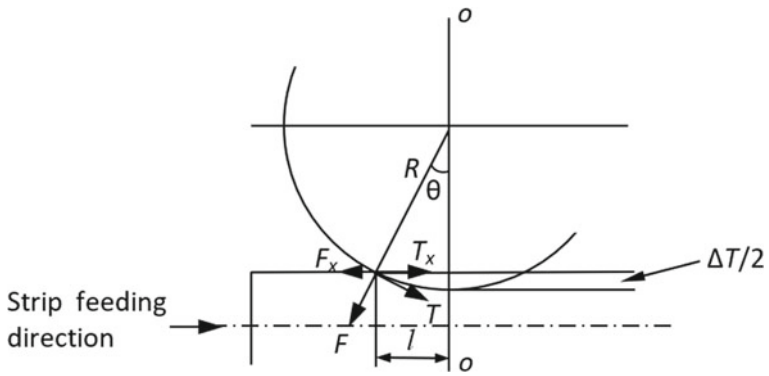

Fig. 18 The outmost edge of a strip during feeding

In auger flighting rolling, the strip's inner edge is deformed very slightly or not deformed at all. The area at the outermost edge of the strip where the largest thickness reduction occurs determines the strip feeding condition.

When the outer edge of the strip contacts the roll surface during feeding (Fig. 18), the relationship of the unit friction force T and unit normal contact force F that a roll gives to the strip at the contact point is $T = \mu F$, where μ is the coefficient of friction at the contact point between the roll surface and strip. When the critical bite condition occurs and the coefficient of friction equals the tangent of the angle of friction $\theta_{\max}$, the two horizontal force components must be in equilibrium, which is $T_x + F_x = 0$ or $\mu F \cos\theta_{\max} - F \sin\theta_{\max} = 0$. Therefore, $\mu = \tan\theta_{\max}$.

For the rolls to "bite" the strip, the condition in which the angle of contact is less than or equal to the angle of friction must be satisfied

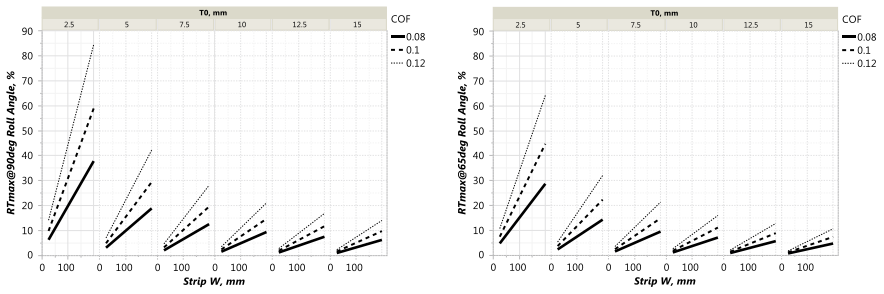
$$\tan\theta \le \tan\theta_{\max} \text{or } \tan\theta \le \mu \tag{47}$$

From Fig. 18, it is seen that $\cos\theta = 1 - \frac{\Delta T}{2R}$ and $\sin\theta = \frac{l}{R} = \frac{\sqrt{R^2 - \left(R - \frac{\Delta T}{2}\right)^2}}{R} = \frac{\sqrt{4R\Delta T - \Delta T^2}}{2R}$. Then $\tan\theta = \frac{\sqrt{4R\Delta T - \Delta T^2}}{2R - \Delta T} \le \mu$. By squaring both sides and neglecting the second order of the thickness reduction ΔT, the maximum strip thickness reduction to ensure the strip will be gripped by the rolls is obtained.

$$\Delta T \le \frac{\mu^2}{1 + \mu^2} R \tag{48}$$

Because the radius R of a roll at the outer edge of the strip (also shown in Fig. 9) is

$$R = (c + W) \sin\frac{\alpha}{2} \tag{49}$$



By substituting Eq. (49) for R in Eq. (48), the maximum strip thickness reduction at the outer edge can also be expressed as

$$\Delta T \leq \frac{\mu^2}{1+\mu^2}(c+W)\sin\frac{\alpha}{2} \tag{50}$$

Equation (50) demonstrates that the maximum allowable thickness reduction for secure biting is affected by the coefficient of friction, the roll included angle and the strip width. In production, the biting condition is usually expressed by the maximum thickness reduction ratio $R_T\max = \frac{\Delta T}{T_0} \times 100\% \leq \frac{\mu^2}{1+\mu^2}\frac{c+W}{T_0}\sin\frac{\alpha}{2} \times 100\%$.

The $R_T\max$ (up to 50% of T_0) of the commonly used strips under cold rolling friction conditions ($0.08 \leq \mu \leq 0.12$) with 90° and 65° roll angles are shown in Fig. 19. The selected R_T must be below the curves in the figures. The amount of friction plays a significant role in strip biting. With higher friction, the maximum thickness reduction of the strip necessary to establish biting is considerably larger when the initial strip thickness and width are fixed. The biting condition is improved by increasing the roll included angle and decreasing the initial strip thickness. The thickness reduction at the outer edge of a strip often exceeds the allowable bite condition values. In this situation, the lead of the outer strip should be prepared by either roughing the surfaces to increase the friction, beveling them to reduce the initial thickness or scarfing a portion of the outer strip to let the biting approach to the inner edge.

Over the course of biting, as the strip gradually enters the roll gap, the contact point where the unit contact force and unit frictional force act is moving toward the exit of the roll gap. Once biting is complete and the strip completely fills the roll gap, the total contact force shifts to a location at about half of the contact arc (the angle of contact is reduced by half). Under this circumference, rolling will continue because the bite condition, Eq. (47), is always satisfied. During rolling, at any cross-section along the width of the strip, there always is a neutral plane N where the surfaces of the strip and the rolls have the same linear velocity. At entrance, the surface velocity of the strip is lower than that of the rolls and the friction between the strip and rolls

(a) 90° roll angle (b) 65° roll angle

Fig. 19 Maximum strip thickness reduction ($c = 10.3237$ mm). (Color figure online)

helps draw the material into the roll gap. At exit, the surface velocity of the strip is faster than that of the rolls and the friction between the strip and rolls resists the outflow of the material.

4.4 Roll Offset

The roll offset is a setup adjustment that purposely positions one roll slightly behind the other roll in the rolling direction to achieve the same or similar effect as hangout rolling. When an offset is used, the roll gap changes and the actual rolled strip thickness along the width deviates from the design specification values. Therefore, it is important to understand the relationship between the offset and the rolled strip thickness.

4.4.1 Changes in the Roll Gap Because of the Roll Offset

Assume that the strip always enters the roll gap perpendicular to the roll surfaces and that the elastic recovery in the strip and rolls is not considered. By applying the cosine law, the distance from the roll surface to its centerline R_i at any location along the strip width (see Fig. 20a) is:

$$R_i^2 = \left(\frac{c+w}{\cos\xi}\right)^2 + \left(\frac{c+w}{\cos\beta}\right)^2 - 2\left(\frac{c+w}{\cos\xi}\right)\left(\frac{c+w}{\cos\beta}\right)\cos\frac{\alpha}{2} \tag{51}$$

The relationship of the three angles is $\xi = \frac{\alpha}{2} - \beta$. The geometry of the rolled strip without roll offset is $T_0 = 2W\tan\beta + T_1$. From Fig. 20b, the following relationship can be established

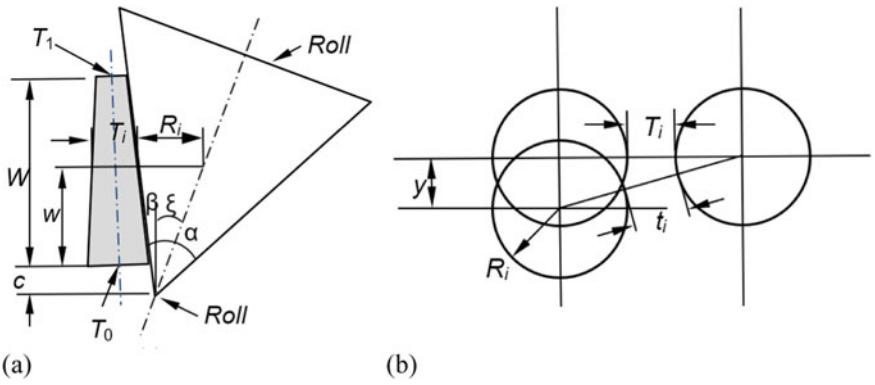


Fig. 20 Schematics of roll offset. (Color figure online)

$$(2R_i + T_i)^2 + y^2 = (2R_i + t_i)^2 \tag{52}$$

where R_i is an arbitrary distance from the roll surface to the roll centerline at the strip width w ($R_i \neq$ the roll radius at location i), T_i is the strip thickness without roll offset at the strip width w, y is the roll offset amount, t_i is the strip thickness with roll offset at the strip width w, and ξ is the roll tilting angle to the vertical mill centerline, which is usually fixed by design.

With a roll offset y, the contact between the strip and rolls is no longer a straight line. The roll gap also changes from a simple trapezoid to a complex configuration. In fact, Eq. (52) expresses a hyperbola relationship of the roll offset and the thickness of the rolled strip along its width. Now, substitute Eq. (51) for R_i in Eq. (52) and select the original strip thickness T_0 and T_1. By running the equation from the roll tip to roll base, the roll gaps under varying roll offsets can be obtained, as shown in Fig. 21.

Figure 21 reveals a number of unique roll gap characteristics that the roll gap lacks when there is no roll offset. These characteristics have a direct impact on the profile of the rolled strip

- First, the roll gap increases as the roll offset increases.
- Second, the larger the roll offset, the greater the thickness reduction at the strip's outer edge.
- Third, because of the hyperbola effect, the roll offset creates a concave profile on the roller strip surfaces. The concave curvature at the roll tip region is much larger

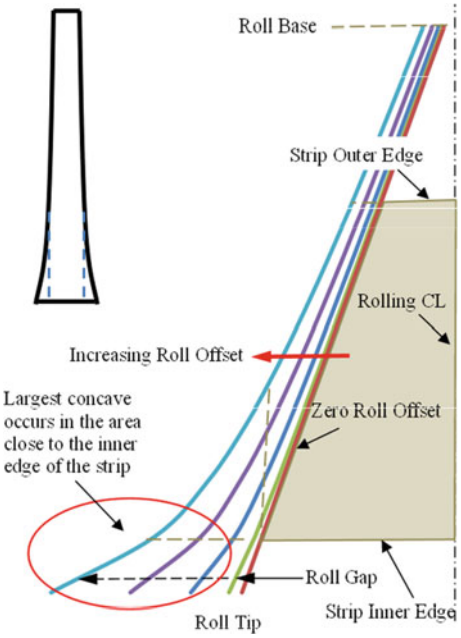

Fig. 21 Influence of roll offset on roll gap. (Color figure online)

than that at the roll base region. When a large roll offset presents, the curvature in the roll tip region is so large that a portion of the inner edge of the strip may not be rolled at all (the dashed lines in the insert in Fig. 21).

This effect is similar to what hangout rolling can achieve. The unrolled or "hang-out" portion increases with the increasing roll offset. The roll offset can also bend the rolled strip naturally to the side of the rear roll, which assists in the formation of a helicoid auger flighting. This bending effect should be considered when determining which roll is set with the forward offset, according to the rotational direction, either the left hand or the right hand, of the rolled auger flighting.

Because of the curved contact zone between the strip and rolls, the strip through the roll gap is twisted from its inner edge to its outer edge. The strip may not always run on a path perpendicular to the connecting line of the two-roll centers, as assumed, which may cause the actual roll gap to be different from the calculated one. As a result, the strip may be rolled to an incorrect thickness, causing the auger flighting to deviate from the required dimensions. To achieve the required thickness in the rolled strip, a new and yet smaller roll gap must be calculated first, from which the amount of roll offset can be determined. The roll offset should be used with caution and the offset amount should be limited if it must be used.

4.4.2 Determination of the Roll Offset Amount for the Required Thickness of the Rolled Strip

Assume R_0 is the distance from the roll surface to roll centerline at the inner edge of the strip T_0 or t_0 ($w = 0$), R_1 is the distance from the roll surface to roll centerline at the inner edge of the strip T_1 or t_1 ($w = W$), T_0 is the initial rolled strip thickness at the inner edge without a roll offset ($w = 0$), t_0 is the targeted rolled strip thickness at the inner edge with a roll offset ($w = 0$), T_1 is the initial rolled strip thickness at the outer edge without a roll offset ($w = W$), and t_1 is the targeted rolled strip thickness at the outer edge with a roll offset ($w = W$).

The following equations are obtained by inserting the above parameters into Eqs. (51) and (52):

$$R_0^2 = c^2\left[\left(\frac{1}{\cos\xi}\right)^2 + \left(\frac{1}{\cos\beta}\right)^2 - 2\left(\frac{1}{\cos\xi}\right)\left(\frac{1}{\cos\beta}\right)\cos\frac{\alpha}{2}\right] \tag{53}$$

$$R_1^2 = (c+W)^2\left[\left(\frac{1}{\cos\xi}\right)^2 + \left(\frac{1}{\cos\beta}\right)^2 - 2\left(\frac{1}{\cos\xi}\right)\left(\frac{1}{\cos\beta}\right)\cos\frac{\alpha}{2}\right] \tag{54}$$

$$R_0 = \frac{c}{c+W}R_1 \tag{55}$$

$$T_0 = \sqrt{(2R_0 + t_0)^2 - y^2} - 2R_0 \tag{56}$$

$$T_1 = \sqrt{(2R_1 + t_1)^2 - y^2} - 2R_1 \tag{57}$$

Then

$$\sqrt{\left(2\frac{c}{c+W}R_1 + t_0\right)^2 - y^2} - 2\frac{c}{c+W}R_1 = 2W\tan\beta + \sqrt{(2R_1 + t_1)^2 - y^2} - 2R_1 \tag{58}$$

The roll offset y, the only unknown in Eq. (58), can be solved by iteration. After obtaining y and inserting it into Eqs. (56) and (57), the initial roll gaps or the strip thicknesses T_0 at the inner edge and T_1 at the outer edge, respectively, are determined. The combination of the required dimensions of the to be rolled strip and the geometry of the rolls may create a situation where the two rolls can come into contact with each other at their bases. In designing an auger flighting rolling, this situation must be checked to prevent the roll bases from contacting.

4.4.3 Strip Deviation Angles

When an offset is created, the strip exits the roll gap at a deviated angle. The deviation angle is an acute angle between the strip feeding direction (perpendicular to the mill front frame face) when it enters the rolling mill and the strip exiting direction when it leaves the roll gap (Fig. 22). The larger the offset, the larger the deviation angle will be. Because the deviation angles at the inner edge and the outer edge are different, the strip also exits the roll gap with a slight twist. This twisting can be expressed by a twisting angle, which is the difference of the deviation angles of the inner and outer

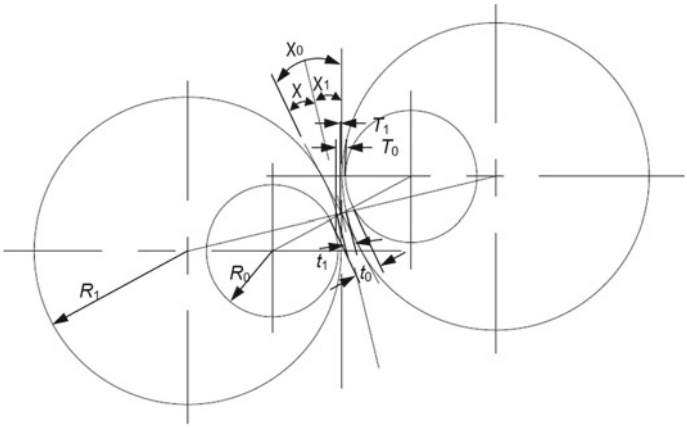

Fig. 22 Calculation of strip deviation and twisting angles. (Color figure online)

edges of the rolled strip. In addition, the roll force component in the rolling direction perpendicular to the mill front frame face increases.

Assume χ_0, χ_1 are the strip deviation angles at the inner edge and outer edge of the rolled strip, respectively, and χ is the strip twisting angle. The strip deviation angles at either the inner or outer edge are, respectively,

$$\chi_0 = \cos^{-1}\left(\frac{R_0 + \frac{T_0}{2}}{R_0 + \frac{t_0}{2}}\right) \text{and } \chi_1 = \cos^{-1}\left(\frac{R_1 + \frac{T_1}{2}}{R_1 + \frac{t_1}{2}}\right) \tag{59}$$

The strip twisting angle is $\chi = \chi_0 - \chi_1$.

5 Design Considerations of the Main Roll Assembly

5.1 Design of Main Roll Shafts

In roll shaft design, the minimum shaft diameter at the location with the highest stresses must have the strength necessary for the shaft to support the loads with a designated life and without premature failure. The shaft is usually subjected to cyclic stresses, which are caused by the combined bending and torsional loads. In this case, the stresses in the main roll shafts are the result of a bending moment originating from the vertical component of the roll separating force F_y, a torsional moment from the torque T, a bending moment from the rotational motion of the strip during rolling and an axial force from the horizontal component of the roll separating force F_x.

Here, only the bending moment from the vertical component of the roll separating force F_y and the torsional moment from the torque T are considered. The other two factors are excluded because: (1) the bending moment from the rotational motion of the strip during rolling is smaller than and in a different phase from the bending moment from the vertical component of the roll separating force F_y, and (2) the axial force is in compressive, which reduces the overall tensile stress at the most critical location in the shaft. The transverse shear also is omitted from this calculation due to its insignificant contribution to the overall stress state when the ratio of the length and diameter of the shaft is sufficiently large. Further, it is assumed that the plane sections remain plane and perpendicular to the neutral axis during bending.

From the mechanics of the materials, the minimum shaft diameter at the critical section A' under combined bending and torsional moments at the critical section is $D_{\min} = \sqrt[3]{\frac{32}{\pi\sigma_{\text{allow}}}\sqrt{M_{\max}^2 + \frac{3}{4}T^2}}$, where σ_{allow} is the allowable working stress of the shaft $\sigma_{\text{allow}} = \frac{\sigma_y}{n_{\text{safe}}}$, σ_y is the yield strength of the shaft material, and n_{safe} is a safety factor. (See Fig. 23.)

It is necessary to note that since the diameters of a main roll shaft vary along its length, the minimum shaft diameter can occur at a location where the bending moment is not at its maximum value. Therefore, the calculation is carried out at

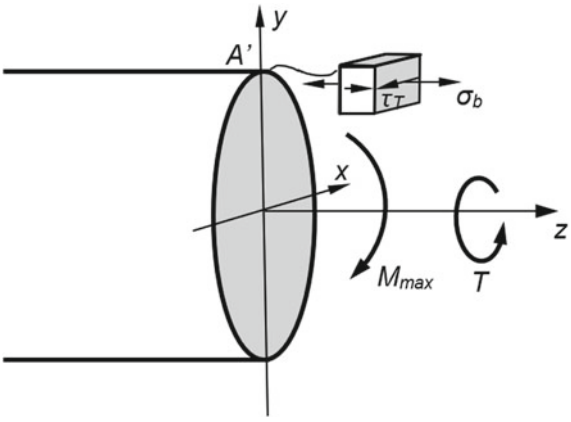

Fig. 23 Stress state at the location A′ of the shaft surface under the combined loads

various locations in addition to the supports (bearing journals) to define the most critical section and the minimum shaft diameter.

5.2 Main Roll Driving Power

The total power provided by the main rolls' driving motor in auger flighting rolling is calculated by considering the following torques: the torques driving the two rolls in rolling P_R, the torques overcoming the frictions in the bearings on the main roll shafts due to the reaction forces P_B, the torques overcoming the frictions in the transmission system (drive chain from the roll-driving motor to the rolls) P_G, the torques during no-load idle running P_M, and the torques coming from the dynamic motion when the rolls change their rotational speed P_D, such as at the start and end of rolling. These powers are

$$P_R = T_t \omega_R = T_t \frac{2\pi n_R}{60} = T_t \frac{\pi}{30} \frac{n_M}{i} \tag{60}$$

where P_R is the power driving the two rolls in kW, T_t is the two roll or total torque in kN-m calculated by using the equations given in Sect. 3.4, ω_R is the angular speed of the rolls in 1/s, n_R is the number of revolutions of rolls per minute (rpm) $= \frac{n_M}{i}$, n_M is the number of revolutions of roll-driving motor per minute (rpm), and i is the gear ratio of the drive chain from roll-driving motor to rolls.

For a two-roll auger rolling mill where the main shafts are laid in an angle approximately equal to one-half of the main roll included angle, the torque to overcome the friction forces in the two main roll bearings and one thrust bearing on each shaft is calculated by the following formula:

$$T_b = 2\left(\mu_{bA} N_A \frac{d_A}{2} + \mu_{bB} N_B \frac{d_B}{2}\right) + 2\mu_{bT} F_x \frac{d_T}{2} \tag{61}$$

The power required for overcoming the friction torque is calculated by

$$P_B = T_b \omega_R = T_b \frac{\pi}{30} \frac{n_M}{i} \tag{62}$$

where P_B is the power overcoming the friction in the four main roll bearings in kW; d_A, d_B, and d_T are the diameters of the main roll shafts at bearings A and B and the thrust bearing, respectively; μ_{bA}, μ_{bB}, and μ_{bT} are the coefficients of friction in bearings A and B and the thrust bearing, respectively; N_A is the reaction force at support A; and N_B is the reaction force at support B.

The torque generated by the frictions in the transmission system of the rolling mill can be determined by the efficiency of the system

$$T_g = \left(\frac{1}{\eta} - 1\right)(T_t + T_b) \tag{63}$$

The power required for overcoming the friction torque in the transmission system is calculated by

$$P_G = T_g \omega_R = T_g \frac{\pi}{30} \frac{n_M}{i}, \tag{64}$$

where η is the efficiency of the main roll power transmission system.

During the no-load idling run, the torque is generated by the friction forces in the bearings, including the main roll bearings and thrust bearing, supporting a proportion of the mass of the main roll assemblies and the components of the transmission system.

$$T_m = \sum_n (mg)_i \mu_{bi} \frac{d_i}{2} \tag{65}$$

where m is the mass of a component in kg, g is acceleration of gravity (=9.81 m/s^2), (mg) is gravity force in N of the component to be supported by a bearing, μ_b is the coefficient of friction of the bearings, and d is the bearing neck diameter of the shaft.

The power in the idling run is

$$P_M = T_m \omega_R = T_m \frac{\pi}{30} \frac{n_M}{i} \tag{66}$$

A dynamic motion happens when the rolling mill starts rotating from an idling condition to full rolling speed, and vice versa. During this period, when a component in the transmission system of mass m and diameter d rotates about its axis in a uniform angular acceleration $d\omega/dt$, the dynamic torque required to generate this acceleration

is

$$T_{d_{\text{comp}}} = F\frac{d}{2} = (ma)\frac{d}{2} = \left(m\frac{d}{2}\frac{d\omega}{dt}\right)\frac{d}{2} = \left(m\frac{d}{2}\right)^2\frac{2\pi}{60}\frac{dn}{dt} = I\frac{2\pi}{60}\left(\frac{n_2 - n_1}{\Delta t}\right) \tag{67}$$

where a is acceleration in m/s^2, I is the torsional moment of inertia of the rotating component $= \left(m\frac{d}{2}\right)^2$, and dn is the rpm change from n_1 to n_2 during the time Δt, which is positive when the rotational speed increases and is negative when the rotational speed decreases.

The total dynamic torque is a summation of the dynamic torques of all of the rotational components in the transmission system

$$T_d = \sum_n T_{d_{\text{comp}}} = \sum_n \left(m_i\frac{d_i}{2}\right)^2\frac{2\pi}{60}\frac{dn_i}{dt} = \sum_n I_i\frac{2\pi}{60}\left(\frac{n_{2i} - n_{1i}}{\Delta t_i}\right) \tag{68}$$

The power required to generate this acceleration is

$$P_D = T_d\omega_R = T_d\frac{\pi}{30}\frac{n_M}{i} \tag{69}$$

The total power that the main rolls' driving motor must provide is as follows, once the different rolling stages or conditions are taken into consideration

(1) Steady auger flighting rolling stage with constant rolling speed

$$P_{\text{Stable}} = P_R + P_B + P_G + P_M \tag{70}$$

(2) Idle running with no load

$$P_{\text{Idle}} = P_G + P_M \tag{71}$$

(3) Dynamic motion during rolling

$$P_{\text{Dynamic Rolling}} = P_R + P_B + P_G + P_M \pm P_D \tag{72}$$

(4) Dynamic motion with no load

$$P_{\text{Dynamic No Load}} = P_G + P_M \pm P_D \tag{73}$$

The above equations were used to calculate the driving powers of the main roll power transmission system in rolling an auger flighting. The results were compared with the actual driving powers of the rolling mill. Since the exact efficiency, friction condition, mass, and dimensions of many components in the overall power transmission system were unavailable or inaccurate, the results from the calculations are

Table 8 Calculated and measured rolling torque (N-m) and power (kW)

	@ $\eta = 85\%$	@ $\eta = 95\%$	Mill reading
Main shaft motor torque T_t, N-m	82.0	73.4	82.3
P_{Stable}, kW	11.56	10.35	11.6
P_{Idle}, kW	1.74	0.53	1.3
$P_{\text{Dynamic Rolling}}$, kW	11.70 (accel.)/11.42 (decel.)	10.49 (accel.)/10.21 (decel.)	n/a
$P_{\text{Dynamic No Load}}$, kW	1.88 (accel.)/1.60 (decel.)	0.67 (accel.)/0.39 (decel.)	n/a

approximate. An important fact is that the calculated values are in the same orders of magnitude as the measured ones.

These equations can be used either to assess a rolling mill's capability when a new product is to be rolled, or to design a new rolling mill when an estimation of the required motor power is needed.

In addition to the driving powers, the total torque was also calculated and compared to the actual torque. The actual and estimated rolling parameters used in the calculations are:

- Bearing neck diameters of the mail roll shafts: $d_A = 266$ mm, $d_B = d_T = 187$ mm
- Mass of one mail roll shaft: $m \approx 800$ kg
- Main motor speed: 1,346 rpm
- Gearbox ratio: 143.8797
- Main roll speed: 9.355 rpm
- Main roll included angle: 90°
- Time from idle to full speed and vice versa: $\Delta t = 0.2$ s
- Coefficient of friction of rolling: $\mu = 0.15$
- Efficiency of the main shaft power transmission system: $\eta = 80\%$ and 90%
- Coefficient of friction of bearings: $\mu_b = 0.003$
- Reaction forces at bearing necks: $N_a = 867.5$ kN, $N_b = 265.2$ kN
- Axial force (thrust from the axial component of the roll separating force): $F_x = 602.3$ kN

The results are given in Table 8.

6 Conclusions

This article describes the mathematical development of the fundamental kinematics and mechanics of auger flighting rolling, from which the contact area, rolling force, and torque are calculated and the affecting factors evaluated. Slip characteristics between the strip and forming rolls and the effects of roll offset are studied. The

design considerations, primarily of the main roll shafts and the required rolling mill power, are also given. The application results were compared to the actual rolling readings with satisfactory agreement.

Evaluating an Automated Avoidance of Ring Climbing in Radial–Axial Ring Rolling

Simon Husmann and Bernd Kuhlenkötter

Abstract The forming process of radial–axial ring rolling involves certain instabilities, causing from the underlying principle of the synchronous and continuous deformation in two opposite rolling gaps. To reduce the occurring consequential errors like climbing of the ring in the radial rolling gap, we installed an image processing system for error detection. Combined with the integration of the camera setting into the control software of the rolling machine, it is possible to test automated rolling strategies to stabilise the forming process in the case of upcoming ring climbing. The paper will illustrate how an intervention limit, in form of limit value, for the control system could be evaluated via statistical process control and evaluates if there is a systematic climbing behaviour of the ring. The combination of an expert interview with an effect analysis of the forming parameters on the stabilising impact leads to the development of an ideal forming strategy. The defined strategy is validated in a final design of experiments.

Keywords Ring rolling · Image processing · Ring climbing

1 Introduction

Radial–axial ring rolling is the most important technology to produce axial symmetrical workpieces. The forming is executed in two opposite arranged rolling gaps, the radial and the axial rolling gap, see Fig. 1. The mandrel is moved in a translational way towards the main roll and therefore defines the ring's wall thickness and its radial contour. Meanwhile, the upper axial roll is also moved linearly towards the lower axial roll to define the height of the ring's cross section. The suppressed material primarily flows into the tangential, respectively, circumferential direction

and therefore increases the diameter of the ring as intended. This way it is possible to form rings with a large diameter as well as a seamless and homogenous structure. The produced components are used because of their huge load capacity in various industries such as the energy and transport sector, the aerospace industry, and in many fields of general mechanical engineering [1, 2].

Due to the fact that the ring is formed continuously and synchronously in two rolling gaps the process itself is unstable and needs to get stabilised through the guide rolls. These also determine the ring's position on the rolling table and could influence it in given boundaries. Because of the unstable process, different process errors can occur. This paper will only focus on the phenomenon of ring climbing, which describes a vertical movement of the ring in the radial gap away from the rolling table. This process error can cause serious deformations of the ring's cross section and could lead to a dish-shaped workpiece and waviness. In this case, the forming process cannot be continued and the ring has to be scrapped.

This work focuses on the evaluation of an automated stabilising control system which should avoid ring climbing and which was developed in recent years. After a short presentation of the corresponding state of the art and the experimental set-up, the evaluation of an intervention limit will be introduced. Based on this intervention limit an ideal stabilising control strategy will be derivated through the combination of an expert interview and an effective study of selected process parameters. Design of experiments will be used for the final evaluation of the stabilising control strategy before the paper closes with brief conclusions.

2 State of the Art

The following state of the art will focus on the avoidance of the phenomenon of ring climbing. While the majority of the research efforts focus on the causal analysis regarding the phenomenon of a climbing ring, only MARCZINSKI, BRISELAT and GOLDBACH mention the thesis, that a climbing ring could be stabilised through different rotational speeds for the axial rolls [3–5]. However, none of the authors has proven the thesis in an experimental or simulative approach or stated the level of speed difference.

Also the displacement of the ring has no proven influence on the climbing behaviour of the ring but has an effect on the ratio of the axial rolls' speed and the radial pass reduction rate [6]. This adjustment of the reduction rate can be used to stabilise the ring [7]. Also, the displacement of the ring is mentioned as a general parameter to stabilise a ring, not specifically in case of a climbing ring [8].

Moreover, different approaches to prevent the climbing of a ring exist. LIEB describes the possibility to observe the axial drive torque to prevent ring climbing, but only deduces this approach in theory without a proof [9]. Furthermore, LIEB mentions a reduction of the chance of ring climbing by tilting the mandrel without explaining if this is mentioned as a preventive or as a reactive measure [10].

Koppers et al. describe that a rolling strategy with high pass reduction rates reduces the evolution of bulges and connect this to the observation of a reduced chance of ring climbing [11]. Also, as a preventive strategy, PENG refers to a geometrical adjustment of the guide rolls [12].

All these publications have in common, that they are either not supported by an experimental or simulative verification if they suggest a reactive rolling strategy or they focus only on preventive measures. Therefore this paper will illustrate how an automated reactive avoidance of a climbing ring could be evaluated.

3 Experimental Set-up

The Chair of Production Systems uses a radial–axial ring rolling machine with a ring's maximum diameter of 1,000 mm, a maximum height of 160 mm, and a unit weight of up to 50 kg. The machine provides rolling forces up to 200 kN in radial and 160 kN in the axial direction. In all presented experiments, the blanks are made of the same alloy, from the same batch, exhibit the same starting geometries as well as the same finishing geometries.

The used camera system consists of an intelligent Matrox Iris GT 1900 camera, which has a resolution of 1600 x 1200 pixels and a maximum frame rate of 15 fps. An intelligent camera has an integrated processor and allows image processing and information extraction without an external PC system. The camera is combined with a 50 mm lens and a Heliopan Digital E27 infrared band-elimination filter. The used algorithm in the image processing set-up was specially developed to detect

the climbing height during radial–axial ring rolling and was presented in a prior publication [13]. A constant airstream in front of the camera lens is realised to reduce the distortion through loose scale particles and heated air.

4 Evaluation of the Intervention Limit

The lower axial roll is always set to a higher level as the rolling table to make sure the roll stays in contact with the workpiece and thereby ensure the forming ability of the roll. Likewise, this disables the friction between the ring and the rolling table. Because of this fact, a process-related gap exists between the ring and the table, which is no sign of a climbing ring, see Fig. 2.

To determine the level of this process-related gap and therefore define a control limit (CL) for the stabilising control system, four rings (R1–R4) are rolled with a standardised configuration of the rolling machine. The rolling processes were captured with an additional video camera to ensure the reliability of the measured data. All recorded data, the video files, the image processing data, and the logged machine data show a non-exemplarily rolling behaviour of ring R4. This ring had an unstable rolling behaviour resulting in a significantly high climbing heights. Therefore, this ring will not be used to define the process-related gap and the correlating control limit. The method of statistical process control (SPC) is used to define the mentioned control limit. The limit is calculated by the process mean $\overline{\overline{x}}$, the process standard deviation $\overline{s}$, and a coefficient A_3:

$$CL = \overline{\overline{x}} + A_3 * \overline{s} \tag{1}$$

For a probability of 99.73% and three rolled rings, the coefficient A_3 could be determined to 1.954. Based on the measured climbing heights of the rings R1–R3 the process mean results to 0.75 mm, the process standard deviation to 0.88, and therefore, the control limit is set to 2.470 mm.

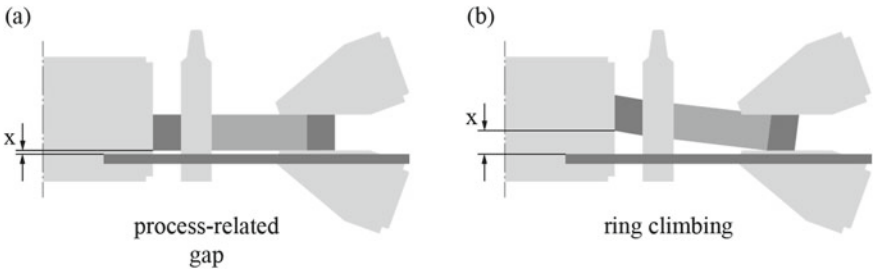

Fig. 2 Schematic difference between **a** the process-related gap and **b** a climbing of the ring

5 Development of an Ideal Stabilising Rolling Strategy

The development of an ideal stabilising control strategy to reduce the climbing of the workpiece during radial–axial ring rolling processes is based on two aspects. On the one hand, the development is influenced by a statistical effect analysis presented in prior publications [14]. These findings show mainly that an adjustment of the rolling table's height has a high impact on the climbing behaviour, especially in correlation with the adjustment of the guide rolls' height difference. On the other hand, the industrial experience is considered through an expert interview.

6 Expert Interview

The interview was held with a rolling-mill worker with over 33 years of experience in forming rings in one of Germany's most important ring manufacturers. According to scientific practice, the interviewee was informed beforehand about the theme procedure of the interview [15]. The most important results of the interview are:

- A definition of a climbing ring, especially of a control limit, is non-existent. At the moment a ring raises significantly from the rolling table, the worker will adjust the control system.
- To stabilise the ring, the worker will set the following adaptions in the listed order
  - Reduction of the main roll speed to gain more time and eventually stabilise the ring in a first step. The amount of reduction is not quantifiable.
  - Increase in the rotational speed of the upper axial roll by 2–3%. This is normally combined with a displacement of the ring of a maximum of 5° towards the radial entrance.
  - Furthermore, it is possible to generate a radial directed force on the workpiece by moving the axial framework. But this method increases the chance of a radial deformation which results in a non-circular ring.
- The above-mentioned measures are implemented in an overlay, respectively, simultaneously, not separated from each other.
- The level of the applied measures is not influenced by the actual duration of the rolling process.
- The measures are held until the ring gets into a stable state near the rolling table. Then the automated rolling procedure is continued.
- If the measures have no effect the worker interrupts the rolling process. The ring is flipped over and a new rolling process starts or the ring needs to be heated again before a new rolling process is started.
- The phenomenon of a climbing ring occurs regularly, often daily.
- A wrong adjustment of the rolling table, high wear of the rolls, and the inhomogeneous temperature of the ring are determined as causes for the phenomenon of a climbing ring.

6.1 Implementation of the Stabilising Control System

Based on the effect study and the expert interview the image processing system is connected to the rolling control to implement the stabilising control system. The implemented stabilising control system is activated automatically, if the rolling process was started, the ring's climbing height exceeds the defined control limit of 2.47 mm and the combined rolling in radial and axial direction is not yet finished. The minimum duration of the stabilising measures is set to 2.0 s. The validation of the implementation is realised in two steps. First, it is tested in the simulation mode of the rolling mill, in which the tools move without rolling an actual ring, with an artificially created and predefined signal to simulate a climbing ring. In the second phase of validation a ring is rolled, while the test signal for a climbing ring is applied in recurring order with durations of 15, 10, and 5 s. The reduction of the main roll speed, the adjustment of the upper axial roll speed in contrast to the lower axial roll speed, and the displacement of the ring are tested.

The first validation shows that the control system reacts as intended but also that especially the engine to accomplish the displacement of the ring has a slow reaction time. The residues of the second validation phase all show a high peak at the beginning of each test signal sequence, marked in the grey areas, with a fast decrease afterwards and a following stable execution of the planned measures, see Fig. 3. Also a high peak occurs at the change back into the automated rolling mode. The residues of the main roll adjustment have an arithmetic mean of 0.393%, the measure of the displacement of the ring of 0.029° and the adjustment of the upper axial roll of 0.274% in the correlating phase. These are significantly lower than the residues during automated control of the rolling mill, especially in the starting phase of the rolling process.

6.2 Derivation of the Stabilising Rolling Strategy

While the measures to stabilise a climbing workpiece during a radial–axial ring rolling process have been derived in their quality before, this chapter focuses on the quantitative validation of the correlating factors. Therefore, a reference has to be set before the design of experiments is conducted. The rolling table has been adjusted with a gap of 1 mm from the upper rolling table edge to the upper edge of the lower axial roll to increase the chance of a climbing ring. To support this chance, the guide rolls have been adjusted with a height difference of 17 mm to each other, while the guide roll on this entrance site of the radial gap has been mounted in the higher position. The reference ring was rolled with the automated control system of the rolling mill. The ring shows a significant increase in its maximum climbing height of 16.06 mm and an average mean of 4.63 mm, see Fig. 4. This equals an increase of about six times the average climbing height, compared to rings rolled with no adjustment of the machinery (R1–R3) which have an average climbing height of

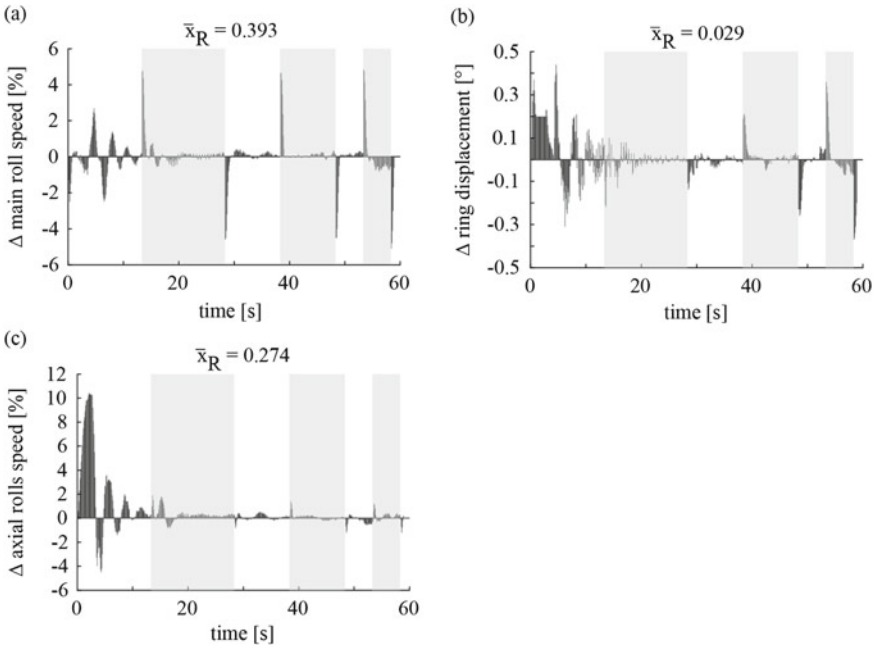

Fig. 3 Residues of **a** the main roll speed, **b** the ring displacement and **c** the axial rolls' speed difference for the evaluation of the implementation of the stabilising control system

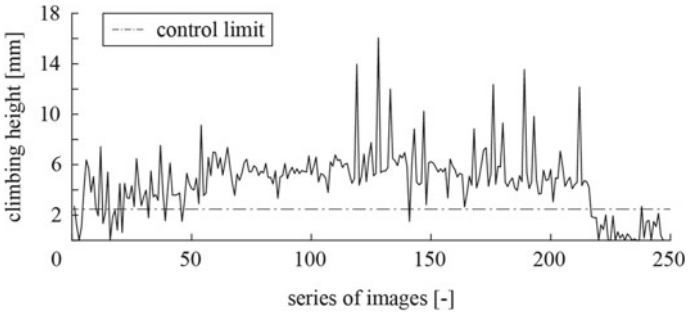

Fig. 4 Climbing heights of the reference ring to evaluate the effectiveness of the stabilising control system

0.75 mm. This is why the reference ring represents a good reference regarding the maximised chance of a climbing ring.

The validation of the process parameters is accomplished via design of experiments with 16 runs (Q1–Q16). The corresponding factors are the rotational speed of the main roll *nMr*, the difference of the axial rolls rotational speed *ΔnAx*, the displacement of the ring *Rd*, and the dynamic of the axial speed difference *axDyn*, see Table 1.

Table 1 Definition of factors and their levels for the design of experiment

Parameter	Unit	Standard	Minimum	Maximum	In short
Main roll speed	(%)	46.5	23.25	41.85	nMr
Axial speed difference	(%)	0	2	5	ΔnAx
Ring displacement	(°)	Automatic	0.74	5	Rd
Dynamic of the axial speed difference	active = 1 inactive = 0	Inactive	0	1	axDyn

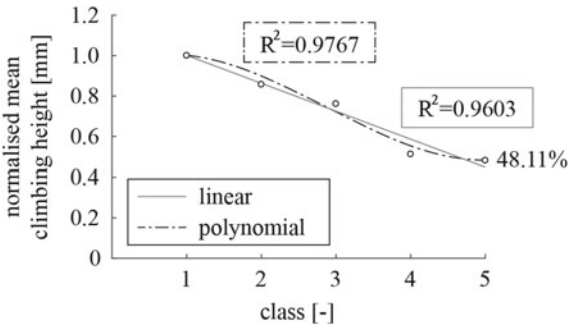

Fig. 5 Classification of the climbing behaviour

Previous ring rolling experiments have shown, that a classification of the normalised single climbing heights over time illustrates a trend of a decreasing average climbing height over the rolling time, see Fig. 5. Because of this effect, the stabilising control system tests a dynamic for the axial rolls' speed difference which decreases the level of intensity linearly over the rolling time. Hereby the effectiveness of this dynamic approach is evaluated in a first step. The intensity is reduced in time steps of 3 mm to the absolute minimum of the normalised data of 48.11% of the initial axial rolls' speed difference.

The reduction of the main roll speed to 41.85% of the maximum potential speed equals a decrease to 90%. The defined minimum of 23.25% which represents a reduction to 50% ensures a large width of variation without slowing down the process excessively. The maximum of the axial rolls' speed difference is defined with 5%, otherwise, the upper roll will lose its forming character and the ring might slip through the axial rolling gap [16]. In this case, the axial roll would also lose the possibility to stabilise the ring and therefore the influence on the climbing height. The minimum of 2% results from the maximum of the process-related variation of the axial rolls' speed difference of the reference ring. This definition is supported by the expert interview which stated an implementation of 2–3% for the axial rolls' speed difference and it also corresponds with the literarily documented industrial level of the axial rolls' speed difference to minimise the chance of a climbing ring [4]. The ring displacement maximum originates from the expert interview and is set to 5°, whereas the minimum of 0.74° is defined by the average maximum of the previously rolled rings (R1–R3).

6.3 Definition of the Dependent Variable

Before the experiments are carried out, it is necessary to define the specific dependent variable. While the amount of repeated transgressions of the control limit may have a higher informative content than the average climbing height, since a low rate indicates a better stabilising control, it lacks in interpreting control interventions without repeated transgressions. Therefore, the authors chose to use the arithmetic mean of the climbing height during the control intervention as the dependent variable. Whereas the median would be more robust, the arithmetic mean is influenced by outliers and therefore better considers repeated transgressions. To maximise the importance of control limit transgressions, a weighted average with a factor of 1.5 is used. The initial transgression of the control limit is not part of the arithmetic mean, respectively, of the dependent variable so that only climbing heights during an active stabilising control system are included.

6.4 Validation via Design of Experiments

Through a plausibility scrutiny with the logged machine data, a screen recorder, and the detected climbing heights ring Q10 had to be excluded from the study. The climbing heights detected via the image processing system could not be reproduced with the screen recorder or the logged data. All the other rings were formed without interruptions to the predefined outer diameter of 800 mm, from a starting diameter of 250 mm.

For all rings, the correlating climbing heights were displayed in contrast to the reference ring, see Fig. 6. While for nearly all rings the reference ring shows a significant higher average climbing height, the ring Q1 tends to climb extensively near the end of the forming. Furthermore, the reference ring shows a longer rolling time, which also indicates an unstable forming process.

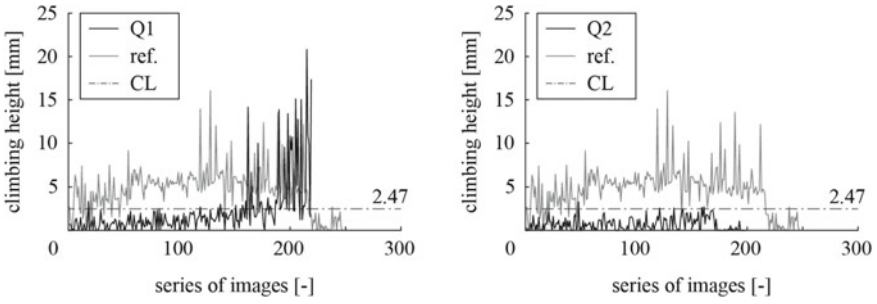

Fig. 6 Excerpt of the measured climbing heights for rings Q1 and Q2

The box plots of all rings including the reference highlight the stable forming of most of the runs, except Q1, and therefore an overall effective stabilising control, see Fig. 7. The median of the reference ring as well as the 75th and 25th percentiles exceed the rings with active stabilising control. The rings with the highest outliers Q1, Q5, and Q7 do not share a parameter with the same factor level for all.

To evaluate basically the indicated difference between the reference ring and all other runs the Wilcoxon signed-rank test is performed, see Table 2. With the assumption H_0 of paired data in each case and a significance level of 0.05, the test could discard this assumption for all rings. Therefore, a significant difference between the reference and all runs is proven which is an additional evidence for an efficient stabilising control system.

The display of the dependent variable y shows a high similarity to the box plots. High peaks for the rings Q1 and the reference ring and low to medium height bars for all other runs of the design of experiments.

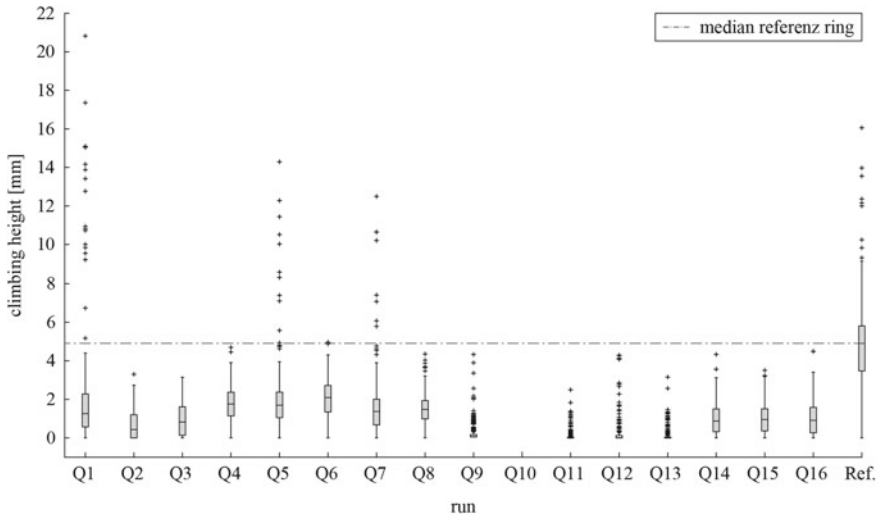

Fig. 7 Boxplot of all measured climbing heights

Table 2 Results of the Wilcoxon signed-rank test for the comparison of each ring to the reference ring

	Q1	Q2	Q3	Q4	Q5	Q6	Q7	Q8
H_0	1	1	1	1	1	1	1	1
p	$1.6*10^{-32}$	$1.1*10^{-53}$	$4.1*10^{-51}$	$1.1*10^{-39}$	$2.0*10^{-40}$	$8.5*10^{-38}$	$9.6*10^{-44}$	$7.2*10^{-46}$
	Q9	Q10	Q11	Q12	Q13	Q14	Q15	Q16
H_0	1	–	1	1	1	1	1	1
p	$3.1*10^{-68}$	–	$1.5*10^{-69}$	$1.6*10^{-63}$	$3{,}7*10^{-69}$	$3.8*10^{-50}$	$4.7*10^{-51}$	$3.9*10^{-48}$

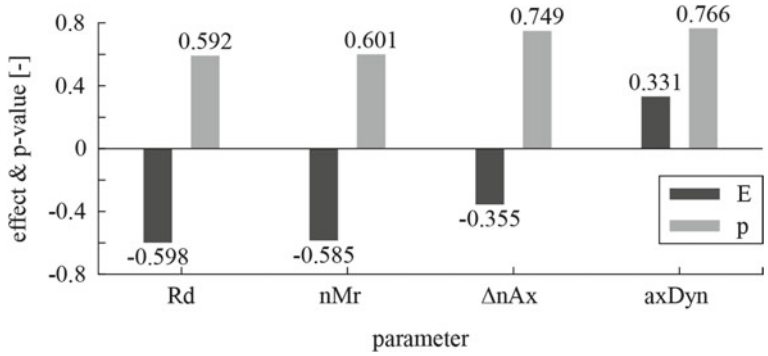

Fig. 8 Effects and p-values for all factors resulting from design of experiments

The computation of the effects E and the correlating significance level p, based on the defined dependent variable, allows a more detailed interpretation, see Fig. 8. Noticeable are the high p-values since they reflect a lack of statistical significance. On the one hand, this is referable to an intrinsic problem of the manipulation of the dependent variable. The intentional influence on the climbing height will resolve in an increased spread and therefore in a higher standard deviation. Since the significance level is influenced by the standard deviation, the p-values will increase too. On the other hand, mass forming processes are underlying higher variations through the high forces and solid workpieces. This adds up through the statically indeterminable system of a radial–axial ring rolling process. This process-related variation combined with a narrow set control limit leads also to an increased spread and therefore to increased significance levels. Furthermore, the amount of runs is comparably low regarding other processes and design of experiments. Due to these facts, the gained results have to be seen as a tendency and correlations, not as causalities or as universal transferable results.

A negative effect, as the ring displacement and the main roll speed show, has to be interpreted as lower ring climbing heights, therefore effects with a negative level have a positive influence on the stabilisation of the rolling process. On the contrary, the dynamic approach of the axial rolls' speed difference has a negative influence on the stabilising behaviour.

The levels of effects are not directly comparable, because they are based on different units. In a normalised comparison the effect of the axial rolls' speed difference with a level of 0.018 mm/min^{-1} is higher than the level of the main roll speed with 0.002 mm/min^{-1}. But this only describes the single effects without paying attention to the correlations between these factors.

For the interpretation of the correlations, a negative gradient also represents a positive stabilisation of the ring and is therefore preferable. All compared pairs interact with each other but with differences in the level of interaction. The correlations between the radial roll speed and the axial dynamic, respectively, the axial dynamic and the axial speed difference are comparatively low. Due to the strong effect of the

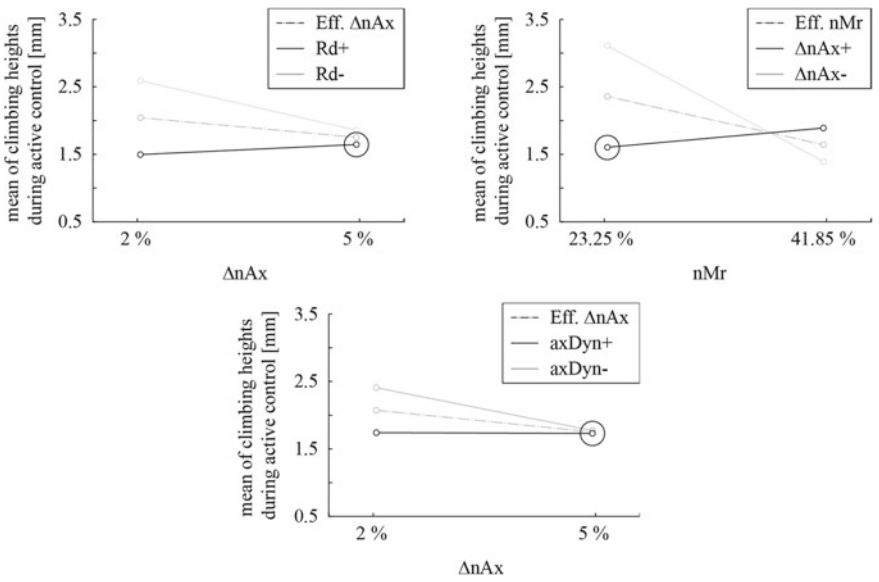

Fig. 9 Different correlations with the marked optimum for the derivation of the stabilising control system

axial speed difference on the climbing height of the ring, this factor is the focus of the derivation of the stabilising control strategy. Through the assumption of the ideal axial speed difference of 5% the interpretation of the corresponding correlations leads to the marked minimum level for the factors of the main roll speed (50%) and the axial dynamic (static) as well as the maximum for the ring displacement (5°) by choosing the optimum of the correlations, respectively, the minimal mean climbing height, see Fig. 9.

This configuration of the factor levels is equivalent to the rolled ring Q14 with a dependent variable y of 1.318 mm. In combination with nine transgressions during the rolling process this run is a valid representation of a rolling process with maximised chance of climbing, see Fig. 10. Compared to the reference ring this combination reduced the arithmetic mean of the climbing heights by about 78.66% and the rolling time is reduced about 11.3%, which is a sign of an effective stabilising control strategy.

7 Conclusions

This paper presents an experimental approach to evaluate an automated stabilising control system to avoid ring climbing during the process of radial–axial ring rolling. To ensure the differentiation between the process-related gap in the radial rolling gap and a climbing ring a control limit was defined. For this purpose, the approach of

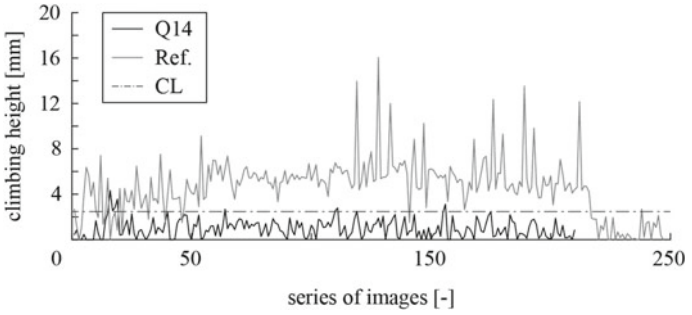

Fig. 10 Measured climbing heights of ring Q14 compared to the reference ring

statistical process control was used and a control limit of 2.47 mm was determined. The definition of the stabilising strategy is based on an expert interview combined with an effect study. The designed stabilising control strategy was implemented on the radial–axial ring rolling machine of the Chair of Production Systems and was successfully tested both in a simulative and experimental way. The final validation of the stabilising control strategy was performed via design of experiments with 16 runs. Therefore a forming reference with a maximised chance of a climbing ring had to be set and a dependent variable, the weighted arithmetic mean of the climbing heights during the control intervention, was defined. The design of experiments and the interpretation of the corresponding effect levels and correlations resulted in an effective stabilising control strategy by adjusting the axial speed difference and the displacement of the ring to the defined maximum of 5% and 5° in the case of a climbing ring. The addressed dynamic of the axial speed difference should not be used because overall it increases the climbing height. The main roll speed should be set to its minimum of 50%. In contrast to the rolled reference ring, this combination of process parameters has reduced the arithmetic mean of the measured climbing heights by about 78.66% and shortened the rolling time by about 11.3%.

Effect of Delivery Angle on Longitudinal Buckling in Temper Rolling of Thin Steel Strips

Toshiro Okazaki, Yukio Kimura, Hideo Kijima, and Masaru Miyake

Abstract The shape defect called "longitudinal buckling" tends to occur in temper rolling of double reduced thin strips. Although previous research investigated the effects of several rolling conditions on longitudinal buckling, the effect of large delivery angles of over 4° has not been studied experimentally. In this paper, the effect of large delivery angles was investigated in a laboratory rolling experiment. The results showed that the longitudinal buckling pattern becomes more distinct and the number of waves decreases as the delivery angle increases, and buckling disappears when the delivery angle exceeds 24°. At the same delivery angle, the buckling form does not change depending on the distance between the work roll and the auxiliary roll. Following this experimental study, an elementary analysis of the buckling characteristics of a sheet winding around a work roll was carried out, and it was found that the change in the number of waves depending on the delivery angle in the analysis was in good agreement with the experimental results when the delivery angle was larger than 10°. It is estimated that longitudinal buckling is initiated around the roll gap and changes under the influence of the shape of the sheet winding around the work roll.

1 Introduction

A striped surface pattern called cross buckle or longitudinal buckle may occur during temper rolling of thin steel sheets. In particular, longitudinal buckle appears as a wave shape parallel to the longitudinal direction and is generally thought to occur easily in thin sheets that have undergone secondary cold rolling after cold rolling and annealing. Sheets with this type of surface defect often require additional processes such as a correction process.

Longitudinal buckle is considered to be a buckling phenomenon of the steel sheet that occurs at the delivery side of the rolling mill due to the residual stress in the steel sheet caused by rolling [1]. Various studies have been made on buckling phenomenon of thin sheets. Abdelkhalek et al. proposed an FEM model of the flatness defects which appear during rolling of thin sheets [2]. Abdelkhalek et al. also studied the behavior of the flatness that may arise when the rolling tension is released using an FEM model [3]. Fischer et al. and Friedl et al. used analytical buckling calculation to predict the buckling mode of thin sheets related to rolling and leveling [4, 5]. Coman also used analytical buckling model and estimated the critical load and the mode of the buckling with linear distribution of residual stress [6]. Tran et al. carried out an experiment to simulate flatness defects of thin sheets by using thermal stresses, and the behavior was in good agreement with FEM result [7, 8].

On the other hand, there are few studies on longitudinal buckle. Kijima et al. carried out an experimental investigation of the influence of rolling conditions on the occurrence of longitudinal buckle, which revealed the following trends [9].

- When the rolling load is reduced, the wave height decreases.
- Longitudinal buckle occurs regardless of the rolling tension.
- The wave height is reduced by reducing the work roll roughness.
- The wave height increases due to an increase in the delivery angle at the exit side of the rolling mill.

Komori obtained the wavelength of longitudinal buckle by an elementary analysis of buckling, and showed that the wavelength of the longitudinal buckle obtained by the analysis was in good agreement with the trend in the experimental values [10]. The results of that analysis also showed that buckling is less likely when the arithmetic average roughness of the temper rolling rolls is low, which is consistent with the experimental results.

Changing the rolling load and/or work roll roughness is a possible approach for preventing longitudinal buckle. However, in many cases, these changes have a large effect on product properties and are difficult in practice. On the other hand, changing the delivery angle is an important method for preventing longitudinal buckle which has relatively little effect on product properties. In general temper rolling mills, auxiliary rolls are installed on the exit side for purposes such as threading stabilization and tension measurement, and these rolls can also be used to give the strip a delivery angle relative to the horizontal pass line at the exit side.

In a previous study, Kijima et al. investigated the influence of the delivery angle in a laboratory experiment with a delivery angle range of 0°–4° [9]. However, the behavior with larger delivery angles has not been studied experimentally or analytically.

In this report, we conducted a laboratory experiment to examine the effect of larger delivery angles (>4°) on the behavior of longitudinal buckle caused by temper rolling (rolling reduction $\leqq$2%) of a steel sheet that has been cold-rolled and annealed and then subjected to secondary cold rolling (rolling reduction of approximately 40%). There was a possibility that the shape of the part where the steel sheet is wound around the work roll (winding part) on the rolling exit side affects longitudinal buckle generation behavior. In order to investigate this possibility, we also carried out an elementary analysis of the buckling mode of the winding part and compared the analysis results with the results of the laboratory experiment.

Furthermore, when a steel strip is given a delivery angle, it has been shown that the rolled material does not follow the work roll near the roll bite outlet [11]. In other words, a noncontact region exists after exiting from roll bite, and there is also a possibility that this phenomenon may affect buckling behavior. Therefore, we carried out an FEM analysis to investigate the contact state between the roll and the steel sheet near the roll bite outlet in temper rolling of steel sheets subjected to secondary cold rolling.

2 Experiment

A temper rolling experiment using a coil rolling mill was conducted to clarify the occurrence of longitudinal buckle. Figure 1 shows a schematic diagram of the laboratory rolling mill used in the experiment, and Table 1 shows the rolling conditions. The rolling mill was a 2Hi type. The work roll diameter was 330 mm, and the roll surface roughness was set to 1.3 μmRa by cylindrical polishing. An auxiliary roll with a diameter of 200 mm was installed on the exit side of the rolling stand, and

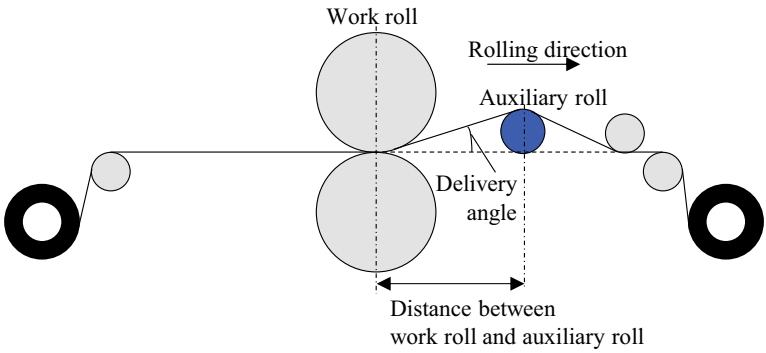

Fig. 1 Schematic illustration of rolling equipment in experiment. (Color figure online)

Table 1 Experiment conditions

Rolling load per width (kN/mm)	5.3
Thickness at entry side (mm)	0.15
Width (mm)	300
Unit tension at entry side (MPa)	100
Unit tension at delivery side (MPa)	100
Work roll diameter (mm)	330
Roughness of work roll surface (μm*Ra*)	1.3
Auxiliary roll diameter (mm)	200
Distance between work roll and auxiliary roll (mm)	225, 375
Delivery angle (°)	0–40
Rolling speed (m/min)	10
Lubrication	Dry

the delivery angle on the exit side of the rolling mill was changed in the range of 0°–40° by changing the height of the auxiliary roll. When the delivery angle was 0°, the auxiliary roll was not placed in contact with the steel sheet. The auxiliary roll was also movable in the rolling direction. In order to investigate the effect of the distance from the winding part to the auxiliary roll, two horizontal distances between the work roll and the center of the auxiliary roll were set: 225 and 375 mm.

The specimen used in this experiment was a cold-rolled steel sheet with a thickness of 0.25 mm and a width of 300 mm that was secondarily cold-rolled to a thickness of 0.15 mm. The yield stress of the specimen was 657 MPa. The rolling conditions were a rolling load of 5.3 kN/mm, an inlet/outlet tension of 100 MPa, and a rolling speed of 10 m/min. The lubrication condition was dry.

After temper rolling, a steel sheet sample taken from the coil was placed on a surface plate with the upper surface during rolling upward, and the surface profile in the width direction was measured with a scanning laser distance meter.

Figure 2 shows the appearance of the sample after rolling when the horizontal distance between the center of the work roll and the auxiliary roll was 225 mm and

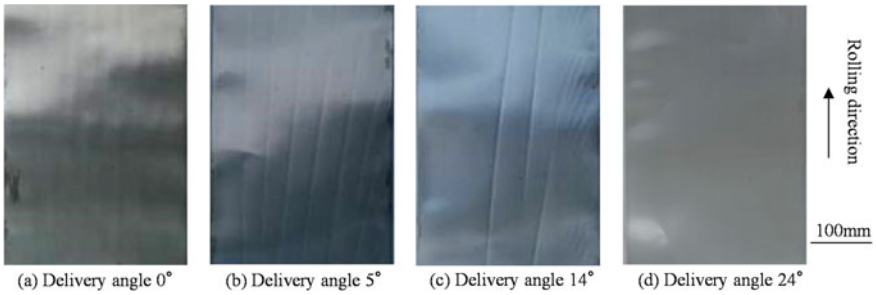

Fig. 2 Appearance of sheet after skin-pass rolling (Distance between work roll and auxiliary roll: 225 mm). (Color figure online)

the delivery angle was changed by changing the height of the auxiliary roll. When the delivery angle is 0°, a number of relatively unclear longitudinal buckles can be observed. When the delivery angle is increased from 5° to 14°, the number of longitudinal buckles (wave number) decreases, and each buckle appears as a clear longitudinal buckle. However, when the delivery angle is increased further to 24°, no longitudinal buckles can be seen. Although not shown in the figure, rolling was also performed with delivery angles larger than 24°, but no longitudinal buckles was observed at these higher delivery angles. In some delivery angle conditions, the longitudinal buckles are not parallel to the rolling direction and not uniformly distributed in width direction. The angle and distribution of longitudinal buckles are considered to be affected by the stress in the longitudinal direction [1], and the difference in elongation in the width direction may have caused the angle and distribution to be not uniform.

Figure 3 shows the measurement results of the surface profile when the horizontal distance between the center of the work roll and the auxiliary roll was 225 mm. The figure shows the profile around the center of the width, where the amount of warpage is small when the steel sheet is left stationary. The measurement location in the longitudinal direction was selected so that longitudinal buckles could be clearly observed visually. At the delivery angle of 14°, the position 175 mm from the left edge of the sheet in Fig. 2 was defined as 0 mm on the horizontal axis in order to show the point where the uneven shape was clear. The surface profile is uneven when the delivery angle is 0°, 5°, or 14°, and this uneven shape becomes increasingly distinct as the delivery angle increases. A clear concavo-convex shape can be confirmed at the delivery angle of 14°, and it has a convex shape toward the bottom surface during rolling. However, the irregular shape is not seen at the delivery angle of 24°.

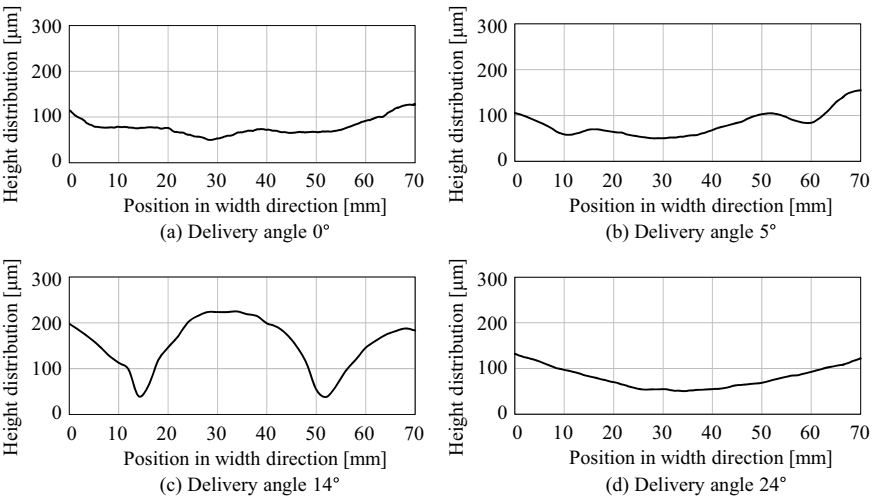

Fig. 3 Wave chart of longitudinal buckling (Distance between work roll and auxiliary roll: 225 mm)

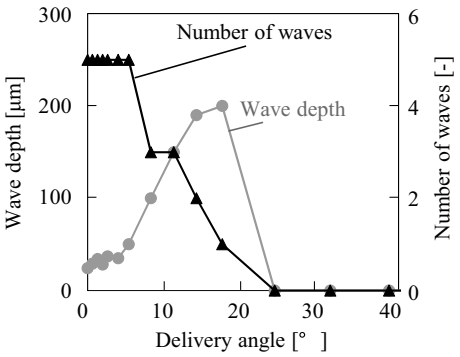

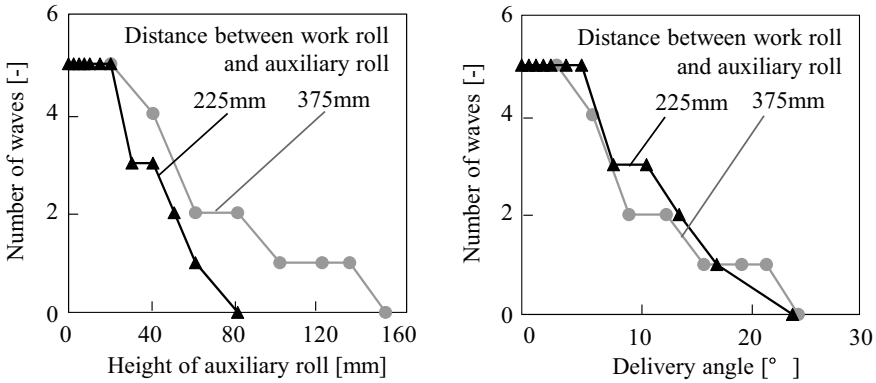

Fig. 4 Effect of delivery angle on buckling behavior (Distance between work roll and auxiliary roll: 225 mm)

From Figs. 2 and 3, in the steel sheet which displays longitudinal buckle, it can be seen that there are some locations where concave and convex portions are locally adjacent on the surface profile. Using the measured surface profile, the height difference between the concave and convex portions was evaluated as the wave depth. At this time, in order to eliminate the influence of the warp shape of the steel sheet, a quadratic approximate curve of the measured surface profile was obtained by the least square method, and the wave depth was evaluated with the difference from the measured surface profile as the evaluation object. The number of longitudinal buckles (wave number) in the entire width was evaluated from the appearance of the steel sheet.

Figure 4 shows the effect of the delivery angle on buckling behavior, i.e., changes in the wave number and wave depth when the horizontal distance between the center of the work roll and the auxiliary roll is 225 mm. The wave number decreases as the delivery angle increases and becomes zero when the delivery angle exceeds 24° and the longitudinal buckle disappears. The wave depth increases as the delivery angle rises and then reaches 0 μm when the delivery angle exceeds 24° and the longitudinal buckle disappears.

Figure 5 compares the change in the wave number of the longitudinal buckle with respect to the delivery angle for the cases where the distance between the work roll center and the auxiliary roll is 225 mm and 375 mm. When compared at the same roll height, the wave number is different depending on the distance between the rolls, but when compared at the same delivery angle, the wave number is very close.

Next, the steel sheet was observed for longitudinal buckle after rolling and passing the auxiliary roll when the distance between the work roll center and the auxiliary roll was 375 mm. When a longitudinal buckle was present after the sheet had passed the auxiliary roll, visual observation of the underside of the sheet between the work roll and the auxiliary roll revealed that the longitudinal buckle was already present before the sheet passed the auxiliary roll.

(a) Influence of height of auxiliary roll (b) Influence of delivery angle

Fig. 5 Effect of the distance between work roll and auxiliary roll on buckling behavior

3 Elementary Analysis

Since the wave number and wave depth of the longitudinal buckle changed depending on the delivery angle, the shape of the part where the steel sheet is wound around the work roll (winding part) may have an effect on the behavior of the longitudinal buckle. For verification, the winding part was modeled as a flat plate with curvature, and the buckling mode was obtained by an elementary analysis and compared with the experimental results.

The model examined in this paper is described in the following. If the elastic strain in the width direction of the plate is assumed to be zero due to restraint by the roll in the vicinity of the exit of the roll bite, Eq. (1) holds. Here, ε_z is the strain in the plate width direction, E is Young's modulus, ν is Poisson's ratio, and σ_x,σ_y,and σ_z are stress in the longitudinal direction, thickness direction, and width direction, respectively. In this paper, tensile stress is denoted as negative and compressive stress as positive.

$$\varepsilon_z = \frac{1}{E}\{\sigma_z - \nu(\sigma_x + \sigma_y)\} = 0 \tag{1}$$

Here, as the stress state at the roll bite outlet, longitudinal stress is assumed to be tension t_f, thickness direction stress is the deformation resistance k_f of the rolled material, and width direction stress σ_z is expressed by Eq. (2) from Eq. (1).

$$\sigma_z = \nu(k_f - t_f) \tag{2}$$

In this model, it is assumed that the stress in the width direction expressed by Eq. (2) acts uniformly on the winding part, and it is considered that a longitudinal buckle occurs if this stress exceeds the elastic buckling limit. Although this is a bold

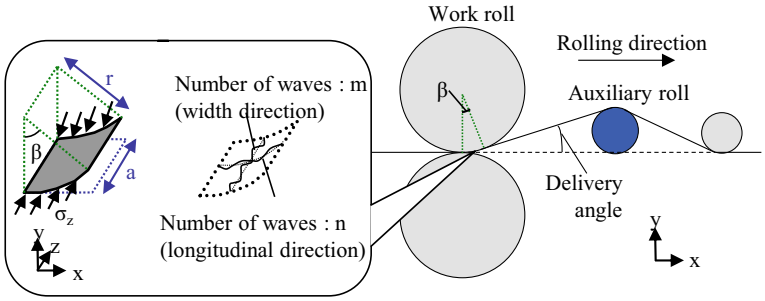

Fig. 6 Buckling model of sheet with curvature. (Color figure online)

assumption, this hypothesis is adopted in this report in order to use the elementary analysis method.

In this report, longitudinal buckle is modeled as an elastic deformation of a flat plate with the same curvature as the work roll in an unloaded state, as shown in Fig. 6, and the buckling limit stress σ_{cr} is calculated by Eqs. (3)–(5) [12]. Here, a is the sheet width, h is the sheet thickness, r is the radius of curvature (work roll radius), β is the winding angle (delivery angle), and m and n are the sheet width direction and longitudinal direction wave number, respectively.

In reality, a steel sheet exists as a continuous strip in the longitudinal direction. However, in this analysis, the part from just below the work roll center to the part wound around the work roll (i.e., the portion of the strip corresponding to β in Fig. 6) is modeled. The longitudinal ends and widthwise edges of this steel sheet are treated as free ends; that is, restraint by the rolling roll and the continuous steel strip existing in the longitudinal direction is not considered, and the tension acting on the sheet is also disregarded. Furthermore, the pressure of the work roll on the steel sheet is ignored. In general, residual stress after rolling is not uniform in the longitudinal direction and sheet width direction [13–15]. Here, however, it is assumed that the stress in the sheet width direction acts uniformly in the flat plate.

$$\sigma_{cr} = \alpha E \frac{\left(\frac{n^2\pi^2}{\beta^2} + \lambda^2\right)^2}{(1-\nu^2)\lambda^2} + E\frac{\lambda^2}{\left(\frac{n^2\pi^2}{\beta^2} + \lambda^2\right)^2} \tag{3}$$

$$\lambda = \frac{m\pi r}{a} \tag{4}$$

$$\alpha = \frac{h^2}{12r^2} \tag{5}$$

Figure 7 shows the theoretical value of the buckling limit stress σ_{cr} calculated by Eq. (3) using the conditions shown in Table 1. Assuming that the steel sheet is bent along the roll, the longitudinal wave number n is 1. Under this condition, the stress

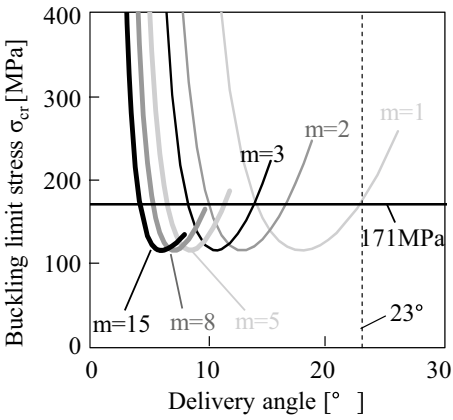

Fig. 7 Calculated buckling limit stress σ_{cr} (Number of waves in longitudinal direction: n = 1)

in the width direction calculated by Eq. (2) is approximately 171 MPa. It may also be noted that Poisson's ratio was set to 0.3.

The results in Fig. 7 show that the buckling limit stress is 171 MPa or more at any wave number *m* in the plate width direction when the delivery angle is 23° or more, which means no buckling occurs. In addition, when the delivery angle is small, the buckling limit stress is small under the condition that the wave number *m* in the sheet width direction is large. Conversely, when the delivery angle is large, the buckling limit stress is small under the condition that the wave number *m* in the sheet width direction is small. In other words, as the delivery angle increases, buckling occurs more easily at a smaller wave number *m*.

Based on the analysis results shown in Figs. 7, 8 shows the wave number *m* in the width direction that minimizes the buckling limit stress at each delivery angle. The figure also shows the change in the wave number of the longitudinal buckle depending on the delivery angle in the experiment, as shown above in Fig. 4. The analysis results and experimental results are in close agreement at high delivery angles (>10°).

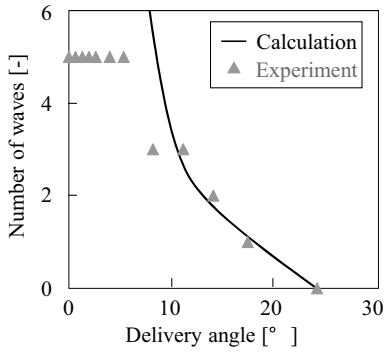

Fig. 8 Effect of delivery angle on buckling behavior (Distance between work roll and auxiliary roll: 225 mm)

Based on the experiments and analysis described above, the influence of the rolling exit delivery angle on the occurrence of longitudinal buckle is discussed.

First, the experimental results are compared with the conventional knowledge. The study by Kijima et al. revealed that the wave height increases and the longitudinal buckle becomes increasingly distinct as the delivery angle increases in the range of 0°–4°, which is similar to the present experimental results [9]. Komori obtained the wavelength of the longitudinal buckle by an elementary analysis of buckling [10]. Assuming deformation near the roll bite, a waveform close to that in the experiment by Kijima et al. was predicted when the delivery angle was 0°, showing that prediction is possible. From the above, it can be understood that the longitudinal buckle wave number is determined by deformation near the roll bite when the delivery angle is 0°.

Next, the experimental results when the delivery angle is larger than the conventional conditions are discussed. The experimental results shown in Figs. 2 and 4 clarified the change in the wave number of the longitudinal buckle when the delivery angle is increased. At this time, the longitudinal buckle already existed before the steel plate passed the auxiliary roll, and when the delivery angle was the same, the longitudinal buckle wave number did not change even if the distance between the work roll and the auxiliary roll was changed. From this, it is considered that the longitudinal buckle wave number is determined by the restraint condition of the steel sheet at the winding part from the vicinity of the roll bite exit.

In addition, the above experimental results are discussed in comparison with the analysis results. The analysis results in Fig. 7 show that buckling in the width direction of a flat plate with curvature becomes more likely at a smaller wave number m as the delivery angle increases, and no buckling occurs beyond a certain delivery angle. This shows good qualitative agreement with the experimental results in Fig. 4. From the comparison of the experimental and analytical results for the longitudinal buckle wave number shown in Fig. 8, it can be seen that the changes in both the experimental and analytical results are very similar at high delivery angles (>10°). Therefore, the longitudinal buckle observed at a high delivery angle is a buckling phenomenon due to compressive stress in the plate width direction on the roll bite exit side, and the plate shape after buckling is assumed to be determined by the shape of the winding part around the work roll. In the analysis, the stress in the plate width direction is assumed to be as shown by Eq. (2). However, even if the actual stress in the width direction is different, a flat sheet with curvature becomes more prone to buckling at a small wave number in the plate width direction as the delivery angle increases. Since there is no change in this characteristic of easy buckling at a small m, the analysis shows good qualitative agreement with the actual phenomenon.

4 FEM Analysis

An FEM analysis simulating the temper rolling experiment described in Chap. 2 was conducted, and the contact condition between the roll and the steel sheet near the roll bite outlet was investigated. Abaqus/Standard Ver. 6.12 was used as the solver, and a two-dimensional plane strain elastoplastic analysis was performed by the implicit method. The rolled material was an elastoplastic material with Young's modulus of 205.8 GPa and Poisson's ratio of 0.3. The yield stress shown in Fig. 9 was used.

The work roll was made of an elastic material with Young's modulus of 205.8 GPa and Poisson's ratio of 0.3. As shown in Fig. 10, a rigid part was provided at the center of the roll, corresponding to half of the roll diameter. A penalty method was used for the surface contact between the rolling roll and the rolled material. The friction model was Amonton-Coulomb friction with a friction coefficient of 0.05 [16–18].

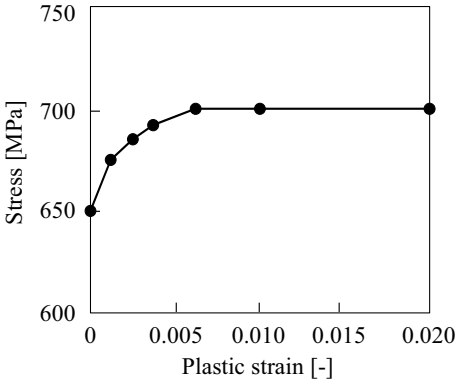

Fig. 9 Stress–strain curve

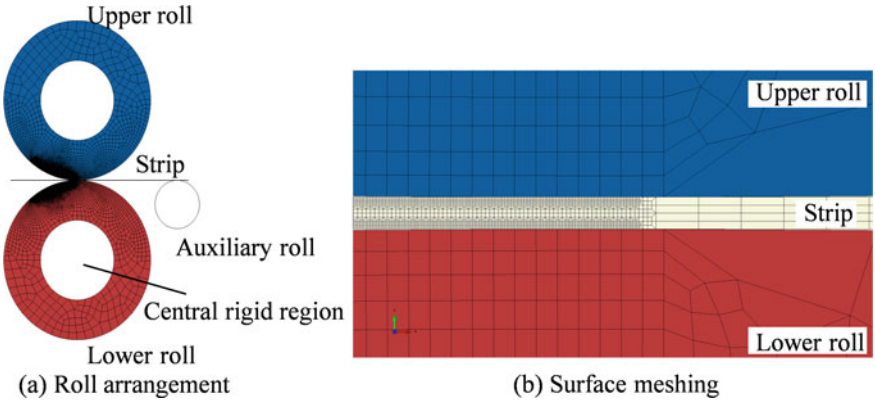

Fig. 10 Rolling model of FEM. (Color figure online)

The exit side auxiliary roll was a rigid body, and friction with the rolled material was ignored. The distance between the center of the work roll and the auxiliary roll was 225 mm. In the element division of the rolling region, the surface of the rolled material was a 10 μm square mesh, the mesh between the rolling roll and the delivery side auxiliary roll was a four-element mesh. The element division of the roll surface was a 100 μm secondary element. Mesh condition is uniform in the rolling region, and rolling distance is 100 mm which is longer than the length of area where the rolled material is in contact with the roll with the delivery angle of 24° (about 70 mm).

The analysis was performed for delivery angle conditions of 4° and 24°. In the analysis, after first determining the roll screw-down position where a rolling load of 5.3 kN/mm was obtained under the condition of a delivery angle of 4°, rolling was performed with that roll position fixed under both delivery angle conditions of 4° and 24°.

Figure 11 shows the curvature distribution of the upper roll surface near the roll bite exit and the center of thickness of the rolled material. The downward convex curvature is positive. The point at which the curvature of the roll surface has a large positive maximum corresponds to the roll bite exit. Immediately after the exit of the roll bite, there is a difference in the curvature between the upper roll surface and the center of thickness of the rolled material, indicating that the rolled material is not following the roll surface; in other words, the rolled material is not in contact with the roll. Further downstream, however, the center of thickness of the rolled material coincides with the curvature of the upper roll surface, which means the rolled material and the roll are in contact. Focusing on the length of the area where the rolled material is not in contact with the roll, the noncontact length is 3.8 mm with both the delivery

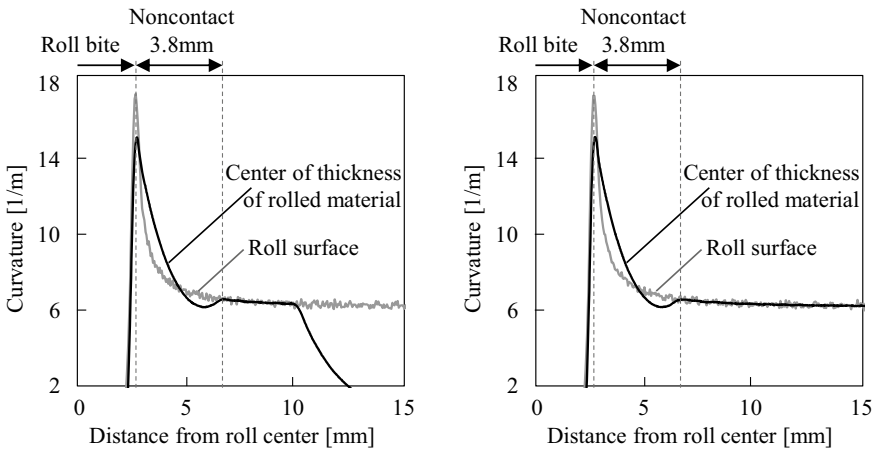

Fig. 11 Curvature distribution of upper roll surface

angles of 4° and 24°; that is, there is no change in this condition even if the delivery angle is increased.

5 Discussion

As shown in the experiments and analysis described above, the elementary analysis shows good qualitative agreement with the actual phenomenon. On the other hand, there are the following differences between the actual phenomenon and the analysis model. First, the analytical model does not consider the fact that a steel sheet exists continuously in the longitudinal direction. If a sheet is actually a continuous strip, compressive stress may have the effect of suppressing buckling. Furthermore, the analysis model assumes that the steel sheet is bent along the roll, and the longitudinal wave number n is 1. If the longitudinal wave number n is assumed to be 1, the analytical results will agree qualitatively with the experimental results, but if higher wave numbers are assumed, buckling may occur even at the delivery angle of 23° or more. Moreover, the FEM analysis results suggest the possibility that there is a region where the rolled material and the roll are not in contact immediately after the roll bite, regardless of the delivery angle.

In addition, the buckling shape assumes a uniform sine curve in the width direction, but the actual shape is not uniform in the width direction, as shown in Figs. 2 and 3, and in some cases, the buckling shape may be convex toward the bottom surface. The surface pressure between the work roll and the steel sheet acts to suppress out-of-plane deformation of the steel sheet, and the surface pressure distribution may be localized, which may be related to the wave shape of the longitudinal buckle. In this model, it is assumed that the stress in the plate width direction due to restraint in the roll bite acts uniformly at the winding part, but as mentioned above, this is a bold assumption. Moreover, it was assumed that the elastic strain in the width direction of the whole winding part is zero, but the validity of this assumption also needs to be examined.

Due to these differences, it is difficult to explain all the experimental results using an analytical model. On the other hand, since the wave numbers at high delivery angles are in good agreement, it can be said that the assumptions made in the analysis model have a great influence on the actual buckling behavior.

From the above discussion, the wave number at the occurrence of a longitudinal buckle can be explained by the mechanism proposed in the past when the delivery angle is 0°. When the delivery angle is increased, the change in the wave number can be explained by the buckling behavior of a flat plate with curvature subjected to compressive stress in the width direction. In addition, the buckling shape observed as a longitudinal buckle is not only determined by the deformation near the roll bite, but the contact state with the downstream work roll has a significant effect. Therefore, it is necessary to understand the longitudinal buckle phenomenon by dividing longitudinal buckling into the generation behavior of buckling, in which

many microwaves are generated, and buckle development behavior, in which the buckling shape grows and disappears.

6 Conclusion

The behavior of longitudinal buckle in temper rolling of steel sheets after secondary cold rolling was investigated in a laboratory experiment using larger delivery angles than in past studies. In addition, the buckling characteristics of the part where the steel sheet is wound around the work roll (winding part) was obtained by an elementary analysis and compared with the experimental results. As a result, the following findings were obtained.

(1) From the experimental results, it was found that the wave number of longitudinal buckle decreased and the individual waves became more distinct as the delivery angle increased. Longitudinal buckle did not occur when the delivery angle exceeded a certain level.
(2) The experimental results also indicated that the distance between the work roll and the auxiliary roll had little effect on longitudinal buckle when the delivery angle was the same.
(3) The analysis of the buckling behavior of the winding part showed that buckling occurs more easily at a small wave number m in the width direction as the delivery angle increase, but buckling does not occur at a certain angle or more. This characteristic is similar to the experimental results under the condition of high delivery angles (more than 10°), suggesting that the generation of longitudinal buckle is related to the shape of the winding part.
(4) From the FEM analysis results, it was found that a region where the rolled material and the roll are not in contact exists immediately after the roll bite exit. The existence of this noncontact region may affect the buckling phenomenon.

A Fast Computational Model for the Local Stress Distribution and Mechanical and Thermal Work Roll Deformations with Effects on Strip Profile and Flatness During Hot Rolling of Strip in Four-High Mills

Christian Overhagen

Abstract A fast model is presented for the three-dimensional stress distribution in the roll gap. This local data is used to calculate the 3D deformation of the work roll barrel by flattening and deflection using a combined analytical and finite element procedure. Detailed information about the work roll deformation can therefore be obtained because the model does not rely on a constant roll force. The local strip and work roll temperatures are calculated by a numerical solution of the heat equation and the evolution of thermal roll crown is calculated for a given rolling campaign. The strip shape is found by the intersection of the deformed roll with the initial strip shape. An upper-bound technique is applied for the resulting strip flatness. Typical methods of profile and flatness adjustment are discussed with effects on strip profile and flatness. These are static roll crowns as well as work roll bending, zonal roll cooling, and axially shiftable S-shaped grinded rolls (CVC—continuous variable crown).

1 Introduction

Hot strip rolling is one of the most important and commonly applied metal deformation processes. The quality of the rolled product in terms of thickness and flatness distribution is greatly affected by the mechanical and thermal loads which act on the work and backup rolls.

Therefore, a mathematical description of these effects has been a research item for a long time. Most works are based on the slab method or Elementary Plasticity Theory (EPT), assuming plane strain conditions and a constant roll force along the strip width. In the presented research work, these simplified approaches were extended to

gain a more detailed solution to the problem without increasing computation times extremely.

Most of the older approaches are limited to the cold rolling process or disregard flatness effects. Beisemann introduced mechanical models for a variety of rolling mills [1], which are suitable for the calculation of the strip profiles, but disregard roll flattening effects. Rieckmann [2] built a simplified model for the thickness profile and flatness during cold rolling on a six-high mill using a correction factor to account for flatness effects. The flatness calculation was extended by Elsen [3], who introduced an upper bound model to account for the inner lateral material flow. Ren, Tieu et al. have presented a two-dimensional method based on the slab theory for the calculation of the normal stress distribution in cold rolling [4].

The current paper shows a two-dimensional rolling model based on Ren, Tieu et al. [4] to calculate the non-constant rolling force distribution along the lateral strip direction in hot rolling. In the present paper, these roll force and stress distributions are fed into sub-models for roll flattening and roll deflection to calculate the effects on the strip thickness and flatness distributions. The most important of the sub-models are presented and the effects on the strip thickness distribution are discussed.

2 Modelling of the Stress Distribution in Flat Rolling

To enable the calculation of the thickness profile and flatness distribution, a method for calculation of the local stress distribution in the three spatial coordinates must be employed. Different approaches are available for this task. Nowadays, the finite element method (FEM) has reached a highly developed state in metal forming and is used for detailed process simulations in rolling processes [5]. However, for online process control as well as fast design calculations in flat rolling, fast analytical rolling models are more feasible. Simple analytical rolling models have been present for a long time since von Karman introduced the force equilibrium on the strip element in the roll gap and deduced the so-called von Karman's differential equation of the roll gap [6]. The equation in this simple form is limited to a one-dimensional stress distribution. To account for the two-dimensional distribution of stresses, a second differential equation for the lateral direction must be introduced, as to replace the standard strip element with a volume element, that is of infinitesimal width and length and has two inclination angles. These angles are referred to in terms of the spatial derivatives of the two-dimensional height distribution inside the roll gap $h(x, y)$. The two ordinary differential equations for the distribution of the related horizontal and lateral forces are therefore given by Eq. (1), see also [7].

$$\frac{df_x}{dx} = \sigma_N \frac{\partial h}{\partial x} \sqrt{1 + \left(\frac{1}{2}\frac{\partial h}{\partial y}\right)^2} \pm 2\tau_{Fx} \sqrt{1 + \left(\frac{1}{2}\frac{\partial h}{\partial y}\right)^2}$$

$$\frac{df_y}{dy} = \sigma_N \frac{\partial h}{\partial y}\sqrt{1+\left(\frac{1}{2}\frac{\partial h}{\partial x}\right)^2} \pm 2\tau_{Fy}\sqrt{1+\left(\frac{1}{2}\frac{\partial h}{\partial x}\right)^2} \tag{1}$$

In Eq. (1), σ_N is the normal stress acting perpendicular to the roll surface. τ_{Fx} and τ_{Fy} are the frictional shear stress components in the horizontal and lateral directions, respectively.

By simultaneous solution of the differential equations given in Eq. (1), the distribution of the normal stress acting on the work roll–strip interface is calculated in the horizontal and lateral directions. For this purpose, it is important to couple the stresses in the plastic region by using the von Mises yield criterion in 3D [8]:

$$2k_f^2 = \left(\sigma_{xx}-\sigma_{yy}\right)^2 + \left(\sigma_{yy}-\sigma_{zz}\right)^2 + \left(\sigma_{zz}-\sigma_{xx}\right)^2 + 6\left(\tau_{xy}^2+\tau_{yz}^2+\tau_{zx}^2\right) \tag{2}$$

Figure 1 shows a calculated normal stress distribution for a hot flat rolling pass with initial height $h_0 = 4\ mm$ and final height $h_1 = 2\ mm$, work roll barrel diameter of $d_w = 780\ mm$, rolled material C55, and friction coefficient $\mu = 0.3$ at a rolling temperature of $T = 1100°\ C$ and a rolling speed of $2\ m/s$.

The stress distribution as shown in Fig. 1 is valid for the case where the rolls retain their circular shape and there is no roll deformation. In the next sections, the treatment of thermal and mechanical roll deformations is discussed in detail.

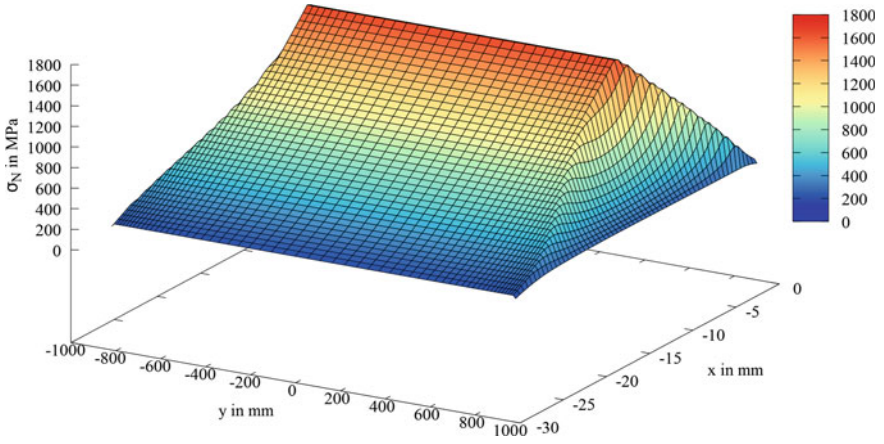

Fig. 1 Calculated two-dimensional stress distribution. (Color figure online)

3 Mechanical Loading of Work and Backup Rolls

To account for the mechanical loading of work and backup rolls, two important effects are regarded, i.e. the work and backup roll deflection as well as the work roll flattening. For the deflection calculation, the one-dimensional finite beam element method is applied, where for the roll flattening, a modified Boussinesq's method is used [3, 8].

3.1 Deflection of Rolls in a Four-High Mill

In a four-high mill, the work rolls are in contact with the strip as well as the backup rolls. The deflection system is modelled using one-dimensional finite beam elements. Instead of using beam elements of a constant area moment of inertia, a beam element thickness that is a linear function of the element length coordinate is used [7]. The contact problem between work and backup rolls is treated analytically. For the radial contact of two cylindrical bodies, the contact elasticity can be written as given in Eq. (3) [7, 9]:

$$\frac{du_r}{df} = \frac{1}{8}\left[C_1 \ln\left(\frac{8R_1}{\sqrt{f\ R_{12}\,(C_1+C_2)}}\right) + C_2 \ln\left(\frac{8R_2}{\sqrt{f\ R_{12}\,(C_1+C_2)}}\right) - (C_1+C_2)\right] \tag{3}$$

In this equation, C_1 and C_2 represent the elastic properties of the roll materials as defined by $C_i = \frac{16}{\pi} \cdot \frac{(1-\nu_i^2)}{E_i}$, R_1 and R_2 are the respective roll radii and f is the contact force per unit barrel length. R_{12} is a mean contact radius defined as $R_{12} = 1/(1/R_1 + 1/R_2)$. u_r is the combined contact displacement in the radial direction of the two cylinders.

Taking Eq. (3) into the reciprocal, the contact stiffness of two meeting nodes of work and backup rolls can be calculated. It should be noted that the contact stiffness in dependent on the contact force. The global finite element equation system of the four-high deflection problem is now written in the following way [7]:

$$\begin{bmatrix} \mathbf{K_W}+\mathbf{K_C} & -\mathbf{K_C} \\ -\mathbf{K_C} & \mathbf{K_B}+\mathbf{K_C} \end{bmatrix} \begin{bmatrix} \mathbf{u_W} \\ \mathbf{u_B} \end{bmatrix} = \begin{bmatrix} \mathbf{f_W}+\mathbf{u_0}\mathbf{K_C} \\ \mathbf{f_B}-\mathbf{u_0}\mathbf{K_C} \end{bmatrix} \tag{4}$$

$\mathbf{K_W}$ and $\mathbf{K_B}$ are the per-roll stiffness matrices for the work and backup rolls, respectively, and $\mathbf{K_C}$ is the contact stiffness matrix. $\mathbf{f_W}$ and $\mathbf{f_B}$ are the load vectors for the work and backup rolls. $\mathbf{u_0}$ is the initial distance vector of the work and backup roll surfaces and is of interest when special grinded roll contours are used, especially for CVC grinded rolls. $\mathbf{u_W}$ and $\mathbf{u_B}$ are the resultant deflection vectors of the work and backup rolls, respectively.

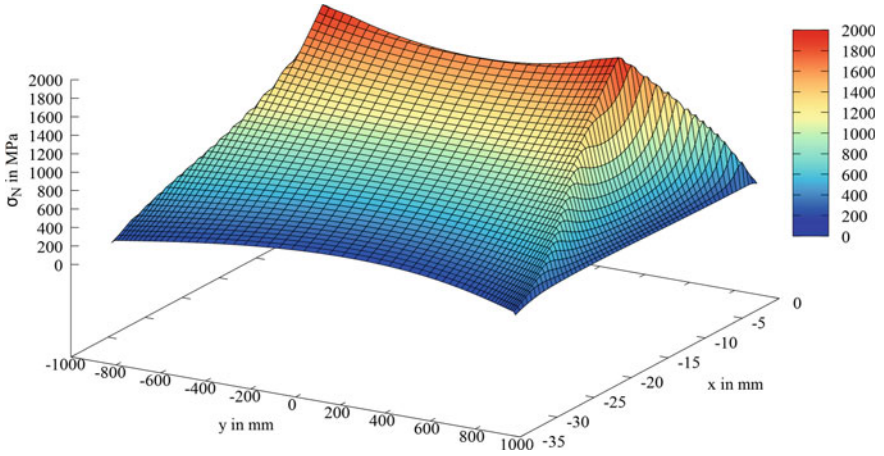

Fig. 2 Calculated stress field influenced by elastic roll deformation (flattening and deflection). (Color figure online)

3.2 Work Roll Flattening

Non-cylindrical work roll flattening is accounted for using a modified Boussinesq approach [7]. With this approach, the local effects of the two-dimensional roll pressure distribution as calculated by the rolling model (see Fig. 1) can be calculated. Therefore, a three-dimensional roll deformation model is obtained.

It is interesting to observe the effect of the roll deflection on the stress distribution in the roll gap. Figure 2 shows the stress distribution that is obtained for the case shown in Fig. 1 if the mechanical roll deformation effects are taken into consideration.

4 Thermal Loading of Work Rolls During a Strip Rolling Campaign

Generally, the heat equation describes the thermal processes which lead to a characteristic temperature profile of the work roll during rolling. The main goal of the present modelling is the calculation of the thermal roll crown contour $V_S(y)$. It is calculated as given in Eq. (5). The roll temperature profile must be integrated over each cross section of the roll to find the thermal crown distribution [10].

$$V_S(y) = \frac{2\alpha}{R} \int_0^R r[T(r, y) - T_0]\, dr \tag{5}$$

In this equation, α is the thermal expansion coefficient of the roll, R is the outer radius of the roll, $T(r, y)$ is the axial–radial temperature field of the roll, and T_0 is the initial or ambient temperature.

It should be noted that small thermal fluctuations in a very thin surface layer can be neglected for the thermal crown. However, the boundary conditions for the heat equations at the roll surface must be formulated so that the temperature profile equals the case where the thermal fluctuations had been considered. Therefore, an azimuthal averaging of the heat fluxes is done as described by Robinson et al. [11]. With this simplification which is well met in practice, the three-dimensional heat transfer problem can be reduced to a two-dimensional problem in axisymmetric coordinates. Therefore, a cylindrical coordinate system (radial and axial) can be used for the work roll barrels. The two-dimensional heat equation to be solved for the work is then given in Eq. (6), where ρ and c_p are the mass density and specific heat of the roll material, respectively.

$$\frac{\partial T}{\partial t}\rho c_p = \frac{1}{r}\frac{\partial}{\partial}\left(r\lambda\frac{\partial T}{\partial r}\right) + \frac{\partial}{\partial y}\left(\lambda\frac{\partial T}{\partial y}\right) \tag{6}$$

Exemplarily, Fig. 3 shows the evolution of the thermal roll crown during a rolling campaign of 20 strips in a hot strip mill.

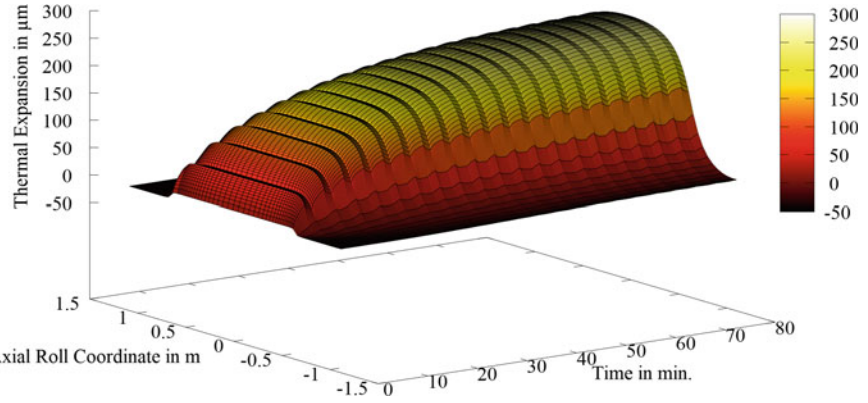

Fig. 3 Evolution of thermal work roll crown during a hot rolling campaign of 20 strips. (Color figure online)

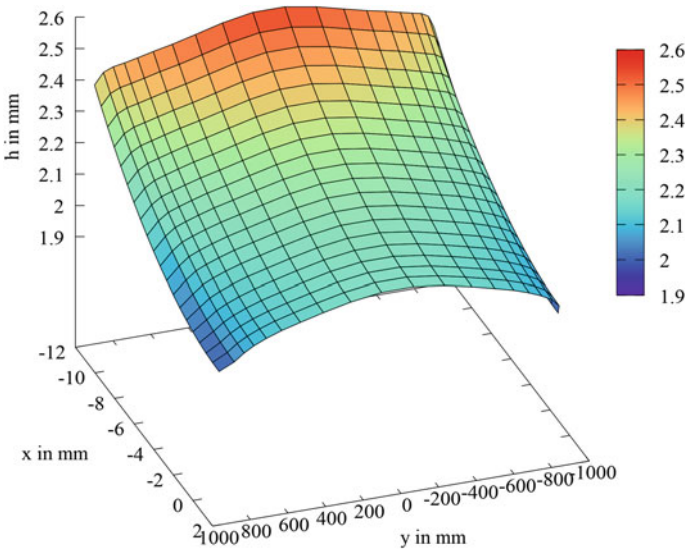

Fig. 4 Calculated example for the two-dimensional strip height distribution in the roll gap for a final pass on a hot strip. (Color figure online)

5 Combining the Mechanical and Thermal Roll Deformations to a Deformed Roll Barrel and Exit Strip Shape

With the mechanically and thermally deformed work roll geometry, the two-dimensional distribution of the strip thickness in the roll gap can be calculated. This height data in the form *h(x,y)* is then used for the next iteration of the rolling model in terms of the spatial derivatives $\frac{\partial h}{\partial x}$ and $\frac{\partial h}{\partial y}$ in Eq. (1). This iteration is repeated, until a converged solution for the stress and strip thickness distributions in the roll gap has been found. Figure 4 shows a result for the strip thickness distribution for a final pass of a hot strip rolling schedule (x: rolling direction, y: lateral direction). This distribution is found by intersecting the deformed roll barrel contours, which are calculated by the sub-models described earlier in the present paper.

6 Methods to Influence the Roll Crown and Strip Shape

During operation of a rolling mill, it is important to control the previously discussed effects which affect strip thickness and flatness to achieve the desired tolerances. The principal effects are now shown with computation examples which were carried out using the complete model that was described above.

We can subdivide the methods that can be used to control the strip shape in different groups. Firstly, the roll crown can be influenced directly by a roll camber. This is shown by an example in Fig. 5. A parabolic camber is grinded into a work roll surface so that the roll shape becomes convex. This reduces the strip convexity as shown in Fig. 5. In extreme cases, as seen for the 0.4 mm camber, it can already cause a concave strip shape under load.

These roll crowns are static, which means that they cannot be changed without changing the rolls. A more dynamic approach is the continuous variable crown approach (CVC), in which work and/or backup rolls are grinded to an S-shape and are axially movable. With this technique, different roll crown profiles can be set up by axial shifting of the rolls.

The principal features of this method are illustrated in Fig. 6. In this example, a third-order polynomial is used for the roll surface contours. When the two work rolls are shifted relative to each other, the roll gap profile can be adjusted very sensitively.

Figure 7 shows the effects of the CVC shifting on the roll surface contour at the effective barrel length (top picture), and on the resulting strip profile (bottom picture).

The adjustment range of the CVC system depends on the polynomial function used; in other words, the polynomial can be designed to achieve a predefined adjustment range of roll gap contours. The roll surface contours are given as a polynomial of third order for the top and bottom work rolls as a function of the axial roll barrel coordinate y:

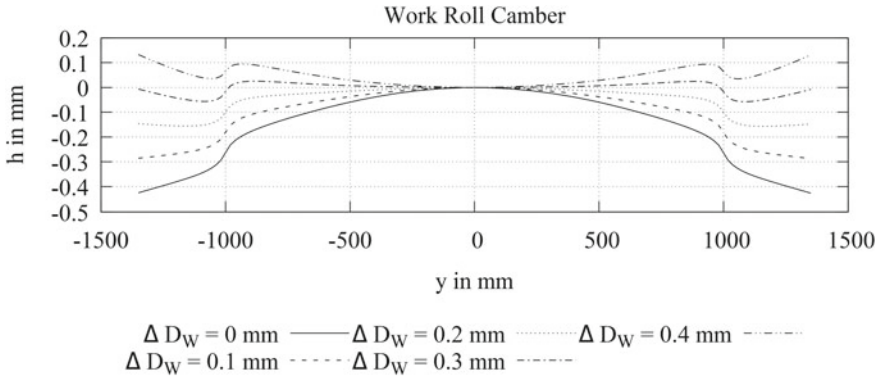

Fig. 5 Effects of work roll camber of the roll gap profiles under load

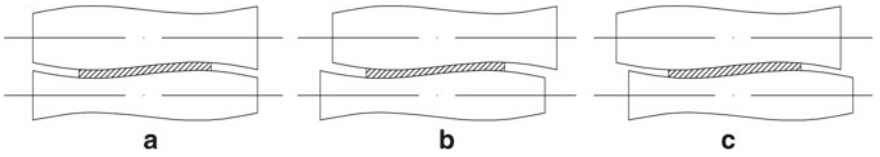

Fig. 6 Methods for influencing the strip thickness distribution with the CVC process: **a** neutral shift; **b** shift for concave strip; **c** shift for convex strip [7]

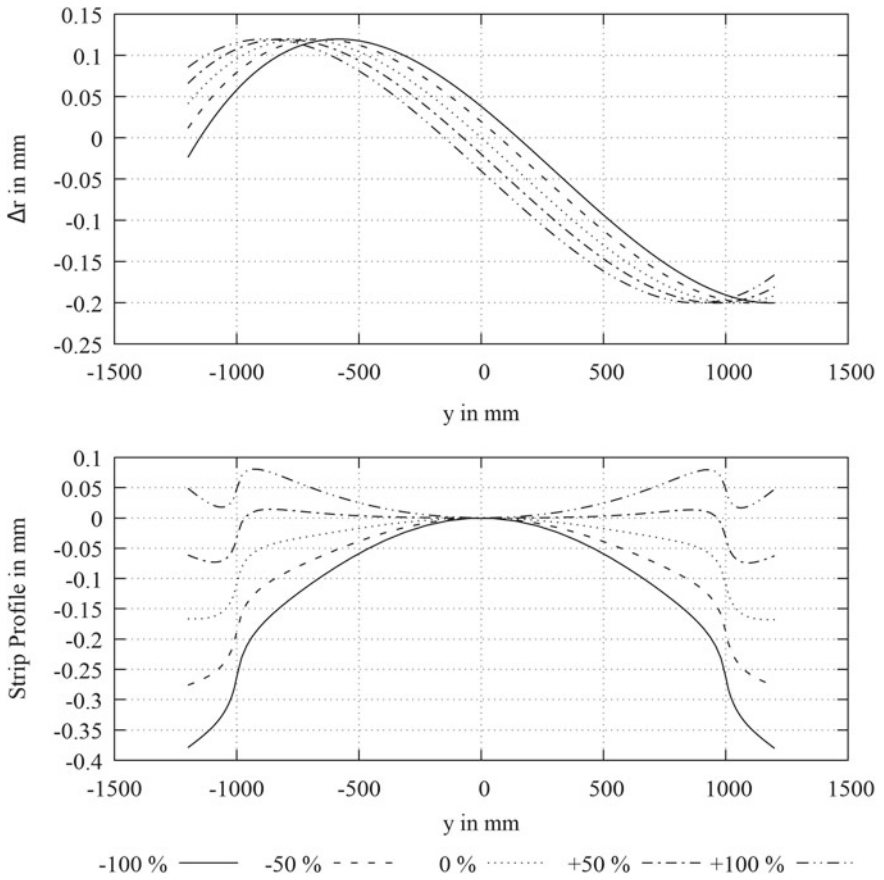

Fig. 7 Roll shapes in the effective barrel region and roll gap profiles for different shifting positions of a CVC system

$$R_{top}(y) = R_0 + Ay^3 + By^2 + Cy$$
$$R_{bot}(y) = R_0 - Ay^3 + By^2 - Cy \tag{7}$$

Apparently, $R_{bot}(y) = R_{top}(-y)$. When the vertical distance of the work roll axes is denoted by a_M, the unloaded roll gap contour (or thickness distribution) $h(y)$ can be worked out under influence of a symmetric axial roll shift c:

$$h(y) = 2Ac^3 - 2Bc^2 + 6Acy^2 + 2Cc - 2By^2 + a_M - 2R_0 \tag{8}$$

From Eq. (8), the adjustable roll crown follows as the difference between the strip thicknesses and strip center and strip edge (l_b: effective barrel length) to Eq. (9):

$$cr(c) = 6Al_b^2c - 2Bl_b^2 \tag{9}$$

Here, it is important to note that cr depends on the roll shift c only linearly, which conveniently simplifies an inverse calculation of the appropriate shift for a given roll crown.

Furthermore, we can calculate the roll contour coefficients A, B, and C from Eq. (8) and therefore design the roll contour for an appreciated adjustment range between a minimum crown $cr_{\min}$ and a maximum crown $cr_{\max}$. The coefficients B and C depend on the adjustment range and follow Eq. (10), where $c_{\max}$ is the maximum axial roll shift.

$$\begin{aligned} A &= -\frac{cr_{\min} - cr_{\max}}{12 l_b^2 c_{\max}} \\ B &= -\frac{cr_{\min} + cr_{\max}}{4 l_b^2} \end{aligned} \tag{10}$$

The so-called wedge factor C is chosen according to a maximum work roll radius difference Δr_m that is desirable acc. to Eq. (11).

$$C = \frac{B^2 - \left(\frac{27 \Delta r_m A^2}{4}\right)^{\frac{2}{3}}}{3A} \tag{11}$$

An in situ control of the strip profile can also be implemented by work and/or backup roll counter bending. The so-called WORB method (work roll bending) uses extra hydraulic cylinders at the work roll journals. This counter bending can be executed against the backup rolls (in-crown bending) or away from the backup rolls (counter-crown bending). The BURB method (backup roll bending) uses a similar technique at the backup roll journals but is not very commonly applied, since much higher forces are necessary compared to the WORB method.

Figure 8 shows the effects of work roll bending (WORB) on the relative roll gap profile and on the contact forces that are present between the work and backup rolls.

A comparison of Figs. 7 and 8 shows, that the effect of WORB concentrates more on the strip edges, where the CVC has a more homogeneous effect throughout the barrel length of the rolls.

It was shown that the thermal profile of the work rolls also has a great significance for the strip thickness distribution. An active intervention in this effect can be carried out by a zonal roll cooling system. The roll cooling system, which is discussed here consists of 37 spray nozzles, which can be controlled independently. Therefore, different roll cooling programmes can be realized. Figure 9 shows three different fundamental cooling programmes (standard cooling, centre cooling, edge cooling) which can be combined with one another. The dimensionless intensity factor is a number between 0 and 1 for each of the spray nozzles. These data have been taken from Degner [12].

Figure 10 shows the effect of the three different work roll cooling programmes on the roll gap shape of the 6th pass of a 7-pass schedule. It is shown by the computation,

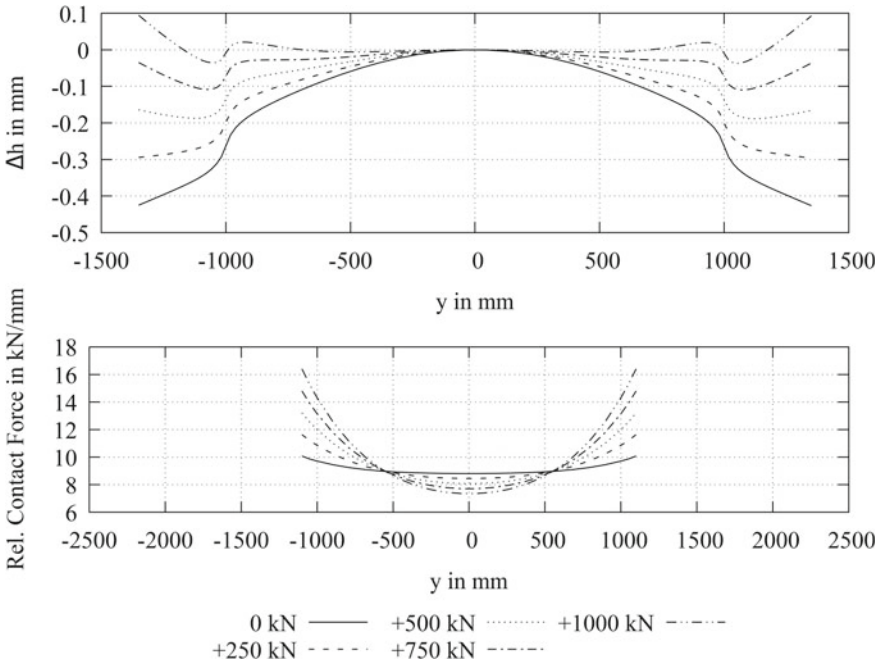

Fig. 8 Effects of work roll bending (WORB) on the roll gap shape (top) and the contact forces at work roll interface

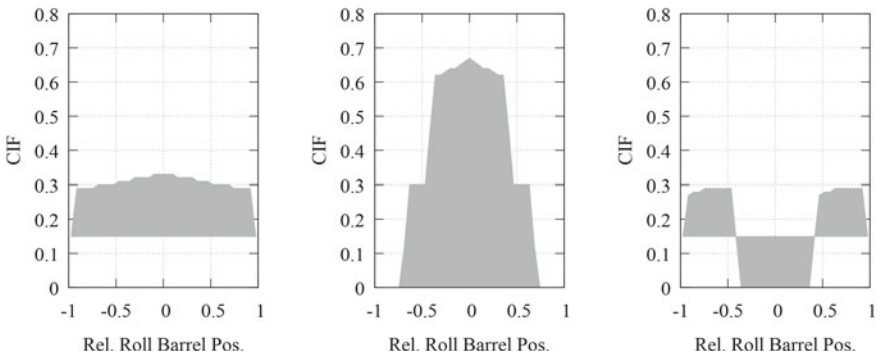

Fig. 9 Distribution of the cooling intensity factor (CIF) for three different cooling programmes (standard cooling, center cooling, edge cooling)

that the edge cooling programme leads to the best improvements of the thickness profile.

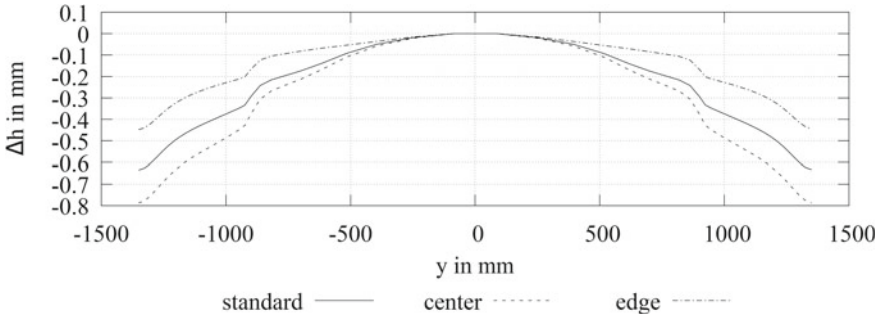

Fig. 10 Effects on a roll gap shape of the three different cooling programmes defined in Fig. 9

7 A Model for Flatness Effects

Apart from the thickness profile, flatness is another important parameter of a flat-rolled product. Flatness defects originate from an inhomogeneous distribution of elongations along the strip width.

If we subdivide the strip width into N narrow elements, the related elongation of each element i with respect to the centre element (index c) is given as in Eq. (12).

$$\left(\frac{\Delta L}{L}\right)_i = \left(\frac{\gamma_c \beta_c}{\gamma_i \beta_i} - 1\right) \tag{12}$$

In this equation, $\gamma_i = h_{1i}/h_{0i}$ is the compression ratio and $\beta_i = b_{1i}/b_{0i}$ is the spread ratio of each strip element.

The initial and final thicknesses of each strip element h_{0i} and h_{1i} is found from the entry and exit strip profiles, where the exit strip profile is calculated as shown in the preceding sections. The local spread ratio β_i is of greater importance, as it resembles the lateral material flow. It can be easily shown that a neglection of the local spread by simply setting $\beta_i = 1$ does not yield practical results and therefore an amount of lateral flow will occur, even in cold rolling of thin strips.

For cold rolling, Rieckmann [2] found that a correction factor in the order of magnitude of $m = 0.01$ can be used to achieve practical results, avoiding the difficult assessment of the inner lateral flow, see Eq. (13).

$$\left(\frac{\Delta L}{L}\right)_i \approx m \cdot \left(\frac{\gamma_c}{\gamma_i} - 1\right) \tag{13}$$

From these circumstances, we can deduce that the local spread plays an important role in the development of flatness faults and cannot be neglected.

To gain a simplified solution which is feasible for a fast analytical model, a method presented by Elsen and Pawelski [3] is employed in the current analysis. This method is based on the upper bound method.

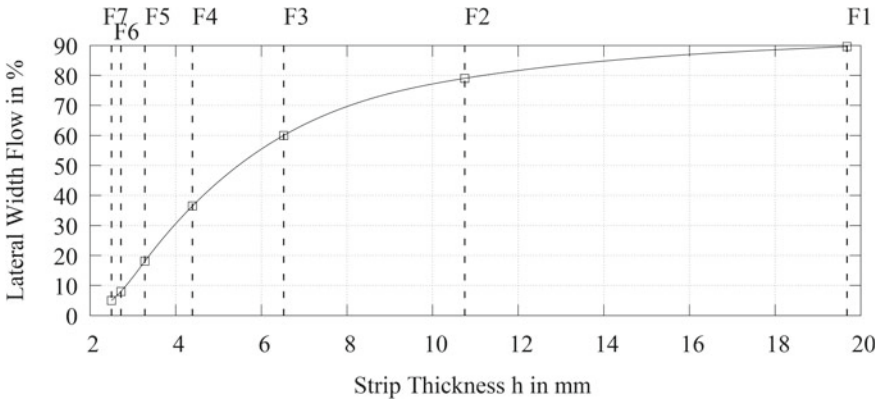

Fig. 11 Lateral flow parameter in seven stands of a hot strip finishing mill in stands F1–F7 and the degradation of the lateral flow with decreasing strip thickness

The model assumes that the strip can be treated a stack of strips having a finite width which are undergoing a compression deformation from an initial height h_0 to a final height of h_1. Each strip element does not spread freely, but the spread is affected by shear deformations occurring at sides where two strip elements meet. According to the upper bound approach, the upper bound on forming power J^* is written out as given by Eq. (14), combining the ideal power P_{id}, the frictional power P_F, the shearing power P_S and the tension power P_T:

$$J^* = P_{id} + P_F + P_S - P_T \tag{14}$$

A free parameter $\omega = -\frac{\dot{\varepsilon}_{lateral}}{\dot{\varepsilon}_{vertical}}$ is a measure for the lateral material flow, resembling the relation of the lateral and vertical strain rates. The velocity field is dependent on this parameter and it is chosen according to a minimum of J^* in Eq. (14) using the golden section search technique (UVMGS of IMSL [13]). With this approach, the dependence of the width flow on the strip thickness could be calculated. Figure 11 shows a plot of the function ω as a function of the strip thickness throughout the hot rolling process of the finishing train of a hot strip mill.

8 Conclusions and Outlook

The present model for rolling processes in four-high mills allows the calculation of the two-dimensional normal stress, and based upon, the mechanical and thermal loading on the rolling tools which lead to a certain thickness and flatness defects. The computation time is in the order of few minutes on an office PC for a seven-pass rolling schedule of a hot strip finishing mill including all mechanical and thermal effects. The effects influencing the strip thickness profile can be shown with the model,

including the interdependence of thermal and mechanical effects. In its current form, the model is set up for two high and four high mills. For the future, an extension to 12-high and 20-high mills is planned to analyse the cold rolling processes for thin strips and foils.

The ongoing digitization of manufacturing processes in the steel industry calls for extremely fast process models to enable prediction and control of thickness profile and flatness during hot and cold rolling. These models will be mostly based on data-driven approaches like neural networks. Because of the low computation times of the present offline optimization model, it is very well suited to generate a big set of data to be fed into these data-driven models.

Investigation of a Novel Constructive Hot Ring Rolling Process for Double Metal Composite Ring

Jiadong Deng, Zhe Cheng, Dongsheng Qian, Jikang Liu, and Rongwen Wu

Abstract Double metal composite ring has the advantages of two materials, and is used in specific fields. The traditional manufacture method is welding. And some scholars try to use ring rolling process to produce a composite ring. However, the interface connection quality is not good. In this paper, a novel constructive hot ring rolling process to manufacture a seamless double metal composite ring is proposed. First, two separate rings with different metals are assembled together. And then the surface interface area on the upper and lower of the assembled ring are welded in an oxygen-free environment, which can suppress the interfacial oxidation during heating process. After that, the surface welded ring is cleaned and heated. Finally, the target double metal composite ring is formed by hot ring rolling. An experiment of constructive hot ring rolling process for double metal composite ring was done. The interface healing effect of the composite ring was studied. The result indicated that the interface healing degree was significantly improved by this method.

1 Introduction

With the ever-growing demands of material performance, it is difficult for a single metal or alloy to meet the requirements. Multi-material composite component refers to the combination of two or more materials through a certain method, which has the comprehensive properties of different materials, and can greatly save precious metal materials or alloy elements, thus greatly reducing the cost and saving resources [1]. Double metal ring belongs to multi-material composite component, which can be used in the fields of nuclear power, petrochemical and engineering machinery, etc. Such as nuclear pressurized water reactor shell is working in severe condition like high temperature, high pressure, corrosion, etc. for a long time. Therefore, its quality and performance requirements are very high. One method is to use double metal structure, that is, the outer layer is low alloy steel matrix and the inner layer is built up welding with stainless steel [2]. At present, the main manufacturing methods of double metal ring parts are casting [3] and welding [4]. The casting method is mainly used for small- and medium-size double metal rings with a big difference in material melting point, such as casting a layer of copper alloy material on the inner surface of the steel ring. The welding method mainly adopts surfacing welding to add new material layer by layer on the surface of the matrix material. But the production efficiency is low, and prone to produce welding defects.

Ring rolling is an advanced plastic process to manufacture seamless rings. By the feeding and rotating motion of the rolls, the thickness or height of the ring is reduced, the diameter is enlarged and the section profile is formed, as shown in Fig. 1. At present, the process is mainly used in the manufacturing of single metal ring [5–7]. Professor Hirt et al. [8, 9] tried to do ring rolling experiment and simulation of double metal ring. After simple assembling of the inner and outer ring parts with double metals, the hot ring rolling was executed. But the connect effect was not well and the interface was still clear, as shown in the reference [8]. The multi-metal plate rolling process is more mature than double metal ring rolling. Manesh and Taheri [10] and Sheikh [11] studied multi-metal plate rolling connection technology, including the connection of steel and aluminum, aluminum, and magnesium. Bay [12] and Maeda and Teshima [13] discussed the mechanism of interface healing during rolling and emphasized that the key to accomplish rolling connection is to eliminate surface

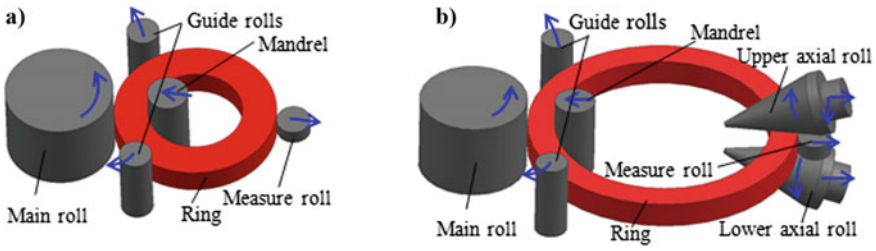

Fig. 1 **a** Radial ring rolling; **b** radial-axial ring rolling. (Color figure online)

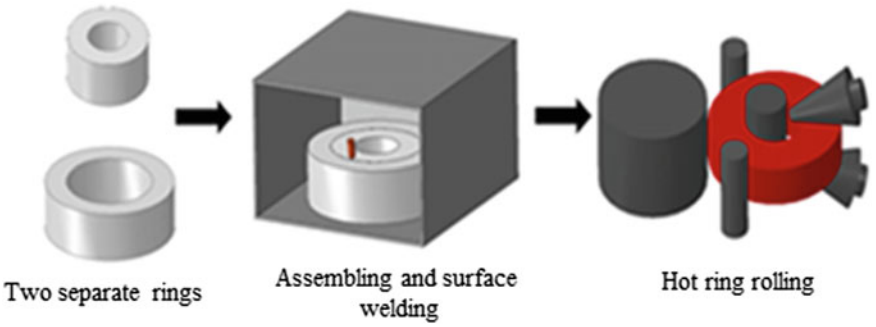

Fig. 2 Main process flow of constructive hot ring rolling process for double metal composite ring. (Color figure online)

oxidation layer and attachments. Xie et al. [14] proposed the use of vacuum rolling method for composite plate rolling of stainless steel and carbon steel. In addition, Sun et al. [15, 16] also obtained a good interface healing effect by thermal compression deformation under high-vacuum conditions.

By the above, it can be inferred that the reason for the poor interfacial healing may be related to the severe interfacial oxidation during the heating process. In this paper, a novel constructive hot ring rolling process for double metal composite ring is proposed, and its basic technical process is shown in Fig. 2. First, two separate rings with different metals are assembled together. And then the surface interface area on the upper and lower of the assembled ring are welded in oxygen-free environment, which can suppress the interfacial oxidation during heating process. After that, the surface welded ring is cleaned and heated. Finally, the target double metal composite ring is formed by hot ring rolling.

2 Experimental Procedure

To verify the feasibility of the above constructive hot ring rolling process, a constructive hot ring rolling experiment of a small-sized double metal ring with 20 steel and 304 stainless steel was tried. Before hot ring rolling, double metal ring blank is constructed based on laboratory conditions. The material of outer ring blank is 20 steel, and the material of inner ring blank is 304 stainless steel. The sizes of the ring blanks are shown in Fig. 3.

The main process of double metal ring blank construction is shown in Fig. 4. The two blank units were machined to the design sizes. Then, the surfaces of the ring blank units were cleaned with acetone. After drying, the inner and outer ring blank units are assembled together to obtain a combined ring blank. The interface of the ring blank is directly in contact with air in this state and easily oxidized during subsequent heating process. Therefore, it is necessary to seal around the upper and

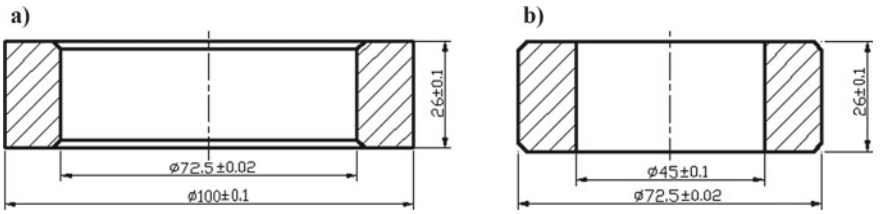

Fig. 3 Size diagram of the ring blanks: **a** outer ring blank; **b** inner ring blank

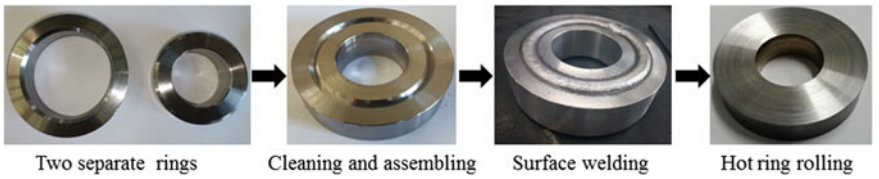

Fig. 4 The main process of double metal ring blank construction. (Color figure online)

lower end faces of the combined ring blank along the interface area in an oxygen-free environment. Thus, the interface is not easy to oxidize during subsequent heating, which can promote interface healing. Finally, the protruding weld material on the end face of the ring billet was removed to ensure the flatness so that the ring blank could be smoothly put into the rolling hole.

The hot ring rolling experiment was performed on a laboratory HHRM160 ring rolling machine (as shown in Fig. 5a). Before ring rolling, the constructed double metal ring blank was heated in a resistance heating furnace to 1150 °C and held for 1 h. Then it was taken out on the ring rolling machine to perform hot ring rolling experiment. The main rolling parameters are shown in Table 1 and the rolling ratio was 2. Figure 5b showed the rolling process, the ring diameter grew normally. Figure 5c showed the rolled ring, and no obvious interface can be seen on the end face of the ring.

3 Results and Discussion

After hot ring rolling, the rolled ring was cooled in the air. When the temperature of the ring decreased to room temperature, then it was cut along the cross section, as shown in Fig. 6. After grinding and polishing the cross section of the ring sample, it can be found that there is no obvious crack on the ring cross section, which indicates that the ring interface achieved healing in macro-scale.

In order to further observe the behavior of the interface evolution during the hot ring rolling process, the cross-sectional sampling was chosen on the ring blank and the rolled ring. After grinding and polishing, the chemical etching treatment was conducted on the sample surface. Because the sample contained two different materials, the chemical etching treatment should proceed by region. The 20 steel region was etched by alcoholic solution with 3% nitric acid. The 304 stainless steel region was etched by mixed solution with 40 ml hydrochloric acid, 20 ml nitric acid, 40 ml glycerol, 20 ml hydrogen peroxide. Then the sample was observed by metallurgical microscope. The low power (25 magnification times) of the full-scale

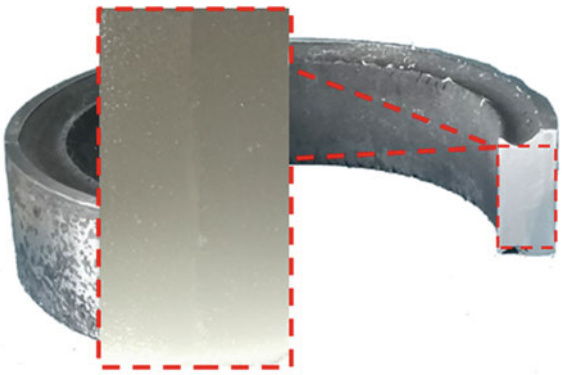

Fig. 6 Macro forming effect of the cross section of the rolled double metal ring. (Color figure online)

metallographic diagram of the ring cross section is obtained, as shown in Fig. 7. It can be found that the cross-sectional sample after corrosion has a limit at the material boundary. The limit of the ring blank is very obvious, and the rolled ring has a fuzzy line.

In order to more clearly observe the healing effect of the interface zone, the center interface areas of the cross section on the above-constructed ring blank and the rolled ring were magnified 500 times on a microscope to observe the high-power morphology, as shown in Fig. 8. The dark seam in the diagram is the interface area. The width of the interface area on the constructed ring blank is larger than 70 μm. The width of the interface area on the rolled ring is smaller than 3 μm. It can be found the interface healing effect is significant.

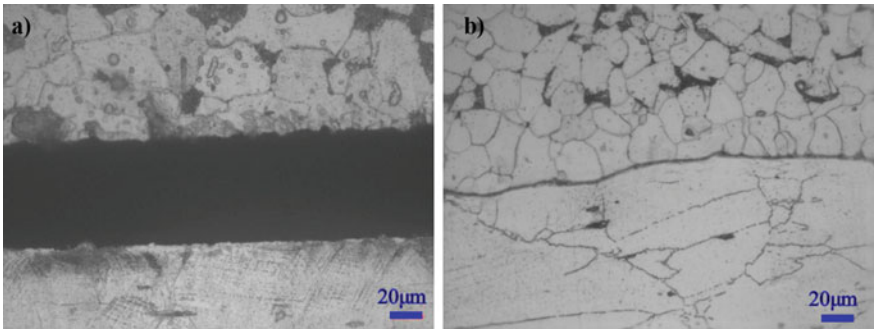

Fig. 8 High-power metallography diagram of the central interface region: **a** construct ring blank; **b** rolled ring. (Color figure online)

Further, small-size tensile test was carried out to evaluate interface bonding strength. From the rolled double metal ring, the tensile samples were taken in the radial direction at three zones A, B, and C. The sampling positions and dimensions of the tensile samples were shown in Fig. 9. The prepared tensile sample was tested on a small size tensile testing machine, as shown in Fig. 10a. The blue part is the marked stainless steel material. It can be found that the geometric position of the tensile sample after fracture is similar and close to the boundary of the two metals.

To measure the interface bonding degree, a comparison of the tensile strength of double metal ring and single metal ring was supplemented. Because the tensile

Table 2 Tensile strength result

Samples	Tensile strength (MPa)
The rolled 20 steel ring	481.6
Position A on the rolled double metal ring	470.6
Position B on the rolled double metal ring	474.5
Position C on the rolled double metal ring	477.3

strength of the 20 steel is smaller than the 304 stainless steel. So a sample was sampled from a rolled ring with single 20 steel. The tensile strength comparison between the rolled double metal ring and the rolled 20 steel ring was shown in Table 2. The tensile strength of the samples was similar. One side, the interface bonding degree along peripheral direction was uniform. On the other hand, the tensile strength of the rolled double metal ring is close to the rolled 20 steel. That is, the strength can reach the lower strength base material of the two materials. The result further indicates that the interface of the double metal ring by constructive hot ring rolling process is well-healed.

4 Conclusions

In this paper, a novel constructive hot ring rolling process to manufacture a seamless double metal composite ring is proposed. Before hot ring rolling, welding the surface interface area of assembled ring in oxygen-free environment, can suppress the interfacial oxidation during heating process and improve the interface healing degree in hot ring rolling. By the experiment of constructive hot ring rolling process for double metal composite ring, the interface healing degree was significantly improved. Further investigations should focus on the mechanism of the interface healing during hot ring rolling and the influence laws of process conditions on interface healing.

Effect of Feed Rate on Texture Evolution of 42CrMo Casting Blank During Hot Ring Rolling

Huiping Qi, Fangcheng Qin, Yongtang Li, Huiqin Chen, Chongyu Liu, and Haiquan Qi

Abstract The compact casting-rolling technique is an advanced method to produce seamless ring parts. The technique has been paid much attention in recent years. To find out the textual evolution rule of materials in this compact process, hot ring rolling of 42CrMo casting blank was conducted at different mandrel feed rates. The macro-textures of the as-obtained products were studied by X-ray diffraction, and micro-textural associated grain orientations were examined by electron backscattered diffraction techniques. The dominant textures in hot-rolled rings were similar, with γ-fibre consisted of {111}<110> and {111}<112> orientations as the most intense components. The α-fibre and ε-fibre textures in the entire thickness of hot-rolled rings did not show significant change as feed rate increased. Moreover, shear textures, including Copper-type {112}<111> and Goss {110}<001> components were presented in different regions of hot-rolled rings. The grain refinement was found closely related to grain orientation and micro-texture evolution in the entire thickness. The inhomogeneous distribution of grain size in the hot-rolled ring at a higher feed rate resulted in poor plasticity and toughness, which was caused by inhomogeneous γ-fibre orientations, especially in the center layer of the ring. Overall,

1 Introduction

42CrMo ring parts with excellent balance between strength and ductility are widely applied in aerospace, wind power, high-speed rail, and automobile industry. The ring rolling technique is an advanced method to produce the seamless 42CrMo ring parts [1]. During hot ring rolling (HRR), the ring blank driven by friction passes through the gap between the mandrel and driven roll. Consequently, accumulated strain expands from contact area with rollers to the inside of the ring due to the progressively narrowed gap between the mandrel and driven roll. This, in turn, continuously enlarges the diameter and reduces the thickness. So far, numerous studies dealing with deformation behavior and microstructure evolution of as-forged 42CrMo, GCr15 bearing steel, and TA15 titanium alloys have been subjected to HRR [2–7]. In recent years, to save energy, protect environment and reduce cost, a compact casting–rolling forming process was proposed and paid much attention [8–10]. However, in the compact cast-rolling forming process, unforged ring billets are directly used for ring rolling. The geometrical dimensions and microstructural modification must be integrated controlled during HRR. Therefore, hot compression testing was used on as-cast 42CrMo alloys to establish its recrystallization models [11]. Effects of rolling ratio, initial rolling temperature, and feed rate of mandrel on the recrystallization fraction and grain size have been clarified [12–14]. The precise dimensional accuracy and good microstructures were obtained in 42CrMo rings produced by compact casting–rolling process [8, 14].

Many merits such as considerable saved energy, reduced costs, and environmental protection are presented in the compact process when compared with the existing one. However, the texture evolution mechanism and its effect on mechanical properties of 42CrMo casting ring blank during HRR are still unclear [1]. Some studies suggested that improvement in strength and ductility are closely related to grain refinement and texture components of hot-rolled rings in their entire thickness. The shear texture was examined at the top part with a maximum shear strain but the cold rolling texture was operated at the middle and bottom parts of IF steel subjected to differential speed rolling [15]. The formation of shear texture is important for obtaining large grain refinement at the top part when compared to other parts of the specimen. Under the same hot-rolled reduction of grain-oriented silicon steel, much finer microstructures could give rise to higher elongations in fine-grain strips when compared to coarse-grains ones [16]. For fine-grain strips, good ductility could be obtained by a reduction of more than 30%. However, it takes reduction amount of 50% to get good ductility for coarse-grain ones. The increase of rolling reduction will

enhance α and γ fibre textures in hot-rolled strips. Elongation of less than 2% with tensile and yield strength around 1400 MPa has so far been achieved for SAE 1050 steels cold-rolled with a large thickness reduction around 70% [17]. The textures showed no significant changes when thickness reduction amount was less than 50%. Weak γ-fibre with uniform orientation distribution was formed for high strength ultra-low carbon bake hardening steel subjected to hot rolling [18]. The intensities of {111}<110>-{111}<112> for γ-fibre and {111}-{112}<110> for α-fibre were then enhanced by cold rolling. The γ-fibre intensity could be improved by reducing the reduction amount during cold rolling, correspondingly deep drawability of the materials was improved.

Thus, clarification of textural development of 42CrMo rings produced by HRR is important for a better fundamental understanding of the process and possible advanced applications. HRR process of 42CrMo casting blank was conducted at different mandrel feed rates. The influences of mandrel feed rate on the macro- and micro-texture evolution were investigated by XRD and EBSD techniques, respectively. The associated mechanisms of grain refinement were clarified in an effort to fabricate high-performance rings using compact casting–rolling.

2 Experimental

2.1 Preparation of XRD and EBSD Samples

Medium-carbon low alloy 42CrMo steel with chemical compositions of 0.44C, 0.28Si, 0.72Mn, 0.22Mo, 1.13Cr, 0.12Ni, 0.08Cu, 0.012P, 0.007Cu, and balance Fe (in wt%) were used. The casting ring blanks, whose outer diameter, inner diameter, and height were 240, 120, and 45 mm, respectively, were produced according to the previously reported method [1]. HRR tests were performed on a vertical ring rolling equipment [19]. The reduction principle of the entire thickness (three steps: 15-10-5 mm) was adopted in HRR at different feed rates of mandrel. The detailed parameters of HRR process are shown in Table 1 [1]. After HRR, rolled rings were cooled to room temperature in air. The textural samples for XRD and EBSD observations were cut from casting ring blanks and hot-rolled rings. The samples were located in the outer layer (location 1), inner layer (location 3), and center layer (location 2), as shown in Fig. 1. The geometrical dimensions of XRD and EBSD specimens were set to 15 mm × 10 mm × 5 mm and 5 mm × 5 mm × 3 mm, respectively. The XRD specimens were etched by 4% Nital. The EBSD specimens were electrolytic polished in 5% perchloric acid alcoholic solution for 60 s at a voltage of 30 V and electric current of 0.8 A. The corresponding scanning area of 250 μm × 250 μm and step size of 1.5 μm were selected.

Table 1 Parameters used for hot ring rolling

Rolling parameters	Items	Values
Radius of driven roll R1/idle roll R2/guide roll R3/mm	–	340/52.5/52.5
Rotation rate of driven roll n1/(r/min)	–	62
Feed rate of mandrel roll v/(mm/s)	A1	3-2-1.5
	A2	4-3-2
Dimension of casting ring billets/(mm × mm × mm)	–	φ 240 ×φ 120 × 45
Dimension of rolled ring/(mm × mm × mm)	A1	φ 332 ×φ 272 × 51.1
	A2	φ 331 ×φ 271 × 50.5
Rolling ratio λ	–	2.6

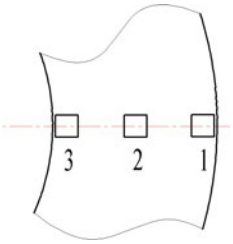

Fig. 1 Sampling location. (Color figure online)

2.2 Textural Characterization

The grain orientations and texture components were studied by means of EBSD system equipped with field emission SEM. EBSD data were analyzed using post-processing TSL-OIM software. After hot rolling, the textural components were quantitatively determined by measuring incomplete pole figures {110}, {200} and {211} at polar angles from 0o to 70o using Schulz back reflection technique on a Panalytical Xpert MRD high-resolution X-Ray diffractometer with Co-kα1 radiation [20]. The orientation distribution functions (ODFs) were obtained by the two-step method [21, 22]. Different textural fibres were then extracted from ODFs and the results were discussed.

3 Results

3.1 Texture of Casting Ring Blank

The initial casting microstructure of 42CrMo with an average grain size of 87 μm can be extracted from the literature [1]. By comparison, Fig. 2 showed initial texture mainly characterized by strong {112}<131> and near {110}<112> components with

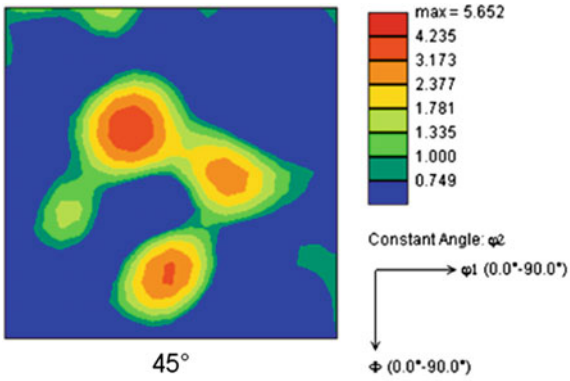

Fig. 2 Orientation distribution function at $\varphi 2 =$ 45o (Bunge notation) of 42CrMo casting ring blank. (Color figure online)

intensities of 4.5 and 3.4, respectively. In addition, {111}<110> with weak intensity of 2.5 and near {111}<110> components were also observed.

3.2 Textures of Casting Blank After HRR

The changes in geometrical dimensions of casting ring blank should follow the development of mechanical properties [1]. At a feed rate of 4-3-2 mm/s, the average ultimate strength of 1160 MPa and yield strength of 961 MPa did not obviously vary but the average total elongation and Charpy impact decreased to 8% and 11.5 J, respectively. These obtained values of hot-rolled rings were superior to reported one [14]. Refined grains with average diameter of 32 μm and homogeneous microstructure can be obtained near the outer layer and inner layer of A1-rolled ring [1]. Inhomogeneous microstructures were observed near the center layer, where small amounts of irregular and coarse grains would play dominant roles. At feed rate of 4-3-2 mm/s, the grain refinement degree decreased slightly with an average diameter around 44 μm. The inhomogeneous grain distribution in the entire thickness of A2 ring was also clearly observed.

After HRR, XRD was used to quantitatively determine the textures of the entire thickness of 42CrMo-rolled rings. Figures 3 and 4 show $\varphi = 45^{o}$ ODF sections (Roe notation) of hot-rolled rings at different feed rates. Compared to the initial condition, the texture showed complete changes (Fig. 2). The textural components of A1 and A2 rings after HRR process were identified as γ-fibre of <111 >//RD, with {111}<110> and {111}<112> shown as dominant components. However, γ-fibre texture looked weak near the outer layer of A2-rolled ring. Both α-fibre and ε-fibre textures did not illustrate significant changes with increased feed rate in the entire thickness of hot-rolled rings. The shear textures consisted of Copper-type {112}<111> and Goss {110}<001> components presented in different regions of hot-rolled rings. During hot rolling, shear deformation was caused by high friction between surface of the rollers and ring, resulting in the formation of Goss texture [16]. Large strains in

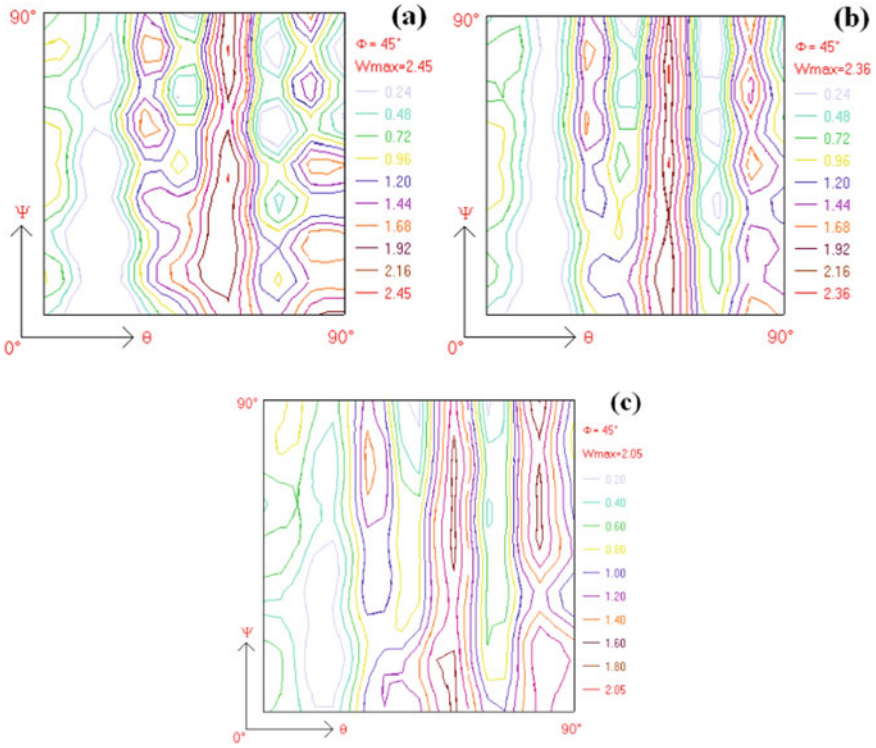

Fig. 3 $\varphi = 45o$ sections (Roe notation) of ODFs in A1-rolled rings at locations: **a** 1, **b** 2, and **c** 3. (Color figure online)

each pass and deformation heat were formed due to increased shear deformation as a function of feed rate. For A1 ring after HRR process, the intensities of Goss texture in surface appeared larger than that in center, but through-thickness texture was mainly dominated by γ-fibre orientation. In Fig. 3, the intensities of Goss texture in outer layer and inner layer increased with feed rate but slightly weakened in the center layer. These features induced inhomogeneous orientation distributions of γ-fibre and shear textures.

4 Discussion

Good mechanical properties are closely connected with refined grains and texture components. The superior ultimate tensile strengths and yield strengths should mainly be attributed to strengthening caused by grain refinement in the entire thickness of hot-rolled rings. Therefore, a better understanding of the analytical strengthening mechanisms would be essential to clarify the effects rules of mandrel feed

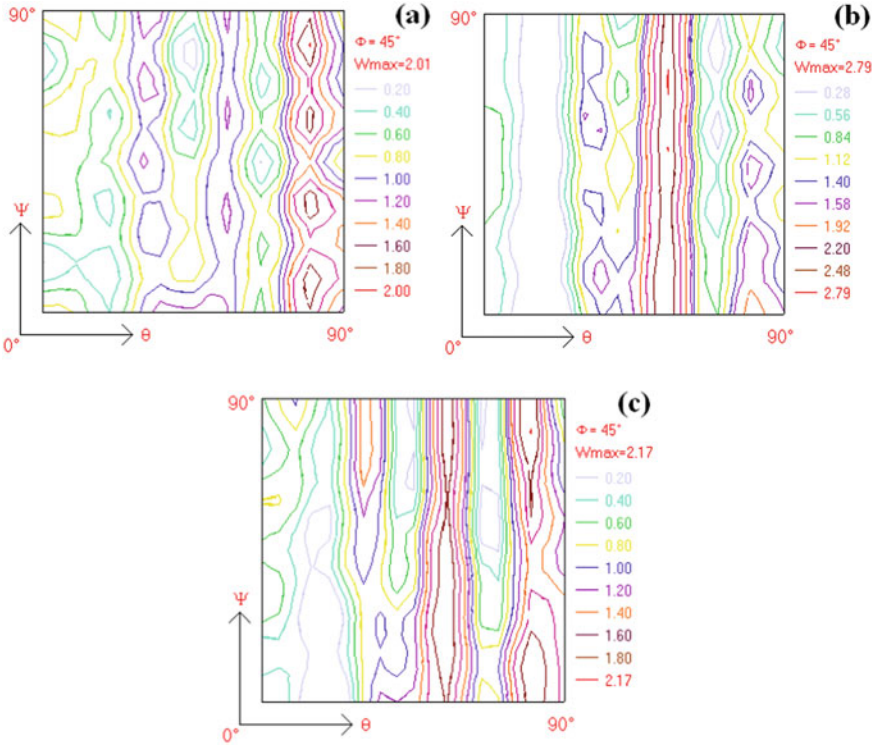

Fig. 4 φ = 45o sections (Roe notation) of ODFs in A2-rolled rings at locations: **a** 1, **b** 2, and **c** 3. (Color figure online)

rate on the microstructure, texture, and mechanical properties of 42CrMo casting blank processed by HRR. [1] The reason for this had to do with microstructure with finer grains, which should have more grain boundary per unit area when compared to initial coarse grains. Therefore, fine grains could provide more obstructions for dislocation motions at grain boundaries during room-temperature tensile deformation [23]. The above results agreed well with the behavior described by Hall–Petch equation for dislocation glide mechanism. In addition, poor plasticity and toughness would strongly depend on inhomogeneous distribution of grain size, which may be associated with shear deformation existing in the entire thickness of the rings. The difference in shear deformation between the surface layer and center layer during HRR was not obvious at low feed rates. However, the additional shear in center layer looked smaller than that in surface layer when feed rate increased.

Figure 5 summarizes the orientation density distribution of textures along the α-fibre, γ-fibre, and ε-fibre. As feed rate rose, significant texture evolution occurred, especially γ-fibre. The inhomogeneous orientation distributions of γ-fibre texture are displayed in Fig. 5c, d. α-fibre texture mainly consisted of {001}<110> and near {112}<110> components (Fig. 5a), implying typical rolling texture. The rolling

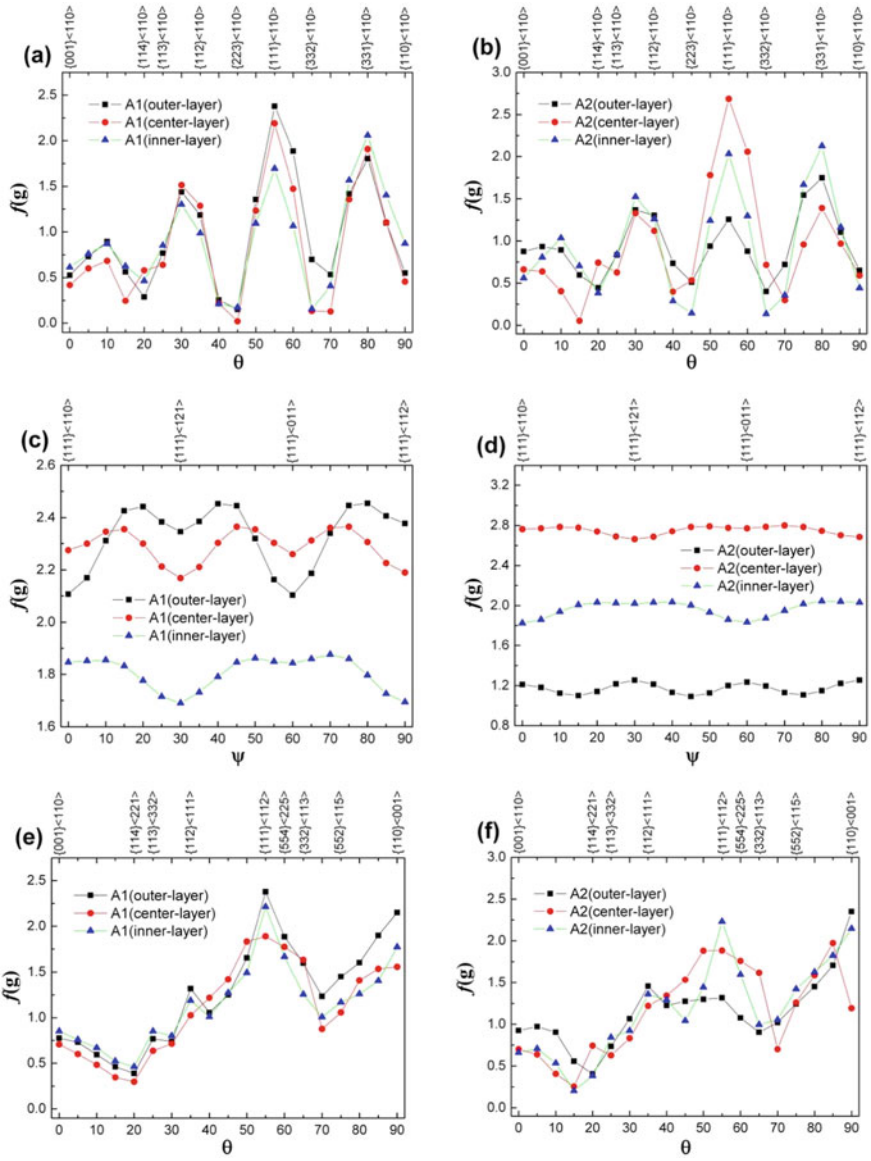

Fig. 5 Orientation density distribution of: **a**, **b** α-fibre, **c**, **d** γ-fibre, and **e**, **f** ε-fibre in the entire thickness of 42CrMo hot-rolled rings. (Color figure online)

texture did not show significant change with the increasing feed rate, but both recrystallization textures {111}<110> and {111}<112> components became stronger. Also, the recrystallization textures with intensities of 2.1–2.5 along γ-fibre dominated the outer layer and center layer. At feed rate from 3-2-1.5 mm/s to 4-3-2 mm/s, recrystallization textures were significant affected (Fig. 5d). Note that textures in the center layer continued strengthening up to approximately 2.8 but the textures in outer layer decreased sharply to 1.2. This induced a rather inhomogeneous distribution of recrystallization texture in the center layer. Thus, variation in recrystallization texture with feed rate obviously influenced the inhomogeneous grain refinement in the entire thickness of 42CrMo hot-rolled rings, especially in center layer [1].

Figure 6 exhibits the grain orientation in the outer-, center- and inner layers of 42CrMo rings after HRR process. Large numbers of sub-grains were recorded in the entire thickness of the rings at different feed rates. The grains were characterized by different orientations. Besides, <111> orientation in A1 hot-rolled ring was significant, and refined sub-grains with <211> orientation was obtained in both outer- and inner layers of A1 ring. The <110> orientation dominated the center layer. The <111> orientation in A2-rolled ring increased with feed rate. Also, transformation from <111> to <001> orientation enhanced, and grains with <110> orientation in both outer- and center layers decreased, leading to inhomogeneous orientation distribution in the entire thickness of hot-rolled rings.

The grain orientation directly reflected the preferred orientation tendency of texture during HRR process. The recrystallization grains with orientations of {111}<110> and {111}<112> were registered in outer- and center layers of A1 hot-rolled ring. However, {111}<112> grains were only found in the outer layer of A2 hot-rolled ring, and the slight preferred orientation was clearly displayed. In Fig. 6f, refined shear grains with {112}<111> were observed, leading to the competition between formation and growth of the grains. On the other hand, recrystallization nuclei were formed in interior of the grain and triangle grain boundaries. The reason for this had to do with large misorientation and high-density nucleation at grain boundaries, which contributed to bow out of the grain nucleation. The nucleation mechanisms of recrystallization grains were dominated by *in situ* recrystallization accompanied by random nucleation. In particular, new grains formed by *in situ* recrystallization had similar orientation in the matrix but those induced by random nucleation displayed different orientation. Moreover, grain orientations were closely related to distribution of grain size at higher feed rates.

Similar to microstructure and texture evolution of bcc metals [24], the texture components would generally develop into two families during rolling process. The γ-fibre contained <111> parallel to normal direction and α-fibre consisted of <110> parallel to rolling direction of the ring surface. Thus, mixed stress state may be induced during rolling process. The dominance of shear stress would induce textures with {110} component. Ryttberg et al. [25] suggested that cold rolling texture components in bcc metals and relative strength of different rolling textures mainly depended on degree of deformation. However, textures were quite independent of other parameters. By comparison, the above results showed slight decrease in tendency of textural

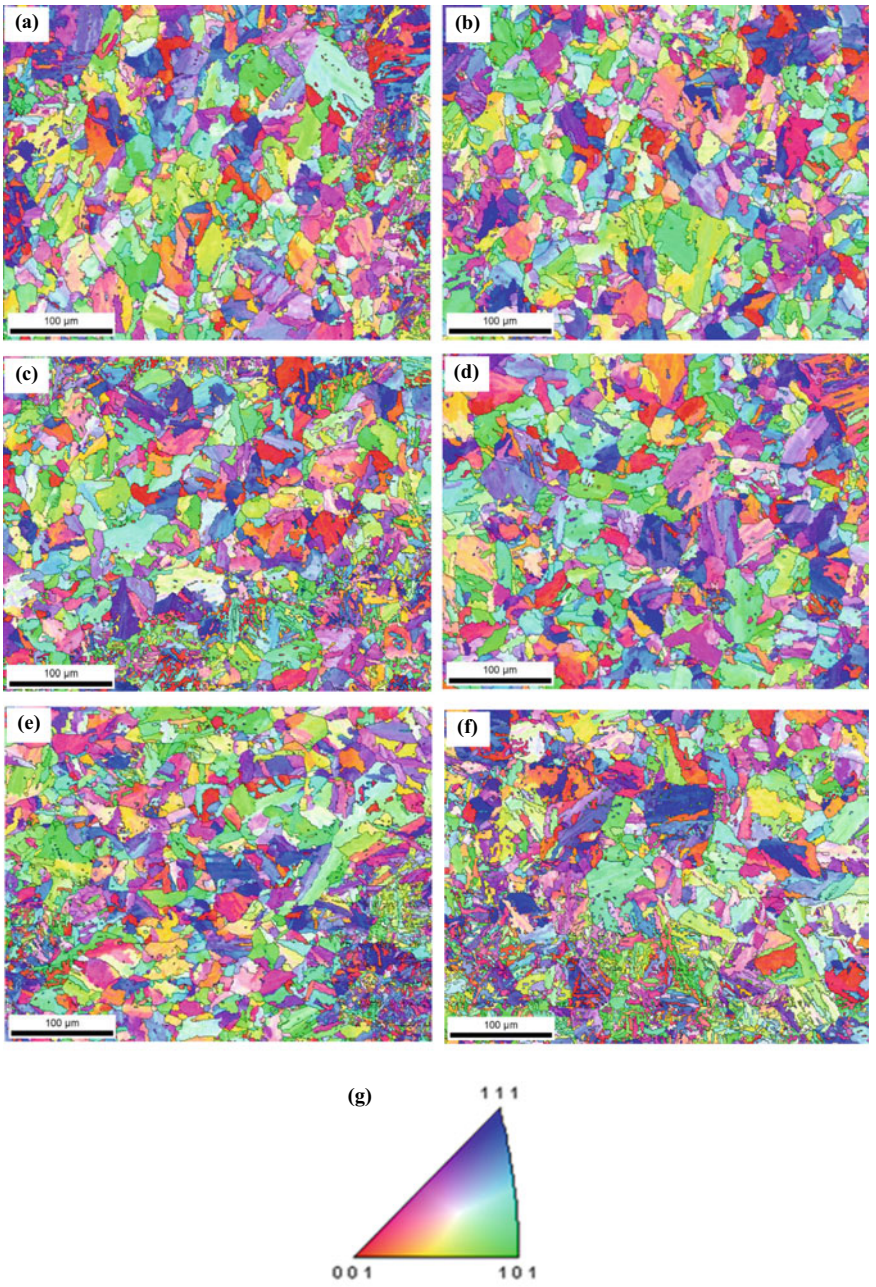

Fig. 6 Grain orientation maps of 42CrMo hot-rolled rings in different areas: **a** 1 of A1, **b** 2 of A1, **c** 3 of A1, **d** 1 of A2, **e** 2 of A2, **f** 3 of A2, and **g** inverse pole figure. (Color figure online)

intensity near the outer layer of hot-rolled ring with the increased feed rate. In addition, γ-fibre components looked more intense in the center layer. These combined textures revealed that HRR process led formation of mixed compression strain with additional shear strain associated with the distance from the surface layer to center layer. Furthermore, such complex texture evolution strongly depended on distribution of additional shear strain caused by non-symmetrical deformation model of HRR process in nature [15, 25]. The high intensity of shear texture, including Copper-type {112}<111> and Goss {110}<001> components showed intense shear strain effectively contributing to the shear texture evolution during HRR. During hot rolling, the shear deformation was caused by high friction between the surface of rollers and the ring, resulting in Goss texture [16]. Large strain in each pass and deformation heat was formed due to the increase in shear deformation with feed rate. Therefore, shear texture would give rise to comparatively higher fractions of refined grains. Previous studies showed that crystallographic orientation of deformed grains would affect the nucleation and following growth of recrystallization nuclei [26]. The nucleation rate and driving force for recrystallized nuclei growth depended on stored energy of various grains and scaled by their Taylor factor M [27]. For example, the Taylor factors were very low for both orientations {110}<001> and {112}<111>, unlikely to form nuclei [26, 28]. Goss texture would form by shear deformation [21]. The textures were characterized by {110}<001> and {112}<111> orientations with very low Taylor factors in the surface layer of 42CrMo rings after HRR process. Besides, stored energy in {110}<001> and {112}<111> grains can only be reduced since no orientation could nucleate easily. On the other hand, Taylor factors for γ-fibre orientations between {111}<110> and {111}<112> looked higher than those of α-fibre orientations between {001}<110> and {112}<110>. The intensities of γ-fibre orientations were also much higher than Goss component (Fig. 5). Consequently, higher stored energy played a dominant role in surface layer when compared to center layer, resulting in preferred nucleation of grains along γ-fibre orientations. Finally, the inhomogeneous distribution of grain size was caused by the distinctly inhomogeneous γ-fibre orientations in the entire thickness of A2 ring after HRR process, especially in the center layer.

As a result, the grain refinement and its uniform distribution in the entire thickness of hot-rolled rings depended heavily on corresponding grain orientation and textural development. This, in turn, should influence the plasticity of the rings, including their elongation and reduction of area. Note that strength and plasticity could be considered as conflicting properties, but elongation increased considerably since fine-grains in a preferential orientation suited better the imposed strain [16, 29]. Here, the texture components and relative strengths of different textures exhibited significant evolution with feed rate. However, the direct effecting mechanism of texture on plasticity was still unclear and should be explored in future studies.

5 Conclusions

The texture evolution of 42CrMo casting blank subjected to HRR process was studied at different feed rates. The mechanisms of grain refinement were examined throughout the entire thickness of hot-rolled rings. The following conclusions could be drawn:

(1) The dominant textures in the hot-rolled rings were similar, with γ-fibre consisting of {111}<110> and {111}<112> orientations as the most intense components. The α-fibre and ε-fibre textures did not significantly change with feed rate in the entire thickness of the hot-rolled rings. Moreover, shear textures, including Copper-type {112}<111> and Goss {110}<001> components were presented in different regions of the rings after HRR process.

(2) Grain refinement was closely related to grain orientation and textural development in the entire thickness of the hot-rolled rings. The inhomogeneous distribution of grain size in the hot-rolled ring at high feed rates induced poor plasticity of 8% and toughness of 11.5 J caused by inhomogeneous γ-fibre orientations, especially in center layer of the ring. Thus, the integrated control of microstructure and mechanical properties could be realized by the application of compact cast-rolling forming process.

A Novel Flexible Skew Rolling Process for Step Shafts: Feasibility Study

Longfei Lin, Baoyu Wang, and Jinxia Shen

Abstract When the larger-size step shafts with small scale are manufactured, both the forging and rolling method bring about high cost for its need for heavy loading or special dies. This paper develops a novel flexible skew rolling (FSR) process to produce step shafts. The process includes four stages: radial rolling, rollers inclining, skew rolling, and rollers leveling. Each roller has three freedoms (circle rotation, radial rotation, and radial-feeding motion), which can manufacture different axles by programming different rollers' movements that can achieve flexible rolling with the same tools. In order to conduct the experiment and verify the process feasibility, a flexible skew rolling mill with dual-rotatable-shafts (DRM-80) was invented and manufactured, and both rollers have three freedoms that can be dynamically adjusted during the whole rolling process. Feasibility experiments were performed at the DRM-80 mill, a Ø80 × 390 mm C45 steel billet was used to manufacture a single-step shaft. A large and long shaft (total length 605 mm, minimum diameter 50 mm) was formed and has well dimensional accuracy and no serious defects. The main forming defects include knurled pockmarks, helical grooves, side cavity, and diameter tolerance. The experimental FSR part is free from internal cracks by observing the transverse and longitudinal sections. The study results verified that the novel flexible skew rolling process is positive and the new type DRM-80 mill is reliable.

1 Introduction

The near-net-shaped shafts play an important role in axisymmetric profiles manufacturing and die-forging billets preforming which are widely used in machine-building, automotive, and railway industries [1–3]. These shafts are generally formed by forging process (open die forging [4–6], radial forging [7, 8]) or rolling process (cross-wedge rolling [9, 10]). Nevertheless, the forging process can manufacture various shafts by common rollers but needs high forging force (overall deformation) that results in large tonnage of the forging equipment. Conversely, the rolling process can realize lightly foaming by regional deformation but needs large-size special tools. Hence, the cross-wedge rolling process is suitable for rolling in mass quantities because of the lack of flexibility. For manufacturing the small number of products, both the forging and rolling method bring about high cost.

To manufacture shafts flexible the axial feed rolling process was proposed first in Germany (1986) [11]. The schematic diagram of this process is shown in Fig. 1a, the rolling device of this process consists of rollers and chuck, the axial rotation and radial feeding motion are conducted by two rollers, the axial linear movement is conducted by chuck. Two stages are included: the billet deforms radially to the target diameter under the radial movement of rollers and then is stretched axially to the target length under the axial linear movement of truck. Early researchers focused on this flexible process and meaningful research has been conducted, and the relationships

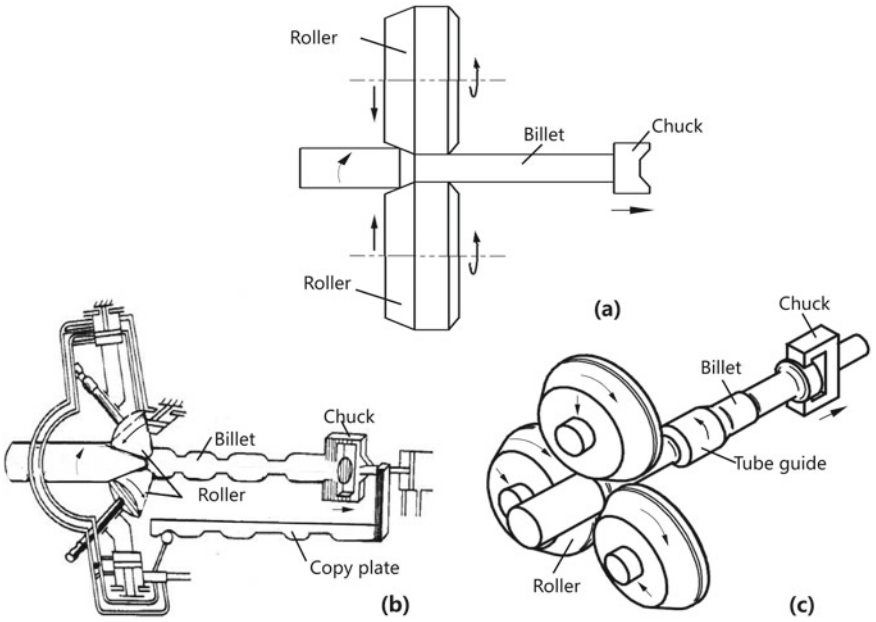

Fig. 1 The flexible rolling process under research phase: **a** axial-feed rolling; **b** copy skew rolling; **c** CNC skew rolling

of the main process parameters and the defects were analyzed by finite element method and engineering experimentation [12]. Whereafter, Chinese researcher Xu [13, 14] conducted series of studies, the contact surface and kinematics analysis of this process are presented. The theoretical analysis, deformation process simulation, and test machine have been investigated. The most striking feature of the process is that a simple-shape die with small size can manufacture various multiple-shaft parts for the formed geometry of the shaft is controlled by the roller's movements. Hence, the main advantage of this process is flexibility.

Another method for flexible producing shaft is skew rolling with three tapered rollers which can be divided into two types. One type of this process is a copy of skew rolling, which is originated in the Soviet Union by Zerikov (1968) [9], as shown in Fig. 1b, this process needs a copy plate to control movements of tapered rollers. The other type is CNC skew rolling which is carried out by Pater Z successfully completed the forming of the rail car axles by a CNC 3-roller mill (2020) [15], and the schematic diagram of CNC skew rolling is shown in Fig. 1c. In CNC skew rolling, apart from axial rotating, these tapered rollers can also move radially toward the axis of the workpiece. By programming the motions of CNC mill, it becomes possible to produce elongated parts with any shape.

Nevertheless, Both axial feed rolling, the copy skew rolling and CNC skew rolling, a chuck is required to draw the forming workpiece for its axis movement, and leads to the following considerations: (1) a considerable amount of chucking allowance that may reduce the material utilization; (2) the maximum rolling length is limited by the chuck stroke that needs an elongated equipment for long axis production. These inevitable limitations limited their applications, until now, all these above flexible forming methods are still under the experiment exploration.

2 Flexible Skew Rolling Process (FSR)

In this paper, a novel flexible skew rolling (FSR) process is presented and the schematic design of two-roller FSR process was shown in Fig. 2a. The rolling device of FSR process mainly consists of two tapered rollers and two tube guides. Two rollers both have three freedoms: the rotation N_0 around its own axis, the radial feed V_0 toward the workspace axis, and the angle adjustment rotation W_0. Two tube guides are fixed on both sides of the rollers for limiting the position of the workplace. The roller motions (N_0, V_0, W_0) are controlled by automatic system, the process is divided into four stages which is shown in Fig. 2b:

I. Radial rolling: two leveled rollers have the motions of N_0 and V_0. The workpiece diameter d_1 is determined by the gap distance between the two rollers, and the front step of the bar is formed at the meantime;
II. Rollers inclining: two rollers have the motion of W_0. The swing angle β is changed and increases to the target value;

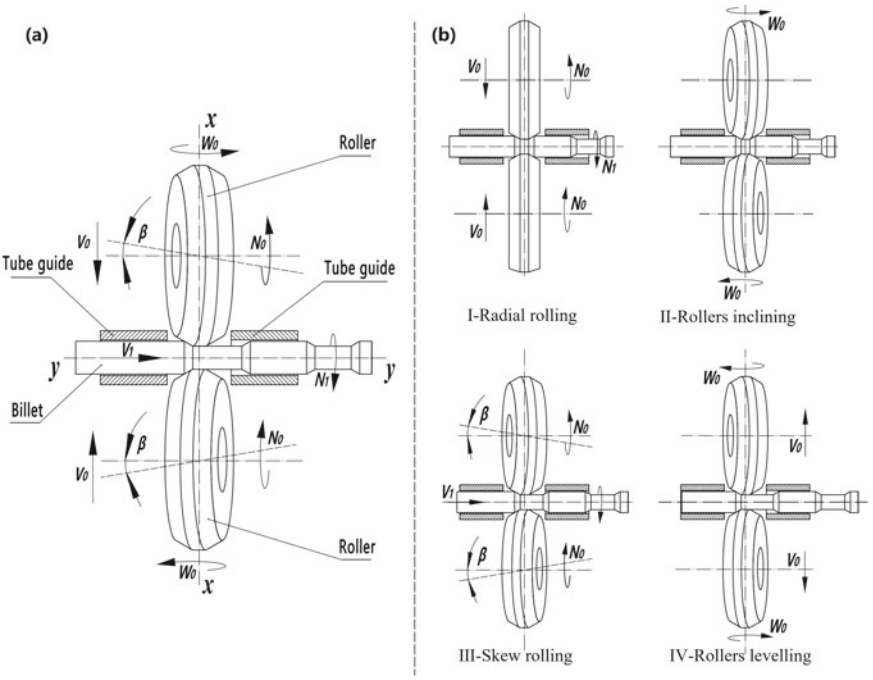

Fig. 2 The flexible skew rolling (FSR): **a** schematic diagram; **b** process stages

III. Skew rolling: two inclined rollers (with invariant angle β) only have the motion of $N_{0.}$ The workpiece rotates circularly and moves axially, then the diameter of workpiece is reduced toward the free end of the bar;
IV. Rollers leveling: two rollers have the motions of V_0 and $W_{0.}$ Two rollers are leveled and backed to the original state.

By controlling the motions of two rollers, FSR process can flexibly form various shafts. According to the above analysis, the FSR process with none-chuck has enormous advantages over low-waste material, unlimited-length of shaft, and compact-structure equipment.

3 Rolling Mill (DRM-80)

To verify the feasibility of the process, a laboratory flexible skew rolling mill is indispensable. Up to now, the skew rolling mill mainly includes skew piercing mill, square-frame rolling mill, power-box rolling mill, and double-arm rolling mill [16]. These mills are widely used in the industrial production of tube piercing, ball rolling, thread rolling, spline rolling, worm rolling, and knurl rolling, which has a great contribution to metal-forming industry. However, all these mills above cannot meet

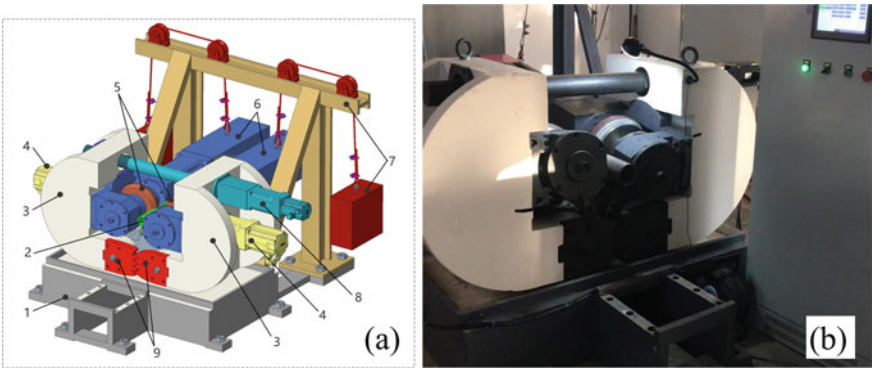

Fig. 3 The DRM-80 mill was designed and constructed: **a** the 3D model; **b** the physical mill. (Color figure online)

the movement requirements of FSR process because the rollers are required three degrees of freedom.

The FSR mill (named as DRM-80, the D stands for dual-rotatable shafts, the R stands for rolling process, the M stands for mill and 80 stands for the maximum diameter of the billet) with dual-rotatable shafts was invented and constructed, and the 3D model of this rolling mill is shown in Fig. 3a. The mill has a segment structure and mainly consists of ten components: a base unit—1, two tube guides—2, two-arm stands—3, two-angle adjusting systems—4, two rollers—5, two main rotating systems—6, a counter-balance unit—7, radial feeding system—8, a radial feeding synchronous unit—9, and a servo control system.

Two main rotating systems of this mill are correspondently mounted under two-arm stands, and drive the two rollers rotating around its own axle. In the same circumstance, two-angle adjusting systems are fixed on the two-arm stands and also inclines the whole main rotating systems to adjust the swing angle. In order to achieve two rollers radial feed together with the same speed at anytime, the radial feeding system and radial feeding synchronous unit are matched, so the radial feeding synchronous unit was proposed. The radial feeding synchronous unit is worked by two matched synchronous gears that ensure two arm stands open or close together. The physical mill is presented in Fig. 3b, and the technical specifications are given in Table 1. What need to pay more attention is that the overall dimension of the mill is only 1.8 m $\times$ 1.7 m $\times$ 1.6 m, the total power is 70 kW and the maximum roller diameter is 350 mm, but the maximum billet diameter can up to 80 mm, the body of the DRM-80 mill has the advantages of compactness and high strength.

Therefore, the designed DRM-80 machine makes it possible to accomplish FSR process test result from the rollers can rotate in the same direction, radial feed toward the workpiece, and adjust the swing angle β dynamically. What's more, this innovative type of mill may have a promising potential in industrial application for the superiority of convenient installation and adjustment, high strength frame, compact structure, and multifunctional rolling and precision control by servosystem.

Table 1 The technical specifications of DRM-80

Parameter	Unit	Value
Main rotating motor power	kW	2 × 30
Main rotating speed	rmp	43
Main rotating torque	Nm	7000
Radial feeding motor power	kW	3
Radial feeding speed	mm/s	5
Radial feeding torque	ton	22
Angle adjusting motor power	kW	2 × 2.3
Angle adjusting speed	°/s	10
Angle adjusting torque	Nm	900
Angle adjusting range	°	±12
Rolling center line range	Mm	±0.15
Maximum roller diameter	mm	350
Maximum billet diameter	mm	80
Overall dimensions	m	1.8 × 1.7 × 1.6
Total weight	ton	5

4 Feasibility Experiment

The purpose of FSR test is to verify the feasibility of the FSR process and equipment, as Fig. 2 shows, rollers inclining and rollers leveling are roller adjustment stages, radial rolling, and skew rolling are billet forming stages.

A single-step shaft foming test was presented, in which a shaft with the minimum diameter 50 mm was formed from a Φ80 × 390 mm C45 steel billet. Because the rolled part only has one step, the rolling process only includes three stages (radial rolling, rollers inclining and skew rolling). However, the FSR process of this shaft doesn't include all these stages but all the billet forming stages were included, so the feasibility experiment is reliable.

4.1 Rollers Design

The FSR roller is radically different from the traditional roller, cross-wedge rolling die, ball rolling roller, or other skew rolling roller. The FSR roller is inspired by the piercing roller but has some development because the center stress state(to avoid center crack) and the four forming stages are taken into account at the same time. Hence, as shown in Fig. 4a, the roller is a symmetrical structure that can be divided into sizing zone in the middle, forming zone on both sides. The roller parameters are diameter D_0= 340 mm, length L_0= 120 mm, forming angle $\alpha = 20°$, and sizing width $L = 25$ mm.

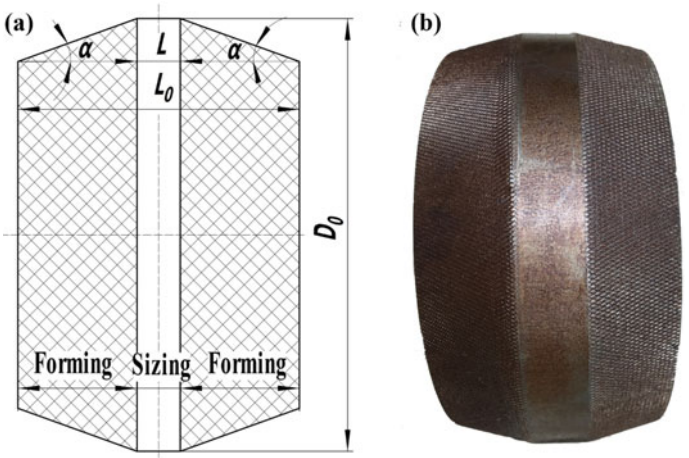

Fig. 4 The FSR roller: **a** geometric model; **b** physical graphics. (Color figure online)

Figure 4b shows the FSR roller used in hot FSR experiments. Because the roller stands high-speed revolution and large rolling force during the hot FSR rolling (temperature is about 1050 °C), so the value of HRC hardness generally needs greater than 50. In consequence, the roller is made by hot-die-material H13 and heat treatment has been done between rough lathing and precise grinding process. Notably, the forming zone surface was knurled by hatching knurling with the size of 2 mm.

4.2 Movements Design

The most significant characteristics of the FSR process is programming different movements to finish each adjusting stage and forming stage. The forming process was designed and the movement parameters were programmed according to Fig. 5. Firstly, at the radial rolling stage, two leveled rollers rotate with a constant speed of N_0= 30 rpm and radial feed speed V_0= 1.5 mm/s. After radial rolling stage (10 s later), the roller reaches the target diameter of 50 mm. Secondly, at the roller inclining stage, two leveled rollers are adjusted into inclined (the swing angle $\beta = 8°$) by the radial rotating movement (W_0= 1 rpm). Thirdly, at the skew rolling stage, two rollers remain the inclined angle $\beta = 8°$ and rotate with speed N_0= 30 rpm. The workpiece rotates and moves axially under the friction action between rollers and workpiece. At the end of this stage, the workpiece is formed into step shaft.

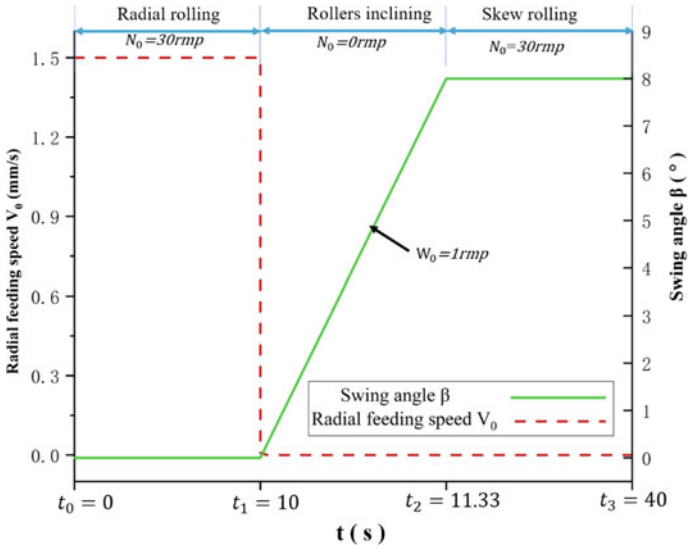

Fig. 5 The FSR rolling stages and process parameters of Φ80 mm single-step shaft. (Color figure online)

4.3 FSR Rolling Test on DRM-80

Feasibility experiments were performed on the DRM-80 mill, and a Φ80 × 390 mm C45 steel billet was used to manufacture a single-step shaft. Prior to rolling, the C45 billet is preheated to 1050 °C in an electric tube furnace, and then immediately transferred into the workspace of the DRM-80 mill.

The test was performed at the University of Science and Technology Beijing, China. The motions of rollers were controlled by the servo program which was preset before. The deformation stages of the shaft were shown in Fig. 6. The workpiece rotated stably under the constraint of tube guides during the whole FSR rolling. After FSR rolling, the mill was stopped and the product was removed from the machine manually. By the feasibility test, the following conclusions are obtained: (1) the novel FSR process is feasible and optimistic; (2) the DRM-80 mill can complete the complex motions regulate dynamically and its technical specifications (shown in Table 1) are sufficient; (3) the temperature of billet is relative stability during the whole rolling process, which is the same as radial forging [7, 8], thus the FSR process can form large and long shafts with one-time heating; (4) the capacity of the DRM-80 mill for hot forming process is that the diameter of the billet can reach 80 mm and its length is unlimited in theory.

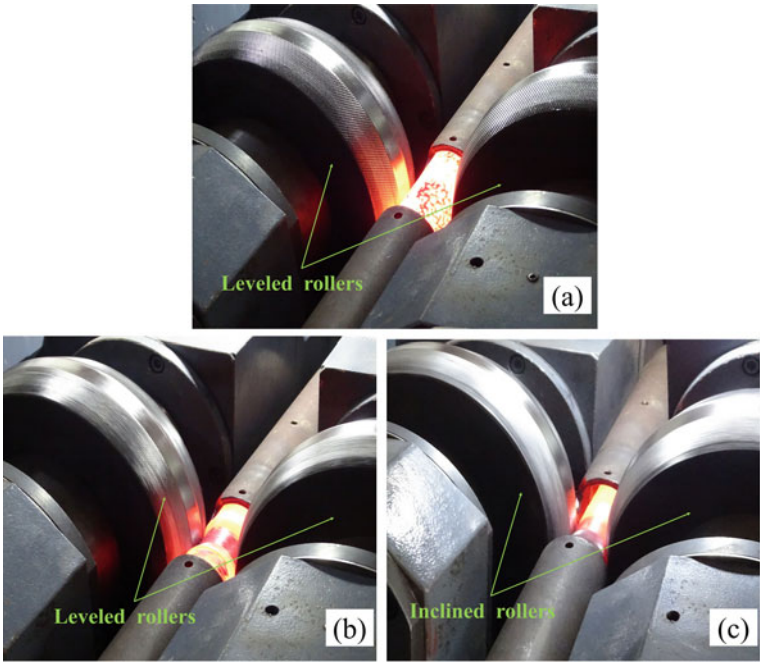

Fig. 6 The laboratory performance of Φ80 mm single-step shaft FSR rolling: **a** beginning; **b** radial rolling; **c** skew rolling. (Color figure online)

5 Results and Discussion

The initial billet is a bar with Ø80 × 390 mm, the diameter of the rolled part is Φ50 mm and the length of the workpiece is 605 mm, which is shown in Fig. 6a, the reduction of this part is up to 60%.

The formed diameter d_1 is measured by the Vernier caliper and the tolerance $\Delta d \approx 1.0$ mm. It turns out that the FSR geometric accuracy is similar to the cross-wedge rolling process (0.8 mm), and better than radial forging process (1.2 mm) [17].

There are forming defects as shown in Fig. 6b, the knurl pockmarks are remained on the step-surface because the rollers were knurled by hatching knurling on the tapered forming zone surface (Fig. 4). In addition, the shallow helical grooves, which are formed by the stage of skew rolling, are obviously presented on the bar surfaces. The helical grooves are the common characteristics of skew rolling and cross-wedge rolling process [18, 19], for which is mainly that the width of the rollers' sizing zone is too short or the chamfering angle between the forming and sizing zone of the rollers is unreasonable, thus the further research is necessary.

The transverse and longitudinal sections of the shaft are observed in Fig. 7c, d. The rolled part are free from any internal defects such as central cracks which frequently occur in skew rolling processes because the stress distribution of FSR is

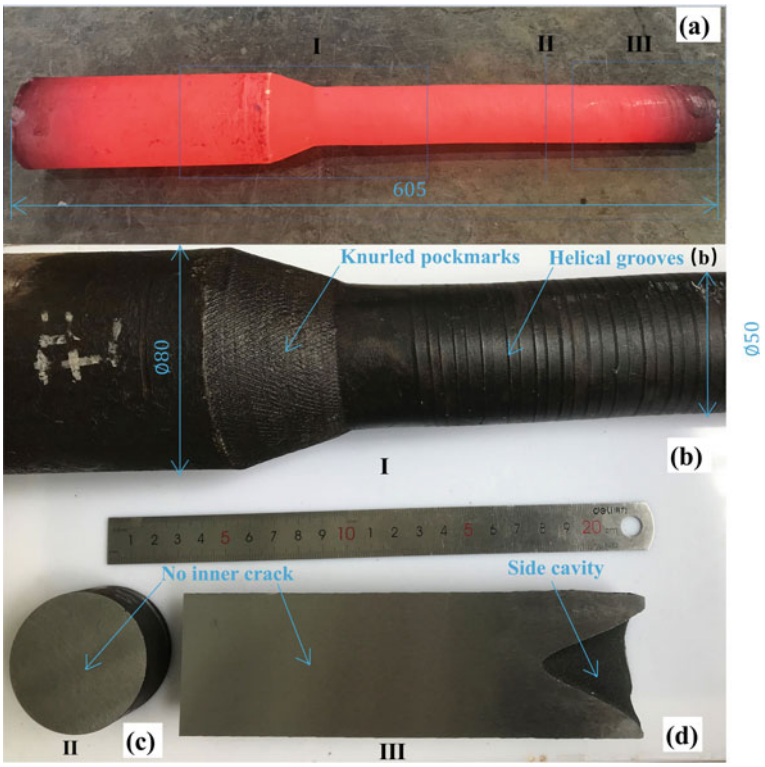

Fig. 7 The manufactured Ø80 mm single-step shaft. (Color figure online)

two orientations tension and one orientation compression [20–22]. Therefore, the relationship between internal defect and inner stress state will be researched in the study of the future.

Another observed defect is the side cavity which is created on the edge of the product as seen in Fig. 7d, which can be explained by the material flow of the outer sphere is rapider than the internal. The side cavity defect leads to the material wastes but does not affect the quality of products.

In conclusion, through hot FSR rolling experiments performed by the DRM-80 mill, it can be proved that both the process and mill are reliable. Although the FSR product has some defects such as knurled pockmarks, helical grooves, and side cavity, the internal metal is free of central cracks. All these observed defects are typical limitations in cross-wedge rolling process [2, 9, 18], which can be removed in later precision machining, so these defects do not affect the quality of produced shaft in any way.

6 Conclusion

- A novel method for forming near-net-shaped shafts, flexible skew rolling process (FSR), has been proposed and verified through a Φ80 mm billet physical experiment. The FSR process is divided into four process stages: radial rolling, rollers inclining, skew rolling and rollers leveling. By coupling the uniform-roller's motions (N_0, V_0, W_0), it can flexible produce elongated-shafts with various sizes.
- A laboratory flexible skew rolling mill (DRM-80) has been invented and constructed to carry out the FSR experiment. The overall dimensions of this mill is 1.8 m × 1.7 m × 1.6 m, the total power is 70 kW, and the maximum diameter of rollers is Φ350 mm, but the maximum billet diameter can up to Φ80 mm. It is worth noting that this type of mill may have a promising potential in industrial application for its convenient installation and adjustment, the frame with high strength, compact structure, and precision rolling by servo control.
- A single-step shaft (length 605 mm, minimum diameter Φ50 mm) was formed and analyzed, the value of diameter tolerance of the shaft is 1.0 mm. Although some forming defects are existed, such as knurled pockmarks, helical grooves, and side cavity, the rolled part is free from internal cracks. The forming defects can be removed by later machining.

A Computational Study on the Producible Rolling Thickness in Ultra-Thin Strip Rolling

Xiao Liu, Chao Yu, and Hong Xiao

Abstract The cold rolling process of a thin strip is difficult to continue when the strip has been thinned to a certain thickness. The Stone formula is the most common approach for predicting this limit, but it was found that the results obtained from this formula are rather inaccurate when applied in experiments or the production of ultra-thin strip rolling. In this paper, a theoretical computational model of producible rolling thickness for an ultra-thin strip based on the Fleck theory was established and the single-pass reduction can be obtained in accordance with the given unit width rolling force, the technical parameters of the rolling mill, the yield strength of the material, and the initial thickness of the strip. The relationship between single-pass reduction and the ratio of the initial thickness of the strip to the theoretical limiting producible thickness under the condition of the maximum allowable rolling force of the rolling mill was discussed. This study provides theoretical guidance for practical production by defining the product specification ranges and rolling regulations for existing rolling mills and determining the roller diameters and force and energy parameters for the design of rolling mills.

Keywords Ultra-thin strip rolling · Producible rolling thickness · Stone formula

1 Introduction

Products with thickness ranging from 0.02 to 0.10 mm are generally called ultra-thin strips, whereas products with a thickness below 0.02 mm are called super-thin strips [1]. The thickness is considered ultra-thin when it approaches the Stone minimum thickness at which point the cold rolling process is difficult to continue. Ultra-thin strips not only provide an important basis for the development of advanced science and technology but are also an embodiment of microforming and micromanufacturing capabilities.

Many researchers have conducted extensive and profound studies using theoretical analysis, finite element simulations, and experimental exploration. Stone [2, 3] treated the profile of the contact deformation zone an arc with increased radius in the studies of the calculation of the average unit pressure for cold strip rolling and this approach considers that the ratio of roller diameter to strip thickness is very large and that the rolling pressure is massive during the cold rolling process. Fleck et al. [4, 5] emphasized that the contact profile of the contact deformation zone of an ultra-thin strip is noncircular, that is, a neutral zone with no obvious reduction in the strip thickness is present, and accurately calculated the contact profile shape and the corresponding contact pressure distribution based on Hertz contact theory. Sutcliffe and Rayner [6] and Ren et al. [7] proved that a neutral zone is present in the contact deformation zone of ultra-thin strip rolling, in agreement with Fleck theory. Limiting producible rolling thickness is a classical problem in the theory of thin strip rolling. When a strip is thinned to a certain thickness in the cold rolling process of a thin strip, the cold rolling process will be difficult to continue. For a given rolling pressure, a small thickness of the strip corresponds to small single-pass reductions, thus requiring high rolling pressure. A minimum thickness referred to as the limiting producible thickness, below which plastic deformation does not occur, exists even if the rolling force and the number of rolling passes are increased. The work of Stone is the most representative among studies on limiting producible thickness. Stone solved the contact profile length of the deformation zone by using the Hitchcock equation and deduced the limiting producible thickness formula by the critical condition of the tangency of two curves. Ford and Alexander [8] considered the elastic recovery of the strip on the basis of Stone theory. Currently, in actual production, the selection of the roller diameter or the determination of product specifications for the existing rolling mills is generally based on the Stone theory formula for the limiting producible thickness. However, when the strip thickness was much smaller than the limiting producible thickness calculated by the Stone formula, a nearly 10% reduction was still obtained by Pawelski and Kading [9] in rolling experiments of deoxidation aluminum. A strip thickness that is smaller than the limiting producible thickness calculated by the Stone formula was achieved in practical production in a thin strip tandem cold rolling mill owned by Baosteel(China). The derivation of the limiting producible thickness by Stone and its improvement by Ford and Alexander was based on the assumption that the work roll remains circular after the contact flattening deformation. Xiao et al. [10] deduced a new formula for the conditional limiting producible thickness considering the restriction of the rolling force and a new formula for the theoretical limiting producible thickness without considering the rolling force restrictions by the rolling pressure distribution in the inlet plastic zone and neutral zone. For the formula of the theoretical limiting producible thickness, tens or even hundreds of roll passes are needed to reach this value, and the single-pass reduction is infinitesimal. In actual production, rolling indefinitely to reach a certain thickness is impossible because of the limitation of productivity. Determine the maximum single-pass reduction for a given foil thickness and technical parameters of the rolling mill, i.e., the limiting producible thickness considers a feasible

rolling force of the rolling mill, which is more practical. The production efficiency is a practical criterion.

In this study, a theoretical calculation model for the producible rolling thickness of ultra-thin strips was established based on Fleck theory. Under the given technical parameters of the rolling mill and the initial thickness of the rolling piece, the single-pass reduction can be calculated in accordance with the given unit width rolling force. The relationship between single-pass reduction and the ratio of the initial thickness of the strips to the theoretical limiting producible thickness under the maximum allowable rolling force of the rolling mill was discussed.

2 Theory of the Producible Rolling Thickness

2.1 Theoretical Model

When the thickness of ultra-thin strips is between the Stone minimum thickness and the theoretical limiting producible thickness, a certain amount of plastic deformation per pass can still be achieved even though a neutral zone is present. Under these conditions, the contact deformation zone was analyzed, and a theoretical description for the contact deformation zone given by Fleck in ultra-thin strip rolling was used, as shown in Fig. 1. The deformation zone is divided into the inlet elastic zone A, the inlet plastic zone B, the neutral zone C, the outlet plastic zone D, and the outlet elastic zone E. Plastic deformation of the metal mainly occurs at the plastic zones B and D, which are separated by the neutral zone C where no significant plastic reduction or slip exists between roll and strip and the roll surfaces are pressed into two horizontal planes by contact elasticity.

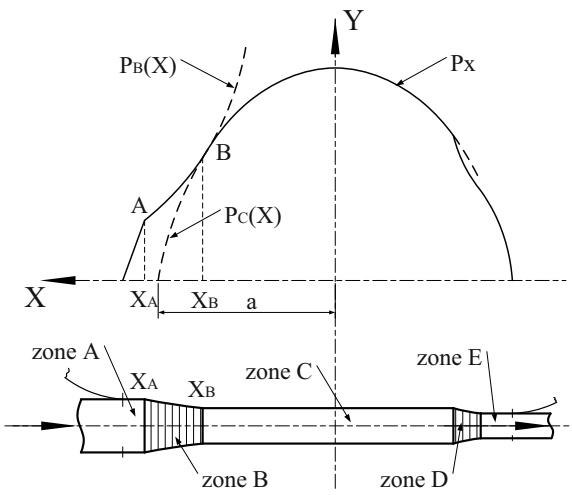

Fig. 1 A schematic of the Fleck model

The centerline of rolls is taken as the Y-axis and the reverse rolling direction as the X-axis. The contact pressure can be expressed by the Tresca plastic yield criterion in the inlet plastic zone [10] as follows:

$$p_B(x) = (1.15\sigma_S - \sigma_T)exp[\frac{2\mu}{h_0}(X_A - x)] \tag{1}$$

where X_A is the initial coordinate of the plastic deformation zone of the strip, σ_S is the yield strength of the strip, σ_T is the mean tensile stress, μ is the Coulomb friction coefficient at the entrance of the contact deformation zone, and h_0 is the initial thickness of the strip.

In the neutral zone C, Hertz theory shows that the contact pressure is a semielliptical distribution given by

$$p_C(x) = p_0[1 - (\frac{x}{a})^2]^{1/2} \tag{2}$$

where p_0 is the maximum unit contact pressure and $2a$ is the length of equivalent contact arc that is expressed as follows:

$$a = \frac{8(1 - \upsilon^2)}{\pi E} R\overline{p} \tag{3}$$

where $\overline{p}$ is the average unit pressure, E and υ are the elastic modulus and the Poisson ratio of the work roll, respectively.

The contact pressure per unit width p_w, a can be expressed as

$$a = \left[\frac{2(1 - \upsilon^2)}{\pi E} Dp_w\right]^{1/2} = \left(\frac{1}{4} C D p_w\right)^{1/2} \tag{4}$$

where $C = \frac{8(1-\upsilon^2)}{\pi E}$ and D is the roller diameter.

The semielliptical distribution is simplified to a parabolic distribution in accordance with Wrinkler elastic theory [11] to obtain the pressure at any point in the flattening zone in a convenient manner. The unit contact pressure observed when the roll surfaces are flattened to become two horizontal planes by the contact elasticity is given by (Figs. 2 and 3)

$$p_C(x) = \frac{3}{CDa}(a^2 - x^2) \tag{5}$$

At the junction ($x = X_B$) of the inlet plastic zone and the neutral zone, $p_B(x)$ and $p_C(x)$ satisfy the condition that the values of the functions and derivatives are equal, as shown in Fig. 4.

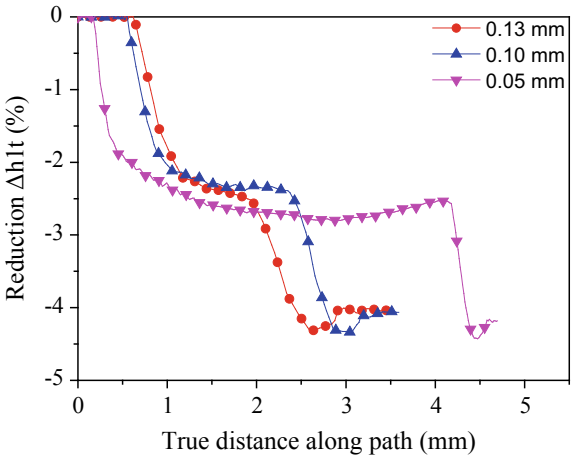

Fig. 2 The contact pressure at 1% reduction. (Color figure online)

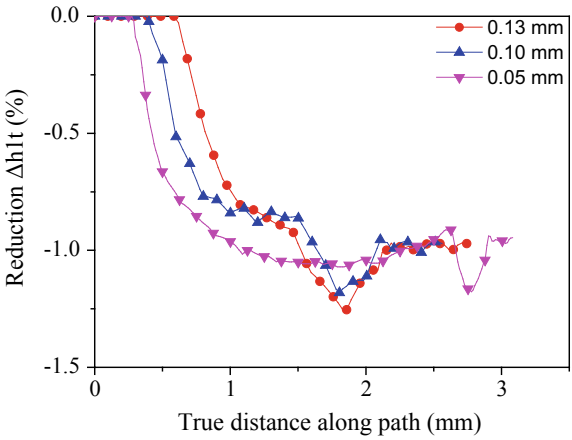

Fig. 3 The roll profile at 1% reduction. (Color figure online)

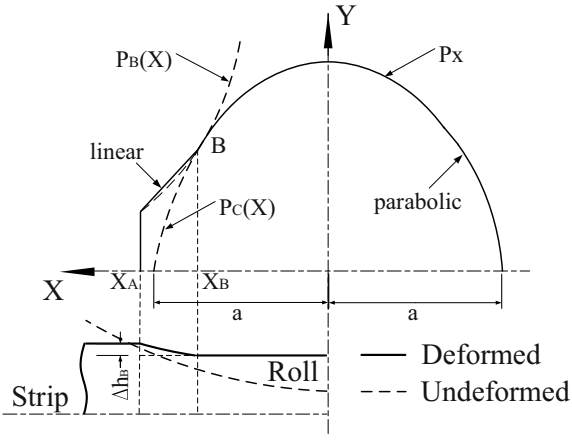

Fig. 4 Deformed and undeformed shapes of the roll under contact pressure

$$p_B(X_B) = p_C(X_B) \tag{6}$$

$$dp_B(X_B)/dx = dp_C(X_B)/dx \tag{7}$$

Equations (1) and (5) are substituted into Eq. (6), and we obtain

$$\frac{3}{CDa}(a^2 - X_B^2) = (1.15\sigma_S - \sigma_T) exp[\frac{2\mu}{h_0}(X_A - X_B)] \tag{8}$$

A derivative of the solution of Eq. (8) is taken, and we obtain

$$-\frac{6}{CDa}X_B = (1.15\sigma_S - \sigma_T)\left(-\frac{2\mu}{h_0}\right) exp[\frac{2\mu}{h_0}(X_A - X_B)] \tag{9}$$

Comparing Eq. (9) with Eq. (8), we can assume that

$$H = (1.15\sigma_S - \sigma_T) exp[\frac{2\mu}{h_0}(X_A - X_B)] \tag{10}$$

and combine Eqs. (8) and (9). Hence, we obtain

$$\begin{cases} \frac{3}{CDa}(a^2 - X_B^2) = H \\ \frac{6}{CDa}X_B = \frac{2\mu}{h_0}H \end{cases} \tag{11}$$

After solving the above equations, we obtain

$$X_B = \frac{CD\mu a}{3h_0}H \tag{12}$$

$$H = \frac{3h_0^2}{2CDa\mu^2}\left(\sqrt{1 + \frac{4a^2\mu^2}{h_0^2}} - 1\right) \tag{13}$$

If the initial thickness h_0 and the contact pressure per unit width p_w are known, then the equivalent contact arc length $2a$ and the value H can be obtained by Eqs. (4) and (13), which can be used to solve $(X_A - X_B)$, i.e., the length of the inlet plastic zone,

$$X_A - X_B = \frac{h_0}{2\mu}\ln\left(\frac{H}{1.15\sigma_S - \sigma_T}\right) \tag{14}$$

with the coordinate values of X_A and X_B.

For ultra-thin strip rolling, the length of the contact deformation zone is much smaller than the roller diameter. The roll is regarded as a semi-infinite body, and the surface displacement of the roll under distributed load can be solved by elastic half-space theory. Figure 4 shows the deformed and undeformed shapes of the roll under contact pressure.

On the basis of the following assumptions,

(1) The distribution of the contact pressure in the inlet elastic zone is neglected, and.
(2) The contact pressure tends to be parabolic except for the inlet plastic zone,

the deformation of the inlet plastic zone can be obtained.

For the distributed load P_x shown in the figure, the normal displacement of any point on the roller surface can be expressed as follows:

$$U_y = -\frac{2\left(1-\upsilon^2\right)}{\pi E}\left[\int_{-a}^{X_a} P_x \ln|\xi - x|dx + \left(\frac{1}{2(1-\upsilon)} - \ln R\right)\int_{-a}^{Xa} P_x dx\right] \tag{15}$$

where R is the roller radius.

P_x is simplified into a linear distribution in the interval $[X_B, X_A]$ and a parabolic distribution in the interval $[-a, X_B]$, and we obtain

$$P_x = \begin{cases} \dfrac{3}{CDa}\left(a^2 - x^2\right), x \in [-a, X_B] \\ P_{X_A} + \dfrac{P_{X_B} - P_{X_A}}{X_A - X_B}(X_A - x), x \in (X_B, X_A] \end{cases} \tag{16}$$

where $P_{X_A} = 1.15\sigma_S - \sigma_T$, $P_{X_B} = \frac{3}{CDa}\left(a^2 - X_B^2\right)$.

Then, the deformation of the inlet plastic zone can be calculated by the following formula:

$$\Delta h_B = 2\left[\frac{(X_A + X_B)(X_A - X_B)}{2R} - \Delta u\right] \tag{17}$$

where Δu is the difference in the normal displacement between points A and B on the roller circumferential surface.

From the Lagrange mean value theorem,

$$\Delta u = \frac{dU_y}{d\xi}(X_A - X_B) \tag{18}$$

and $\xi = \frac{X_A + X_B}{2}$, in other words, the derivative is solved at the midpoint in the interval $[X_B, X_A]$.

When substituting Eq. (16) into Eq. (18) and taking the derivative, we obtain

$$\frac{dU_y}{d\xi}=\frac{2\left(1-\upsilon^2\right)}{\pi E}\left[\int_{-a}^{X_B}\frac{3}{CDa}\left(a^2-x^2\right)\frac{1}{\xi-x}dx+\int_{X_B}^{X_A}\left(P_{X_A}+\frac{P_{X_B}-P_{X_A}}{X_A-X_B}\left(X_A-x\right)\right)\frac{1}{\xi-x}dx\right] \tag{19}$$

Given the similarity in the numerical values of X_A, X_B, and a, the integral of Eq. (19) is solved and simplified as follows:

$$\frac{dU_y}{d\xi}=-\frac{2\left(1-\upsilon^2\right)}{\pi E}\left\{\frac{3}{2CDa}(a+x)^2\Big|_{-a}^{X_B}+\left[-P_{X_A}\ln(\xi-x)+\frac{P_{X_B}-P_{X_A}}{X_A-X_B}x\right]\Big|_{X_B}^{X_A}\right\} \tag{20}$$

After substituting into Eq. (18), we obtain

$$\Delta u=-(X_A-X_B)\left\{\frac{3(X_A+X_B+2a)}{16R}+\frac{2\left(1-\upsilon^2\right)}{\pi E}\left[\frac{3}{CDa}\left(a^2-X_B^2\right)-(1.15\sigma_S-\sigma_T)\right]\right\} \tag{21}$$

The initial form of the formula for the theoretical limiting producible thickness is given by

$$h_{\min}^{X}=\frac{1}{3}CD\mu(1.15\sigma_S-\sigma_T) \tag{22}$$

After substituting Eq. (22) into Eq. (21) and simplifying, we obtain

$$\Delta u=-\left[\frac{3(X_A+X_B+2a)}{16R}+\frac{3(a-X_B)}{4R}-\frac{3h_{\min}^{X}}{8R\mu}\right](X_A-X_B) \tag{23}$$

Equation (23) is substituted into Eq. (17), and we obtain

$$\Delta h_B=\left[\frac{(5X_A+8X_B-9a)}{8R}+\frac{3h_{\min}^{X}}{4R\mu}\right](X_A-X_B) \tag{24}$$

In the contact deformation zone of ultra-thin strip rolling, the plastic deformation occurs mainly in the plastic zone at the entrance and the exit. If no plastic deformation occurs at the entrance, i.e., no plastic deformation occurs under the maximum contact pressure from the entry point to the lowest point of the roll surface, then the same conditions are found in the plastic zone at the exit. Currently, the contact deformation zone includes only the inlet elastic zone, the neutral zone, and the outlet elastic zone within which the upper and lower roller surfaces are pressed into two horizontal planes by contact elasticity. The contact pressure between the roll and the ultra-thin strip and the elastic deformation of the strip are symmetrically distributed on both

sides of the central line of the rolls in accordance with Eq. (5), and the length of the contact profile at the entry side is equal to that at the exit side.

When a minimal plastic deformation occurs at the entrance side of the contact deformation zone, on the basis of Fig. 1, the length of the plastic deformation zone at the entrance is minimal relative to the length of the contact profile at the entrance side. Similarly, the plastic deformation at the exit is minimal relative to the length of the contact contour at the exit side. The length of the contact profile and the plastic deformation at the exit side of the contact deformation zone are smaller than but approximately equal to those at the entrance side. If the exit thickness is approximately equal to the entrance thickness and metalwork hardening is not considered, then the length of the entrance side contact profile is assumed to be approximately equal to that of the exit side. On the basis of Eqs. (1) and (5), the distribution of the contact pressure at the exit side is symmetrical to that at the entrance side, i.e., the length and plastic deformation of the inlet plastic zone are equal to those of the outlet plastic zone. Thus, the total plastic reduction can be calculated as follows:

$$\Delta h{=}2\Delta h_B = \left[\frac{(5X_A + 8X_B - 9a)}{4R} + \frac{3h_{\min}^X}{2R\mu}\right](X_A - X_B) \tag{25}$$

When the thickness of the strip is close to the theoretical limiting producible thickness, the elastic flattening of the roll is considerable, and the length of the neutral zone is large. As a result, the lengths of the plastic zones at the entrance and exit are relatively small. If the unit width contact pressure is assumed to be approximately equal to the unit width rolling force, then the single-pass reduction can be accurately computed by the comprehensive Eqs. (12), (13), (14) and (25) when the technical parameters of rolling mill and unit width rolling force provided by the rolling mill are known.

From Eqs. (3) and (4), we obtain

$$a = CR\overline{p},\ p_w = CD\overline{p}^2 \tag{26}$$

where $C = \frac{8(1-\upsilon^2)}{\pi E}$, if $p_r = C\overline{p}$, $\sigma_r = C\sigma_e$, $h_r = h_0/h_{\min}^X$, where $\sigma_e = 1.15\sigma_S - \sigma_p$,

Equation (13) can be rewritten as

$$H = \frac{h_r^2\sigma_r\sigma_e}{3p_r}\left(\sqrt{1 + \left(\frac{3p_r}{h_r\sigma_r}\right)^2} - 1\right) \tag{27}$$

Equations (12) and (14) are rewriting, and we obtain

$$X_B = \frac{h_0}{2\mu}\left(\sqrt{1 + \left(\frac{3p_r}{h_r\sigma_r}\right)^2} - 1\right) \tag{28}$$

$$X_A - X_B = \frac{h_0}{2\mu} \ln \left[\frac{h_r^2 \sigma_r}{3p_r} \left(\sqrt{1 + \left(\frac{3p_r}{h_r \sigma_r} \right)^2} - 1 \right) \right] \tag{29}$$

After substituting Eqs. (22), (28), and (29) into Eq. (25) and simplifying, we obtain

$$\frac{\Delta h}{h_0} = \frac{1}{24\mu} \left\{ 5h_r \sigma_r \ln \left[\frac{h_r^2 \sigma_r}{3p_r} \left(\sqrt{1 + \left(\frac{3p_r}{h_r \sigma_r} \right)^2} - 1 \right) \right] + 13h_r \sigma_r \left(\sqrt{1 + \left(\frac{3p_r}{h_r \sigma_r} \right)^2} - 1 \right) - 27p_r + 12\sigma_r \right\} \ln \left[\frac{h_r^2 \sigma_r}{3p_r} \left(\sqrt{1 + \left(\frac{3p_r}{h_r \sigma_r} \right)^2} - 1 \right) \right] \tag{30}$$

Steel rolls and oil lubrication are commonly used in cold strip rolling, and the numerical fluctuations of elastic modulus, Poisson's ratio, and friction coefficient are negligible. Thus, these parameters can be treated as constants. Without considering work hardening, a single-pass reduction is essentially a function of the average unit pressure, the equivalent yield strength, and the ratio of the initial thickness to the theoretical limiting producible thickness of the strip obtained from Eq. (30) that can be expressed by

$$\Delta h / h_0 = f(p_r, \sigma_r, h_r) = f\left(C\overline{p}, C\sigma_e, h_0 / h_{\min}^X\right) \tag{31}$$

2.2 The Producible Rolling Thickness

In fact, the unit width rolling force provided by the rolling mill is not infinite in ultra-thin strip rolling. Ensuring that the rolls can operate normally and that no surface peeling or fatigue damage will occur is necessary [12]. From Fig. 1, the distribution of the contact pressure within the contact deformation zone is semielliptical as shown by Eq. (2). The failure strength of rolls is given by

$$p_0 = \frac{4\overline{p}}{\pi} = \frac{4}{\pi} \sqrt{\frac{p_w}{CD}} \leq [\sigma_H] \tag{32}$$

where $[\sigma_H]$ is the allowable contact stress of the roll.

Equation (32) is simplified to present the restrictive conditions for $\overline{p}$ and p_w, and we obtain

$$\overline{p} \leq \frac{\pi [\sigma_H]}{4}, \quad p_w \leq \frac{CD\pi^2 [\sigma_H]^2}{16} \tag{33}$$

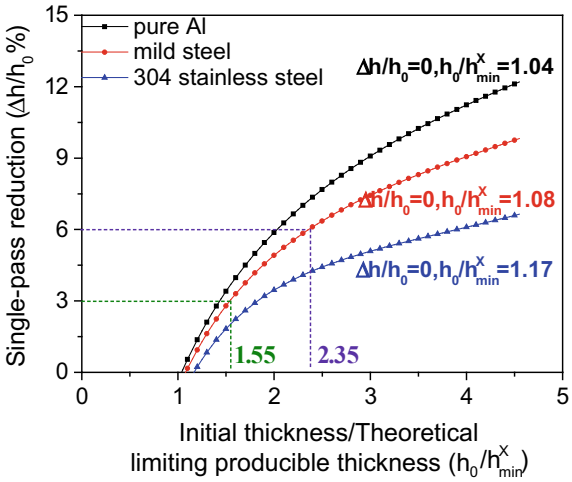

Fig. 5 The relationship between single-pass reduction and the ratio of the initial thickness of the strip to the theoretical limiting producible thickness. (Color figure online)

The surface hardness of steel rolls is higher after quenching. Hence, the allowable contact stress of the roll is 2400 MPa, i.e., the maximum allowable unit width rolling force of the mill corresponds to the average unit pressure value. Given the calculation parameters for steel rolls of elastic modulus of 216 GPa, roller diameter of 210 mm, friction coefficient of 0.1, and mean tension stress of 0. Equation (30) is used to compute the single-pass reductions of three types of different ultra-thin strips, namely, pure Al, mild steel, and 304 stainless steel, which have yield strengths of 180, 350, and 650 MPa, respectively.

The Stone minimum thickness is given by

$$h_{\min}^{S} = 3.58\frac{D\mu(1.15\sigma_S - \sigma_T)}{E} \tag{34}$$

Figure 5 demonstrates the relationship between the single-pass reduction and the ratio of the initial thickness of the strip to the theoretical limiting producible thickness in the rolling process of three different materials under the maximum allowable average unit pressure, and the initial thickness of the strip ranges from the Stone minimum thickness to the theoretical limiting producible thickness. As can be seen from Fig. 5, for a certain strip yield strength, the single-pass reduction increases with the increase in the ratio of the initial thickness to the theoretical limiting producible thickness, but the growth rate decreases. When the ratio of the initial thickness to the theoretical limiting producible thickness is the same, a smaller single-pass reduction is obtained if the yield strength of the strip is larger. The note of the curve such as $\Delta h/h_0 = 0, h_0/h_{\min}^{X} = 1.04$ means that when there is no plastic deformation, the initial thickness of the strip is equal to the conditional limiting producible thickness and it is 1.04 times the theoretical limiting producible thickness. For a given unit width rolling force provided by the rolling mill, the relationship between the single-pass reduction and the ratio of the initial thickness of strip to the theoretical

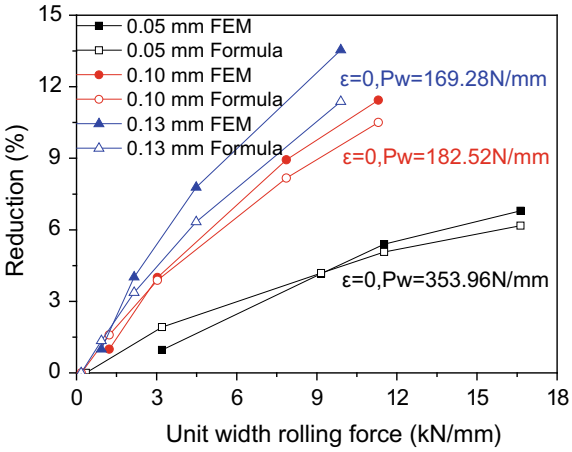

Fig. 6 Comparison between analytical and simulation results for different thickness specifications. (Color figure online)

limiting producible thickness can be obtained by the theoretical calculation model. Furthermore, the relationship can be used to measure the rolling difficulty for the producible rolling thickness.

Actual production gives rise to high productivity requirements, i.e., to ensure a certain single-pass reduction. The red curve of Mild steel with a yield strength of 350 MPa in Fig. 5 is taken as an example. When $h_0/h^X_{\min} \geq 2.35$, i.e., $h_0/h^S_{\min} \geq 0.51$, the rolling process is difficult to some extent, and a certain proportion of the neutral zone exists in the contact deformation zone at this time. However, a significant single-pass reduction can be obtained, and this steel can still be produced in the necessary amounts. When $1.55 < h_0/h^X_{\min} \leq 2.35$, i.e., $0.34 < h_0/h^S_{\min} \leq 0.51$, the obtained single-pass reduction ranges from 3 to 6%, and the length of the neutral zone in the contact deformation zone is larger than that of the plastic zone. In case of a special need, a small amount of the product can be produced, but the process is difficult. For $h_0/h^X_{\min} \leq 1.55$, i.e., $h_0/h^S_{\min} \leq 0.34$, the maximum single-pass reduction is only 3%, and the length of the neutral zone is much higher than the length of the plastic zone. This material is difficult to roll, and the number of rolling passes must be increased to obtain qualified products. If the yield strength of the rolled piece is high and single-pass reduction is small, then the rolling difficulty will increase but can be improved by annealing the strip to reduce the yield strength.

3 Results and Discussion

To validate the theoretical model, the finite element model was used to calculate the contact pressure per unit width corresponding to four different single-pass reductions for ultra-thin strips with a yield strength of 339.4 MPa and thicknesses of 0.13, 0.10, and 0.05 mm. A half rolling model of thin strips was established in commercial software ABAQUS based on rolling symmetry and the assumption of plane strain. The roll and strip were set as elastic and elastic–plastic, respectively. The contact between the roll and strip obeyed the Coulomb friction model, for which the friction coefficient was 0.1. The CPE4R (four nodes) bilinear plane strain reduction integral elements were adopted. The roll mesh was refined at the contact zone between roll and strip to balance the requirements of low calculation time and high accuracy.

There is good agreement between the contact pressure and the strip profiles obtained from the FEM model and those given by Fleck. This approach substituted the material parameters into the theoretical model to solve for the single-pass reduction and compare with the results of the finite element simulations. The minimum values of the maximum allowable rolling force required for the rolling ultra-thin strips with different thicknesses are shown in Fig. 6 where ε means the reduction of the strip. As the initial thickness approaches the theoretical limiting producible thickness, the results of the theoretical computation become closer to the results of the finite element simulations.

The rolling force is obtained from the contact pressure expressed by Eq. (5) on the basis of the assumption of parabolic distribution. The length of the neutral zone in the contact deformation zone accounts for a large proportion of the 0.05-mm-thick strip near the theoretical limiting producible thickness, whereas the length of the plastic deformation zone is small. Here, the rolling force follows the parabolic distribution approximately. Thus, the accuracy of the solution is high. For the 0.13-mm-thick strip, i.e., close to the Stone minimum thickness, a certain length of the plastic zone is still observed in the contact deformation zone and the contact pressure distribution has an obvious peak value. The actual distribution of the contact pressure is different from the parabolic distribution. Consequently, the error is relatively large.

The deformation of the exit plastic zone was assumed to be equal to that of the entrance plastic zone to compute the total deformation. When the thickness and the reduction are small, the plastic deformation of the exit is smaller than that of the entrance and the total deformation is smaller at this time. The error is within the allowable range.

As the thickness of the ultra-thin strip decreases from the Stone minimum thickness to the theoretical limiting producible thickness, the proportion of the length of the neutral zone in the contact deformation zone increases continuously, and the rolling force tends to assume a parabolic distribution. Although the maximum single-pass reduction that can be achieved is small, it can still be reduced, bringing the sample within the range of producible rolling thickness. The closer the thickness of the ultra-thin strip is to the theoretical minimum rolling thickness, the higher the computation accuracy of the theoretical model is. Generally, when the unit width

rolling force is given, the theoretical computation value is smaller than the simulation value, showing that the theoretical model is more conservative and that a large single-pass plastic reduction can be obtained in actual production.

4 Conclusions

(1) Under the condition of the maximum allowable rolling force of rolling mill, single-pass reduction is a function of the equivalent yield strength of strip, and the ratio of the initial thickness to the theoretical limiting producible thickness. For given technical parameters of a rolling mill, a high ratio corresponds to a high single-pass reduction that can be obtained. Under the same ratio, great yield strength leads to a small single-pass reduction rate, and the corresponding conditional limiting producible thickness increases.

(2) A mild steel with a yield strength of 350 MPa is taken as an example, first, for $h_0/h^X_{\min} \geq 2.35$, i.e., $h_0/h^S_{\min} \geq 0.51$, the rolling process is somewhat difficult, but the desired thickness can be produced in the necessary amount. For $1.55 < h_0/h^X_{\min} \leq 2.35$, i.e., $0.34 < h_0/h^S_{\min} \leq 0.51$, the rolling process is more difficult, but if special needs arise, then the desired thickness can be produced in a small amount. For $h_0/h^X_{\min} \leq 1.55$, i.e., $h_0/h^S_{\min} \leq 0.34$, the rolling process is difficult and uneconomical, thus requiring that the number of rolling passes is increased to obtain qualified products.

Forming Surface Texture on Copper Sheets by Electrically Assisted Micro-Rolling

Zhenhai Xu, Shaoxi Xue, Chunju Wang, Rui Xi, Debin Shan, Guo Bin, and Baosheng Liu

Abstract Electrically assisted (EA) forming is a promising process due to its advantages, such as reducing forming load, increasing formability, and decreasing springback. In order to reduce material waste and environmental pollution in the manufacturing process of surface texture, the EA micro-rolling process was used to form surface texture on T2 copper sheets. The EA micro-rolling system consisted of a micro-rolling device and a power supply. Effects of the voltage, frequency, and pulse duration on feature height were investigated. Compared with conventional micro-rolling, the EA micro-rolling process increased the feature height significantly, improved the flatness of the sheet with surface texture, and decreased the surface roughness remarkably. The influences of electric current for different grain sizes were not identical. The rise of feature height was more significant for rolled sheets than that for annealed sheets. Moreover, the feature height has little variations under voltage magnitude of this study when the grain size was greater. This study proves that forming quality of surface textured sheets can be improved under appropriate electric parameters and the EA micro-rolling process would be a promising surface texturing method.

1 Introduction

Recently, surface texturing has been attracting increasing attention from researchers due to its special functions in hydrophobicity, biocompatibility, tribology, and drag reduction [1]. Various types of texture produce different functions. Two levels of surface roughness such as micro- and nanostructures are a necessity to produce surfaces with a super-hydrophobic property, for example, the surface of lotus leaf is composed of the micro-pillars of 5–10 μm and nano hairs. In Cassie state, nano hairs can produce liquid–air interface to enhance the contact angle, which produces the super-hydrophobic property, but not in Wenzel state [1, 2]. The special types of grooves in aircrafts and vehicles can limit the generation of turbulent flow and related Reynolds stress, which reduce the skin friction. It is reported that compared with semicircular, trapezoid, and blade with an aspect ratio of 0.5, surfaces with equilateral triangle have the best drag reduction effect, and the optimum nondimensional riblet width $s^+ = \frac{s\sqrt{\tau_{0/\rho}}}{v}$ (s is the width of the riblet grooves, τ_0 is the wall shear stress at a smooth surface, ρ is the density, and v is the dynamic viscosity) is between 15 and 20 when the drag reduction achieves maximal [3, 4]. Yang et al. [5] calculated the width $s \leq 0.047$ mm and height $h \leq 0.039$ mm of the V-type groove on the surface of the underwater vehicle, and found that the drag reduction effect can reach 1.77%.

The surface texture is mainly fabricated by electrochemical micromachining, chemical texturing, and micromachining. These manufacturing methods allow for fine shape precision, but pose material waste and environmental concerns. The rolling process as one of many micro-forming methods has the advantages of high efficiency, low cost, and low forming load [6]. Romans and Hirt [7] proposed the riblet rolling process, and the roll was wound with a small high-strength steel wire. They found that the riblet height and rolling force were affected by thickness reduction. Zhou et al. [8] developed a desktop surface texturing rolling system. The flatness of the textured sheet was improved and the channel depth became uniform by asymmetric rolling speed. Gao et al. [9] developed the roll-to-plate (R2P) imprinting process. They studied the effects of grain and geometry size on rolling load and feature height by experiments and numerical simulations.

To further improve the forming quality of surface texture and weaken the size effect, an electric current was introduced into the forming process. Ross et al. [10] found the forming force was significantly decreased and the formability was enhanced by the EA compression test. Perkins et al. [11] carried out a series of EA compression tests of different metals. The threshold current density was identified, beyond which the effect of the electricity on the forming was obvious. Siopis et al. [12] found that if the samples underwent pre-plastic deformation, the flow stress drop was more significant. The electric current could decrease the residual stress in the EA embossing process [13]. Based on the promising advantage of EA forming, the EA rolling processes were also investigated. Compared with conventional micro-rolling, channel depth of the surface texturing on AA3003-H14 and Ti-6Al-4V were improved by the EA micro-rolling [14].

Although it has been indicated that EA micro-rolling is a promising method for surface texturing, the effect of electricity on the forming quality of surface texturing has not been made clear. Therefore, EA micro-rolling was performed on copper sheets to study the effect of electric parameters on feature height, flatness of sheets, and surface roughness of surface texture.

2 Experimental

A commercial T2 copper sheet with a thickness of 1 mm in the rolled state was chosen as the experimental material. To investigate the grain size effect, the rolled T2 copper sheets were annealed at 350 °C and 850 °C for 1 h, respectively. The samples were ground, polished, etched, and examined using an optical microscope (OM). The microstructures and grain size d are shown in Fig. 1 and Table 1, respectively. The sheet was sheared into slices with a size of 10 mm in length and 5 mm in width for rolling.

The EA micro-rolling system consisted of a micro-rolling device and the power supply, as shown in Fig. 2. The parameters of the power supply were shown in Table 2. The micro-rolling device and power supply were connected by a brush. The insulation blocks were inserted between the micro-rolling system and the two rolls. The geometry of surface texturing on the upper roll is shown in Fig. 2a and the surface of the lower roll had no texture.

3 Results and Discussion

3.1 Feature Height

The EA micro-rolling tests were carried out at a clearance of 0.2 mm and a roll speed of 0.76 r/min at room temperature. The feature heights of surface texture at different voltages, frequencies, and pulse durations by the EA micro-rolling test are shown in Fig. 3. The black line in Fig. 3a shows that feature height has a significant improvement at 10 V. Compared with the result at 0 V, the feature heights arise by 5.84% at 5 V and 24.32% at 10 V, respectively. However, there is little variation in the feature height when the voltage is changed from 10 to 30 V. It has been proved by Cao et al. [10] that joule heating plays the main role in increasing the feature height. Due to rapid roll speed and deformation process, the effect of different temperatures is weak on the feature height when voltage increases from 10 to 30 V. The cross sections of surface texture at 0 and 30 V for rolled samples are shown in Fig. 4. The grains in the grooves are obviously elongated and fibered at each voltage level, while other grains have little deformation. The microstructures show little difference at the different voltage levels. However, the feature height at 30 V is significantly greater than that at 0 V, and the symmetry of the texture is greater at 30 V. It is also found from Table 3 that as the thickness of the sheet decreases, the spread slightly increases and the length increases when the electric current is present, however, the variation is little with the increase in voltage.

The feature height increases with the frequency increase. Variable frequencies significantly affect the feature height. With an increase in pulse duration, the feature

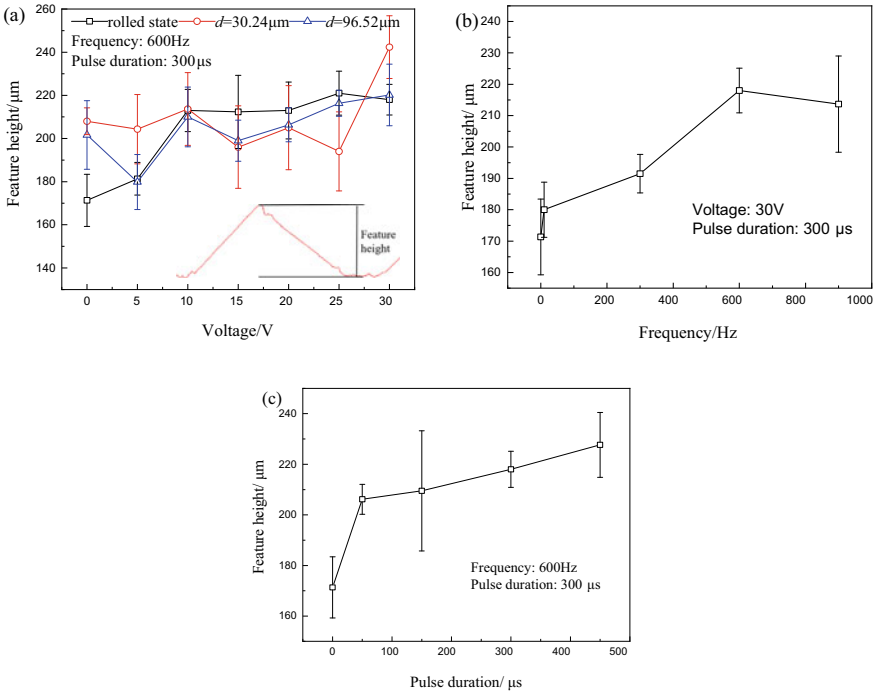

Fig. 3 Feature height under different electrical parameters: **a** voltage, **b** frequency, **c** pulse duration. (Color figure online)

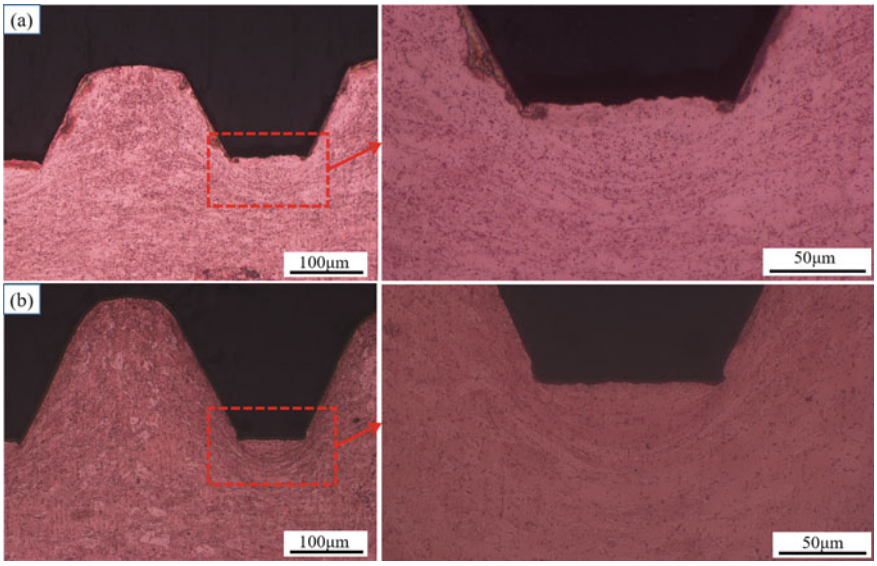

Fig. 4 Cross section of surface texture at different voltages **a** 0 V, **b** 30 V. (Color figure online)

Table 3 Variation of the shape of rolled sheets

Voltage (V)	Thickness (mm)	Spread (mm)	Length (mm)
Initial	1	10	50
0	0.837	10.133	66
10	0.877	10.15	63.4
20	0.847	10.19	65.6
30	0.85	10.13	66

height becomes larger. The feature height increases by 20.26% at 50 μs and 32.92% at 450 μs compared with that at 0 μs. Frequency and pulse duration are also related to the increase in joule heating.

The experimental results of different grain sizes treated by the EA micro-rolling process are shown in Fig. 3a. Compared with the rolled state, feature height has a significant increase in the annealed state, however, feature height is greater for $d = 30.24$ μm than that for $d = 96.52$ μm. The reason is that the feature size restricts the deformation, meanwhile, the number of the grains participating in the plastic deformation reduces due to the big grain size, resulting in the greater deformation resistance. When the electric current is present, the feature height for $d = 30.24$ μm has little variation below 25 V. However, height increases by 16.51% at 30 V and above that at 0 V. For $d = 96.52$ μm, the heights slightly increase when voltages range from 0 to 30 V. These results are different from that for the rolled state. The reason for the above phenomena is that the threshold current density increases with increase of grain sizes [15]. Compared with the annealing state, a higher dislocation density is present in the rolled state. The dislocation movement is improved under the action of electrical current. Therefore, the EA micro-rolling process has a significant effect on feature height for a rolled state at lower voltage. We will explore the threshold current density for $d = 96.52$ μm in future research.

3.2 Flatness of Sheet

The rolled T2 copper sheets at different voltage levels are shown in Fig. 5. The flatness of sheets is improved because the voltage increases. The sheets tend to bend at 0 and 5 V. When the voltage is above 10 V, the bending deformation of sheets is greatly reduced. The bending deformation on one side is mainly because power is turned off in advance in order to avoid electrical discharge. In the micro-rolling process of surface texturing, the bending is caused by asymmetric deformation behavior between the top surface and the bottom surface due to the texture being only on the top surface. As shown in Ref. [4], the sheets bent downward when the deformation on the top surface was larger than that on the bottom surface. Later on, they balanced the deformation through asymmetric roll speed. However, in this study, the bending deformation is reduced by the introduction of electricity. It is indicated that the electrical current can reduce the difference in contact pressure and

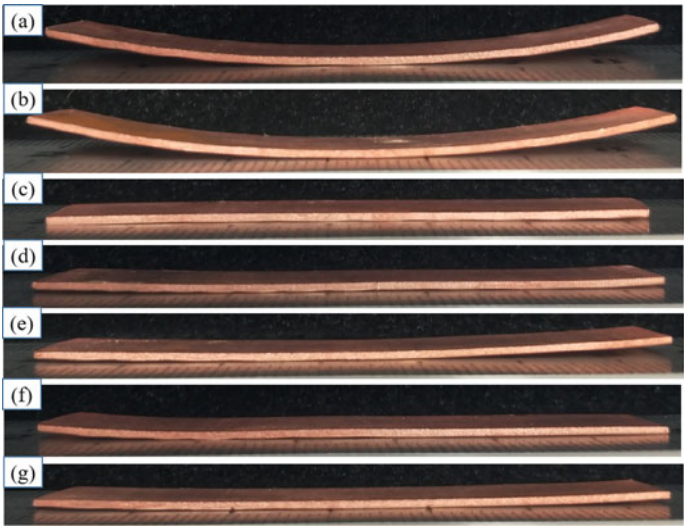

Fig. 5 T2 copper sheets at different voltage levels: **a** 0 V, **b** 5 V, **c** 10 V, **d**)15 V, **e** 20 V, **f** 25 V, **g** 30 V. (Color figure online)

deformation between the top surface and the bottom surface, and then improve the flatness of the sheets.

3.3 Surface Quality

Figure 6 shows the line roughness on the top surface at different voltage levels. The measured position is marked by the red dash in the inset on the right corner of Fig. 6. The line roughness sharply increases after rolling. However, a decrease is significant in EA micro-rolling process, especially at 10 V. At the same time, line roughness slightly increases with the voltage increase. The surface quality is directly affected by the plastic deformation. In the micro-rolling process, dislocations are generated and slide off the surface of the sheets to form steps, at the same time as the coordinated deformation between the different grains, both resulting in a worse surface at 0 V. Electric current can promote the dislocation slide off and overcome obstacles, resulting in a decrease in the slip band generation and grain rotation. The surface in the groove is smoother, as shown in Fig. 4, which indicates that electric current can improve the deformation uniformity. Therefore, the EA micro-rolling process is conducive to the surface quality of sheets.

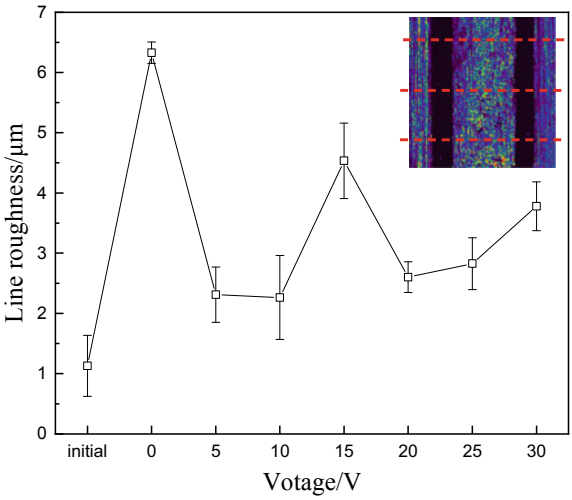

Fig. 6 Line roughness on top surface at different voltage levels. (Color figure online)

4 Conclusions

The effects of the electric current on forming the quality of surface texture were investigated. The feature height shows a significant increase in the EA micro-rolling process. Feature height is firstly increased and then almost unchanged when the voltage increases. The application of electric current in the micro-rolling process can improve the flatness of sheets and reduce the bending deformation. Compared with conventional micro-rolling, line roughness is significantly decreased in the EA micro-rolling process. The grains in the grooves are elongated at both 0 and 30 V, and the difference of microstructures is little. Effects of the electric current on samples with different grain sizes are different due to the threshold current density relating to the grain size. The feature height is significantly improved at 10 V for rolled sheets and 30 V for annealed sheets with a grain size d of 30.24 μm. Nevertheless the voltage at which the feature height for $d = 96.52$ μm will be remarkably increased is above 30 V.

Decoupling of Adverse Effect of Inter-Roll Thrust Force on Steering Control During Strip Rolling

Kazuma Yamaguchi and Atsushi Ishii

Abstract Inter-roll thrust force due to roll misalignment in a 4-high strip rolling mill affects the difference in roll forces measured by load cell on the work side and that on the drive side. Since the roll force difference is utilized for strip steering control, in which roll gap tilting control is done assuming the roll force difference reflects strip off-centering behavior, the inter-roll thrust force gives a serious disturbance to the steering control and may cause troubles like tail crash. In this paper, an inter-roll thrust force decoupling method for the steering control is proposed. The method utilizes measured thrust counter forces acting against work roll chocks to obtain effective roll force difference for the steering control. Validity of the decoupling method is confirmed using a laboratory 4-high mill which can control cross angles between rolls and measure the work roll thrust counter forces.

Keywords Thrust force · Off-centering · Hot strip mill · Steering control · Decoupling method

1 Introduction

In a 4-high strip rolling mill, misalignment between work roll (WR) and backup roll (BUR) causes inter-roll thrust forces which act in the opposite direction to each other (Fig. 1) [1]. The inter-roll thrust forces may cause rolling asymmetry in the widthwise direction [2] as well as shorten fatigue life of roll bearings [3]. Liu et al. proposed a theoretical model to calculate the inter-roll thrust forces, and it was shown that the inter-roll thrust forces depend on the friction coefficient and the cross angle between the rolls [4]. In addition, effects of a roll shifting [5] and a dynamic cross [6] on the inter-roll thrust forces were analyzed.

The inter-roll thrust forces should be balanced by thrust counter forces acting from mill housing through roll chocks, but undesirable moments remain on rolls due to the vertical distance between acting positions of the inter-roll thrust forces

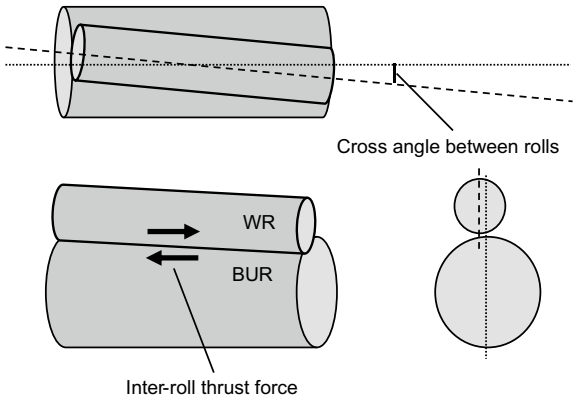

Fig. 1 Cross angle between rolls and inter-roll thrust force

and the thrust counter forces. A difference in roll forces measured by a load cell on the work side (WS) and that on the drive side (DS) is changed such that moment balance of BUR can be maintained even with the moment due to the inter-roll thrust force (Fig. 2) [7, 8]. The change in the roll force difference resulting from the thrust force causes rolling asymmetry in the widthwise direction, and consequently may cause problems such as tail crash due to strip off-centering. Therefore, obtaining the change in the roll force difference is important in a rolling operation.

The change in roll force difference adversely affects strip off-centering in two ways. The first is its influence as a direct factor. Asymmetric vertical deformation of a rolling mill due to the roll force difference causes an unintentional roll gap difference in the widthwise direction which causes strip off-centering. Furumoto et al. carried out a coupled analysis of elastic deformation of rolls and plastic deformation of a rolled strip considering this influence [9]. In addition, they indicated that a Mill Stabilizing Device (MSD) [10] which eliminates the clearance between WR chock or BUR chock and mill housing can reduce the strip off-centering due to

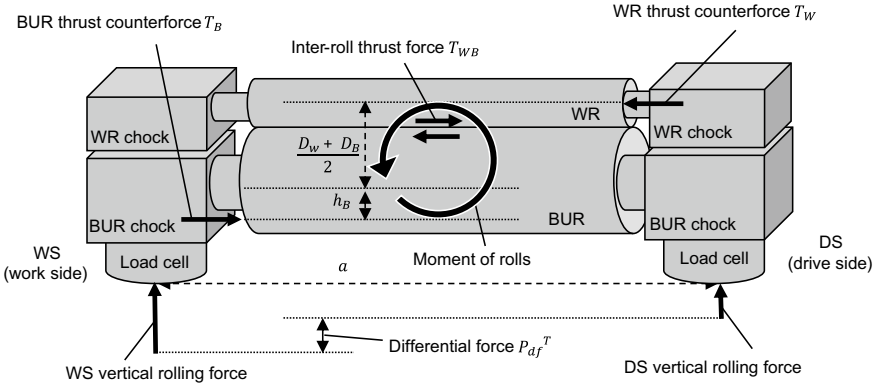

Fig. 2 Effect of thrust force on differential force

inter-roll thrust forces. However, the results also show that MSD cannot perfectly eliminate the inter-roll thrust forces due to wear status of WR chocks and BUR chocks. The second is its influence as an indirect factor. The roll force difference may be utilized for strip steering control, in which roll gap tilting control, namely leveling, is done during rolling by assuming the roll force difference reflects strip off-centering behavior. The inter-roll thrust forces act as a serious disturbance to this steering control. Nakajima et al. firstly developed this steering control method [11] and recent studies made an attempt at improving control model [12–17]. However, there are few studies that have examined the influence of the inter-roll thrust forces on this steering control or proposed improvement method. In this study, confining our attention to this steering control, an inter-roll thrust force decoupling method which can acquire the effective roll force difference without any adverse effect of the inter-roll thrust forces is proposed. The validity of this decoupling method is confirmed using a laboratory 4-high mill which can control cross angles between rolls and measure the WR thrust counter forces.

2 Experiment

2.1 Characteristics of Laboratory 4-High Rolling Mill

A 4-high cold rolling mill of about one-tenth the size of an actual hot strip mill was used for the experiment. Table 1 lists the mill specifications. This rolling mill can control roll gap, roll cross, roll offset, and WR shift with hydraulic servo devices. In addition, it can measure the top and bottom roll forces, and the thrust counter forces of each roll. Figure 3 shows the measurement system used for measuring the thrust counter force. The measurement system was installed at the axial roll edge. Figure 3 shows the measurement system from an overhead perspective, with the rolls being located on the left side of the image. It can track various types of roll movement such as leveling, roll cross, and roll offset using a linear motion guide, so that it can accurately measure the thrust counter forces by means of load cells.

Table 1 Mill specifications

WR diameter (mm)	BUR diameter (mm)	WR barrel length (mm)	BUR barrel length (mm)	WR chock span (mm)	BUR chock span (mm)	Mill motor power (kW)	Max rolling torque (kN·m/roll)	Max rotational speed (rpm)
80	160	220	200	320	320	3.4 (AC)	±490.3	±40

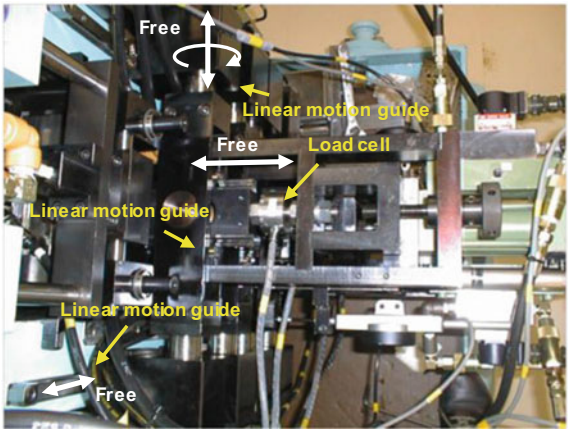

Fig. 3 Measuring equipment of thrust counter force. (Color figure online)

2.2 *Conditions and Procedure of Experiment*

The adverse effects of the inter-roll thrust forces on automatic steering control based on the change in the roll force difference was investigated by means of an aluminum cold rolling experiment. Furthermore, the validity of the decoupling method was also tested. Strip off-centering can become a problem, particularly in the tail end part of the hot strip rolling when the entry side tension is released. Therefore, this experiment tried to simulate the tail end rolling. Initially, a cross angle was given to the top and bottom BUR to generate inter-roll thrust forces, and initial leveling was fixed as a disturbance to create strip off-centering. Second, an aluminum coil was rolled until it converged to steady state. Third, rolling was temporarily stopped and the aluminum coil at the entry side was cut. Finally, tail end rolling was simulated by restarting the rolling, while activating the steering control (Fig. 4). Table 2 shows the experimental conditions. When the steering control is carried out using a lock-on method, a transient change of the roll force difference due to inter-roll thrust forces

[a]Define the direction to move the WS of a roll moves to delivery side as plu
*Initial value (WS-DS)

can become a problem. For example, this change is caused by an increase of the roll force due to the temperature drop of the tail end region. In this experiment, to simulate this influence, the rolling reduction was changed from 10 to 30% in the tail end rolling. The cross angle was −0.08° for the top BUR and +0.08° for the bottom BUR. Regarding the 'sign' of the cross angle, the direction to move the WS of the rolls to the delivery side is defined as 'plus'. Initial leveling was ±0.02 mm, and the direction to open the gap of the WS was defined as 'plus'. For the protection of equipment, rolling was terminated when the quantity of off-centering value exceeded 40 mm.

The steering control was done in three ways: without control, conventional control, and improved control. Without control means a condition without any leveling control. Conventional control means a leveling control method that is used conventionally, which directly refers to the roll force difference signal as an indicator of strip off-centering, and calculates a command value of the leveling $S_{\mathrm{df}}{}^{*}$ by PD control. Improved control means a proposed leveling control method in which the roll force difference due to the inter-roll thrust forces is estimated using measured thrust counter forces, and is decoupled from the roll force difference signal (Fig. 5). f in Fig. 5 denotes the influence coefficient of the inter-roll thrust force on the roll force difference. f can be calculated using Eq. (1) which is derived from the equilibrium condition of the axial direction forces and the moment in the vertical plane of the rolls.

$$f = -\frac{(D_W + D_B + 2h_B)}{a} \tag{1}$$

D_W is a WR diameter, D_B is a BUR diameter, a is a BUR chock span—distance between BUR bearing centers on WS and on DS, and h_B is the vertical distance between the BUR axis and the point of application of the BUR thrust counter forces. BUR thrust forces are supported by thrust counter forces acting from reduction devices as well as mill housing through BUR chocks; thus, h_B does not necessarily agree with the roll axis [8]. Therefore, it is important to obtain h_B accurately when Eq. (1) is applied to steering control. In this experiment, f was identified by observing variation of the thrust counter force and that of the roll force difference before and

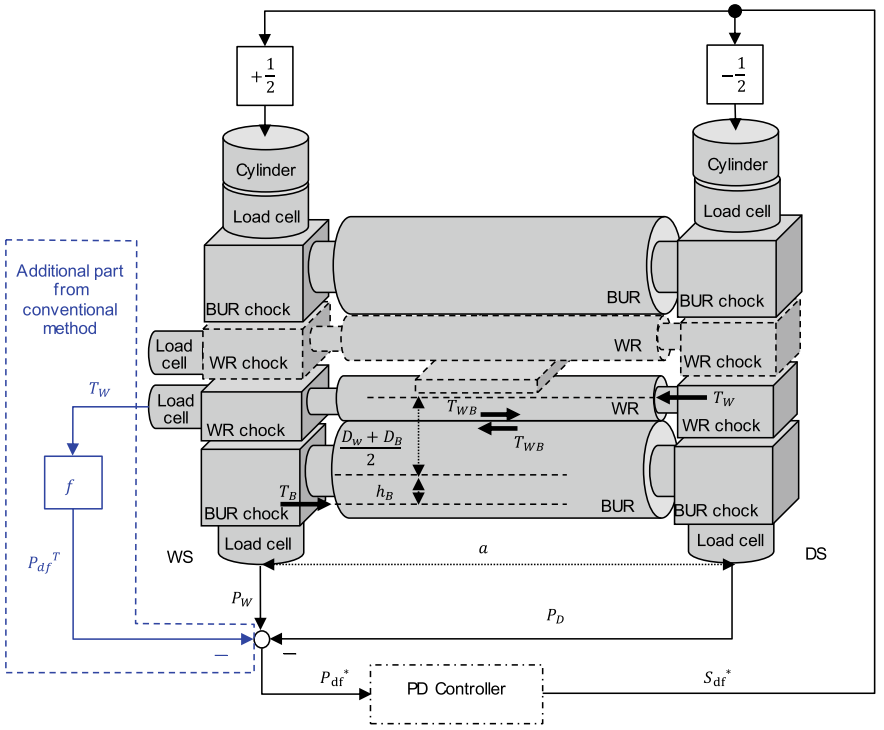

Fig. 5 New improved method for steering control based on differential force considering effect of thrust force. (Color figure online)

after the cross angle was given. Figure 5 shows a steering control model using load cells located on the bottom side, though this rolling mill also has load cells on the top side. Experiments were performed for both cases: using load cells on the bottom side, and those on the top side being used as a reference for steering control. Including the direction of the initial leveling, four cases were tested in total (Table 3).

The control system depicted in Fig. 5 was constructed using LabVIEW which is a system design software application developed by National Instruments Corporation. Proportional gain $K_P = 0.28$ and differential gain $K_d = 0.03$ were set, which happens

Table 3 Experiment list

	BUR cross angle (upper, lower) (°)	Initial leveling[a] (mm)	Reference
Case 1	−0.08, +0.08	+0.02	Bottom load cells
Case 2			Top load cells
Case 3		−0.02	Bottom load cells
Case 4			Top load cells

[a]Initial value (WS-DS)

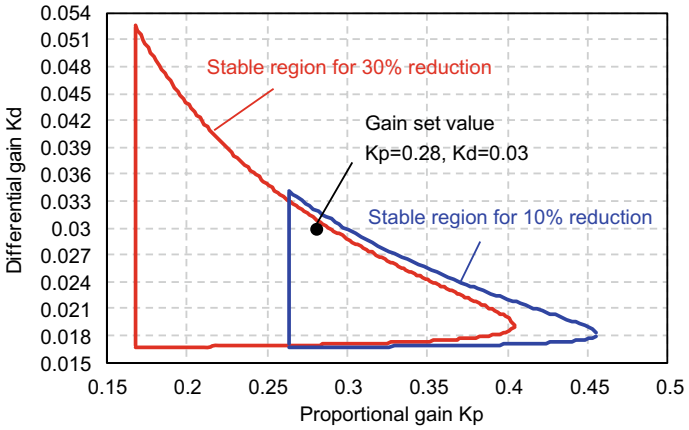

Fig. 6 Calculated stable region in steering control and gain set value. (Color figure online)

to be within a stable control region calculated using the equation of Nakajima et al. [11] when the reduction rate was 10–30% (Fig. 6). Tail end rolling started, and four seconds later steering control began. The control cycle time was two seconds.

2.3 *Results of Experiment*

Figure 7 shows an example of variation of the roll force and the WR thrust counter forces in the tail end rolling. The initial leveling is −0.02 mm and it is without steering control (equivalent to Case 3 or Case 4). Because the reduction rate was changed

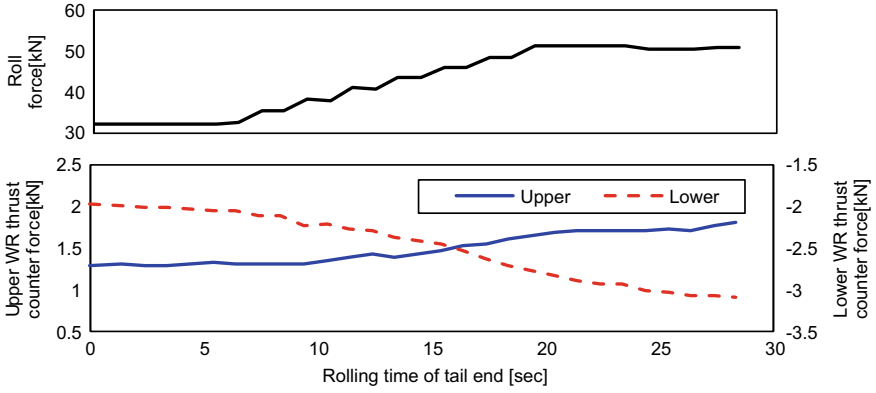

Fig. 7 Example of time series data (leveling −0.02 mm). (Color figure online)

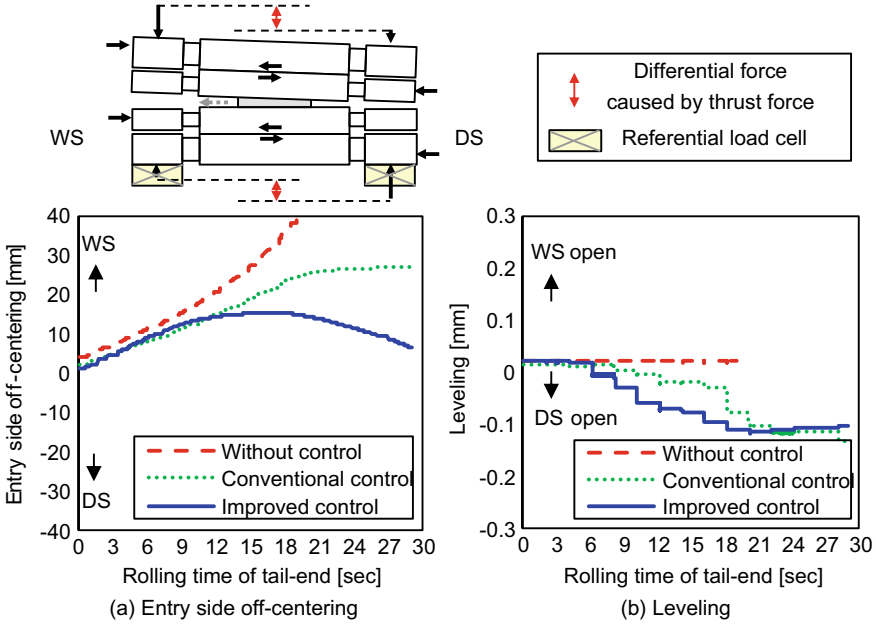

Fig. 8 Results of Case 1. (Color figure online)

from 10 to 30% in 5–20 s, the roll force increased. Consequently, the absolute value of the thrust counter forces increased.

Figures 8, 9, 10, and 11 show the experimental results of the tail end rolling using the three methods (without control, with the conventional control, and with the improved control) in Cases 1–4 as shown in Table 3. Figures 8a, 9a, 10a, and 11a show the entry side off-centering of the strip and Figs. 8b, 9b, 10b, and 11b show the leveling value.

In Case 1 (Fig. 8) where initial leveling is +0.02 mm and bottom load cells are utilized by the leveling controls, strip tail walked toward WS divergently without leveling control. With the conventional control, strip tail behavior was mitigated owing to negative leveling action observed in Fig. 8b. However, comparing the case with the improved control, leveling action was somewhat delayed and strip off-centering was larger in the case with the conventional control.

In Case 2 (Fig. 9) where initial leveling is +0.02 mm and top load cells are utilized by the leveling controls, strip tail also walked toward WS divergently without leveling control. With the conventional control, strip off-centering toward WS was suppressed quickly within 10 s, but due to large negative leveling control action, strip tail overshot the mill center and then walked toward DS. Observing strip tail behavior with leveling action, it seems that strip off-centering would show oscillating behavior in the case with the conventional control. On the other hand, in the case with the improved control, leveling action was rather moderate and strip tail showed more stable behavior than that with the conventional control.

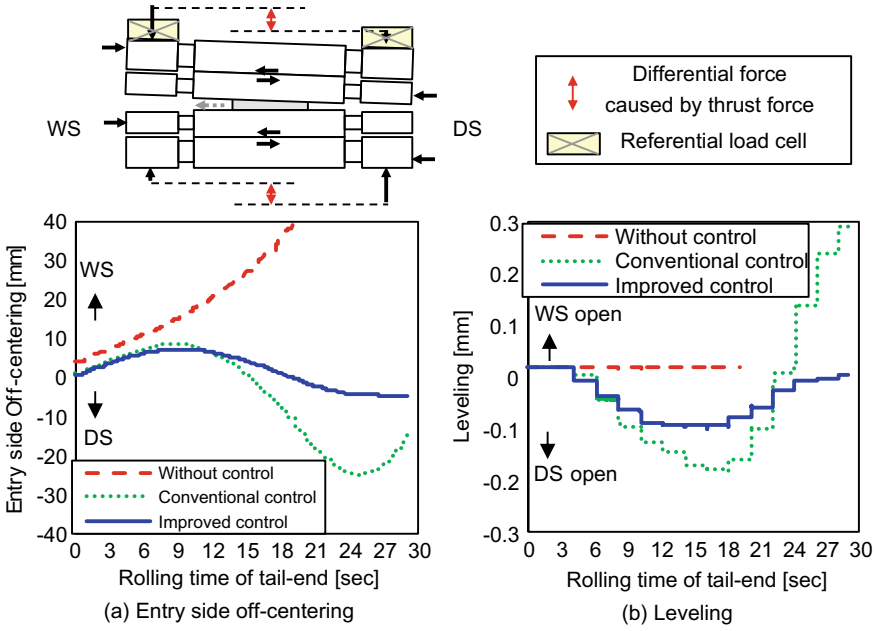

Fig. 9 Results of Case 2. (Color figure online)

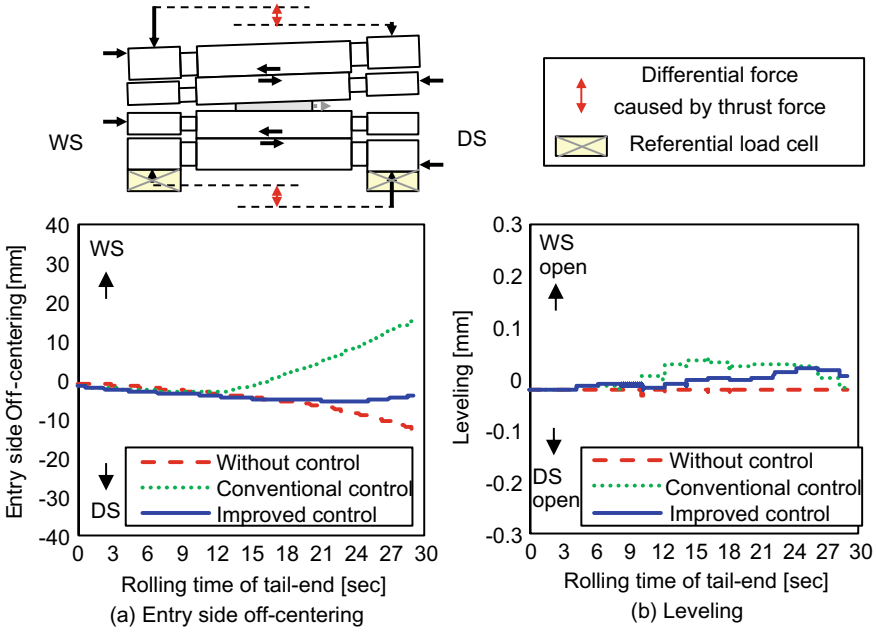

Fig. 10 Results of Case 3. (Color figure online)

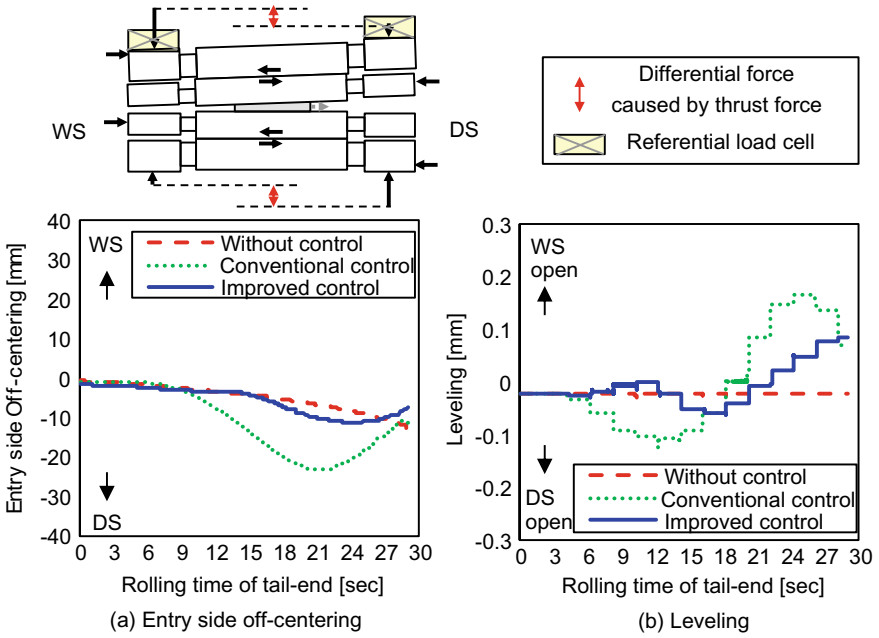

Fig. 11 Results of Case 4. (Color figure online)

In Case 3 (Fig. 10) where initial leveling is −0.02 mm and bottom load cells are utilized by the leveling controls, strip tail gradually but divergently walked toward DS without leveling control. With the conventional control, strip off-centering toward DS was suppressed, but due to large positive leveling control action, strip tail overshot the mill center and then walked toward WS divergently. On the other hand, in the case with the improved control, leveling action was rather moderate and strip tail showed more stable behavior than that with the conventional control.

In Case 4 (Fig. 11) where initial leveling is −0.02 mm and top load cells are utilized by the leveling controls, strip tail also walked toward DS without leveling control. With the conventional control, strip off-centering toward DS was enhanced owing to negative leveling control action. Observing strip tail behavior with leveling action, it seems that strip off-centering would show oscillating behavior in the case with the conventional control in the same way as Case 2. On the other hand, in the case with the improved control, leveling action was rather moderate and strip tail showed more stable behavior than that with the conventional control.

Figure 12 summarizes the maximum value of the entry side off-centering of Case 1–Case 4. In Case 1 and Case 2, results using the conventional control became better than that without control, but in Case 3–Case 4, results using the conventional control got worse than that without control. On the other hand, results of all of the cases using the improved control became better than that without control or the conventional

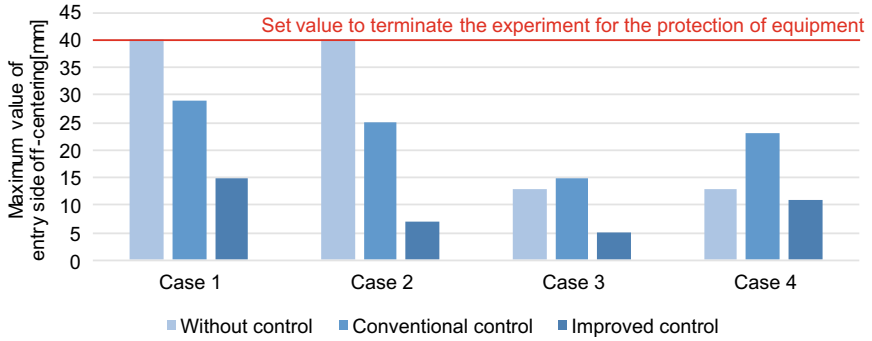

Fig. 12 Maximum value of entry side off-centering of Cases 1–4. (Color figure online)

control. In comparison with the conventional control, the improved control reduced the maximum value of entry side off-centering by half or more.

2.4 Discussion

In Case 1 where initial leveling is +0.02 mm and bottom load cells are utilized by the leveling controls, leveling action with the conventional control is too slow and insufficient. This can be explained by the disturbing effect of the inter-roll thrust force on the roll force difference between WS and DS. Referring to Table 3, bottom BUR cross angle is +0.08°, which causes the inter-roll thrust force on the BUR toward DS, and hence the disturbance of the inter-roll thrust force is larger DS bottom load cell force (negative roll force difference). On the other hand, since strip off-centering toward WS causes larger WS load cell force (positive roll force difference), the disturbance tends to attenuate sensitivity of strip off-centering with the bottom load cells, and hence the leveling control action becomes too slow and insufficient.

In Case 2 where initial leveling is +0.02 mm and top load cells are utilized by the leveling controls, leveling action with the conventional control is too much and oversensitive. This can be explained by the disturbing effect of the inter-roll thrust force on the roll force difference between WS and DS. Referring to Table 3, top BUR cross angle is −0.08°, which causes the inter-roll thrust force on the BUR toward WS, and hence the disturbance of the inter-roll thrust force is larger WS top load cell force (positive roll force difference). Since strip off-centering toward WS causes larger WS load cell force (positive roll force difference), this disturbance tends to enhance sensitivity of strip off-centering with the top load cells, and hence the leveling control action becomes too much and oversensitive.

In Case 3 where initial leveling is −0.02 mm and bottom load cells are utilized by the leveling controls, the conventional control rendered excessive positive leveling control action which led the strip tail to walk divergently toward WS. This can be explained by the disturbing effect of the inter-roll thrust force on the roll force

difference between WS and DS. Referring to Table 3, bottom BUR cross angle is 0.08°, which causes the inter-roll thrust force on the BUR toward DS, and hence the disturbance of the inter-roll thrust force is larger DS bottom load cell force (negative roll force difference). This disturbance is considered to be the main reason for the excessive positive leveling control action.

In Case 4 where initial leveling is −0.02 mm and top load cells are utilized by the leveling controls, the conventional control rendered negative leveling control action in the beginning of the rolling which was false action in view of the strip off-centering toward DS at that time. This false action can be also explained by the disturbing effect of the inter-roll thrust force on the roll force difference between WS and DS. Referring to Table 3, top BUR cross angle is -0.08°, which causes the inter-roll thrust force on the BUR toward WS, and hence the disturbance of the inter-roll thrust force is larger WS top load cell force (positive roll force difference), which causes negative leveling control action. Although the strip off-centering was toward DS and this causes negative roll force difference, the off-centering amount is relatively small at the beginning of the rolling and hence positive roll force difference due to the inter-roll thrust force dominated.

3 Conclusion

This study aimed at automatic steering control based on the effective roll force difference without any adverse effect of the inter-roll thrust forces. To this end, an inter-roll thrust force decoupling method for the steering control has been proposed. Experiments were carried out to investigate the adverse effects of the inter-roll thrust forces on the steering control and to confirm the validity of the decoupling method.

As a result, it has been clarified that the disturbing effect of the inter-roll thrust forces on the roll force difference between WS and DS may seriously damage the performance of the conventional steering control, and that the improved steering control based on the inter-roll thrust force decoupling method exhibits excellent performance. Thus, it has been confirmed that stable steering control, which does not suffer the adverse effects of the inter-roll thrust force, is possible by applying the proposed method.

Part XXII
Sheet Forming

Evaluating the Reliability of a Nondestructive Evaluation (NDE) Tool to Measure the Incoming Sheet Mechanical Properties

Fernando J. Alamos, Jiahui C. Gu, and Hyunok Kim

Abstract Today, the automotive OEMs and part suppliers are increasing their material suppliers globally. Therefore, the same grade steels are supplied by different steel mills and batch conditions to meet this requirement. However, the variation of the incoming mechanical properties can significantly influence the stamping quality associated with necking, wrinkling, and cracking. This increases the overall manufacturing costs and lowers productivity. Nondestructive evaluation (NDE) tools have become useful to reduce this uncertainty by measuring incoming mechanical properties. The measured data can be used during production in a feed-forward control to select the optimal process parameters or as forming process parameter optimization using simulations. A detailed evaluation of a 3MA (micromagnetic, multiparametric microstructure, and stress analysis) Fraunhofer IZFP's device and its viability of implementations in a production environment is introduced. The 3MA equipment was incorporated into an industrial flexible robot and a practical calibration procedure was developed and validated for Bake-Hardening (BH) 340 steel.

1 Introduction

The manufacturing industry is recently experiencing a global scale transformation. This new industrial revolution, often called Industry 4.0, is driven by connectivity, intelligence, and automation [1]. In sheet metal forming, the increased part complexity and emerging high-strength light sheet materials often increase technical challenges associated with the variation of formability and process robustness. To overcome these challenges, smart machines, intelligent systems, and the use of big data have become essential for factories to become more efficient and productive.

Today, the automotive OEMs and part suppliers are globally resourcing various sheet materials from different suppliers considering the geographical distribution of the plants. The same grade steels are supplied by different steel mills and batch conditions to meet this requirement. However, there is significant uncertainty in the incoming material properties of the sheet materials. These uncertainties affect the part quality associated with necking, wrinkling, and cracking, increasing drastically the production cost [2–4]. Nondestructive evaluation (NDE) tools have become useful to reduce this uncertainty by inspecting the incoming coil material properties in production. In several sheet metal forming applications, NDE tools were used to measure incoming mechanical properties, which allows adjusting forming process parameters based on the measured data.

NDE tools have been used in deep drawing of kitchen sink production [5–8]. An eddy current NDE sensor was used to measure the yield strength, tensile strength, uniform elongation, total elongation, and grain size of the incoming material, and a laser triangulation sensor was used to measure the sheet thickness. The measured data was used in simulations to generate the metamodels to determine the process window and as input for a feed-forward control to select the optimal process parameters during production, improving part quality and reducing failure during small-batch productions.

Other studies have used a commercial NDE equipment 3MA (micromagnetic, multiparametric microstructure, and stress analysis), developed by Fraunhofer IZFP to determine the material properties, grain size, and residual stress of strip coils, reporting an important variation in the material properties across same coils [4, 9, 10]. Increased variation in the yield strength, from 160 to 200 MPa, has been reported for an interstitial-free steel-string coil by Wolter et al. [4]. Kim et al. [3] used the 3MA equipment to determine the mechanical properties of the incoming blanks for a sheet forming process to determine the effective servo press parameters to improve part quality and minimize failure. The study showed a good correlation between the measurements from the sensor and the tensile testing results and proposed to use a Machine Learning algorithm instead of a feed-forward control to predict the most effective parameters during the drawing process.

The application of NDE tools has a huge potential in production for the metal forming industry. 3MA has been used to measure mechanical properties in many applications; however, this tool needs to be further improved for practical applications. For example, the calibration procedure recommended by the manufacturer does

not guarantee accurate measurement data of 3MA. Therefore, in this study, a practical calibration procedure was developed and validated for Bake-Hardening (BH) 340 steel. The viability of implementations of 3MA equipment was demonstrated with an automated flexible robot to emulate the production conditions.

2 Approach

In this study, the performance of the automation of a commercial NDE tool, 3MA, integrated with an industrial robot was evaluated. 3MA can measure different properties of ferromagnetic materials by correlating the measured magnetic properties, which are related to the microstructure of the material. Figure 1 illustrates the relationship among microstructure, magnetic properties, and mechanical properties. The batch-to-batch production variation in steel mills varies the microstructure which results in variation of both magnetic and mechanical properties.

The 3MA equipment uses a combination of a field harmonics, eddy current, Barkhausen noise, and incremental permeability analysis [11]. Figure 2 shows how the 3MA probe was mounted to a FANUC LR Mate 200iD/4S industrial robot with a fixture. A batch of BH340 steel with 0.75 mm thickness was used throughout this study. The BH340 steel samples were obtained from two different coils (labeled as HA and HB) of the same mill, to consider variations of the sheet mechanical properties. All blanks were cut to the same size of 508 × 508 mm. Ultimate tensile strength (UTS), yield strength (S_y), and total elongation (e_{tot}) were the measured material properties throughout this study. The automated 3MA equipment integrated with a FANUC flexible robot was first calibrated and then validated for both HA and HB materials individually.

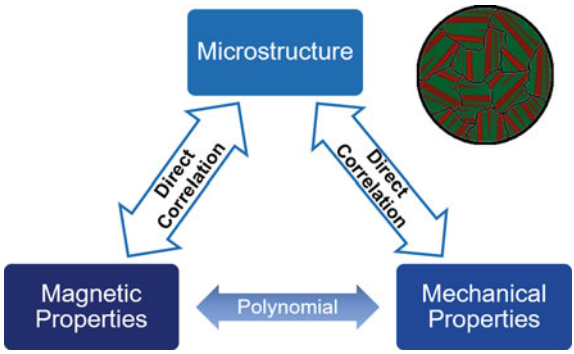

Fig. 1 Principal of 3MA measurement of magnetic properties and its correlations with mechanical properties. (Color figure online)

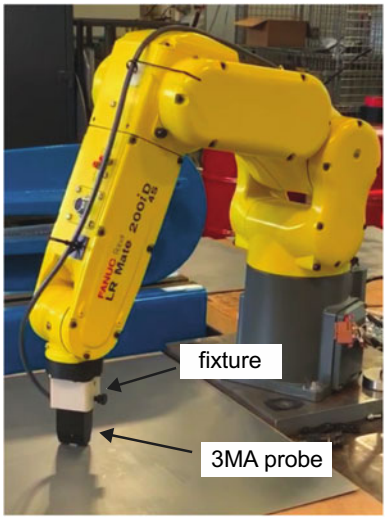

Fig. 2: 3MA probe attached to a FANUC industrial robot. (Color figure online)

2.1 Calibration Procedure

The 3MA equipment is calibrated with tensile test data. The magnetic parameters measured with the 3MA equipment and the tensile testing results of the specimens (UTS, S_y, and e_{tot}) are stored in the same database. Then calibration functions are determined using regression analysis to correlate the magnetic properties to each tensile property. The calibration functions for each tensile property have the following form:

$$y = a_0 + a_1 x_1 + a_2 x_2 + \cdots + a_n x_n \tag{1}$$

where y is the target property, a_i $(i = 0 \ldots n)$ are the computed regression coefficient, and x_i are the 3MA-measured magnetic parameters.

For the calibration of the system, first, 50 tensile specimens for BH340 were drawn on different blanks. The blanks were randomly selected from different batches and different locations to have a representative and broad sampling size. Two sets of tensile specimens were marked at 0°, 45°, and 90° with respect to the rolling direction of the coil, as showed in Fig. 3a, to account for the anisotropic properties of the blank. The gauge area of the specimens was 12.5 mm wide and 50 mm long. The length of area reduction was 57 mm. Second, the automated 3MA-robot system was used to take 40 measurements in four different locations of the specimen (Fig. 3b). The following precautions should be carefully executed for measurement:

- The contacting surface of the 3MA probe needs to be parallel with respect to the blank surface because the measurement is sensitive to contacting angle variation.

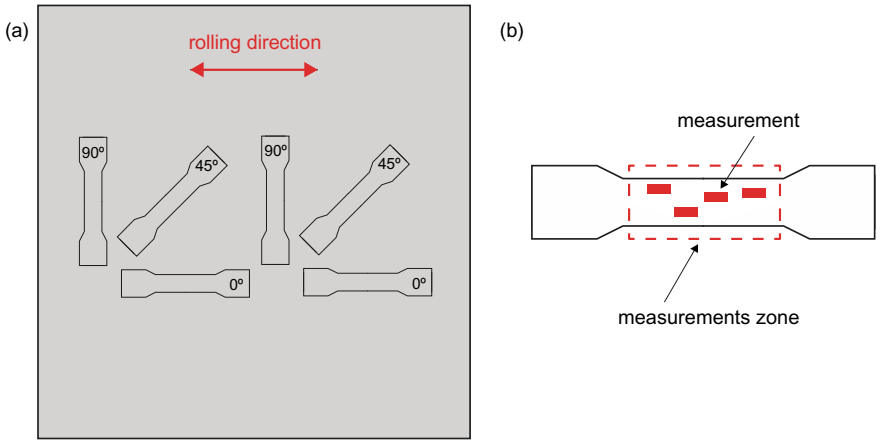

Fig. 3 **a** Layout of the tensile specimens on a blank. **b** Randomly selected four locations with the tensile gauge range for 3MA measurements. (Color figure online)

- The contact force on the probe with the sample should not exceed 15 N; therefore, the robot can be programmed to apply the same contact.
- To avoid edge effects, the 3MA measurement location should have at least 50 mm offset distance from the blank edges.

Third, the specimens were cut and tensile tested following the ASTM E-8 standard. UTS, S_y, and e_{tot} were the measured tensile properties. Finally, calibration functions were used to correlate the 3MA NDE measurements and the tensile testing data. The coefficient of determination (R^2) and the root mean square error (RMSE) values were minimized to find the most reliable regression coefficients a_i in the calibration functions.

2.2 *Validation of the Calibration Function*

To validate the effectiveness of the automated 3MA-robot system after calibration, multiple blanks were randomly selected for the BH340-HA and BH340-HB steel. For each blank, nine measurements were taken at three different positions with the automated 3MA-robot system and direction with respect to the rolling direction (0°, 45°, and 90°). Figure 4 shows the measurement locations for a blank. In addition, all the measurements were repeated by manually holding the 3MA probe to compare the manually measured 3MA data with the automatically measured data and evaluate the effectiveness of the automated system.

An analysis of variance (ANOVA) and a Tukey test were performed to statistically quantify the difference between the mechanical properties measured using the automated 3MA-robot system, the manually handled 3MA equipment, and the

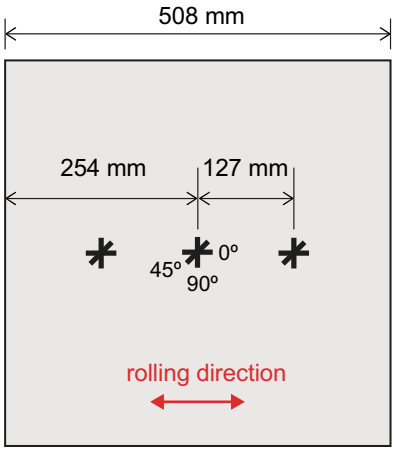

Fig. 4 Nine measurements on each blank for validation at three different locations, 0°, 45°, and 90° with respect to the rolling direction. (Color figure online)

tensile testing results. The results were analyzed with a 95% confidence interval. The ANOVA test compares the similarity of two data sets. Two data sets are significantly different if p-values are lower or equal to 0.05. The assumptions of independence of cases, homoscedasticity, and normality of the residuals were checked. The Anderson–Darling test was used to verify the normality of the residuals. For the cases where the assumption of normality of the residual was invalid, a Kruskal–Wallis nonparametric test was performed, and the p-values were compared with the results from the ANOVA test. The results using both tests gave similar p-values; consequently, the assumptions are satisfied and the standard ANOVA analysis was considered satisfactory [12].

3 Results

3.1 Tensile Testing Results

The detailed tensile testing results are summarized in Table 1. The results show an important variation in the mechanical properties between BH340-HA and -HB batch materials. The BH340-HB steel is stronger and less ductile than the BH340-HA steel. The average UTS is at least 10 MPa higher and the yield strength (S_y) is at least 12 MPa higher for BH340-HB than BH340-HA for all three orientations with respect to the rolling direction. The average total elongation (e_{tot}) is around 2% less ductile for BH340-HB than BH340-HA. The tensile testing results also showed a significant variation in the mechanical properties within the same coil. For example, for BH340-HA, the $S_{y_90^o}$ standard deviation (SD) is 8.83 MPa and the range is 27 MPa, which is 17.2% of the measured value. For $e_{tot\ 90^o}$, the SD is 9.3% and the range is 27.3% of the measured value. Moreover, for some cases, a large variation

Table 1 Tensile testing results for BH340-HA and BH340-HB steels for 0°, 45°, and 90° orientations

Material variation	Property	UTS (MPa)			S_y (MPa)			e_{tot} (%)		
	Angle (°)	0	90	45	0	90	45	0	90	45
BH340-HA	Mean	340.8	341.4	344.1	227.2	233.5	233.5	39.98	39.26	38.95
	St. dev.	9.1	9.0	9.3	8.8	8.4	7.0	2.88	3.64	3.26
	Range	32.0	33.0	34.0	39.0	27.0	28.0	8.60	10.70	10.40
BH340-HB	Mean	350.9	354.6	355.1	241.2	246.2	245.3	37.29	35.71	36.06
	St. dev.	4.6	7.2	7.2	3.7	9.4	4.9	2.48	3.34	3.23
	Range	16.0	20.0	21.0	16.0	38.0	16.0	8.20	9.60	10.10

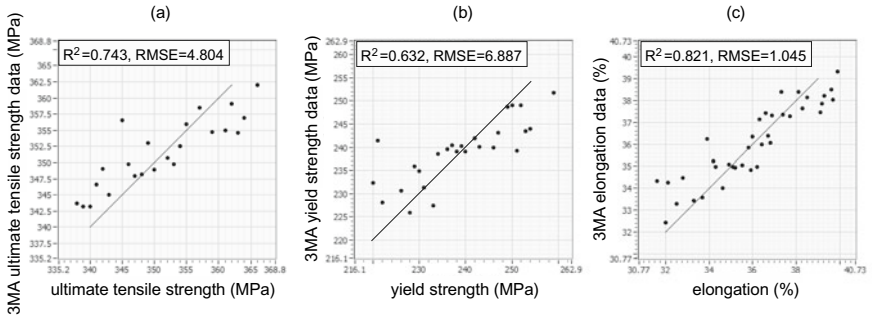

Fig. 5 Calibration correlation plots for UTS **a**, S_y **b**, and e_{tot} **c**

on the material properties was found in the same blank. For example, for a single BH340-HA blank, the values of two different specimens in the rolling direction were 354 and 340 MPa for UTS, 243 and 222 MPa for S_y, and 39.2 and 37.7% for e_{tot}.

3.2 Calibration Model Results

The correlation plots between the 3MA-measured data and the tensile testing properties (ultimate tensile and yield strength, and elongation) are shown in Fig. 5. The manufacturer suggests a model correlation higher than 80%; however, the R^2 values for S_y and UTS were lower than 80%. The correlation was 63.2% for S_y but the RMSE was 6.89 MPa, which is only 2% of the mean value and within the coil specification (6–40 MPa). The UTS model shows a correlation of 74.3%, although the RMSE was 4.8 MPa, which is lower than the 3MA manufacturer specifications (8–40 MPa) [11]. For e_{tot} the correlation is 82%. Therefore, the regression polynomial equations used for the calibration are considered acceptable for the tensile properties. Nevertheless, further tests with 3MA and subsequent statistical analysis were conducted to increase the accuracy of the calibration and the system.

3.3 Validation of the Calibration Function

To prove the repeatability of the automated 3MA-robot system, the same point of the blank, in the same direction, was measured three times. The results showed a consistent value for the same location of the blank. The higher percent deviation (PD) was 1.2% for UTS, 1.4% for S_y, and 3.7% for e_{tot}. All of the results showed a lower PD than specified by the manufacturer [11].

An ANOVA test was performed to quantify the accuracy of the calibration model of the 3MA measurements. The ANOVA test evaluates how similar two different

Table 2 ANOVA p-value results between the 3MA-measured data from the sheet blanks concerning the tensile testing results

Property		UTS			S_y			e_{tot}		
Angle (°)		0	90	45	0	90	45	0	90	45
Material variation	BH340-HA	0.447	0.408	0.002	0.620	0.994	0.155	0.120	0.854	0.173
	BH340-HB	1.000	0.997	0.174	0.074	0.028	0.618	0.797	0.792	0.561

data sets are. From Table 2, it is observed that 89% of the 3MA-measured properties of the new blanks randomly selected from the coil were similar to the tensile testing data (p-values > 0.05). The $UTS_{45°}$ for BH340-HA and $S_{y_90°}$ for BH340-HB showed a small mismatch (p-values $\leq$ 0.05) between the new 3MA measurements and tensile data. Figure 6 shows the box plots for these two cases. The box plot describes groups data based on a five-number summary: minimum, maximum, median, and standard deviation above and below the data mean. Outliers are excluded in the analysis and are represented with a star (*). From the plots, it is observed that the 3MA-measured values for the $UTS_{45°}$ of BH340-HA are slightly higher than the tensile testing results; however, they are within the maximum and minimum values. For $S_{y_90°}$ for BH340-HB, the 3MA-measured values are also within the tensile test data range; however, the 3MA data mean value is lower than the tensile test data mean value. Therefore, the calibration was considered reasonably accurate and robust.

A further analysis used a new calibration model with only 26 random tensile samples from the original 50 samples. The correlation of the calibration (R^2 values) improved over 90% for all the properties. The same blanks were measured again using the new calibration model; however, for this case, the ANOVA test results showed that only 17% of the 3MA-measured data of the new blanks were similar

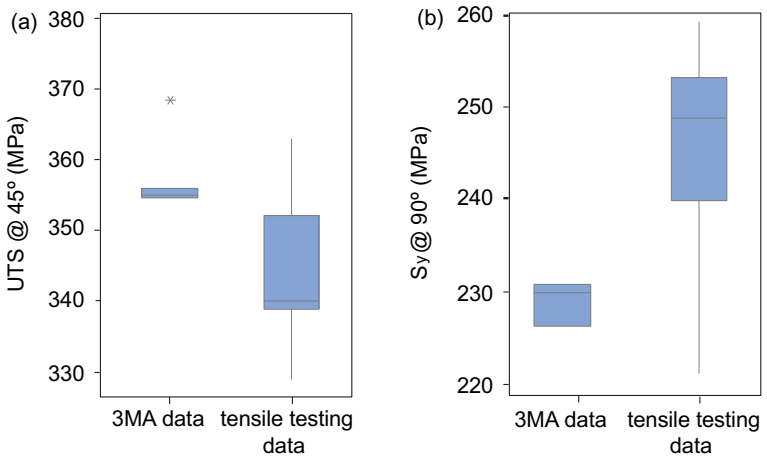

Fig. 6 Box plots for: **a** UTS at 45° for BH340-HA and **b** at 90° for BH340-HB. (Color figure online)

to the tensile testing data. The robustness of 3MA measurements improves significantly with increasing the number of tensile tests; therefore, proper and representative sample size is critical for reliable calibration.

Also, a similar ANOVA test was performed to access the consistency of the 3MA measurement; most measurement variations were made by manually holding the 3MA equipment and then holding it with the flexible robot. An ANOVA test was performed, and the results showed negligible differences of the measured data between both methods.

4 Discussion

In this study, both 3MA data and tensile test data showed a significant variation of the BH340 mechanical properties. Important variations on the material properties (ultimate tensile and yield strength, and elongation) were found even for the same coil. In addition, the automated 3MA-robot system provided accurate, consistent, and repeatable measurements for BH340 steel. Therefore, after a reliable calibration process, automated NDE tools can be practically used in tracking the incoming coil material variations by taking real-time measurements in production to reduce the uncertainties of the process and potentially improve part qualities and reduce costs by adjusting the forming process parameters or machine control.

One of the limitations of 3MA equipment is that different grade or different gauge materials require new calibrations. Different calibration functions need to be used for different coil thickness, or thickness needs to be incorporated as a variable of the calibration function. It is recognized that calibration can be expensive; however, the well-calibrated 3MA tool has great potential for cost-saving by inspecting the incoming coil properties and adjusting forming process in production. Additionally, this study leads to develop generalized material calibration databases and use advanced simulations and machine learning to minimize calibration efforts [4].

The calibration procedures for 3MA recommended by the manufacturer do not fully guarantee a robust calibration. Therefore, from this study, the following calibration procedure for ultimate tensile and yield strength, and elongation is recommended for steel strip coils:

1. Choose at least 24 randomly selected blanks from different parts of the coil for each material variation.
2. Draw two sets of tensile test specimens for each direction (0°, 45°, and 90° with respect to the rolling direction) as shown in Fig. 3a.
3. Record 40 3MA measurements at four random points (10 per each point) for each specimen (Fig. 3b).
4. Conduct tensile testing of the drawn specimens from step 2.
5. Store the 40 3MA measurements and the tensile testing data in the same database and find the calibration functions using regression analysis. The correlation

coefficient of the calibration model should be: R^2 (adjusted) > 0.7 and %RMSE < 10%. If 0.6 < R^2 (adjusted) < 0.7, then %RMSE < 3%.

6. Choose ten randomly selected blanks from different parts of the coil for each material variation and take nine 3MA measurements (three for each direction) for each material as shown in Fig. 4.
7. Run a one-way ANOVA test (significant level = 0.05) for each mechanical property independently, comparing the tensile testing data with respect to the 3MA measurements of step 6. If more than or equal to 75% of the p-values are higher than 0.05 (no significant differences), the calibration is successful. If less than 75% of the p-values are higher than 0.05, the calibration is not successful and more tensile testing data should be included in the ANOVA test.

The 3MA NDE tool is sensitive to the operating conditions and the proper cautions are needed to avoid significant measurement errors. The precautions that need to be considered while taking measurements were discussed in Sect. 2.1.

It was observed that the robustness of the 3MA calibration is significantly improved by increasing the number of tensile testing samples. New advanced high-strength steels typically have a large variation of the material properties because they have multiphase microstructures, which makes them more challenging to obtain consistent mechanical properties [3, 4]; therefore, calibration specimens should be chosen carefully to include the entire range of material properties. Since a coil strip can be kilometers long, it is crucial to select multiple blanks across different parts. Moreover, the 3MA-measured tensile properties are found by computing the calibration functions, which are based on empirical data; therefore, extrapolation outside of the calibration range can lead to significant fault data. For this reason, a wide range of value needs to be used for the calibration to minimize calibration errors.

5 Conclusion

The following conclusions can be made based on this study:

- A significant variation on the incoming mechanical properties was observed for the same batch coil of BH340 steel.
- The automated 3MA equipment integrated with the flexible robot measurements consistently obtains the repeatable results.
- A BH340 steel calibration model for yield and ultimate tensile strength, and total elongation was obtained and validated successfully.
- A new robust calibration procedure was established for industrial applications.
- NDE tools can effectively detect mechanical property variation of the incoming material.
- NDE automated tools used as an input to adjust forming process parameters have a great potential in reducing costs and time for sheet metal forming production environment.

Study on the Effect of Embossing on the Bending Properties of High-Strength Sheet Metals

David Briesenick, Stefan Walzer, and Mathias Liewald

Abstract Selective embossing of sheet metal blanks, prior to processing, offers the possibility of locally modifying material properties. Small indentations applied on the sheet metal surface by a punch lead to increased material strength due to the induced strain hardening. Moreover, such locally embossed sheet metals show an enhanced process window with regard to forming processes and an improved performance under different loading conditions. The experimental study presented in this paper investigates the bending properties of high-strength steel sheets embossed on the tension or the compression surface of the bent blank. The effect of embossing on the bending resistance of two different materials (DP500 and TRIP780) was analyzed by varying the embossing patterns by density and depth. As a result, bending forces required in the tests rise when increasing the proportion of the embossed surface. Therefore, the paper reveals potentials of local embossing with regard to a specific modification of bending properties of sheet metal components, thus enabling their use in lightweight constructions.

1 Introduction

For the last decades, the mobility sector has been exposed to a growing demand for sustainable and efficient vehicle concepts, leading to an increased focus on lightweight construction issues in science and industry. In this context, one lightweight approach consists in replacing conventional steel grades in structural

components of car bodies with high-strength sheet metals in order to fulfill new requirements in crash safety, vehicle rigidity, recycling rates, and production cost [1]. However, certain disadvantages arise when processing advanced high-strength steel (AHSS) sheet metals by conventional forming technologies. Especially, cost-beneficial cold forming methods are accompanied with limited formability of material and enormous springback phenomena. But since the full potential of high-strength steel alloys may only be exploited via work hardening mechanisms, such cold forming processes are of particular interest [2].

Locally different component properties adapted to the component´s functionality enable the production of lightweight and efficient car body structures. Here, a common approach for locally reinforcing such components represents the use of tailored blanks. Merklein et al. [3], for example, suggested a classification in patchwork, tailor welded, tailor rolled, and tailor heat treated blanks and elaborated advantages and disadvantages in terms of formability and processing capabilities. On the contrary, Namoco et al. focused on an approach of local work hardening of aluminum sheets by an embossing and smooth reforming process and investigated its impact on mechanical properties and formability [4, 5]. These findings are supported by Abe et al. [6], having carried out investigations on punch indentations in areas of excessive thinning during deep drawing of aluminum parts. Furthermore, crash-relevant structural sheet metal parts can show a reproducible increase in energy absorption when local material hardening is applied by forming structuring or laser hardening [7]. A new embossing method for near-surface indentations is presented by Walzer and Liewald [8], demonstrating a pattern and indentation depth-related impact on mechanical properties of high-strength sheet metal DP600. Based on these findings, the study presented in this paper investigates sensitivities of embossing parameters such as the depth, location, and density of indentations on the bending properties of high-strength sheet metal specimens. In view of the increase in strength, this method offers a new approach for a local and load compatible reinforcing of sheet metal parts with simultaneous advantages in lightweight design of corresponding sheet metal components. Additionally, proposed tailor embossed blanks may overcome current challenges regarding joining and forming technology of conventional tailored blanks.

2 Experimental Method

Sheet metal components of modern car body structures are often made of multi-phase steels having high mechanical strengths and limited formability. Therefore, two representative high-strength steels with identical sheet thickness t but different mechanical properties were selected for the investigations described below (see Table 1). Dual-phase steel DP500 exhibits a Yield Strength of 340 MPa, a Uniform Tensile Strength (UTS) of 560 MPa, and shows certain formability of 19% for uniform elongation (U.E.). Applied multi-phase Steel TRIP780 enhances crash worthiness of parts by a strain rate and temperature-dependent phase transformation effect and combines high mechanical strength (UTS = 820 MPa) with acceptable formability (U.E. = 14%).

Table 1 Mechanical properties of investigated high-strength steel DP500 and TRIP780

Material	t (mm)	E (GPa)	Yield strength (MPa)	UTS (MPa)	U.E (%)	n	r_m
DP500	1.2	210	340	560	19	0.18	0.88
TRIP780	1.2	210	470	820	14	0.23	0.93

2.1 Embossing Process

For the investigations, sheet metal specimens were initially processed from the selected materials using a CNC-controlled punching machine (TRUPunch 5000R). For this, the semi-finished sheet metal products were first clamped horizontally and then incrementally embossed in the Z-direction with a spherical punch (Ø = 4 mm). Afterwards, the final specimen contours were produced by nibbling with a rectangle punch (Fig. 1). This procedure enables a flexible production of embossed specimens with different patterns and indentation depths for different types of material properties or sheet thicknesses. The punching machine used provides an operating performance of up to 1400 strokes per minute and thus enables an efficient and flexible structuring method for research and small batch industrial applications.

By using the flexibly controlled punching machine, the high-strength steel sheets (DP500, TRIP780) were embossed with different patterns. Here, the distances between indentations were changed in the X- and Y-direction in order to obtain embossing patterns of varying densities. Likewise, embossing depths T were changed (see Table 2). Subsequently, the embossed and separated specimens were ejected from the punching machine, and measurements of the specimen surfaces were performed via confocal microscope (μsurf nanofocus). The measurements revealed that due to the elasticity of the machine frame and tools, small variations of embossed depth T occurred, although machine settings such as dead bottom center were kept constant. Thereby, the depth variation was mainly affected by the material and density of the pattern. For further evaluation, measured diameters of the surface indentations were

TRIP780_F16_T106	TRIP780	106	3	3	16	ND	304

used to calculate a percentage value of embossed area (F) on the specimens (see Fig. 1b).

2.2 Three-Point Bending Test

Properties of the differently embossed specimens were examined using three-point bending tests carried out on a tensile and compression testing machine (Roell + Korthaus RKM100). The testing device was equipped with exchangeable punch having different radii as well as a fixture according to testing standard DIN EN ISO 7438 [9]. The different specimens (see Table 2) were placed between the fixture and the bending sword. In addition, the orientation of surface indentations was varied between top- and downside as depicted in Fig. 2a. The main purpose of these tests was to investigate geometrical and work hardening effects of indentations on the outer tension side or inner compression side of the bending specimen. During the experiments, the bending punch moved by a defined speed of 60 mm/min toward the bottom dead center and deflected the specimen up to 20 mm. At the same time, the force–displacement curve was recorded using the integrated machine load cell and position sensor. Each specimen specification was tested five times consecutively. The curves obtained were averaged taking into account the divergence of measurements. The derivation of the force–displacement curves with respect to displacement (Fds) allowed the determination of extrema such as the maximum force F_{max} which represents the maximum bearable bending force (see Fig. 2b). In general,

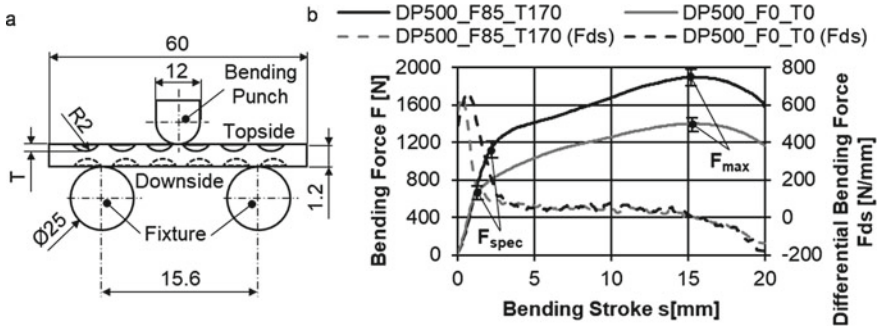

Fig. 2 Illustration of **a** schematic three-point bending test with embossed blank and **b** selected curve characteristics for reference and embossed specimen

measured bending force curves start with a linear increase of force and show a transition between a quasi-elastic and quasi-plastic forming behavior. Simultaneously, the corresponding derived curves (Fds) fall below a minimum value (<200 N/mm) at this point and subsequently tend toward zero. This gradient transition identifies the specific bending force F_{spec}.

3 Results And Discussion

The results gained for specific bending force F_{spec} which represents the switch from elastic to plastic strain and the maximum bending force F_{max} were summarized for selected specimens and plotted in a unified bar chart (see Fig. 3). Untreated specimen made of DP- (DP500_F0_T0) and TRIP-steel (TRIP780_F0_T0) served as reference for the specimen work hardened by embossing. As shown in Fig. 3, the untreated DP500 specimen shows a maximum bending force of 1.41 kN and a specific bending force of 0.67 kN. The untreated high-strength steel TRIP780 exhibits a higher deformation resistance with $F_{max} = 2.18$ kN and $F_{spec} = 1.18$ kN. The embossed specimens generally show an increased bending resistance when exposed to both quasi-elastic and quasi-plastic load conditions. Here, the transition between both load states (F_{spec}) is slightly influenced by the embossing orientation, with marginally higher measured values for blanks embossed on the topside under compressive stresses. Considering measuring divergence, this effect is slightly more pronounced for TRIP780 than for DP500 material. In contrast, maximum bending force F_{max} is not affected by the geometrical orientation of indentations, i.e. regardless of whether top- or downside has been embossed.

The small and near-surface indentations induced by the embossing process lead to work hardening of the material in the surrounded embossed area, which significantly impacts the bending properties of the specimen. For examined parameter space, the specific bending force of the specimens made of DP500 could be increased by

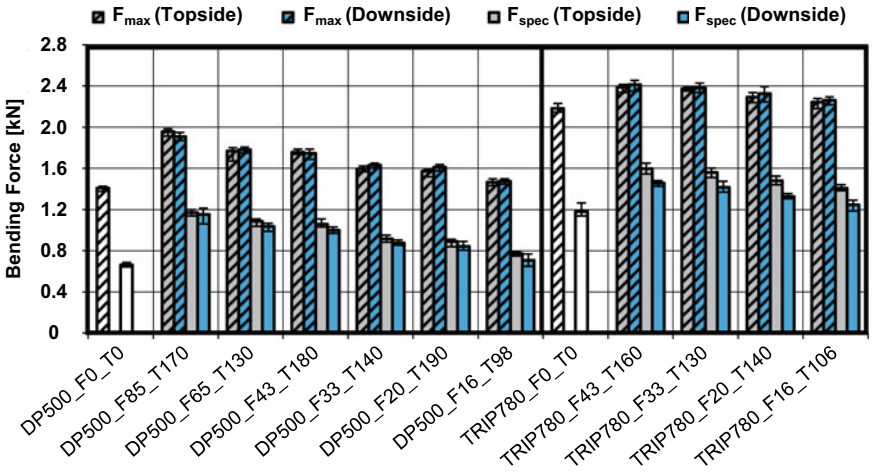

Fig. 3 Experimental results for maximum bending force F_{max} and specific bending force F_{spec} of investigated specimens with distinction between material and orientation of embossing (topside vs. downside). (Color figure online)

the embossing process by 0.046 kN (+7%) up to 0.49 kN (+75%) compared to the reference value of 0.66 kN (DP500_F0_T0). TRIP780 shows a specific bending force increase between 6 and 36% with a maximum increase of F_{spec} from 1.18 to 1.6 kN. The maximum force occurring during bending test (F_{max}) is increased to 1.96 kN (+39%) by embossing DP500 material with high pattern density (F = 85%) and indentation depth (T = 170 μm). Here, the resulting properties are almost comparable to bending properties of the untreated TRIP780 specimen. Minor surface indentations increase the maximum bending force only by 4% compared to the reference of 1.41 kN. The percentage increase of F_{max} for TRIP steel is observed in a range from 3 to 11%, thus showing a minor impact on targeted work hardening of the high-strength material by means of embossing.

In general, the results of the three-point bending test shown in Fig. 3 indicate a significant correlation between the embossing parameters depth T and embossed area F with regard to the bending properties of material DP500. In addition to the increasing F_{spec} and F_{max} values, this can be discerned from the fact that the ratio between F_{spec} and F_{max} as a measure of hardening mechanisms increases from 0.47 to 0.6 with growing embossing depth and density. In this context, further analysis focuses on promising results for DP500 material which is more sensitive to embossing than TRIP780. Therefore, Fig. 4 shows at first a more detailed analysis of the parameter sensitivity for the dual-phase steel. The surface plots exhibit a comparable influence of the parameter embossing depth T and area F on both measured forces F_{spec}, F_{max} and thus the bending properties of the material. Increasing density and/or depth of surface indentations immediately results in an increased resistance of sheet metal part under bending loads. Within investigated parameter range, correlation among

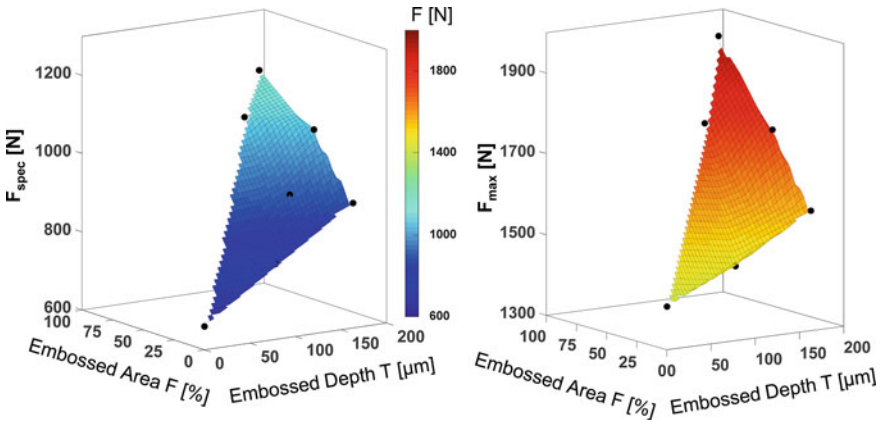

Fig. 4 Evaluation of embossing parameters area ratio F, indentation depth T, and the sensitivity on bending properties F_{spec}, F_{max} of DP500. (Color figure online)

embossing depth T, area F, and bending properties represented by F_{spec}, F_{max} can be described with a linearized response surface (see Fig. 4).

In order to understand the contexts and origins of the observed increased mechanical strength, an analysis of hardness distribution around surface indentions of embossed specimens may provide correlations with work hardening mechanisms. To characterize the increase in the hardness of sheet metal after embossing, microhardness measurements were carried out along thickness direction. For this purpose, four representative DP500 specimens were separated by machining, embedded and polished. Microhardness was measured according to Vickers (MHV) in sheet thickness direction using a pre-defined measuring profile (see Fig. 5). All tests were performed according to the international standard DIN EN ISO 14,577 using the microhardness measuring instrument Picodentor HM500 from Helmut Fischer GmbH. For statistically verified results, 42 hardness measuring points were performed in the field of a single embossed indentation. The measuring distances in horizontal direction amounted to 0.3 mm and in sheet thickness direction 0.2 mm. The maximum applied test load was defined as 300 mN.

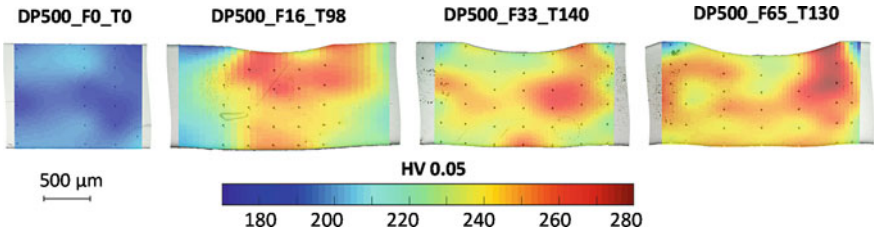

Fig. 5 Microhardness plots of reference specimen and three exemplary embossing setups of DP500 (from left to right). (Color figure online)

As shown in the very left picture of Fig. 5, the reference measurements revealed an averaged hardness value of about 191 HV with a standard deviation of 3.3% for untreated DP500 material without embossings. When comparing these reference measurement values with the measurements of specimen DP500_F65_T130, the considerable impact of embossing on the hardness values becomes more visible. In this case, the detected hardness values amounted to 244 HV with a measured deviation of 5.9%. In average, the difference between the hardness values of the reference specimen and the specimen exhibiting the most indentations amounts to 53 HV, which correspond to an increase of about 28%. In general and contrary to expectations, the highest increase in hardness does not arise below the indentation, but was identified on the highest value (275 HV) in the middle layer of the sheet thickness.

This effect can also be observed with specimen DP500_F33_T140, whose averaged hardness of 239 HV nearly equals the value of highly embossed specimen DP500_F65_T130. The measurements of specimen DP500_F33_T140 indicates an absolute deviation of hardness values by 12.1 HV, respectively 5%, which indicates a reliable comparability between measurements. Specimen DP500_F16_T98 (absolute deviation of 22.8 HV), however, shows a high increase in hardness directly below the punch indentation with a maximum hardness of 268 HV. Additionally, the incremental embossing process and machining sequence of single indentations seem to influence the hardness distribution to be adjusted. Thus, at higher indentation densities, the highest hardness value does not arise below the punch indentation, but is shifted to the mid-level of the sheet metal blank. By contrast, sufficient displacement of the material can be achieved in case of relatively large distances between the individual indentations, causing the highest hardness value to be adjusted directly below the punch indentations. The hardness values on the opposite side of the indentations are very similar even with different specimen setups. No interactions between indentations can be detected here.

The basic research results presented in this paper have shown that embossing of a sheet metal component can significantly increase its strength. Due to this increase in strength, sheet metal size can be reduced, thus leading to new design approaches for sheet metal components in lightweight constructions. In this respect, Fig. 6 illustrates the results of a three-point bending test which shows the potential for weight reduction via the embossing technique. In this investigation, embossed sheet metal blanks with the defined external dimension of 50 × 60 mm and two different embossing patterns were compared to untreated sheet metal blanks that varied in width from 50 to 95 mm and thus differed in weight.

Taking the specimen configuration DP500_F33_T140 as an example, the specific bending force (F_{spec}) of the embossed specimen amounts to 0.9 kN, while the untreated specimen of similar size only provides a bending resistance of 0.64 kN. By iteratively enlarging the specimen width in 5 mm steps, the same specific bending force of 0.9 kN could be achieved with an untreated specimen width of approximately 65 mm. This results in an increase in weight of approximately 32%. Considering the much tighter embossed sample DP500_F85_T170, weight increase even doubles to 64% when comparing the embossed and untreated specimen. The specific bending

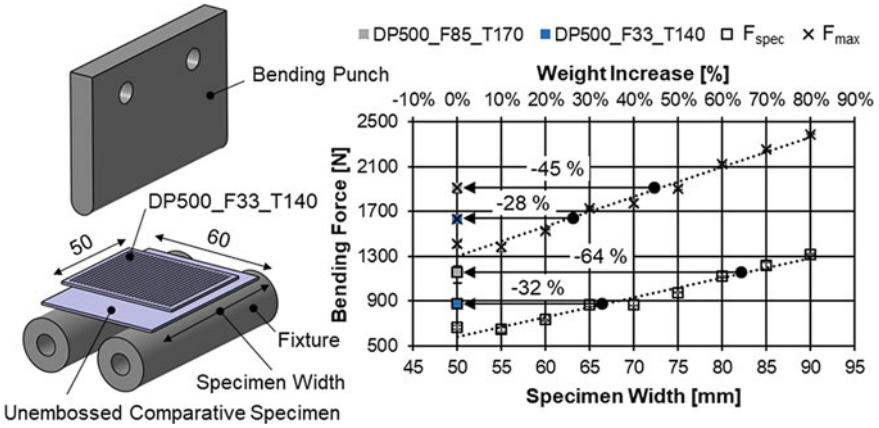

Fig. 6 Investigation of weight-saving potential of embossed DP500 blanks by comparing bending properties of embossed and untreated specimen with different dimensions. (Color figure online)

force for the embossed sample here reaches up to 1.15 kN. To achieve this specific bending force with an untreated specimen, the width must be increased up to 80 mm. Taking into account the absolute force maxima of the three-point bending test (F_{max}), the maximum bending force for the DP500_F33_T140 sample configuration amounts to 1.63 kN. The untreated specimen achieves a comparable maximum bending force with a specimen width of approximately 65 mm, which would correspond to a weight increase of approximately 28%. Similar behavior can be observed with the maximum bending force of specimen DP500_F85_T170. With this specimen configuration, an enlarged width of the untreated specimen compared to the embossed specimen amounts to 22 mm, which corresponds to a weight increase of 45%. Thus, the experimental investigations carried out could demonstrate the enormous potential of weight savings provided by the new embossing approach considered. Looking ahead, the findings obtained will be transferred to load-bearing profiles in the field of battery boxes in e-mobility applications.

The final evaluation of the forming results was carried out by visually inspecting the embossed specimens after bending, thus assessing the deformation behavior of the indentations. In this respect, Fig. 7 shows the embossed specimen DP500_F43_T180 with indentations having a distance of 2 mm in the X- and in Y-direction and a depth T of 180 μm. Bending of the specimen with embossing on the outer tension side (downside) results in an elongation of the spherical indentation diameter from 1.7 to 2.1 mm (+23.5%). On the contrary, bending of the specimen having embossings on the inner compression side (topside) leads to minor compression of the surface indentations in the forming zone of -11.7%. As a conclusion, local deformation of embossing depends on the load direction and occurs higher under tensile than under compressive stress. Based on this assumption, observed tendencies toward marginally higher stiffness and strength of specimens embossed on the topside can be explained

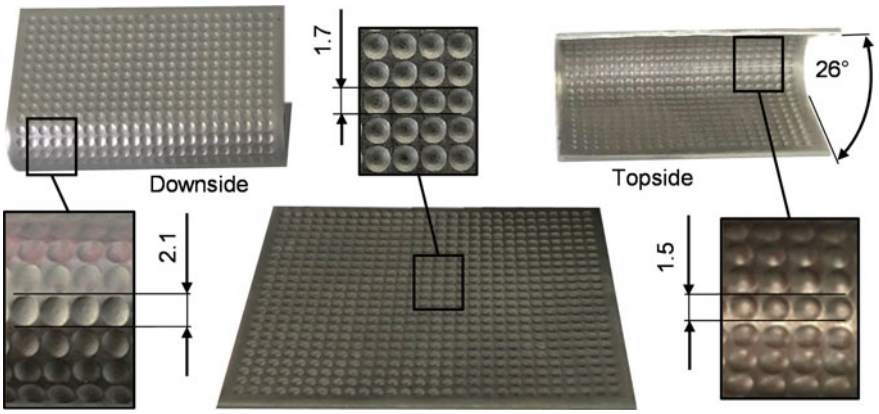

Fig. 7 Visual analysis of three-point bending test results for specimen DP500_F43_T180 on top- or downside. (Color figure online)

(see Fig. 3). Additionally, none of the formed and visually inspected specimens showed any failure such as cracks inside or between the surface indentations.

4 Conclusion and Outlook

The study presented in this paper demonstrates the effect of different embossing patterns on bending behavior of dual- and multi-phase high-strength steels DP500 and TRIP780 with identic sheet thickness. The investigations do reveal increased bending resistance of specimen when increasing pattern density and/or indentation depth, which could be proven by means of the two designated force characteristics (F_{spec}, F_{max}). Especially, dual-phase steel DP500 exhibits an increased sensitivity on work hardening by near-surface indentations with an increased strength of up to 75%. Presented results for dual-phase steel are consistent with observations under uniaxial tensile loads for DP600 [8]. Embossed sheet metal blanks made of TRIP780 steel grade reveal growth rates for elastic-related force F_{spec} of up to 35%. In addition, the study reveals a negligible influence of the localization of the embossing, i.e. whether the indentations are applied on the outer tension side or the inner compression side. Thus, it can be assumed that the occurring work hardening mechanisms may over-compensate geometrically caused effects. In fact that the section modulus is only slightly changed through these very small indentations close to the surface, significant geometric influences with regard to the stiffness can be excluded. Additionally, microhardness measurement of embossed cross sections of DP500 supports these findings by a localization of maximum hardness in the mid-level of the sheet metal blank. As a conclusion, pre-embossing of high-strength sheet metal blanks prior to sheet metal processing significantly influences bending properties of these materials and increases strength under bending loads. Based on these findings, the

developed embossing process allows a tailored adjustment of structural parts and their properties under functional load cases such as crash scenarios. Furthermore, promising new lightweight design possibilities are enabled by tailor embossed sheet metal parts. Exemplary elaborated comparative experiments revealed weight-saving potentials of up to 64% for embossed specimens toward bigger untreated sheet metals with the same bending properties.

Future investigations will address different dual-phase steel grades and sheet thicknesses to exploit further cost and weight-saving potentials for tailor embossed blanks. Besides further developments in the fields of simulation and design of embossing patterns, concept studies for a flexible industrial application of embossing process are necessary for a successful implementation under future technical and economic requirements.

On the Determination of the Forming Limits by Necking and Fracture of Polycarbonate Sheet

A. Rosa-Sainz, G. Centeno, M. B. Silva, J. A. López-Fernández, A. J. Martínez-Donaire, and C. Vallellano

Abstract This research evaluates experimental methodologies for determining forming limits by necking and fracture in polycarbonate (PC) sheets by proposing developments of recent methodologies usually used in sheet metal forming. With this purpose, Nakazima tests with different blank geometries are performed on a 1 mm thick polycarbonate (PC) sheet. The experimentation included the use of Digital Image Correlation (DIC) for the evaluation of strains and thickness measurements for the determination of failure strains. The results provided accurate formability limits by necking and fracture, establishing a general framework for analysing specific forming processes (such as incremental forming) on polymeric sheets. Differences in the shaping of the Forming Limit Curve (FLC) and Fracture Forming Limit (FFL) curves for PC compared to those obtained in metal sheet are also discussed.

Keywords Polycarbonate sheet · Forming limits · Necking · Fracture

1 Introduction

Polymers represent a significant part of the raw materials used nowadays in the manufacturing industry, due to their lightweight, high corrosion resistance, good thermal, and electrical isolation properties, among other advantages. The shaping of polymers is commonly performed by means of thermal operations, involving heating, forming, and cooling operations, these being only economically viable for mass production.

However, the industry has currently a trend for low volume, lightweight, high quality, and customization of products that leads to the development of flexible

processes, short forming cycles, short development, and production times, compatible with rapid prototyping and small-batch production, as it is, for instance, the case of incremental forming of polymeric sheets [1].

Cold forming of polymers remotes to the mid 1960s, where several conventional sheet and bulk metal forming operations were applied to cold plastic deformation of polymers; the review publication of Shaw [2] identifies the most relevant ones. With these works, some advantages of cold forming of polymers were identified such as short time cycles, less energy, better mechanical properties, and simpler and less-expensive tooling. In parallel emerged the need to characterize the polymer's behaviour in cold forming, as the pioneering pressure-dependent yield criteria for polymers by Caddell et al. [3].

Lately, the application of the single point incremental forming process to polymeric sheet [1] raised the interest about cold forming of polymers, its formability, and failure [4, 5].

Marques et al. [6] proposed an experimental methodology to determine the formability limits for four different thermoplastic sheets, polyamide (PA), polycarbonate (PC), polyethylene terephthalate (PET), and polyvinylchloride (PVC). The methodology made use of circle grid analysis (CGA) for the determination of necking limit or forming limit curve (FLC), and the fracture thickness measurements to obtain the "gauge length" strains of fracture limit line (FFL). Results revealed that the FLC and the FFL should be considered as a unique limit, however, the CGA is not the best methodology to determine the necking limit due to the typical stable neck propagation of polymers after the onset of necking as pointed out by Carothers and Hill in [7].

In this scientific and technological framework, this work revisits the methodology for the formability limits by necking and by the fracture of polymer determination, proposing an adaptation of the sheet metal forming procedures. The experimental work is performed by means of experimental Nakazima tests with four different geometries to scan strain paths from pure tension till the equi-biaxial expansion of polycarbonate (PC) sheets with 1 mm thickness.

2 Experimentation

The investigation was carried out on Polycarbonate (PC) sheets with 1 mm thickness, obtained by extrusion. The determination of the formability limits by necking and by fracture of the PC sheets was performed by means of Nakazima tests with a tool following the standard ISO 12,004-2 [8] on a universal sheet testing machine, Erichsen Model 142-20 at room temperature.

The specimens were machined out from the supplied sheets, and four different geometries were considered in order to achieve different strain loading paths, from tensile strain ($\beta = -0.5$) towards equi-biaxial strain ($\beta = 1$). The specimen's geometry was aligned longitudinally with the extrusion direction of the blank. Depending on the geometry and operation conditions, the corresponding strain paths were identified

as tensile strain (TS), plane strain (PS), biaxial strain (BS), and equi-biaxial strain (EBS).

In order to ensure reproducibility of the results, the tests were performed in random order and three repetitions were made for each specimen geometry. In order to minimize the friction, one layer of Polytetrafluoroethylene (PTFE) was sandwiched with two layers of Vaseline between the punch and the polymeric specimen.

The strain measurements on the deformation area, on the vicinity of the zones where cracks are opened, were performed using the digital image correlation (DIC) system ARAMIS v6.2.0-6. The Aramis system was equipped with 2 cameras using an angle between them of 23.6° and lens with 50 mm focal length. The frequency of image acquirement was set to 12 frames/s and a facet size of 13 × 11 pixel. The black and white stochastic pattern on the specimen's surface was defined by a fine spray of matte black on a white background.

3 Methodology

This investigation aims to provide a methodology for the determination of the formability limits by necking and fracture in principal strain space adapting those commonly applied for metals [9, 10] to polymeric sheets.

3.1 Necking Evaluation

Necking is a failure mode that occurs by tension, where relatively large amounts of strain are disproportionately located in a small region of the material. Two different approaches are considered and adapted for the determination of the onset of necking for the PC sheets, a time-dependent and a time-position-dependent approach (also known as "flat-valley") originally proposed by the authors for metal sheet [10].

Figure 1a presents a schematic representation of the Nakazima test tool for a tensile strain geometry. Figure 1b presents a schematic representation of the polymer specimen deformation with the advance of the punch. In this sense, the deformation in polymers is homogeneous along the specimen until a certain reduction of area occurs and local reduction in thickness is achieved (necking). This neck propagates steadily along the length of the specimen, with a cyclic behaviour until the material cannot stand the necking propagation and fracture occurs (refer to Fig. 1b) [11].

Concerning the use of the time-dependent methodology, Fig. 2 presents a schematic evolution of the major strain and the major strain rate with time. The time-dependent approach initially applied to metals is based on the experimental evidence of the necking initiation and its development [10]. The contrast between the localized thinning characteristic of the metals necking, and the necking behaviour for polymers, required some suiting adaptation of the original approach. Further information in this respect can be found elsewhere [12]. The approach makes use of the major

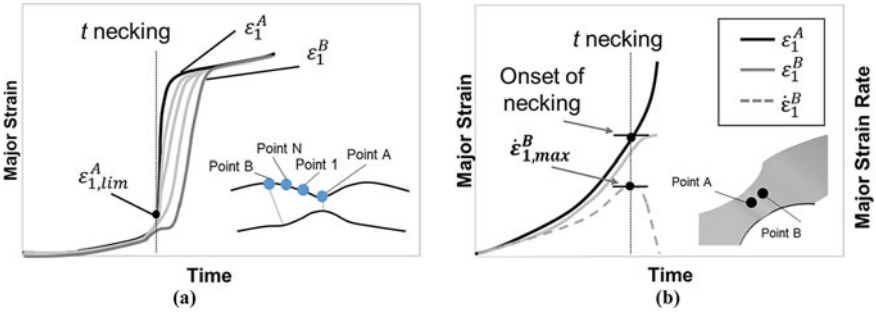

Fig. 2 Schematic representation of time-dependent methodology for a polycarbonate Nakazima test with tensile strain geometry. **a** Evolution of major strains with time for the necking region, and **b** time-dependent approach application adapted from Martinez-Donaire et al. [10]. (Color figure online)

strain temporal analysis and its first time derivative or major strain rate, for a series of points along a section perpendicular to the crack. Figure 1a shows the representation of the major strain with time for several points along a section perpendicular to the site of necking initiation (points A, $P_1 \ldots$, P_N, B). In this sense, point A corresponds to the point where the necking initiates; the points between points A and B also have a monotonical increase of strains, and point B is the first point where the strain starts ceasing (see Fig. 2a, b) temporally identifying the necking region.

On the other hand, the flat-valley approach is based on the direct observation and analysis of the displacements of the superficial layer of the sheet during necking. In this regard, Fig. 3a shows the schematic evolution of the Z-displacement (normal direction to the surface) over the X-position along a section perpendicular to the necking area of a Nakazima specimen, and each profile corresponds to an instant of time. The profile evolution (Z displacement vs. X position) before the onset of necking follows the hemispherical punch geometry (t_1 stage); the onset of necking

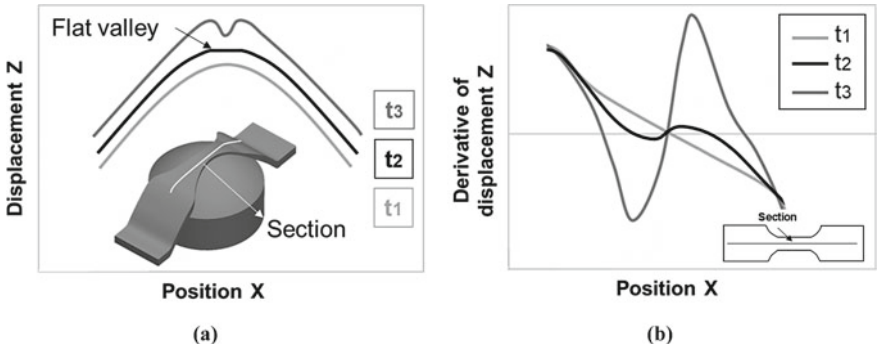

Fig. 3 Schematic representation of flat-valley approach: **a** Z-displacement over the X position and **b** temporal evolution of the Z-displacement spatial derivative on a section perpendicular to the failure area. (Color figure online)

(represented with a dark profile) stage t_2 reveals a flat profile or flat valley corresponding to the inability of the sheet to follow the punch geometry (the top of the profile) as in the previous stage and after the time instant of the onset of necking, the valley is visible (stage t_3). Figure 3b represents the temporal evolution of the Z-displacement spatial derivative for three different stages (t_1, t_2, and t_3) of the same section perpendicular to the necking area (see Fig. 3b for the localization of the section in the specimen). An alternative way to identify the instant of the onset of necking is to consider the first spatial derivative of the Z-displacement and the onset of necking corresponds to the instant where the slope remains locally constant (black curve in Fig. 3b). In polymers, this identification is difficult since the onset of necking and fracture does not occur in the same cross-section, due to the necking propagation along the specimen's length typical of the polymer of [11]. Further details of this methodology applied to polymers can be also found in [12].

3.2 Fracture Limit

The procedure to determine the formability limits by fracture is based on the measurement of the fracture thickness from the fractographies of the fractured specimens, as it is presented in Centeno et al. [9]. The logarithmic strain in the thickness direction is then calculated as follows:

$$\varepsilon_{3f} = \ln \frac{t_f}{t_0} \tag{1}$$

where t_f is the current sheet thickness at fracture and t_0 is the initial sheet thickness.

The general application of this methodology to metals considers that the fracture minor strain gradient in the sheet surface is practically null after necking [13], and it can be estimated as approximately the same as the necking one:

$$\varepsilon_{2f} \cong \varepsilon_{2n} \tag{2}$$

Finally, the fracture major strain is obtained assuming volume constancy [14] as follows:

$$\varepsilon_{1f} = -\varepsilon_{2f} - \varepsilon_{3f} \tag{3}$$

In polymers, due to neck propagation along the specimen, the original methodology developed for determining the fracture forming limit for sheet metal [9] needs to be adjusted for the polymers' behaviour. In this sense, it is more accurate to consider that the minor strain at fracture ε_{2f}^{*} is obtained considering that the local strain loading path slope β^{*} remains constant. The slope β^{*} is obtained at the last measured strains by the DIC system $\left(\varepsilon_1^{DIC}, \varepsilon_2^{DIC}\right)$,

$$\beta^{*} = \frac{d\varepsilon_2^{DIC}}{d\varepsilon_1^{DIC}} \tag{4}$$

Finally, the limit strain pair at fracture $\left(\varepsilon_{1f}^{*}, \varepsilon_{2f}^{*}\right)$ will allow to represent the formability limit by fracture.

4 Results and Discussion

This section presents the determination of the principal strain pairs at the onset of necking and fracture of the experimental plan considered for commercial Polycarbonate sheets with 1 mm thickness by means of the methodology presented in Sect. 3. These principal strain states allow defining the formability limits by necking (FLC) and by fracture (FFL), thus allowing representing the Forming Limit Diagram within the principal strain space.

4.1 Formability Limit by Necking

The methodology described in Sect. 3.1 considered two different approaches to determine the principal strains at the onset of necking, using the time-dependent and the flat-valley approaches [10]. These two approaches were applied to a PC sheet [12] in four different Nakazima specimen geometries to obtain strain paths of tensile strain (TS), plane strain (PS), biaxial strain (BS), and equi-biaxial strain (EBS). As far as the authors are aware, this was the first time that the necking strains were determined in polymeric sheet by these type of approaches, which have been just used in the characterization of necking in sheet metal forming.

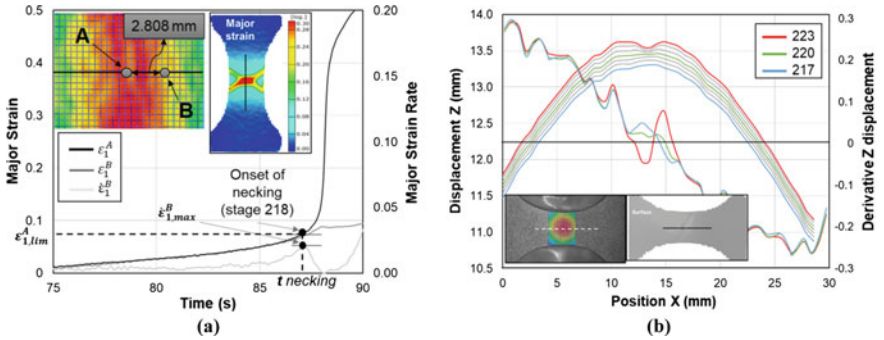

Fig. 4 Application of the methodology to obtain the onset of necking strains for a tensile strain (TS) Nakazima specimen of PC with 1 mm thickness using **a** the time-dependent methodology and **b** the flat-valley approach. (Color figure online)

Figure 4 presents the application of the two approaches to the TS Nakazima specimen of PC sheet. The time-dependent approach allowed to identify points A and B that define the instability region (Fig. 4a), where point B corresponds to the first point where the strain starts ceasing (i.e. onset of necking). The evolution of the strain rate for point B presented in Fig. 4a allows identifying clearly its local maximum $\dot{\varepsilon}^{B}_{1,max}$ and thus the time instant at the onset of necking $t_{necking}$. This approach allowed to obtain the onset of necking which occurs in point A, for the strains $\left(\varepsilon_{1,lim}, \varepsilon_{2,lim}\right)$ at the time instant $t_{necking}$.

The flat-valley approach applied to the TS Nakazima specimen is presented in Fig. 4b. The Z-displacement along a section perpendicular to the necking region presented in Fig. 4b allowed identifying the instant at which the onset of necking initiates (highlighted in green), where the thickness of the central region reduces faster than the adjacent regions and a flatten profile is visible, corresponding to the onset of necking. The spatial derivative of the Z-displacement along the selected section revealed the correspondence for the same instant the occurrence of a greater flatness confirming the onset of necking stage (Fig. 4b highlighted in green), and a sign change for the stages before (Fig. 4b highlighted in blue) and after (Fig. 4b highlighted in red) the onset of necking stage.

Figure 5 presents the application of the two approaches to the PS Nakazima specimen of a PC sheet. Time-dependent methodology is shown in Fig. 5a; the approach allowed identifying the onset of necking delimiting the instability region between point A and point B. In the same way as for TS specimen, the local maximum in the derivative of point B allowed to detect the $t_{necking}$ instant and accordingly, the strains $\left(\varepsilon_{1,lim}, \varepsilon_{2,lim}\right)$ for point A at the onset of necking.

Figure 5b presents the experimental evolutions of the Z-displacement and of the spatial derivative of the Z-displacement of PS Nakazima specimen. The flat-valley approach allowed to identify the onset of necking through the curve evolution; in this sense, highlighted in green corresponds to the instant of the onset of necking due to the slope remaining constant unlike red evolution when the flat is more accused.

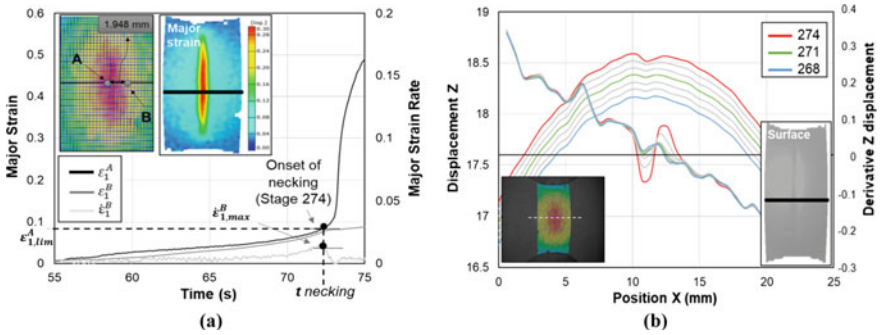

Fig. 5 Application of the methodology to obtain the onset of necking strains for a plane strain (PS) Nakazima specimen of PC with 1 mm thickness using **a** the time-dependent methodology and **b** the flat-valley approach. (Color figure online)

Through the first spatial derivative of the Z-displacement in Fig. 5b, the identification of the onset of necking (highlighted in green) is shown observing a greater flatness and a sign change between previous stages (highlighted in blue) and later stages (highlighted in red).

Figure 6 presents the application of the two approaches to the BS Nakazima specimen of the PC sheet. The time-dependent approach (Fig. 6a), similar to the previous cases (Figs. 4a and 5a), allowed to clearly determine the limit strains at the onset of necking that corresponds to point A strains $(\varepsilon_{1,lim}, \varepsilon_{2,lim})$ at the time instant $t_{necking}$. However, Fig. 6b shows that the flat-valley approach is not as direct, as seen, and the Z-displacement doesn't show a changed slope and the flat valley profile is not visible. As a consequence, the derivative of the Z-displacement does not show a difference in the evolution of the curves. As it was discussed in Rosa et al.[12], it could be necessary to increase the resolution of the DIC system to observe changes at the outer surface topology.

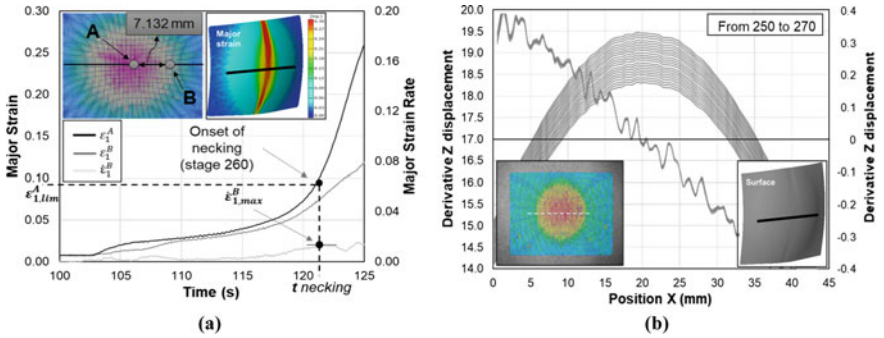

Fig. 6 Application of the methodology to obtain the onset of necking strains for a biaxial strain (BS) Nakazima specimen of PC with 1 mm thickness using **a** the time-dependent methodology and **b** the flat-valley approach. (Color figure online)

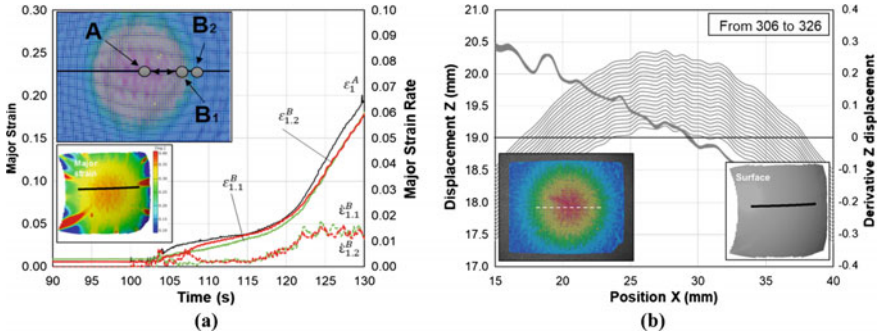

Fig. 7 Application of the methodology to obtain the onset of necking strains for an equi-biaxial strain (EBS) Nakazima specimen of PC with 1 mm thickness using **a** the time-dependent methodology and **b** the flat-valley approach. (Color figure online)

Contrary to the successful application of the presented methodology to the TS, PS, and BS Nakazima specimens, Fig. 7 presents the attempt to apply the two approaches to determine the onset of necking for the EBS Nakazima specimen of the PC sheet. The time-dependent approach revealed that the strain of a series of points along a section perpendicular to the crack showed no ceasing (Fig. 7a). Similarly, the flat-valley approach application in the EBS Nakazima specimen confirmed that the necking is not a failure mode for PC sheet under equi-biaxial strain (Fig. 7b).

4.2 Formability Limit by Fracture

The methodology to determine the fracture strains in metal sheets is based on the measurement of the fracture thickness of the specimens, as described in Sect. 3.2. This procedure, adapted by considering the local strain ratio β^* at the last stages, was applied to the PC for the four different Nakazima specimen geometries. The fractographies of the specimens were obtained with a NIKON® Stereo Microscope SMZ800N, with a magnification of $\times 30$, and allowed the measurement of the fracture thickness. Figure 8 presents the fractographies for a TS Nakazima specimen, where three different areas are clearly identified: transition zone, necking propagation zone, and fracture zone. The transition zone (Fig. 8c) corresponds to the transition between the necked area and the elongated zone, whereas the fracture zone (Fig. 8b) corresponds to the location where the fracture of the specimen occurs. In between these 2 zones, the propagation of the necking zone, typical of polymers, is visible [11].

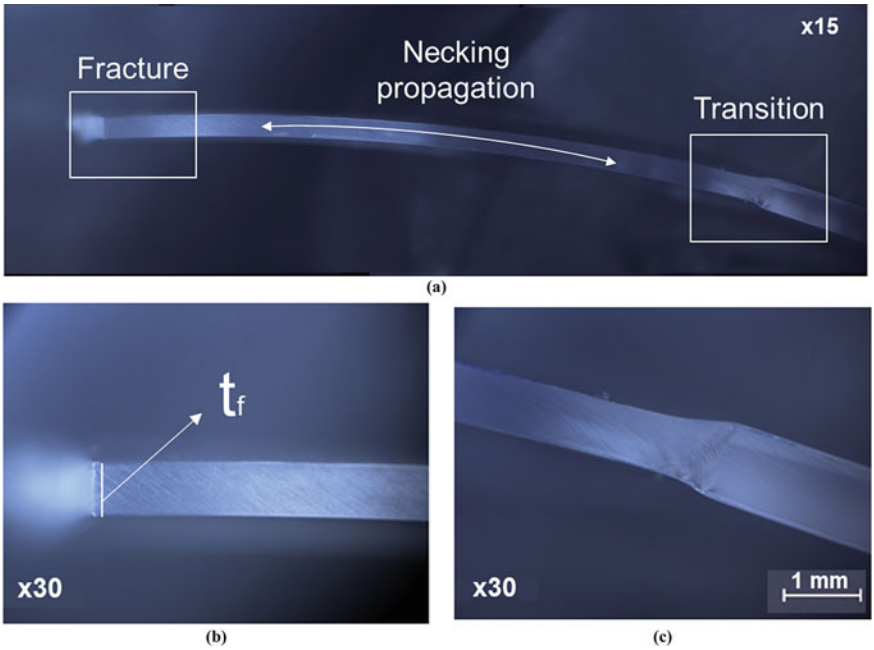

Fig. 8 **a** Fractography of a PT Nakazima specimen in the optical microscope with ×15 augmentation. Detailed view with ×30 augmentation of **b** the fracture zone and **c** the transition zone. (Color figure online)

4.3 Formability Limits in the Principal Strain Space

The formability limits by necking (FLC) and by fracture (FFL) represented in Fig. 9 were determined by means of Nakazima tests using the methodologies previously described in Sect. 3.

On the one hand side, the determination of the forming limit curve followed the methodology presented in Sect. 3.1 is based on the methodology used to determine the FLC for sheet metals. The FLC shows a different behaviour from those previously determined by Silva et al. [4] and Marques et al. [6]. The differences may be related to the use of a DIC system that gives a more accurate definition of the onset of necking due to the steady propagation of the neck than circle grid analysis, which allow measuring the strains only after fracture. The use of a DIC system and the proposed methodology revealed to be adequate to characterize the onset of necking in PC sheets. The resulted FLC can be represented by a straight line in opposition to the typical FLC of metal sheets that typically have a V shape.

On the other hand side, the determination of the fracture limit line (FFL-thickness) followed the methodology presented in Sect. 3.2 based on the procedure used to determine the FFL for sheet metal. This methodology was previously used by the authors [4, 6] and compared with the fracture strains obtained by means of single

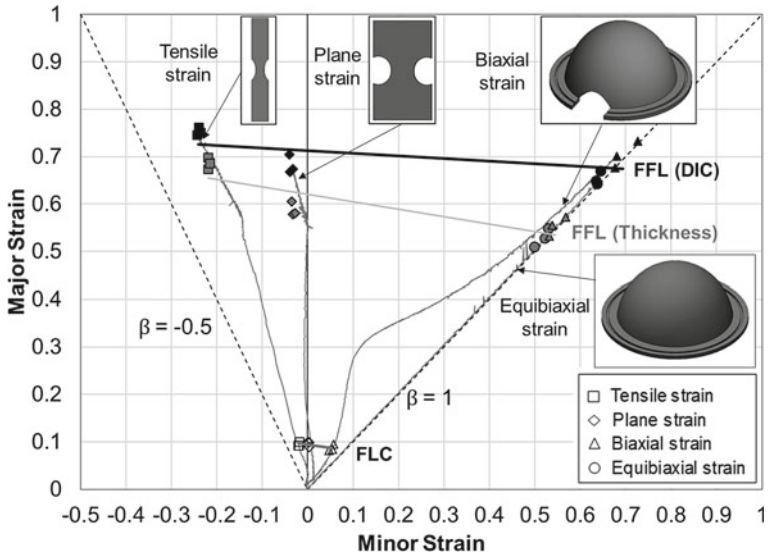

Fig. 9 Formability limits by necking (FLC) and by Fracture (FFL) for PC sheets obtained by means of Nakazima specimens in tensile, plane, biaxial, and equi-biaxial strains

point incremental forming (SPIF) parts. The fracture strains obtained in SPIF and Nakazima tests revealed differences that may be related to the significant springback that polymers experience. As can be seen, the limit strains according to the FFL-thickness are well below of those from FFL-DIC, due to the severe elastic recovery after fracture.

5 Conclusions

The methodologies used to determine the failure limits in sheet metal were adapted to polymeric sheet, allowing the successful determination of necking and fracture limits for PC sheet with 1 mm thickness.

The suiting of the methodology involved, for the first time ever, the determination of necking strains of polymer sheets by means of the time-dependent and flat-valley approaches usually used for sheet metals. The utilization of a DIC system revealed appropriate to obtain the experimental measurements of the strains regardless of the necking propagation typical of polymers, where other techniques like circle grid analysis revealed inappropriate. The resulted FLC for the PC sheet can be represented by a straight line in opposition to the typical FLC V shape for sheet metals.

The determination of the FFL was initially performed using directly the sheet metal methodology and it was verified that the resulting strains were lower than the last strains obtained from the DIC on the instant before fracture. This allowed

concluding that the fracture limit FFL-DIC obtained from the DIC, which can be approximated with a straight line, is the one that should be considered as the fracture limit.

The Effects of Press Ram Vibrations on the Production Quality

Bernd-Arno Behrens, Kai Brunotte, Richard Krimm, and Oliver Commichau

Abstract An indicator for the quality of products that are formed in an embossing process is the contour of the product. Highest contour quality is achieved, if the shape of the forming tool is perfectly imprinted into the material. However, elastic forces and tribological effects, which occur during the forming process, impair the shape-setting progress. In order to improve the embossing process, an electromagnetic actuation unit is presented in this paper, which applies horizontal vibrations into the press ram during the forming process. The actuation unit consists of two strong linear solenoids, which generate oscillating force with variable levels and frequencies. The vibrations improve the shape setting during the embossing process. The concept, design, and the function of the actuators are presented in this paper. Experimental studies on an embossing process in a production environment were performed, to demonstrate the features of the novel system.

Keywords Sheet-bulk forming · Ram vibration · Displacement control

1 Introduction

Sheet-bulk metal forming (SBMF) is a novel process that combines attributes of sheet metal forming and bulk forming operations. This process allows producing sheet metal parts, with very precise functional elements. The ability to merge multiple steps in one operation offers high potential to reduce the manufacturing costs [1,

2]. The SBMF process is defined as a sheet metal operation with a sheet thickness between 1 and 5 mm, combined with a three-dimensional material flow. It is a complex interaction between different forming processes. In order to gain more understanding of the SBMF process, this paper focuses on the appearance of horizontal forces and resulting press displacements occurring during the forming process. SBMF combines many different process steps and therefore depends on many process parameters. Embossing is one process, which can be included in a SBMF operation. The embossing process will be investigated in this paper.

During the embossing process, a topographic geometry is imprinted from the stamp of the tool into a workpiece. Mechanical presses apply high pressure on the part during the embossing process. Usually, the force is directed along the vertical axis of the press frame. Therefore, the rigidity of the press frame is optimized along the vertical axis [3]. However, especially when forming asymmetric parts, the force splits into a vertical as well as a horizontal fraction. The press frame rigidity along the horizontal axes is limited [4] As a result, the horizontal force can cause small amounts of deformation of the press and small displacement of the press ram versus the bolster of the press [5]. One reason for the possible displacement is, that the bearing, which holds the press ram in place, offers small amounts of clearance. The press ram can move horizontally within this horizontal clearance.

2 Superimposed Vibrations

Prior investigations have shown that forming processes can be improved by superimposing oscillations. For instance, the lifetime of a coining tool can be increased, since the vibrations reduced surface pressure peaks, which contribute to the tool wear. In Koch et al. [6], a hydraulic device was added to a sheet-bulk metal forming process. The hydraulic device superimposes vertical vibrations to the process. The results showed that the vibrations reduced the abrasive tool wear during the process. Nonetheless, the study has also proven, that the vibrations do not impair the quality of the tool in terms of accuracy of the geometry imprint into the workpiece. The positive impact of vibrations on the result of embossing processes has also been shown in Behrens et al. [7]. Oscillations have improved the mold filling during the process, allowing to produce within a smaller tolerance band. The paper Müller et al. [8] reports about the reduction of plastic work during the deformation stage by means of overlaying vibrations to the process. Applying vibrations has a number of positive effects on the result. Additionally, it was shown in Kirchner et al. [9] and Osakada et al. [10] that the total necessary force of the process was reduced by means of the vibrations. The reduction of necessary process force could be linked to a better tribological interaction between the tool and the workpiece [11], the reduced friction during the forming process has also been addressed in Siegert and Ulmer [12]. In

Izumi et al. [13], the reduced material strain during the material flow when superimposing ultrasonic vibration has been investigated. Results have shown a significant reduction of such material strains. The reduction of tool wear was studied and experimentally proven in Matsumoto et al. [14].

Overall, the vibrations improve the features of the forming process. However, these investigations focused on oscillations in vertical direction. The effects of horizontal vibrations, perpendicular to the ram travel direction, have not been addressed yet. The limited horizontal stiffness of mechanical servo presses allows to include a system, which is able to force a small-scale horizontal movement of the ram.

3 Horizontal Forces

Horizontal forces are likely to appear during an SBMF process, because many parts are not entirely symmetrical. That leads to an unequal force distribution in horizontal direction. As mentioned before, the forces can cause horizontal displacement of the press ram.

An electromagnetic system, which eliminates horizontal forces that occur during the forming of asymmetric parts by means of electromagnetic counterforce in combination with a control system, was presented in Groene et al. [15]. A numerical study has shown that solenoids with sufficient strength can react in real time to upcoming horizontal forces and hold the press ram in a defined position. In an alternative approach, hydraulic systems were used to reduce horizontal displacement during the forming process [16].

Taking into account, that vibrations of small amplitudes can improve the quality of the embossing process and that solenoids have proven to provide enough force, this paper proposes an actuation unit inducing horizontal vibrations to the press ram.

4 Press Ram Displacement

In order to determine the amount of the press ram displacement under horizontal load, a functional forming tool was designed, which can be used to execute embossing operations under variation of the associated horizontal force. As shown in Fig. 1, the central element of the tool is the stamp, which holds the topographic surface for the embossing. The stamp is held by a bearing. That can be tilted by the angle α between 0° and 10°.

The sheet metal will be placed between the upper and lower tool side, as shown in the figure. The upper tool is rigidly bolted to the press ram, the lower tool side is bolted to the bolster. During the embossing process, horizontal force appears. The maximum of the horizontal force depends on the tilt angle and the applied process force. The experimental study was carried out on a Schuler MSC-2000 press with a nominal force of 2000 kN. The process force in this investigation was set to 500 kN.

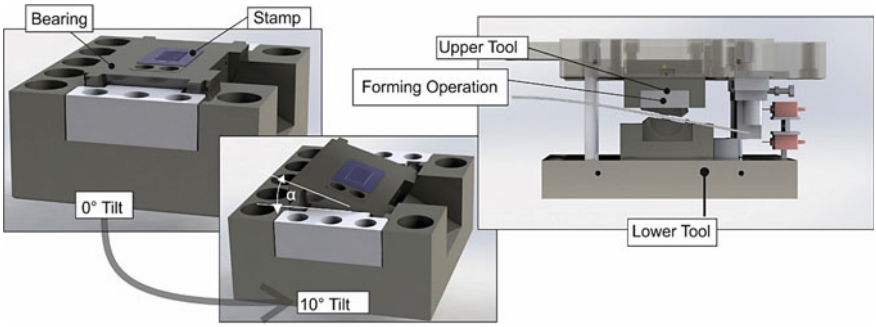

Fig. 1 Adjustable machine tool. (Color figure online)

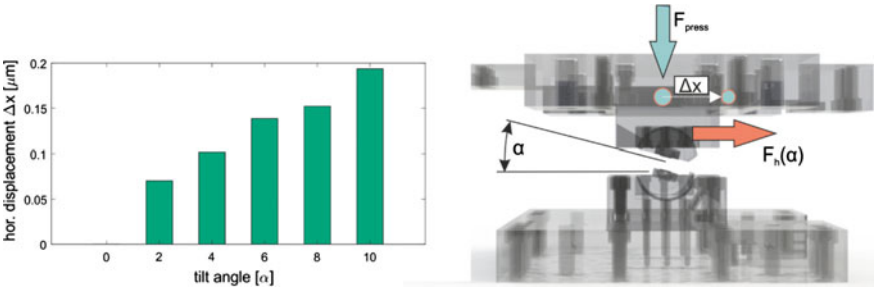

Fig. 2 Ram displacement under variation of the tool tilt angle. (Color figure online)

A Dual-phase steel DP600 with 3 mm thickness was used for the experiment. The measured displacements during the forming process are shown in Fig. 2. As expected, the ram displacement increases, the more the forming tool is tilted. Displacements of almost 0.2 mm have been measured.

The results of the study show that the horizontal displacement during forming asymmetric parts reaches values up to 0.2 mm. Splitting the resulting force into a vertical and a horizontal fraction shows that horizontal forces from 100 kN on are sufficient to trigger horizontal movements of the press ram. In the following section, the device for the application of vibration to the tool is presented.

5 Functional Design of the Actuator

The concept of the system is based on electromagnetic solenoids. The basic components are the magnetic core, a copper wired coil, and the armature. The core and the armature are separated by an air gap. The size of the air gap is adjustable. Both are made of the sheet-metal M400-50A, which has high permittivity. This will improve

the magnetic flux density and the solenoid force accordingly, since there is a proportional relation between those factors. When the coil is excited with a direct current, a magnetic field sets up. The magnetic flux follows the circuit through the magnetic core, passes through the air gap, and returns along the armature. A magnetomotive force appears as a counter effect, trying to close down the air gap for better magnetic flux. The coil is made of 1 × 4 mm flat copper wire with 250 windings. The design allows maximum currents of 20 A. Besides magnetic flux, the size of the pole face impacts the potential force of the magnet. The maximum force also depends on the number of coil windings and the inductivity accordingly. High inductivity leads to high total force on one hand. On the other hand, the inductivity limits the dynamics of the magnet. However, in order to create oscillating force, high dynamics are necessary as well. Therefore, a tradeoff between total force and the dynamics of the force had to be found. With the above-mentioned design parameters, the magnets are able to build up the maximum force of 100 kN in about 50 ms. Therefore, the maximum reachable frequency for this device is 10 Hz. Another limiting factor is the size of the mounting room inside of the press.

The solenoids are designed for use in the tryout press Schuler MSC-2000. A frame was designed which integrates the solenoids in the mounting room of the Servo Press. The designed structure consists of two parts: a frame that holds the armature, which is rigidly attached to the press ram. Another frame is used to connect the magnetic body to the bolster, containing the solenoids and the connectors. The air gap between the magnetic body and the armature is adjustable with a range between 0.5 and 3.5 mm. The non-conductive aluminum alloy EN AW-7075 was used for the mounting plate to avoid magnetization of the framework. There are two actuators integrated on the left side of the forming tool (see Fig. 4). In this setup, the solenoids can frequently pull the press ram to the left side, while the horizontal process force pushed the ram to the right side.

Two frequency converters DCM by Siemens power the solenoids. Both have a nominal current of 29 A. A controlling program was set up that sends the information about the desired frequency and amplitude of the vibration to the converter. This signal is given by a LabVIEW tool, allowing to adjust the amplitude, shape, and frequency of the signal. The LabVIEW tool is connected to the control system of the converter via an I/O-Box, which is connected to the digital and analog I/O ports of the converters. The concept is illustrated in Fig. 3.

The distance between the lower and the upper part of the tool, the ram displacement, respectively, is measured with a laser distance sensor M7L by MEL. The results

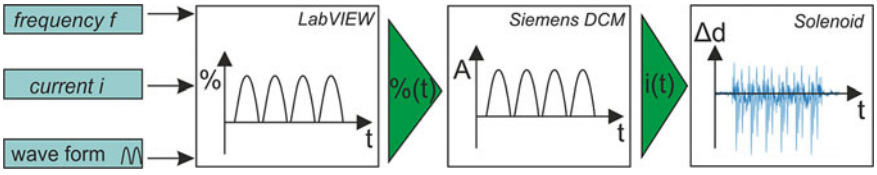

Fig. 3 Connection concept of the actuation unit. (Color figure online)

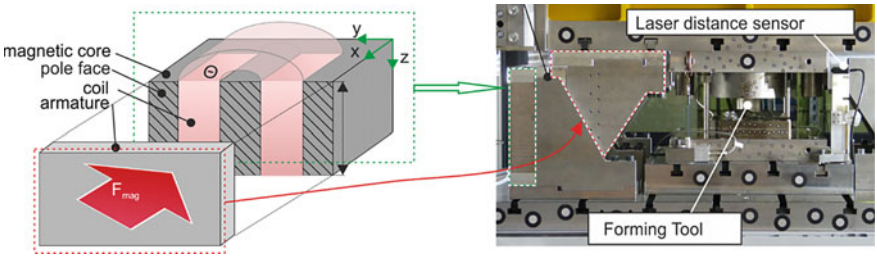

Fig. 4 Experimental setup. (Color figure online)

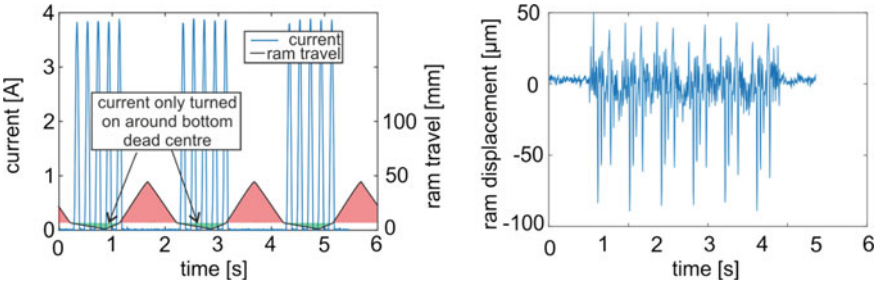
of the distance measurement are recorded with attached notebooks. Additionally, a height sensor was attached to the tool, measuring the distance between the press ram and the bolster of the press. The height measurement was used to only activate the solenoids, while the forming operation is performed. The solenoids must not operate during the backstroke to avoid unnecessary stressing of the press bearings and overheating of the magnets.

6 Oscillation Potential of Solenoids

The setup described in Fig. 4 was used to determine, whether the proposed device is functional. Firstly, the converter has an internal PI-controller, which needs to be set up with correct parameters, to ensure a stable control behavior. With the LabVIEW tool, the signal of a step function was transmitted to the converter, while evaluating the response of the converter. A set of parameters has been found by using the Ziegler–Nichols Method. This is a common heuristic method for tuning a controller.

In the next step, a sinusoidal signal was used to investigate the oscillation potential of the solenoids. The converter was set to 80% of the nominal current to ensure that the converter nor the solenoids experience any permanent damaging by over-excitation. During the experiment, the signals were recorded by the controlling system of the converter. The signals are shown in Fig. 5 (left). As shown, there is a lag of about 50 ms between the analog signal and the current. The lag appears because of internal processing time between the I/O-Ports and the current controller. However, the only consequence of the lag is a phase difference between the LabVIEW signal and the force generation of the solenoids. The oscillation itself is not impaired by this effect. Besides the phase difference, the current controller shows good controlling behavior, as it replicates the given sinusoidal signal perfectly.

The data was recorded while performing an embossing process with the tool presented in Fig. 1. The ram movement followed a sinusoidal path-time curve, as it is usual for eccentric presses. The vibration effect on the press ram by means of the sinusoidal force pulses is shown in Fig. 5 (right). The displacement is clearly detectable, while the ram oscillates in the same frequency as the solenoids. The



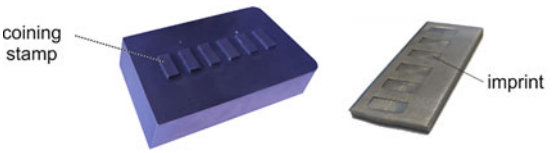


Fig. 5 Current injection in the solenoids and resulting ram vibration. (Color figure online)

amplitude of the oscillation is approximately 60 µm. The displacement graph was recorded while the stamp of the tool touched the workpiece and thus performed the embossing process. This shows that the solenoids are able to induce press ram vibration when the press ram is under load and applies high pressure on the workpiece.

7 Reduction of Abrasive Tool Wear

The production method of coining parts while superimposing the process with horizontal oscillations was tested in an experimental approach. A study was carried out covering the production of 2 × 10.000 coining parts. The experimental setup contains a forming press, a sheet-metal feeding system, and a reel-system. Additionally, the forming tool which was depicted in Fig. 1 was installed in the press. A more detailed description of the forming tool is given in Behrens et al. [17]. The described setup allows fully automated production of coined parts. The geometry of the coining stamp is a rectangular plateau structure, which imprints six plateaus into the sheet metal. The steel type DC04 was used as sheet metal (see Fig. 6).

During the experiments, the forming force was recorded by the press internal strain gauge. Two freshly produced sets of coining stamps were used to ensure comparability between the two production modes mentioned in the table in Fig. 6. A microscopic investigation on the surface of the coining stamps prior to and after the coining operation was performed. The surface roughness was measured along three lines (*left, center, right*) on the plateau (see Fig. 7). Abrasive wear, that leads to

material	DC04
production modes	10.000 - oscillation off 10.000 - oscillation on
geometry	plateau
stroke rate	40 / minute
force	260 kN

Fig. 6 Coining stamp, produced part, and production parameters. (Color figure online)

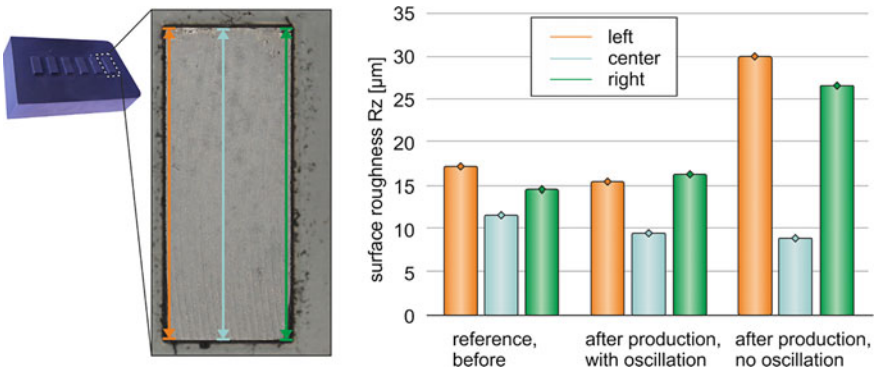

Fig. 7 Results of the microscopic evaluation of a single plateau. (Color figure online)

increased roughness values, was noted. While the coining process without oscillation leads to increased surface roughness, this effect cannot be observed while producing with superimposed oscillation. Further, as shown in the bar diagram, the tool wear seems to appear only on the edges of the plateau structured (orange and green) while the surface roughness remains unaffected on the center line.

The reason for that effect might be, that the material flow, which appears when the coining stamp forces into the sheet metal, always runs across the edges of the stamp. The highly frictional material flow then causes the abrasions. The center line on the other hand does not experience such material flow, since the material extrusion is always directed toward the outer edges of the stamp. Local pressure peaks between the stamp and the sheet could be smoothened by the horizontal oscillation which has the effect that less wear appears.

Although the extend of the study depicts only a small fraction of the lifetime of a coining tool, this study indicates that the abrasive tool wear could be decreased by superimposing the process with horizontal oscillation.

8 Conclusion and Future Work

In the first study, the displacement effect of horizontal force on the press ram position has been shown. Based on these results, an actuation unit was designed. The actuation unit presented in this paper is able to induce horizontal vibrations to the press ram. The development and build-up process were presented, furthermore experimental studies have been performed to determine the functionality of the device. The experiments have shown that solenoids are able to induce oscillating force to the ram and produce oscillating displacement, respectively. A small-scale production study shows indications, that the abrasive wear, that occurs during forming could be decreased by the superimposed oscillation.

Further studies on the potential amplitudes and frequencies are planned in this context. Furthermore, for a full understanding on the impact, a more comprehensive study with more complex coining structure as well as a higher production volume and higher forming force is planned.

Localized Contact Pressure of Blankholder for Stamping Irregular Sheet Parts by Configuring the Height of the Supporting Elements

Kuang-Jau Fann, Mathias Liewald, and Kim Rouven Riedmüller

Abstract This paper presents an engineering procedure for stamping irregular sheet metal parts with an elastic blankholder, providing a localized contact pressure to ensure stamped parts without failures of cracks and wrinkles. This is done by arranging the height of the blankholder supporting elements in a die set, which is made using standard manufacturing quality and is implemented in a press line equipped with standard die cushions. However, the contact pressure is very sensitive to the height of supporting elements. To eliminate the inherent noise from the geometric dimension and tolerance of the die set, a finite element model for optimization of the contact pressure must be created according to the actual die set geometry. In this study, the blankholder geometry for stamping a fender-like part was scanned by GOMATOS and the height of cylindrical supporting elements was measured by inserting feeler gauges between the blankholder and the supporting elements according to the outcomes of finite element analysis.

1 Introduction

In the past decades, a lot of research has been focused on the improvement of stamping press, die cushion, and die technology for manufacturing sheet metal parts with irregular geometries required by the automotive industry in an attempt to control the metal flow between blankholders by the blankholder force, and thus to produce reliable sheet metal parts. Among them, after the servo motor was introduced into the metal forming press [1], the servo press can form a pulsed pressure plate with its flexibility and programmability, especially in its characteristics of a pulsating ram

motion, which makes it widely used in sheet metal stamping industry. At the same time, it has attracted many scholars to engage in the related research of servo presses applied to sheet metal forming process [2–6]. Besides, as for the further development of the die cushions, which are implemented in the bed of conventional single-acting presses, some researchers have used the hydraulic cylinders with proportional servo valves onto the die cushion to control the blankholder force in the stamping process [7] or to provide a pulsating blankholder force [8]. Even multiple cylinders are used to form and to regulate the local blankholder force [7], so that the material flow can be more accurately controlled. As for the research of die technology application, it is based on the fact that the line of force formed between the press and the die cushion during the forming process is too long, that there are too many parameters, and that it is not easy to adjust one by one to ensure the accuracy of the forming results. Therefore, changing the blankholder to an elastic body is one of the ways that can form a localized blankholder force by multiple hydraulic cylinders with proportional servo valves configured for the localized blankholder force [9], and using closed-loop control technology is another way that the blankholder force can be controlled by monitoring the side wall stress of the parts during the stamping process [10]. However, this kind of solution is quite expensive. Alternatively, based on the fact that the single-acting presses used in the sheet stamping process are always equipped with die cushions, the idea that a thermal pin can be placed on the die cushion was thus proposed by [9] to change the blankholder force locally. The length of the thermal pin would be adjusted according to its temperature by heating or cooling, so that the material flow between the blankholder can be controlled and the goal of producing precision-stamped sheet metal parts can be achieved in such a cheap way.

To demonstrate the feasibility to convert the existing force control schema to a height control concept initiated by [9], a pre-study has been conducted by using finite element analysis to investigate the influence of the height of individual pins on the contact pressure between the elastic blankholder and the sheet metal from the resultant cushion forces [11]. In that pre-study, it was found that for applications of stamping fender-like irregular parts, there should be two layers of pins, thermal pins (upper layer) and cushion pins (lower layer), separated by an adapter plate, instead of just one layer. Furthermore, the thermal pins should be configured as supporting elements that closely surround the punch and are located underneath the sheet blank. Under this configuration, a sound part could thus be stamped with the pin heights, which is prescribed and correspondingly determined from the existing optimized pin forces. It was further observed that the elastic blankholder along with the supporting pins are quite stiff. The contact pressure is thus very sensitive to the height adjustment of the supporting pins, which is just in the manufacturing tolerance range of the current industry standard. If no extra care is taken to the tolerance between the parts of the die set, it might easily cause the sheet metal part to fail. This article is thus aimed to experimentally validate the previous finite element analysis, as well as to illustrate the implementation of the supporting elements, for a process stamping irregular sheet metal part regarding the geometric dimensioning and tolerancing in manufacturers' daily lives.

2 Elastic Blankholder Geometry and Finite Element Modeling

The fender-like irregular part used in the previous finite element study is the same as that for the study [10]. Its top face is a slender right trapezoid with different radii at the corners. The radii and size on its bottom face are larger than those of the top face. This irregular part has an inclined wall on each side, which easily induce wrinkles on the inclined walls during the stamping process and make this part hard to manufacture.

The die set used to stamp this irregular part with die cushion and elastic blankholder is shown in Fig. 1. It has a base plate to install the punch and to pile up other components. The cushion pins pass the pin holes of the base plate and lift an adapter plate. Ten supporting elements (thermal pins) are installed on the adapter plate to support the elastic blankholder. That means the adapter plate along with the supporting elements and the elastic blankholder move up and down simultaneously during the stamping process.

All the components of the die set are made and assembled with the current shop standard technique. In particular, the elastic blankholder, which needs a hard and polished top face, is manufactured as following: first, it is milled to a certain thickness, then it is case hardened, and finally it is ground and polished to its final thickness. However, the heat treatment during the case hardening might cause permanent deformation of the elastic blankholder. This deformation might not be able to be eliminated later in the grinding process, as it would be straightened by the uniformly distributed load added due to use of the magnetic workholding chuck during grinding. After grinding, when the chuck is off, the deformation would return as the load has been removed.

The deformation of the blankholder can be observed from the relative height distribution of its top face and its thickness distribution as shown in Fig. 2b, which were obtained by scanning both the top and bottom faces of the blankholder with the optical measurement system GOM ATOS 5M. Some outer areas of the faces were not scanned, because some fixtures to hold the blankholder affected the scanning

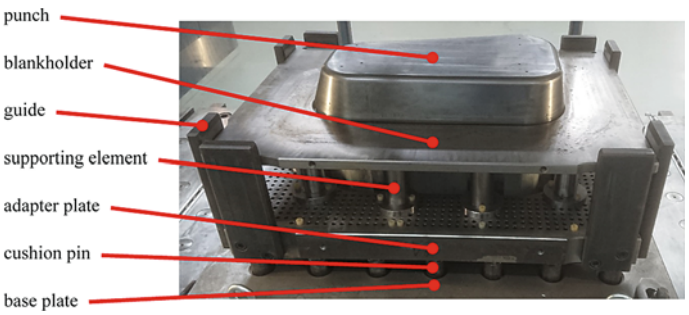

Fig. 1 Lower parts of the die set on a press bed. (Color figure online)

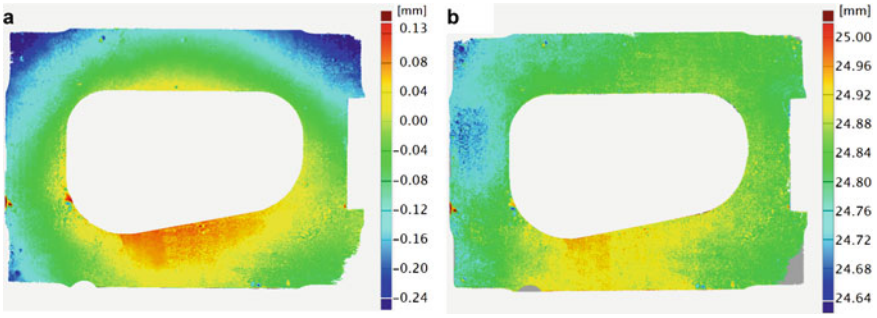

Fig. 2 Geometry of the blankholder **a** relative height of the top face, **b** thickness. (Color figure online)

results. It can be seen that the variation of the thickness is good within the general tolerance range, which is ±0.2 mm for medium tolerance class of a nominal linear measure less than 30 mm according to DIN ISO 2768-1, while the evenness shown in Fig. 2a is within 0.6 mm as the general form tolerance for a specified size less than 1,000 mm according to DIN ISO 2768-2. However, they are far beyond the tolerance for the demand of this application under investigation, in which every individual hundredth mm of the height of the supporting element can cause about 30 kN in the reaction force on the elastic blankholder according to the pre-study via finite element analysis [11]. The same situation also applies to the other components of the die set.

In the pre-study [11], among the components in the die set, only the blankholder is regarded as elastic deformable and modeled just as usual in finite element analysis modeling by directly using the geometry generated from CAD system. To consider the inherent noise attributed to the manufacturing, the actual deformation and thickness should be taken into account during the finite element modeling. This study is thus to investigate if the manufacturing noise affects the results of finite element analysis.

To model this kind of blankholder, the coordinates of the scanned point cloud on the top and bottom faces must be firstly transferred to the existing finite element model by matching all of them around the punch hole with those in the existing model. The point cloud is then transformed, so that the new coordinates of the point cloud can determine a plane by using linear regression, whose normal is the same as that of the existing finite element model and to which the summation of the distance of each point has a minimum. Thereafter, the centroid of the point cloud from the punch hole is preliminarily determined for translation also by linear regressing the point cloud of the long, short, and base side, respectively, while the inclined angle of the slant side is computed for rotation. Once the distance from the point cloud to the existing finite element model has its minimum from the four regarding sides by recursively determining the centroid and the inclined angle, the affine transformation matrix to transfer the whole point cloud is then ascertained. Figure 3a shows that top view of the point cloud on the top face of the blankholder (shown as black area) in comparison with the existing finite element model. It can be noticed that the actual

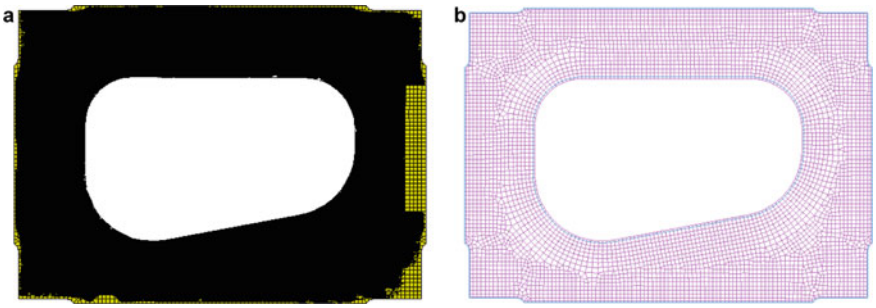

Fig. 3 **a** top view of the point cloud of the top face (*black*) above the existing finite element model (*yellow*), **b** top view of the finite element model for the blankholder in this study (*purple*) above that used in the previous study (*blue*). (Color figure online)

blankholder is smaller than that of the finite element model or as mentioned above from the CAD data. Because the number of the points in the point cloud is too huge to process the further finite element modeling, the faces are approximated and generated with GOM Inspect in a polynomial of degree three for the whole scanned points on the top and bottom faces. By means of projecting the nodes of the existing finite element model to the faces, the finite element model for the approximated actual elastic blankholder is then created, as shown in Fig. 3b. The nodes on the inner and outer edges, which are smaller than the CAD data, are extrapolated and trimmed from the existing finite element model. The blankholder is still modeled with four layers in the thickness. The coordinates of the elements in each layer are interpolated from those of the top and bottom faces.

The other components of the die set were not scanned with GOM ATOS further, because they are regarded as rigid in the previous study and will remain the same in this study. The other concern is that the interaction between the components during the stamping process is quite random, even though the die is driven by the press ram, and the die set is supported by the die cushion, all of which are principally well guided. However, based on the inhomogeneous evenness and thickness, previously observed with GOM ATOS, the base plate must not be exactly flat in order to lift the supporting elements and there should be some clearance between the top face of the supporting elements and the bottom face of the blankholder. The same argument also applies to the other components attached to the press ram and on the press bed. Since the parts are more massive and stiffer than the blankholder, the deformation of those parts are insignificant in this study. In order to get a more accurate description of the contact between the supporting elements and the blankholder, which essentially influences the stiffness of the elastic blankholder, the gap between the supporting elements and the blankholder has been checked with feeler gauges set in a thickness ranging from 0.01 mm. Figure 4a shows the results of the clearance, in which the value represents the minimum of the clearance at that range. That means that the value 0.1 shown for symbol i of #2 indicates the clearance at the inner edge toward to the punch hole has a range larger than 0.1 mm but less than

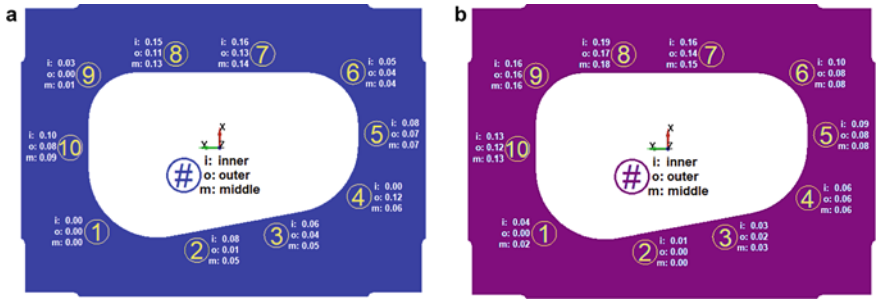

Fig. 4 Clearance from each supporting element to the blankholder measured **a** with feeler gauges, **b** from the finite element model at difference positions related to the punch hole (*o*: outer, *i*: inner, *m*: middle). (Color figure online)

0.11 mm. Correspondingly, the clearances between the rigid supporting elements and the elastic blankholder have been measured from the finite element model and shown in Fig. 4b. The difference of the clearance on each supporting elements can be attributed to that there exist the allowance varying from position to position caused by manufacturing the other components, as well as by assembling the components to the die set. Nevertheless, referring to these clearance results, the finite element model for each supporting element should be correspondingly rotated. This would let the existent contact situation between each supporting element and the blankholder along with the feeler gauges be able to be carried out approximately, because the clearance is significant to the results of this study as mentioned later.

3 Stamping by Elastic Blankholder with Supporting Elements

The finite element analysis of the stiffness of the blankholder with supporting elements has been conducted with LS-DYNA implicit code in the previous study [11], in that, the four elements having a relative lower stiffness are fixed lower than the other six elements and the blankholder is then pressed with the rigid die toward the fixed pins for a given stroke. The blankholder and the supporting elements were modeled as flat. As shown in Fig. 5a, it can be observed that at different position where each supporting element locates, the blankholders have similar stiffness, which is equivalent to the slope of the curves shown in Fig. 5. Furthermore, no gap or backlash-like characteristics can be recognized at the locations of the stiffer supporting elements, while at the positions with less stiff elements a backlash-like characteristic can be recognized. This is because their lower top faces contact the blankholder later. Contrastively, the results from this study shown in Fig. 5b reveal that all positions have a backlash-like characteristics, which shows up as an nonzero

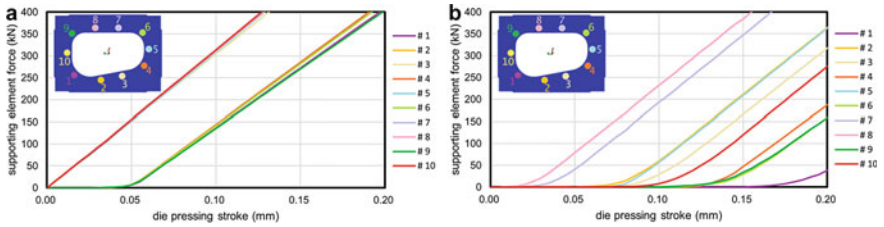

Fig. 5 Stiffness of the blankholder from a finite element model of **a** the previous study [11], **b** this study. (Color figure online)

abscissa intercept on each curve, no matter how high the top face of their corresponding supporting element are. Even the top face of each supporting element is modeled as flat and its maximum clearance to the blankholder is less than 0.0015 mm. The minimum backlash of at least 0.25 mm can be found even at the locations having the strongest stiffness (element #8). This deformation and inhomogeneity in thickness can be attributed to the blankholder being modeled to more or less reflect the actual state after manufacturing.

With such backlash-like characteristics, the distribution of the contact pressure of the blankholder to the blank is then dependent on the total cushion force applied in this study. If the cushion force is small, say 200 kN, there are only two spots popping up on the contact pressure imprint from the supporting elements 7 and 8, because their backlashes are the smallest. If the cushion force reaches 1,110 kN, the backlash of most all supporting elements except the element 1 are eliminated and the corresponding contact pressure appears as shown in Fig. 6b. However, the distribution is quite inhomogeneous in comparison with that from the previous study without regards to the backlash as shown in Fig. 6a. As the backlash is reduced, the contact pressure increases and is spread over a wider area.

Similar results can be observed in the step loading test with LS-DYNA explicit code as shown in Fig. 7, in that, the cushion force stepwise acts on the blankholder from 200 to 800 kN in step of 200 kN, while the die presses and the supporting

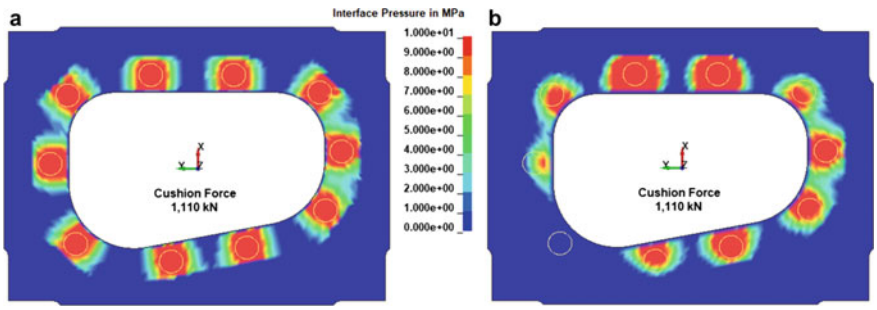

Fig. 6 Contact pressure of the blankholder under the cushion force of 1,110 kN from a finite element model of **a** the previous study [11], **b** this study. (Color figure online)

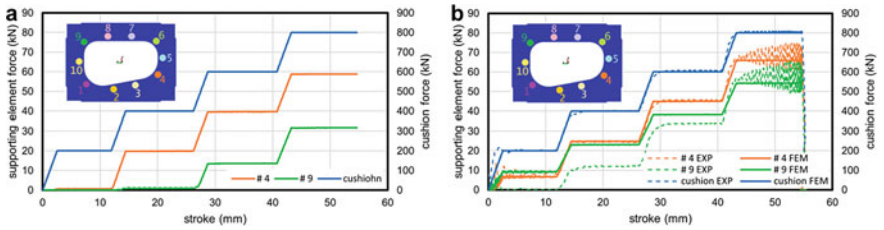

Fig. 7 Force diagram of the supporting element 4 and 9, which is 0.01 mm and 0.02 mm lower than the remaining elements, respectively, from **a** the previous study [11], **b** this study and from experiment. (Color figure online)

elements at position 4 and 9 were positioned 0.01 mm and 0.02 mm lower, respectively, than the remaining elements. The expected results should be those shown in Fig. 7a, in that, the force at position 4 appears first when the cushion force reaches 400 kN and later then the force at position 9 when the cushion force 600 kN. There were no backlash-like characteristics found there due to the intrinsic characteristics of finite element modeling in the previous study, in which the blankholder and the supporting elements are idealized as flat. However, the response shown on the position 9 in the lower loading steps from the results of this study in Fig. 7b can be considered to be the backlash effects from the other elements. It is based on the observation that the blankholder on the position 4 and 9 has similar stiffness there and the curves for the forces there should be parallel to each other, but the force on the position 9 is higher than that on 4 at the beginning and is significantly lower later.

Actually, the step loading test shown in Fig. 7b can be used to determine the backlash on each supporting element in this finite element model, because only the blankholder is modeled as elastic and the superposition method can still be applied. Besides, all available CNC die cushion in the current market can only provide limited number of points to set constant cushion forces for certain cushion stroke range. Therefore, the step loading test actually matches the cushion objective. However, the backlash in the actual die set is very complicated to specify, because all components are elastic and plays always exist among them. Nevertheless, from Fig. 5b, it can be observed that there should no backlash exist for sure, if the applied force is over the threshold, such as 50 kN. This is why the force deviation in Fig. 7b between the results of the finite element analysis and the experiment can be regarded as the backlash effects from the other components. These backlashes cause the results of the finite element analysis shown in Fig. 7 from these two studies to be different to each other. The step loading test with a total cushion force, which can let the force on some supporting elements less than the threshold to detect the backlash characteristics. Depending on the applied step load, the backlash status on each supporting element can be detected with the response force there. The backlash on each supporting element can further determined with the procedure described as follows:

First, the height of each supporting elements is determined, so that all of the supporting elements have the same backlash. According to the needed blankholder force on each supporting element, the further height of each element can be roughly

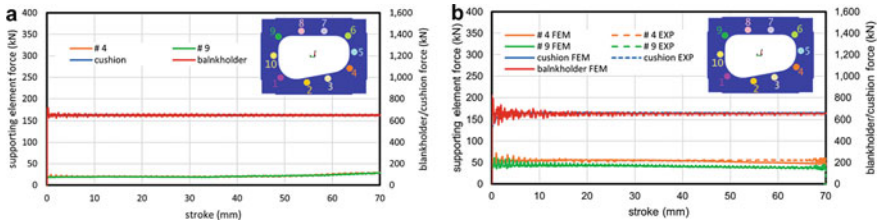

Fig. 8 Force diagram for a stamping irregular sheet part from a finite element model of **a** the previous study [11], **b** this study and from experiment. (Color figure online)

determined by dividing by the stiffness of the blankholder on that element. A first run of the simulation with the height of each element determined by the two previously mentioned steps can then provide the forces on each element. More information of the forces on each element can be provided by further runs of the simulation with the height of each element changed within the range of the feeler gauge, 0.01 mm, in a manner of design of experiment. From the force information obtained by finite element simulation and by the experiments, the backlash on each supporting element can then recursively determined by means of the response surface methodology with the objective of minimum difference of the force between the finite element analysis and the experiments.

Once the backlash on each supporting element has been confirmed, a stamping process can then be conducted. A DC04 sheet in thickness of 1 mm stamped with a constant cushion force of 650 kN for a stroke of 70 mm was conducted in the previous study [11], in that the blankholder force optimized by [6] on each supporting element is approximated by adding the height of the supporting element with feeler gauges. Figure 8a shows the reaction forces on the blankholder and on the supporting elements. The forces on the supporting elements are directly calculated from stiffness about 12 kN, but the results from the finite element analysis shown here are higher as 21 kN. Even though the cushion force stands constant during the stamping process, the force on the blankholder and the supporting elements wobble all the time. It can be attributed to the dynamic nature instincts of explicit finite element code. This phenomenon can also be observed in this study as shown in Fig. 8b. However, those forces from the experiment shown in Fig. 8b, which was executed in an AIDA servo press having the ram capacity of 6,300 kN and the cushion capacity of 1,500 kN along with a centered pattern of 150 mm $\times$ 150 mm for cushion pins of 50 mm diameter each, stay calm. The average force on the supporting element 9 from the finite element analysis is the same as that from experiment, 42 kN, while that on the element 4 is 55 kN and a little bit higher than that from experiment, 53 kN. Figure 9 shows the stamped irregular sheet part, which is made of the first shot and a sound part.

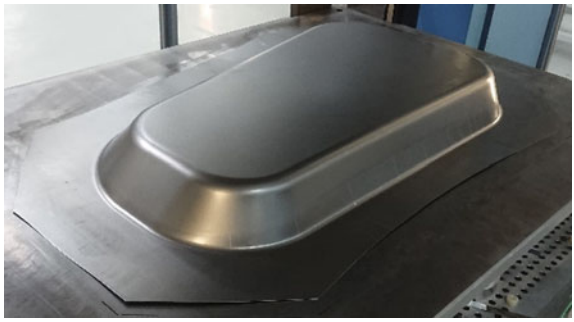

Fig. 9 A stamped irregular sheet part on the elastic blankholder. (Color figure online)

4 Conclusions and Future Works

This study conducts a finite element analysis with a model close to the actual geometry and setup of the blankholder for stamping an irregular sheet metal part. This study investigated the influence of the inherent noise of the geometry induced by current manufacturing processes. These results would be applied in a future study about potential uses of thermal pins to regulate the contact pressure on the blankholder by heating and cooling them to alter their heights. The finite element model of the blankholder is created on the basis of a fitted geometry generated by the optical measurement system GOM ATOS 5M after scanning the blankholder. The clearance between the supporting elements and the blankholder is measured with feeler gauges. Except for the blankholder being modeled as elastic, all other components of the die set including the supporting elements are modeled as rigid in the finite element model.

As a result, the actual blankholder with the supporting elements has backlash-like characteristics. Once the backlash is removed, the blankholder and the supporting elements are all linearly elastic; therefore the superposition method can be applied. However, the present contact pressure built up from the elastic blankholder along with the supporting elements is strongly dependent on the backlash behavior there. Nevertheless, this backlash can be determined by means of a step loading test proposed by this study, when a minimum of force difference between the finite element analysis and the experiments is achieved by recursively modifying the value of the backlash. With this tedious preparation to determine the actual geometry of the blankholder and to confirm the backlash-like behavior related to the supporting elements, a finite element model can be prepared. The model would be used to optimize the process of using an elastic blankholder supported with supporting elements by regulating their heights to adjust the localized contact pressure for stamping irregular sheet parts.

The experiment conducted in this study validates this process, which further makes the process proposed by [9] more feasible, in that, the localized contact pressure of the blankholder would be controlled by regulating the length of thermal pins implemented onto the die set. Therefore, for the future works, it is worth to first develop the process efficiently determining the geometry of the blankholder and

confirming the backlash-like characteristics related to the supporting elements to shorten the preparation period.

Evaluating 980GEN-3 Steel with Tested and Numerical Forming Limit Curves

T. Feister, L. Zoller, J. Gu, and H. Kim

Abstract Forming limit curves (FLC) are widely accepted by industry for predicting necking failure during sheet metal forming. FLCs can be developed directly through material testing or by numerical extrapolation from tensile data. This work evaluates the accuracy of FLCs developed from Nakajima testing using the linear-best-fit method to Keeler, Arcelor V9, and Tata Steel FLC models that are available in the commercial FEM software. Two different stamping shapes and three variations of 980GEN-3 steel were used for physical testing to evaluate the FLC models.

Keywords FLD · FLC · Material variation · Numerical forming limits · FEA

1 Introduction

Using finite element analysis (FEA) has become a standard procedure for determining the formability of a part shape with a given material. Strain-based forming limit diagrams (FLD) remain the most commonly used tool for predicting necking failure during forming. The accuracy of simulation models is directly dependent on the material data that is defined.

Obtaining FLD from experiments would be the more preferable option; however, it can be costly. The problem of accurately predicting part feasibility is made more complex when material variation is considered. FLD changes with material thickness, from one coil to another and even within the same coil.

2 Objective

The objective of this study was to establish a cost-effective method of determining FLD limit diagram for high-strength 980GEN-3 steel using only tensile testing data. Tested FLD and numerical FLD were used to predict splits on two different stamping parts with known failure strain paths.

3 Approach

Three variations of 980GEN-3 steel were evaluated with tensile testing (Fig. 1) and Nakajima forming limit testing. The variations of material were selected to provide a large difference in yield strength (YS) and ultimate tensile strength (UTS). Table 1 shows the difference in yield and ultimate stress between the three variations. Tensile samples were machined in each of the 0, 45, and 90 degrees to the rolling direction. Three samples were tested in each orientation. Axial and transverse extensometers were used to measure the anisotropic coefficient r-value during testing.

Table 1 Rolling direction mechanical properties for three variations of 980GEN-3 steel

Sample	YS (MPa)	UTS (MPa)
1	620	1046
2	636	1007
3	646	1038

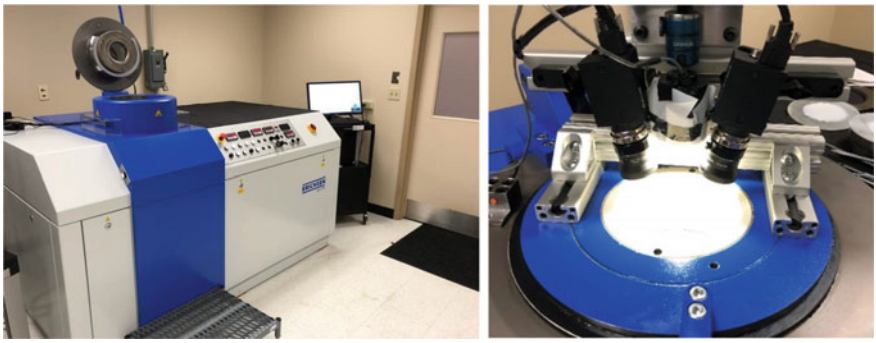

Fig. 2 Erichsen sheet metal forming machine (left) and DIC fixturing (right). (Color figure online)

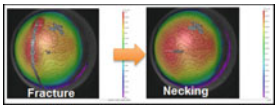
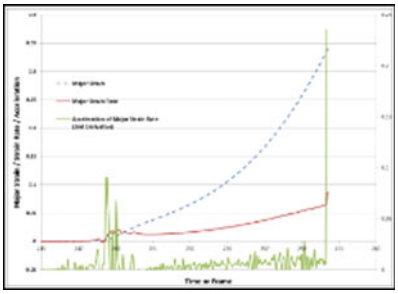
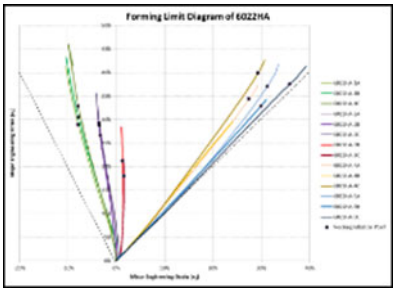
Nakajima forming limit testing was conducted on an Erichsen sheet metal testing machine (Fig. 2). Five types of Nakajima samples were water jet cut. Digital image correlation (DIC) equipment was used to measure the strain during testing. The linear best fit method (Table 2) [1] was used to establish detecting the necking initiation point.

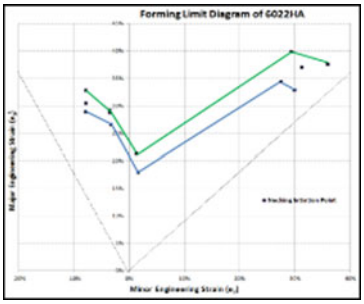
Forming tests were conducted on a 300 ton AIDA servo mechanical press. A universal forming tool and a cross-form tool were used as shown in Fig. 3. 250 kN blank holding force was required to prevent wrinkles on the parts. The forming stroke was adjusted incrementally until necking was observed in the formed parts. One universal formability part was marked with an ARGUS pattern for subsequent strain measurement.

Forming simulations for the universal forming and cross-form dies were performed using PAM-STAMP. Tensile and FLC testing data were used to create material cards. The Coulomb coefficient of friction of 0.12 was used. The Hill 48 yield criterion was used initially. The simulation stroke was defined to match the forming depth that resulted in necking in the physical parts.









The draw-in of one universal forming part was measured with an ATOS blue light scanner. The strain was measured with ARGUS stain analysis. The draw-in and strain were used to compare with simulation results.

4 Results

The FE-predicted flange draw-in length was well matched with the blue light scan results (Fig. 4 and Table 3). However, the predicted maximum strain (36%) fell short of the 40% ARGUS measurement. Various yield criteria were used and compared against the strain measurement. Vegter Lite yield criterion [2] was shown to have the best correlation with the experiment (Fig. 5).

With the Vegter Lite yield criterion and the tested FLC, the formed part strain is slightly over the FLC for the universal forming part (biaxial) and slightly under

for the cross-form (uniaxial) part (Figs. 6 and 7 respectively). The correlation was reasonably good.

The experimental FLCs were compared to numerical FLCs extracted from tensile data alone. Keeler FLCs are higher than the tested FLCs and overpredicted the formability (Fig. 8). Figures 9 and 10 show a good comparison of both Tata and Arcelor V9 FLCs with the tested FLCs.

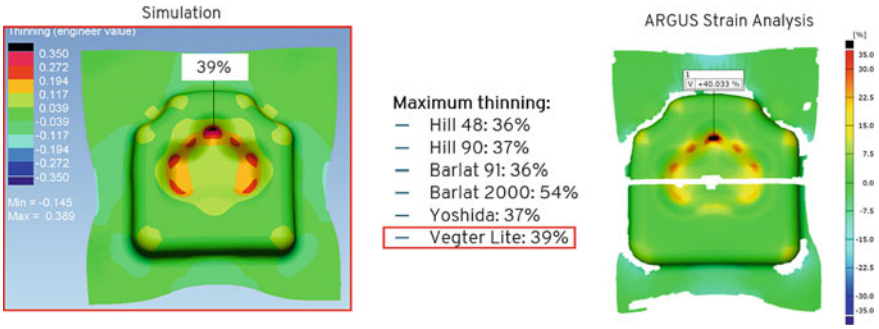

Fig. 5 Maximum thinning as a function of yield criteria compared to the ARGUS strain measurement. (Color figure online)

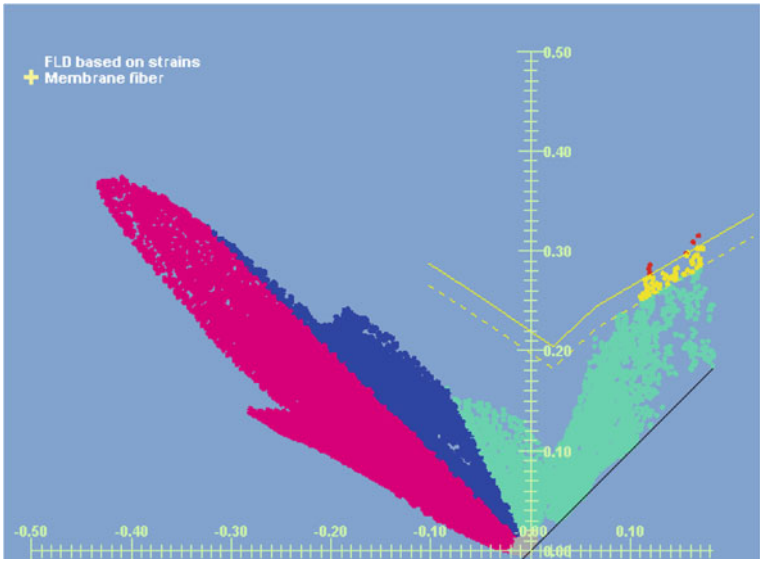

Fig. 6 The universal forming simulation strain path exceeds the forming limit at the end of the stroke. (Color figure online)

5 Conclusions

This work confirmed that the Hill 48 yield criterion is not well suited for modeling sheet forming of high-strength steels. Simulation with the Vegter Lite yield criterion provided a good match of the peak strain when forming 980GEN-3 steel. The linear best fit method gave an accurate forming limit curve that correlated well with biaxial and plane strain failure paths. The Keeler forming limit curve overestimated the formability of the 980GEN-3 steel. Both Tata and Arcelor V9 numerical curves match well with the tested forming limit and the physical necking imitation stroke.

Formability of Functional Corrugated Cup

Y. Harada and Y. Nishikubo

Abstract The formability of the corrugated clad cup was investigated to enhance the functionality of the cup. Deep drawing, which is one of press forming, is a plastic processing technology for forming a thin plate into a three-dimensional container. Depending on the application, the functionality of the container itself was required. In the present study, the drawn cup with a corrugated structure on the side wall was formed by deep drawing. In the experiment, the materials were pure titanium TP270, low carbon steel SPCC, and stainless steel SUS304. In the deep drawing process, the composite die combining the roller die was prepared for forming a clad cup. In the side wall of the corrugated cup, the distance between the waves was approximately 8.6 mm. The thickness strain at the bottom of the drawn cup TP270 was no more than 0.06. It was found that the corrugated clad cups were successfully formed by using the composite die combining the roller die.

Keywords Deep drawing · Pure titanium · Corrugated cup

1 Introduction

In the press forming of a metal sheet, there are processes using deep drawing deformation, bulging deformation, stretch-flange deformation, and bending deformation. Process design and die design are often performed for processing methods using these deformations. In the case of deep drawing, experimental and theoretical studies have been conducted on the shape and material of punch and die dies [1], formability of blanks [2], and selection of lubricants [3]. In addition, research on the forming of containers having functions such as high strength and high corrosion resistance has been conducted for a long time. The performance of CrN film coating to reduce adhesion in the forming process of advanced high strength steel sheets was investigated [4]. The hot-rolled Al/Mg/Al laminates were used to conduct deep drawing at

various temperatures, and microstructure evolution of three typical regions including bottom, corner, and wall was investigated [5].

There have been many research reports on ironing, thickening, embossing, etc. to improve the strength of the side wall of the container. A heat treatment cycle, hardening by water quenching followed by prolonged tempering, was proposed for enhancement of strength and formability of Al-killed AISI 1040 graded steel strips [6]. The modeling and the corresponding experimental validation of angular deep drawing parameters on the tensile strength, wall thickness, and height of the square profile cups was investigated [7]. The effects of embossing and restoration process on the deep drawability of aluminum alloy sheets were examined [8]. In addition, research on the forming of clad containers using laminated sheets is also being conducted. The reason for using a laminated sheet is that the functionality is improved beyond the properties of a single sheet. The effects of several parameters on the deep drawing process of laminated sheets are comprehensively studied [9]. On the other hand, in our research group, the formability of highly corrosion-resistant titanium cups was investigated using titanium materials, one of the functional materials [10, 11]. Titanium is a metal that has high corrosion resistance and is lighter than steel. In many products, such as chemical plants and medical applications, the range of use of titanium is expanding [12]. In previous study, deep drawing of clad cup was performed using a laminate of pure titanium and carbon steel sheets [13]. Each sheet was simply in a stacked state, and the sheets were not joined to each other. The clad cup was formed simultaneously with the deep drawing deformation. Furthermore, attempts were made to form a unique cup that developed the method of forming a clad cup [14]. In addition, we focused on a panel having a corrugated shape and attempted to form the cup having corrugated side walls. In the present study, we formed the corrugated clad cup by deep drawing using the composite die incorporating the roller die and investigated mainly the formability.

2 Experimental Procedure

2.1 Materials

The blank for deep drawing was cut from cold rolled metal sheet by shearing and blanking. Three types of blanks, pure titanium TP270 (high purity type), an ultralow-carbon steel (SPCC: Steel Plate Cold Commercial), and austenite stainless steel SUS304, were used. A pure titanium blank was mainly used. Austenite type steel is the most widely used grade of stainless steel due to its excellent formability and corrosion resistance [15]. The initial diameter and thickness of the blank were 80–85 mm and 0.3–0.5 mm. The die and punch were cold-work tool steel JIS-SKD11. They were heat treated under standard conditions.

Fig. 1 Appearance of actual roller die. (Color figure online)

2.2 Deep Drawing

A trial production of the roller die was performed to form the cup having a wavy side wall. Actual appearance of the produced roller die is shown in Fig. 1. The groove was machined at the shoulders of the die. To deform the side wall of the cup into a wave shape, steel balls were placed in the groove without the gap. The steel balls were rotated during drawing. Steel ball was bearing steel, the diameter was 10 mm. The clearance between the punch and die was set to be equal to the thickness of the sheet. Next, the composite die combining the roller die was prepared for forming the clad cup. Figure 2 shows the schematic illustration of the composite die. The composite die is composed of three dies. Each die is provided with a blank. After the first blank is formed by the upper die, it is formed by the roller die and the lower die to finally form the corrugated clad cup. The deep drawing process was performed using an oil hydraulic press at a forming speed of approximately 10 mm/min. A punch diameter was 40 mm, and the drawing ratio was 1.67 at the upper die. A shoulder radius of punch was 3 mm. The lubricant was the solid powders of molybdenum disulfide (ThreeBond 1910 type, specific gravity: 1.6, viscosity: 1.6 Pa-s). The forming conditions of deep drawing are shown in Table 1.

2.3 Measurement of Thickness Strain and Hardness

The thickness of the drawn cup was measured from the center of the bottom of the cup to the side wall using a digital micrometer (Digimatic outside micrometer type, by Mitutoyo Corporation). In the rolled sheets, it is known that anisotropy is caused by a crystalline structure. The thickness strain of the deep drawn cup was measured along a direction parallel to the rolling direction of the blank. Vickers hardness test was also performed to measure hardness of the drawn cup after deep drawing. The measuring instrument used was the micro Vickers hardness tester (by Akashi Seisakusho, Ltd.).

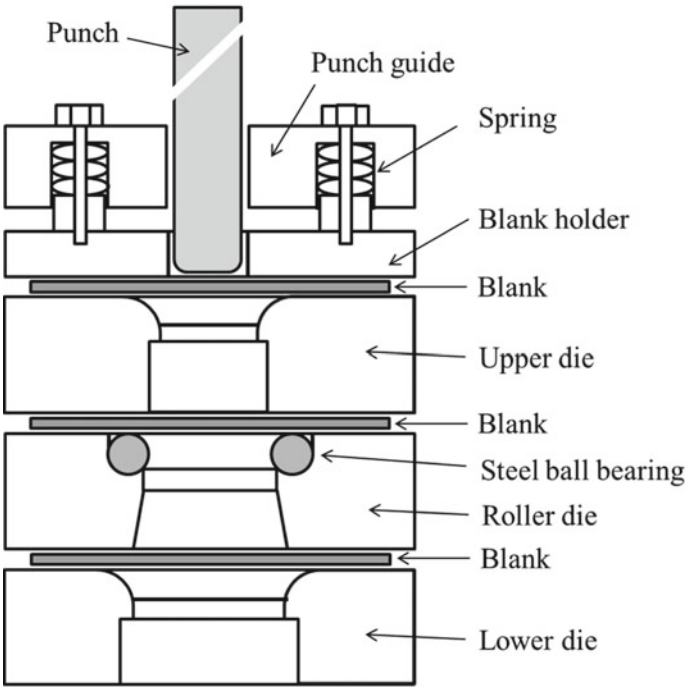

Fig. 2 Deep drawing process by composite die

The hardness of the drawn cup was measured from the center of the bottom of the cup to the side wall. The hardness value was calculated by averaging seven or more measurements.

3 Results and Discussion

3.1 Visual Appearance of Drawn Clad Cup

Using the prototype composite die, a corrugated clad cup was formed. Figure 3 shows the appearance of the corrugated clad cups. The initial blank thickness is 0.3 mm inside the cup and 0.4 mm for the others. The metal constituting the clad cup was the same material. The formability of the drawn cup was sufficient and no fracture at the bottom or wall occurred. Although the outside cup and the inside cup, which were strongly attached to each other, of the clad cup were not bonded to each other, the clad cup could be separated by cutting. In addition, wrinkles were observed at the opening of the drawn cup, as the blank holding force was not sufficient at the opening. In the case of the pure titanium cup, ears were remarkably observed at the

cup opening due to the anisotropy. It is well known that planar anisotropy causes ears to form in drawn cups, producing a wavy edge [16]. Earing is defined as formation of waviness on uppermost section of deep drawn cup [17]. Due to the occurrence of ears in the openings, the effect of blank holder was reduced. On the other hand, the outer diameter of the drawn cup was measured to examine the formability of the clad cup. In the case of the drawn cup SPCC, the outer diameter of the cup was 46.2 mm near the bottom and 46.3 mm near the opening. Similarly, the dimensional error of the outer diameter was small in other cups.

3.2 Evaluation of Formability of the Drawn Clad Cup

Since the inner structure was not visible on the side wall of the drawn cup, the cladding cup was cut. Figure 4 shows the structure of the side wall cut near the center of the drawn cup TP270. The initial blank thickness is 0.3 mm inside the cup and 0.4 mm for the others. There was a gap in the side wall, and a regular wave shape was observed. In the side wall of the cup, the distance between the waves was approximately 8.6 mm. Although wrinkles were observed at the opening of all cups, forming was possible. In addition, as a result of observing the cut portion in other cups, a wavy structure was observed (Fig. 5).

Fig. 3 Appearances of drawn clad cup. (Color figure online)

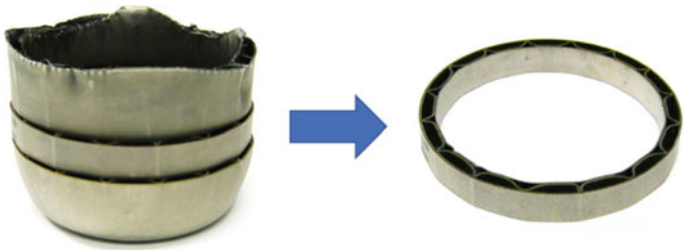

Fig. 4 Cutting near center of side wall of drawn cup TP270. (Color figure online)

Fig. 5 Wavy structure near center of side wall of drawn clad cup

After the cold deep drawing, it is well known that the thickness distribution of formed cups is uneven. The thickness of the wall at the bottom corner tends to decrease, whereas the thickness at the opening tends to increase. The thickness of the drawn clad cup was also measured. Figure 6 shows the thickness strain distribution of the drawn cup TP270. The initial blank thickness is 0.3 mm inside the cup and 0.4 mm for the others. The thickness strain was measured toward the opening from the bottom center of the cup. In the case of corrugated cup, the thickness of the recess on the wavy side wall was measured. In the inside cup, the increase in thickness strain was larger than those in the other cups. Furthermore, the greatest reduction in thickness strain (approximately -0.06) occurred at the bottom corner of the cup. Similarly, for the cup SUS304 and the cup SPCC, the thickness strain was similar to that of the cup TP270.

In the middle cup formed by the roller die, the thickness strain increases near the bottom of the cup. Such a change does not occur in a conventional deep drawing cup [18]. The position showing the increase is an area in contact with a hard ball placed on the shoulder of the roller die. The contact area of the steel ball (red circle)

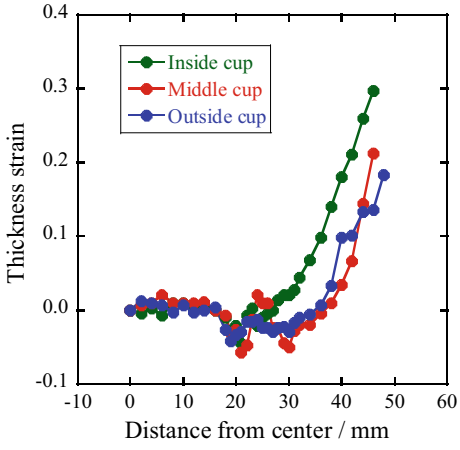

Fig. 6 Distribution of thickness strain of drawn clad cup TP270. (Color figure online)

is shown in Fig. 7. When the material is deformed by the steel ball, the material plastically flows outward. Therefore, the material surface after being brought into contact with the steel ball is in a plastically deformed state. Since the material flows to an unconstrained surface, the thickness strain increases. The mechanism of the increase in the thickness strain is shown in Fig. 8. The material being deformed tends to undergo plastic flow.

The metal sheet after plastic deformation is work-hardened. Work-hardening coefficient (n value) of pure titanium is considerably smaller than other metals. In the case of TP270 type, it is approximately 0.148. Deep drawing was a severe process, however, the hardness of the drawn cup was examined. Hardness of the drawn cup after forming was examined. Figure 9 shows the hardness distribution at the side wall of the drawn cup TP340. In order to measure the hardness, the material was changed from TP270 to TP340. When the sheet thickness was small, it was difficult to measure the hardness. Work-hardening coefficient (n value) of pure titanium TP340 is approximately 0.145. The initial thickness of all blanks is 0.5 mm. Hardness was measured toward the opening from the bottom center of the cup. The measurements were centered on the corners. Hardness of the cup increased from the bottom toward the opening. In each cup, hardness of the opening was approximately 1.3 times that

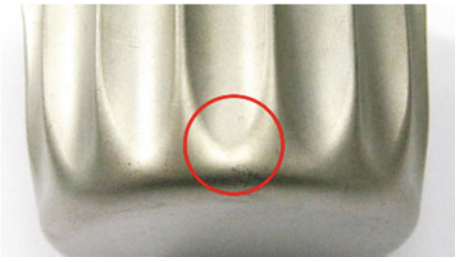

Fig. 7 Contact area of steel ball (red circle). (Color figure online)

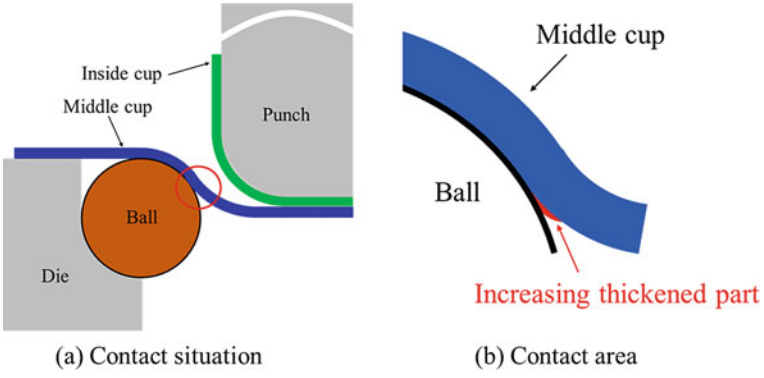

Fig. 8 Mechanism of increase in thickness strain. (Color figure online)

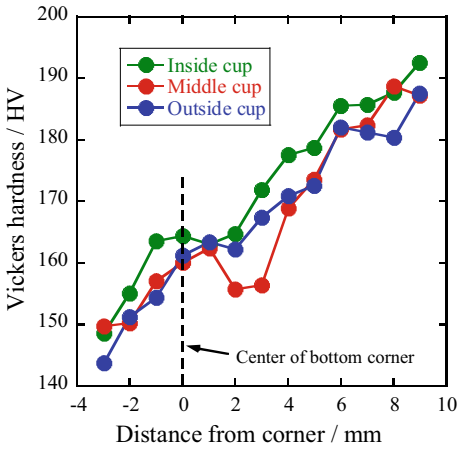

Fig. 9 Vickers hardness of drawn clad cup TP270. (Color figure online)

of the bottom. In the middle cup formed by the roller die, hardness decreases near the bottom of the cup. This reduced area corresponds to the area where the plate thickness strain has increased. Although the plastic flow occurs in this area, the material in no constraint has a small effect of work hardening. For this reason, it is considered that the material having no restraint state did not work harden.

4 Conclusions

The formability of the corrugated clad cup was investigated to enhance the functionality of the cup. The corrugated clad cup was formed using the composite die combining the roller die. The conclusions obtained are as follows:

(1) The corrugated clad cup was formed by using the composite dies including the roller die with steel balls placed on the shoulder of the die.
(2) The cross-section of the side wall of the corrugated clad cup showed a corrugated structure. In addition, the constituent cups were in close contact with each other.
(3) In the drawn cup TP270, the greatest reduction in thickness strain (approximately -0.06) occurred at the bottom corner of the cup.
(4) In the drawn cup TP270, hardness of the cup increased from the bottom toward the opening. In each cup, hardness of the opening was approximately 1.3 times that of the bottom.
(5) In the future, we plan to form corrugated clad cups using different types of blanks. It is considered that the clad cup having functions such as strength and corrosion resistance can be formed.

Acknowledgments The authors would like to thank Mr. T. Fujikami, a former engineering undergraduate at University of Hyogo, for his help in the experimental work. This research was supported in part by a grant from AMADA foundation (AF-2017005).

Experimental and Numerical Investigations into the Influence of the Process Parameters During the Deep Drawing of Fiber Metal Laminates

T. Heggemann, H. Sapli, and W. Homberg

Abstract Reducing fuel consumption and climate-damaging CO_2 emissions are important challenges for the automotive industry. These goals can be achieved by reducing the weight of the car. Extremely lightweight car bodies can be achieved by using exclusively composite materials, which have the major disadvantage of high costs and unsuitability for a large-scale production. A large-scale production of lightweight car body parts with a high stiffness to weight ratio requires more economic materials and new innovative manufacturing technologies. A very promising approach to meet these requirements investigated at the Paderborn University is the combination of high strength steel alloys and unidirectional CFRP prepregs in a special hybrid material—fiber metal laminate (FML)—which can be processed by specially adapted forming technologies such as deep drawing. The paper presents recent results of the combined curing and forming process. The influence of the process parameters, the process limits, the necessary tool systems, and the process strategies are similarly covered by the paper.

1 Introduction

A key goal in the automotive industry is to reduce fuel consumption and thus to reduce the climate-damaging pollutant and CO_2 emissions of future car generations. In the first stage, European legal requirements presupposed a reduction in CO_2 emissions from new vehicles to 130 g CO_2 per km in 2015. In a second stage, the CO_2 emissions from new vehicles will be limited to 95 g per km from 2021 onwards. This goal can be met by reducing the weight of the vehicle, for example, which also leads to

improved driving characteristics. In addition, the mass-dependent resistances, such as acceleration, ascent, and rolling resistance, are lower when the weight is reduced. A mass reduction of 100 kg leads to a fuel saving of 0.3–0.5 l per 100 km with a concomitant CO_2 reduction of 8.5–15 g per km [1].

In most current mass-produced cars, the body has a weight share of about 20% of the total vehicle mass, which offers a great potential for weight savings [2]. Furthermore, reducing the weight of the body has a positive leverage effect on other components of the car, such as the engine, brakes, and chassis. Extremely lightweight designs can be achieved by using exclusively composite materials [3, 7]. Due to the high material costs and their manual processing, the use of exclusively composite materials is limited, for example, to the aviation industry and to expensive high-performance racing cars.

Large-scale production of lightweight car body parts with a high stiffness to weight ratio requires more economic materials and new innovative manufacturing technologies. A very promising approach to meeting these requirements is the combination of high strength steel alloys and unidirectional CFRP prepregs in a special hybrid material—fiber metal laminate (FML). The FML sheets are structured by having the unidirectional CFRP prepreg patches chambered within two sheet metal layers. With this design, the thermosetting matrix material does not come into contact with the tool surfaces, thus offering a high potential for economical large-scale production with well-established, cost-efficient manufacturing technologies, such as deep drawing. In addition, the mechanical properties of the hybrid components produced can be adjusted by the location of the patch, the patch design, the fiber orientation, and the number of CFRP layers used.

The dissimilar material behavior of the sheet metal components and the CFRP prepregs during the forming process require a suitable material and process design in order to achieve the desired mechanical properties and a high shape and dimensional accuracy. Metals in general have approximately isotropic mechanical properties and deform through elastic and plastic flow. The forming behavior of metallic materials depends in general on the load speed, the stress rate, and the temperature [5, 6].

By contrast to metals, composite materials such as CFRP have a high anisotropy and a divergent forming behavior. As far as the carbon fibers are concerned, the mechanical properties in the fiber direction diverge from those in the transverse fiber direction [4]. CFRPs with thermosetting matrix materials require a curing process to attain their final strength. In general, the curing process of the resin is conditioned by the prevailing pressure, the curing temperature, and the curing time.

Most of the body components of mass-produced cars are currently manufactured by forming processes, such as deep drawing using rigid tools, and have complex geometries with unsteady drawing depths. During the deep drawing process, combined tension-tension stresses and pressure-tension stresses are induced in the flange, which is characterized as the main forming zone. The tangential pressure stresses that develop in the flange area can lead to a wrinkling of the metal sheet, which requires the appropriate countermeasures. In order to inhibit the wrinkling of the sheet in the flange area, normal stresses have to be applied by tool elements such as blank holders. If the normal stress applied by the blank holder exceeds a certain

value, the radial tension forces that develop can lead to a thinning of the material and thus to cracks and bottom tears [5, 6].

With regard to the forming behavior of the hybrid FML sheets, typical defects can be observed during the deep drawing process with non-adapted rigid tools. Pressure stresses can cause hydrostatic conditions to develop inside the uncured thermosetting matrix material within the FML sheet, forcing the resin to flow into neighboring areas. Inhomogeneous wall thickness distributions can be observed at points such as the radii areas of the workpieces where the tools induce high contact pressures [8, 9]. As a result, the shape and dimensional accuracy are negatively affected. The main deformation mechanisms for CFRP patches are draping, interlaminar layer slip, transversal flow of the matrix material, and resin percolation inside the prepreg [10–12]. As a result, wrinkles caused by delamination and buckled and torn off rovings can be observed in the flange and frame areas [13].

This paper focuses on two approaches to improving the shape and dimensional accuracy of the deep-drawn FML parts. To reduce the local thinning of the CFRP in the radii and bottom areas, local pre-curing strategies are investigated. The aim of the second approach is to reduce the wrinkling of the FML sheets during the forming process, and hence the effects of different CFRP patch designs and fiber alignments are investigated.

2 Experimental Setup

Experimental investigations were carried out at the LUF focusing on the development of a suitable advanced tool and process design and the resulting shape and dimensional accuracy for the combined forming and curing process of FML sheets. During the deep drawing process, the different areas of the workpiece are affected by numerous stresses in the course of the forming operation. Bending stresses occur in the feed zone in the frame area and in the radius at the punch. The flange and bottom area are affected by normal stresses caused by the blank holder and the punch. The flange, which is the main forming zone, is additionally affected by combined pressure-tension stresses. In the frame area, tension stresses are additionally applied during the forming process. The effect of the combined tensile pressure stresses mentioned and the normal stresses that occur during the forming operation were investigated using a cup-design specimen geometry.

The FML sheets used for the investigations consisted of two circular sheet metal blanks (HCT490X; $s_0 = 0.55$ mm) with an initial diameter of $D_0 = 180$ mm. The sheet metal blanks were arranged as top and bottom layers so that the CFRP prepregs were chambered inside the hybrid blanks. The FML sheets were stacked with one to three layers of unidirectional CFRP prepregs with an initial diameter of $D_0 = 180$ mm, a fiber weight per unit area of 230 g/m^2 and a resin content of 39% as shown in Fig. 1a). In order to minimize the friction between the tool surfaces and the FML sheet, a temperature-stable ethylene tetrafluoroethylene (ETFE) foil with a thickness

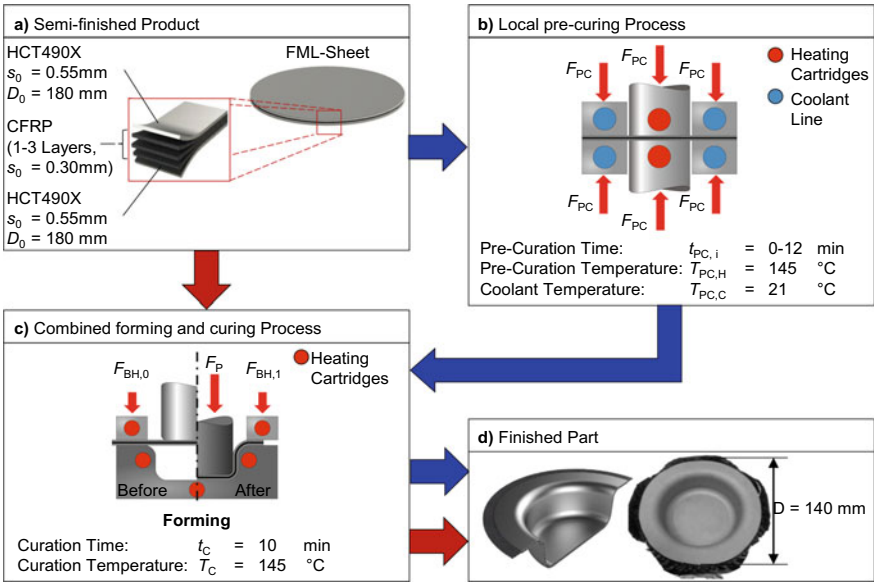

Fig. 1 Schematic image of the semi-finished product (**a**), the pre-curing process (**b**), and the combined forming and curing process (**c**). (Color figure online)

of $s_F = 25$ μm was used. The foil also prevented the resin from contaminating the tools.

In order to investigate the influence of the cross-linking degree of the matrix material on the thickness distribution, in particular in the bottom area and in the radii areas between the bottom and the frame, the specimens were locally pre-cured. The device used for the local pre-curing of the bottom area of the cups consisted of two heated flat circular punches ($T_{PC,H} = 145$ °C) with a diameter of $D_{PC} = 75$ mm and two water-cooled ring tools ($T_{PC,C} = 21$ °C) with an inner diameter of $D_{PC,C} = 79$ mm as shown in Fig. 1b). The pre-curing device was mounted inside a tensile testing machine in order to carry out the pre-curing process under optimal curing conditions for the resin with a defined curing pressure of $p_{PC} = 1$ MPa.

The tool setup for the combined forming and curing operation consisted of a punch, a blank holder, and a die. All the active tool elements can be heated with heating cartridges. The cylindrical punch has a diameter of $D_P = 99$ mm and an edge radius of $R_P = 10$ mm. The die ring has an inner cylindrical diameter of $D_D = 105$ mm and a blanking radius of $R_D = 10$ mm. In the experimental investigations, a drawing depth of $h = 38$ mm was used. The tool setup for the combined forming and curing operation was mounted inside a high precision pillar guide rack in order to achieve a high level of parallelism between the die ring and the blank holder. The whole setup was mounted inside a hydraulic press with a capacity of 1,000 kN. For the experiments, the FML sheets were positioned inside the tool setup. For the combined forming and curing process, the active tools (punch, blank

holder, and die) were heated to a tool temperature of $T_T = 145$ °C. After positioning the FML sheet inside the tool setup, the deep drawing process was started. A blank holder force of $F_{BH,1} = 320$ kN and a punch force of $F_P = 530$ kN were used for the deep drawing process. After the forming process, the FML specimens were cured inside the closed tools for a curing time of $t_C = 10$ min. After the resin of the prepregs had been cured to its final strength, the parts were extracted from the tool setup. The combined forming and curing process and the tool setup are illustrated in Fig. 1c).

For the combined forming and curing process, the FML sheet is positioned on the die. In the next step, the forming process is initiated. The punch force F_{ST} and the blank holder force $F_{BH,1}$ will be set for this, and the FML sheet is formed as the punch moves into the die. The wrinkling of the flange area caused by tangential pressure stresses is suppressed through the normal stresses applied by the blank holder. After the deep drawing process, the FML part remains inside the closed tool until the matrix material is cured to its full strength for a curing time of $t_C = 10$ min. To investigate the influence of the number of CFRP layers on the resulting shape and dimensional accuracy of the FML cups, one to three CFRP layers were used as the core of the hybrid blanks. The semi-finished components used for the first experiments thus consisted of two top-layer circular sheet metal blanks and one to three inner layers of unidirectional CFRP prepregs as shown in Fig. 2. The single-layered FML specimens were arranged with a fiber orientation of 0°. The second layer of CFRP inside the two-layered FML was rotated by 90° compared to the first layer of CFRP, giving the FML sheets an orthotropic design. The third layer inside the three-layered FML sheet was again rotated by 90° compared to the second layer, resulting in a stacking sequence of 0°/90°/0°.

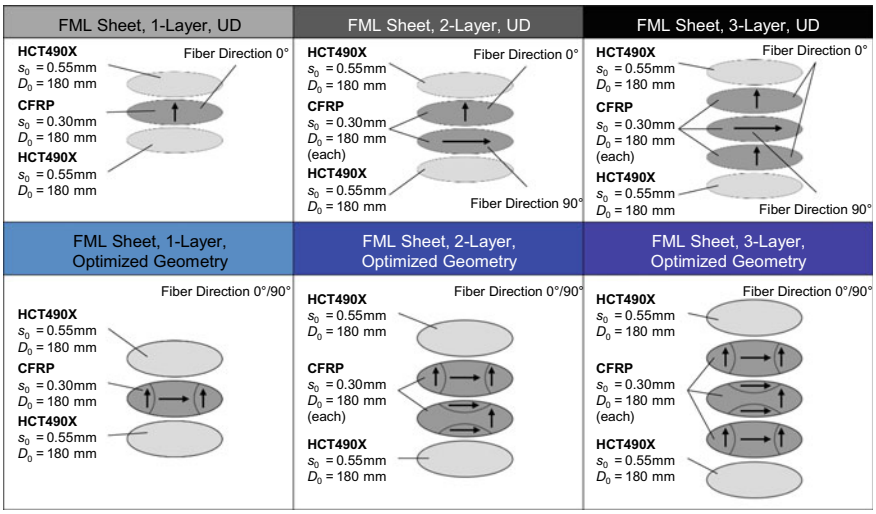

Fig. 2 Schematic image of the FML designs and the layer sequence. (Color figure online)

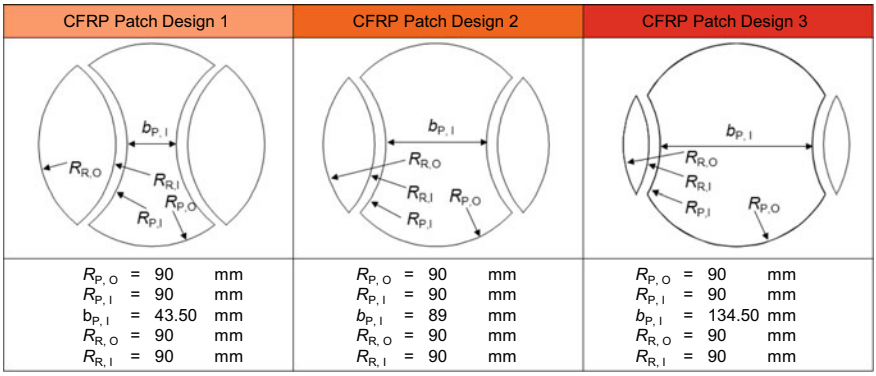

Fig. 3 Schematic image of the CFRP patch Designs. (Color figure online)

In order to investigate the influence of the patch geometries on the forming behavior and on the resulting shape and dimensional accuracy, especially in the frame area of the FML components, three different patch designs were developed for the experimental investigations. The geometries shown in Fig. 3 were thus used.

For every experiment, the circular unidirectional CFRP patch had a constant outer radius of $R_{P,O} = 90$ mm and two circular recesses with constant radii $R_{P,I} = 90$ mm, a varying inner width $b_{P,I}$ at the thinnest point and a fiber direction of 90°. The two recesses were filled by two biconvex UD prepreg patches with radii of $R_{R,O} = R_{R,I} = 90$ mm and a fiber direction rotated by 90° compared to the first patch as shown in Fig. 3. With this patch arrangement, a combined orthotropic 0°/90° fiber orientation results for every prepreg layer of the FML sheets. As a result of this patch alignment, the fibers arranged in the frame and flange area of the specimens are subjected to tangential compressive stresses in the fiber direction during the deep drawing process. Also, with this design, a combination of continuous, long, and short fibers results in the flange and frame area.

In order to analyze the forming result and to evaluate the shape and dimensional accuracy achieved in the FML parts, the specimens were cut in the center and examined by optical and tactile methods such as microscopy and measurements on a coordinate measuring machine.

3 Results

In order to determine the influence of the number of unidirectional CFRP layers used on the resulting shape and dimensional accuracy of the hybrid components, FML sheets with one to three unidirectional CFRP layers were formed and cured inside the tool system developed.

Figure 4 illustrates the correlation between the heights of the wrinkles h_{wr} and the measuring depth z_{md} inside the unidirectional FML specimens that were analyzed.

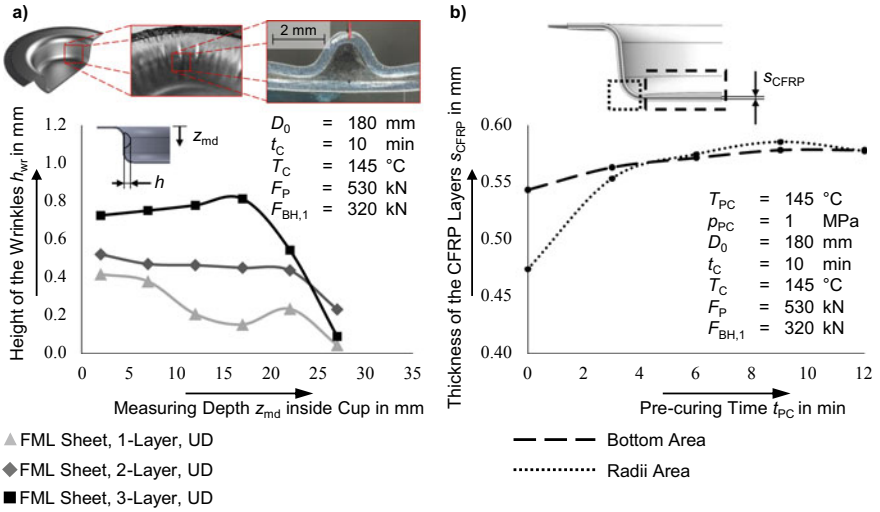

Fig. 4 Wrinkle height h_{wr} inside the specimens as a function of the number of CFRP layers (**a**), thickness of the CFRP layers s_{CFRP} as a function of the pre-curing time t_{PC} (**b**). (Color figure online)

No wrinkles can be determined at the top of the flange area due to the normal force $F_{BH,1}$ applied by the blank holder. Consequently, the first measuring plane for the wrinkle height h_{wr} is in the feed zone and has a depth of $z_{md} = 2.5$ mm from the top surface of the flange. The wrinkles measured at this depth have a wrinkle height of $h_{wr} = 0.42$ mm for an FML sheet with a single-layer unidirectional CFRP patch and they sink steadily up to a measuring depth of $z_{md} = 17$ mm to a value of approximately $h_{wr} = 0.15$ mm. The height of the wrinkles h_{wr} in the frame area then increases up to a measuring depth of $z_{md} = 22$ mm to a value of $h_{wr} = 0.24$ mm. A continuing decrease in the wrinkle height h_{wr} can be determined with an increasing measuring depth z_{md} so that, at a measuring depth of $z_{md} = 27$ mm, wrinkle heights of about $h_{wr} = 0.05$ mm can be detected. No wrinkles can be detected in the radii area between the frame and the bottom of the specimens. Most of the wrinkles occur particularly in areas in which the tangential pressure stresses act almost orthogonally or transversely on the unidirectional fibers. Consequently, most of the wrinkles can be determined around the 0° and 180° directions in one-layered FML components. In FML components with two layers of unidirectional CFRP rotated by 90 degrees to each other, the average wrinkle heights h_{wr} in the feed zone and the frame area are increased by about 79% compared to single-layer FML sheets. Most of the wrinkles can be determined around the 0°, 90°, 180°, and 270° directions. The forming of three-layered FML sheets leads to even higher values for the wrinkle heights h_{wr}, especially in the upper frame area. To sum up, additional FML layers with a unidirectional fiber orientation lead to a significant deterioration in the shape and dimensional accuracy within the FML components. The wrinkles are filled with resin and buckled fibers and hence additional layers of CFRP lead to an increase of the wrinkle height h_{wr}.

During the deep drawing process, the punch induces normal forces at the bottom of the FML parts and high surface pressures at the transition area between the bottom and the frame; this leads to hydrostatic conditions, forcing the resin to flow into neighboring zones. As a result, the wall thickness distribution in these areas is impaired. The pre-curing device as shown in Fig. 1b was used to determine the influence of an upstream pre-curing process on the resulting shape and dimensional accuracy in respect of the thickness of the CFRP layers. Three-layered circular unidirectional CFRP patches were used for the experiments. The pre-curing process was carried out with a pre-curing pressure of $p_{PC} = 1$ MPa, the pre-curing time t_{PC} was varied from $t_{PC} = 0$ min (no pre-curing) to $t_{PC} = 12$ min. The diagram in Fig. 4b shows the relationship between the pre-curing time t_{PC} and the resulting CFRP thickness s_{CFRP} in the bottom and radii areas of the specimens. The forming of specimens without local pre-curing leads to a significant thinning of the CFRP thickness s_{CFRP}, which is especially evident in the radii area. With increasing pre-curing time t_{PC}, the resin gains compressive strength and the resin flow is significantly reduced. With a pre-curing time of at least $t_{PC} = 4$ min, the thinning of the radii and bottom area can be reduced by about 80%, which leads to a distinct improvement in the shape and dimensional accuracy of the FML specimens.

A promising approach to reducing the wrinkle height h_{wr} is to optimize the CFRP patch geometry and the fiber alignment and to adapt the length of the fibers inside the FML sheets. Hence, in further investigations, special prepreg designs as shown in Fig. 3 were used to determine the influence of the CFRP patch geometry in the flange and frame area on the resulting shape and dimensional accuracy of the FML components. The measurement results of the wrinkle heights h_{wr} of the single-layered FML are shown in Fig. 5a. For reference, the gradients of the wrinkle height h_{wr} of the unidirectional FML are marked with a black line and white markers.

The curves marked in light, medium, and dark gray represent the wrinkle heights h_{wr} of those specimens with the patch design under investigation. They tend to absorb compressive forces in fiber direction in the main forming zone and in the frame area during the forming process. The radii $R_{P,O} = R_{P,I} = R_{R,O} = R_{R,I} = 90$ mm were held constant for the investigations. The curve marked in light gray represents the resulting wrinkle height h_{wr} for the investigated patch design 1 with an inner width of $b_{P,I} = 43.50$ mm on the main patch at the thinnest point. The curve marked in medium gray shows the wrinkle heights h_{wr} of the patch design with an inner width of $b_{P,I} = 89.00$ mm, while the dark gray curve represents the patch design with the smallest recesses ($b_{P,I} = 134.50$ mm). For the designs investigated, both short and long and continuous fibers result due to the recess geometry. With regard to the single-layered FML, all the investigated patch designs result in a significant reduction of the wrinkle heights h_{wr} compared to the unidirectional reference specimens up to a measuring depth of $z_{md} = 17.5$ mm. The patches tend to be loaded by compressive stresses in the fiber direction in the edge region of the FML sheets during the forming process, which results in a significant reduction in the wrinkle height.

Compared to the unidirectional reference, the wrinkle height h_{wr} is reduced by almost 74%. Due to the fiber orientation and the shortened fiber length, the fibers can slip into each other in the fiber direction. In addition, flow channels for the resin

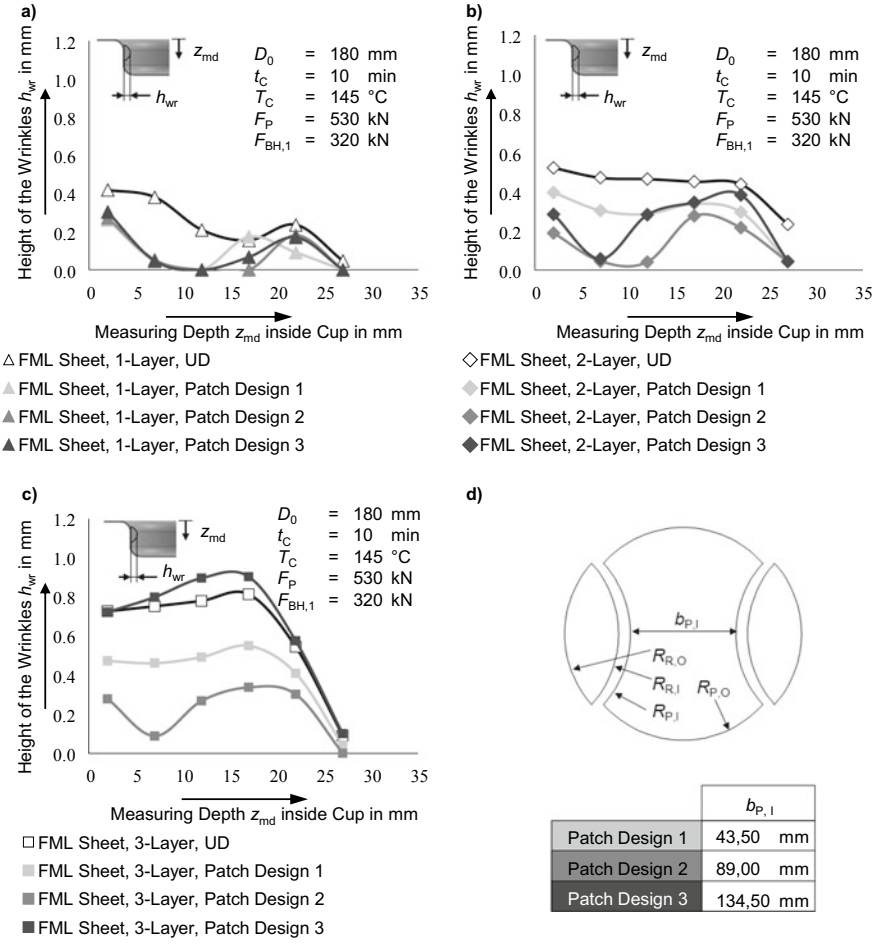

Fig. 5 Wrinkle height h_{wr} inside the specimens as a function of the number of CFRP layers and the patch design (**a**–**c**), schematic image of the patch design (**d**)

are released in the fiber direction. Compared to the transversal fiber direction, the fiber direction offers less flow resistance for the resin. The resin is distributed more homogenously in the frame area and in the feed zone.

The relationship between the measuring depth and the height of the wrinkles h_{wr} for the two-layered FML sheets (the unidirectional references are marked with a black line and white markers, the investigated designs are marked light, medium, and dark gray) is shown in Fig. 5b. The curves of the unidirectional reference and design 1 show a very similar course. A significant reduction in the wrinkle height h_{wr} over the entire frame and feed area can be achieved using patches with a recess of $b_{P,I} = 89.00$ mm. On average, a reduction of the wrinkle height h_{wr} of approximately 70% (h_{wr}) can be achieved.

The wrinkle heights h_{wr} for the three-layered FML specimens are shown in Fig. 5c. A significant reduction in the wrinkle height h_{wr} can be observed for design 2 that was investigated. While the wrinkle heights h_{wr} of the unidirectional reference attain a value of more than 0.70 mm up to a measuring depth of $z_{md} = 20$ mm, the wrinkle heights h_{wr} of design 2 remain below $h_{wr} = 0.35$ mm. On average, a reduction of the wrinkle height h_{wr} of more than 70% can be achieved over the entire frame and feed zone area with design 2. Design 3 does not improve the shape and dimensional accuracy for this stacking sequence, and the height of the wrinkles h_{wr} is even higher than for the reference. A significant improvement can thus be achieved by aligning the patches according to design 2, where the short and long fibers can slip into each other in the forming zone and in the frame area up to the radii area at the bottom of the specimens, thus additionally releasing flow channels. Compared to designs 1 and 3 this fiber arrangement allows a more homogeneous distribution of the resin.

4 Conclusion

In this study, experimental research has been conducted into the development of the process and material design for the production of hybrid components made of FML sheets. The focus of these investigations was to determine the influence of an upstream pre-curing process on the wall thickness distribution, the number of CFRP layers, and the patch geometry, with the aim of improving the shape and dimensional accuracy of the FML parts during the combined forming and curing process. Additional layers of CFRP lead to a significant increase in the measured wrinkle heights h_{wr} inside the FML cups. The local thinning of the bottom area and radii area was reduced through the approach of local pre-curing of the bottom area of the FML sheets. The wrinkle height of the inner metal sheets was reduced by almost 74% on average. For the two and three-layered FML components, the wrinkle heights were reduced by 70%. Future work will investigate the transfer of knowledge from this study to more complex geometries and the development of a numerical model to predict the forming results of FML sheets.

Experimental Analysis on Granular Media-Based Tube Forming with Active Axial Feed

E. Hoffmann, C. Löbbe, and A. E. Tekkaya

Abstract Production of high strength, high stiffness, and safety-relevant profile parts is feasible through the sequence of media-based forming and in-die quenching. As forming media, solid granular media have been recently introduced. In this work, the granular media tube press hardening process with additional axial feeding is investigated in order to enhance the tube thickness distribution and to enlarge the process window. The experiments show that, compared to the process with frictional feed, the limits for insufficient forming and wrinkling are unaffected by the change of the feeding system, while the area for intolerable thinning is reduced. Additionally, through the new feeding system, a higher degree of design freedom could be achieved, e.g., shoulder angles of 90° are possible. Furthermore, for the design of the process, an advanced FEM simulation has been developed, which is based on the Drucker–Prager cap model and covers also the thermal interactions.

Keywords Hydroforming · Hollow profiles · Press hardening · Granular media

1 Introduction

The demand for high-strength profile parts for automotive body construction is high due to increasing safety regulations and economic demands. Granular media-based hydroforming can serve as an alternative process to conventional liquid-based hydroforming and gas forming to achieve press hardened profiles. Mennecart et al. [1] tested the feasibility of granules as a hydroforming medium. Grüner and Merklein [2] used the Drucker–Prager Cap model to describe the granular media behaviour numerically during a hydroforming process. Typically, zirconia beads are used as this material has been proven to achieve the best forming results [3]. Another possible medium would be quartz sand but the pressure transfer is significantly lower, reducing the possible product complexity [3]. Challenges arise in the behaviour of granular materials. The higher the distance from force initiation area in the medium pillar, the higher is the

pressure loss due to internal friction [4]. Additionally, the consolidation pressure of the medium limits the transferred pressure in the volume [5]. Still, in past research, the friction was necessary for the successful production of profile parts. Frictional forces lead to an axial tube feed which negates the tube thinning [6]. To increase the achievable forming limit of the parts produced by this process, a new approach needs to be investigated.

In order to reduce tube thinning while still maintaining low frictional forces in the process, a tool with an active axial feed mechanism was developed. The experiments published in this work using this tool have two objectives. First, the influence of active feed on the process is analysed. A correct adjusted feeding force should stop the tube thinning and enable a better filling of the die cavities [7]. Second, the effect of reducing frictional forces in the process is investigated. Therefore, zirconia beads mixed with boron nitride, a common lubricant which is not carbon-based, are used as the medium. The reduction of frictional forces should lead to a higher possible forming length of the profiles. This effect is investigated through forming of tubes at same forces with different boron nitride fractions in the medium.

2 Experimental Set-Up

For the process tests, a tool for a Müller Weingarten BZE 1000 hydraulic press was developed (Fig. 1). The symmetric tool consists of two independent axial axes for both pressing the granular medium and feeding the tube. The forming force is acting through two hydraulic punches, which can enforce a maximum axial pressure in the medium of 230 MPa, while the feeding axis is driven by servo motors with a

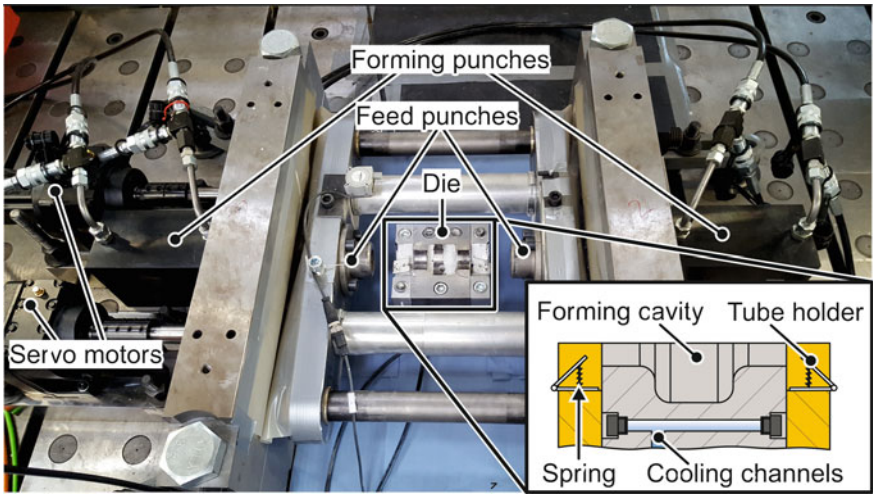

Fig. 1 Granular media-based press hardening tool with active axial feed axis. (Color figure online)

maximum force of 100 kN. The die contains tube holders to reduce the cooling of the tube during closing. Additionally, cooling ducts are drilled into the die to sustain high cooling rates after numerous forming tests. The die closing pressure is applied through the press.

For the tests, 22MnB5 tubes with an outer diameter of $d_{o,d} = 40$ mm, and a thickness of $t_0 = 1.5$ mm (Fig. 2a) are first heated in an oven at 950 °C for 4 min (Fig. 2b). After heating, the tubes are filled with zirconia beads with a diameter of 0.5 mm (Fig. 2c). The filling happens after heating so the medium is still at room temperature, not increasing the necessary cooling rate of the tube for complete martensitic transformation. Afterwards, the tube is inserted into the die and positioned on the tube holders (Fig. 2d). The die closes and, through the closing force, the tube holders are lowered (Fig. 2e). This is timed with the positioning of the form and feed punches to reduce forming time. Consequently, to these steps, the forming process starts. The diameter is increased to 65 mm over a length of 50 mm with a starting temperature of 800 °C. The tube remains in the die for 20 s to reach complete

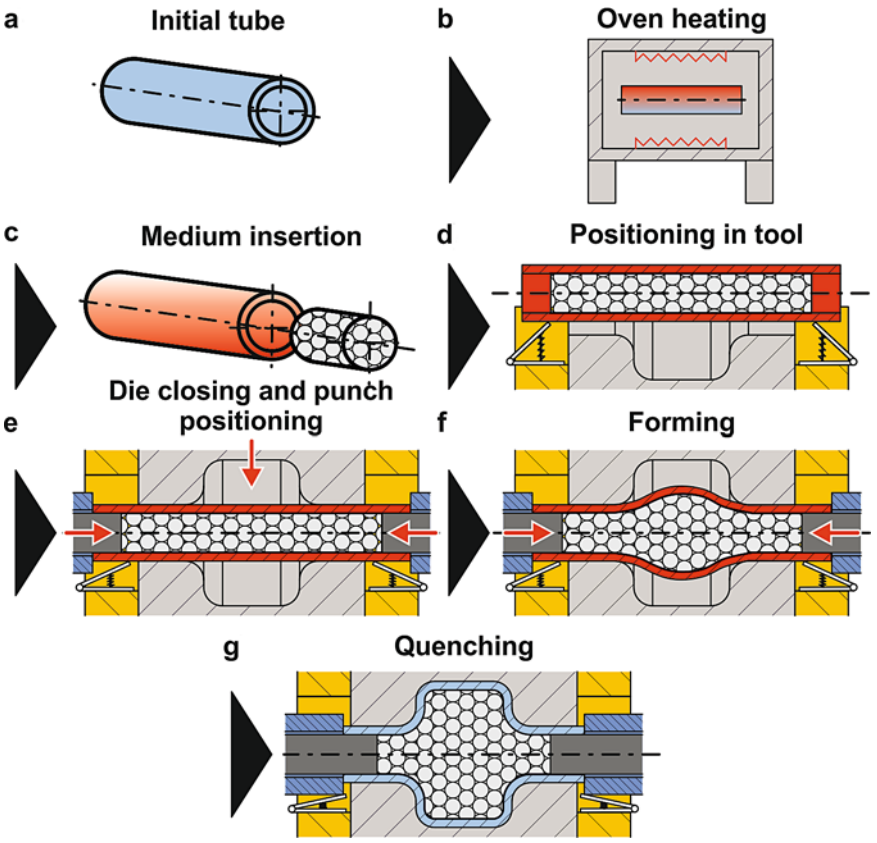

Fig. 2 Forming sequence for the granular media-based press hardening process. (Color figure online)

martensitic transformation (Fig. 2g). The resulting geometry is then measured with an ATOS system and, additionally, the thickness is measured by ultrasonic measurement.

3 Simulation Set-Up

The process simulation is a thermal–mechanical-coupled FEM simulation. The parameters for the simulation are defined in Fig. 3. The granular material is modeled by the Drucker–Prager Cap model, which defines a volume of granular material as a continuum and describes the flow and strain hardening (cap hardening) behaviour

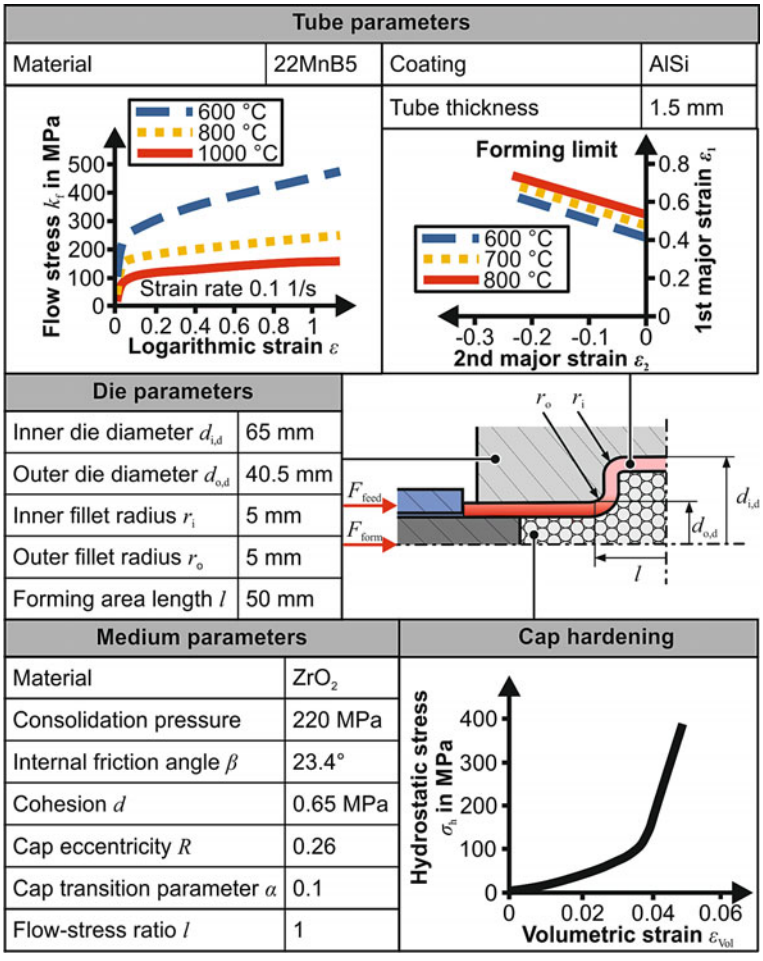

Fig. 3 Simulation parameters for process simulation, also used in [8]. (Color figure online)

of this material [9]. The tube behaves elastoplastic and its properties are influenced by temperature. The temperature dependency of tube properties is achieved by using tabular flow curves for the corresponding temperatures. Temperature-dependent FLC data limits the formability of tube material in the simulation. The die and the punches are mechanical rigid bodies which can transfer temperature.

Friction is defined as a constant value of $\mu = 0.25$ between medium and tube and $\mu = 0.45$ between tube and die [6]. Heat transfer results through conduction between medium, die, and tube. The heat transfer depends on contact pressure. Starting temperature of the tube is 800 °C to compensate for the transfer and loading time from removal of the tube from the oven to insertion into the tool.

While the DPC model for the medium is stable for the case it was characterized for there are still challenges in using this model in metal forming. When adding additives to the medium the internal friction and with this, the flow behavior is changed. Because the medium volume is modelled as a continuum, the medium has to be characterized again after adding additives. Additionally, through the continuum definition, an error on contacts persists, which means that the simulation cannot predict indentations caused by the granular particles. These indentations are a result of the high strength and the dimensions of the medium particles which cause a plastic deformation on the inner tube surface.

4 Discussion

4.1 Influence of Axial Feed

To examine the influence of the axial feed, tests at maximum forming force and at different feeds have been carried out. Feed is defined as

$$f = \frac{v_{\text{feed}}}{v_{\text{form}}} \tag{1}$$

where v_{feed} is the velocity of the axial feed punch and v_{form} the velocity of the forming punch. The active feed has an influence on die cavity filling (Fig. 4). The displayed geometry is measured along the path with the highest cavity filling (Fig. 4a) and the mean curve of the three repetitions is displayed (Fig. 4b). The results are evaluated at a medium pressure of 220 MPa (consolidation pressure of zirconia beads). The press closing force is 1.5 MN. The higher the axial feed, the closer the profile geometry is to the desired geometry. A possible reason for this could be that the axial feed induces bending moments on the tube. These moments might reduce the necessary punch force for the forming process.

For high enough feeds, forming of tubes approximately without thinning is possible (Fig. 5). The values for the experiments are mean values out of the maximum thickness values for three specimens. For a medium pressure of 220 MPa, a feed that

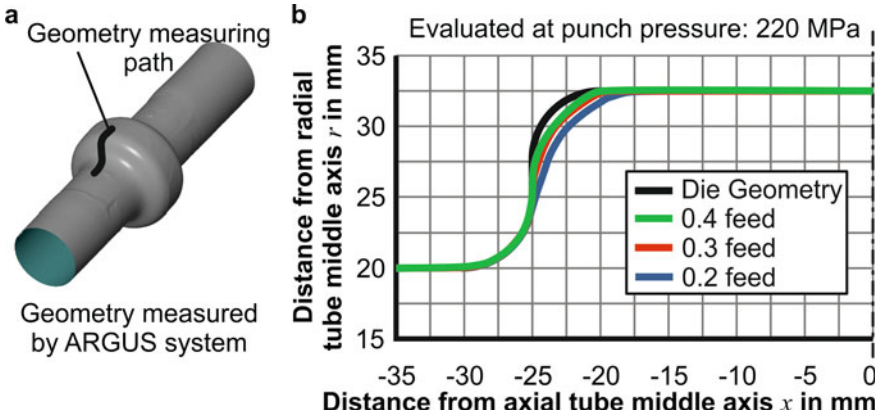

Fig. 4 Influence of axial feed on die cavity filling. **a** Geometry measurement path, **b** resulting part geometry. (Color figure online)

is lower than $f < 0.2$ leads to excessive thinning of the tube. Wrinkling for the evaluated punch pressure occurs at feeds higher than $f > 0.5$. While the thickness strain for $f = 0.2$ is still low the thickness strain for $f = 0.5$, feed is approaching zero showing the effectivity of applying an axial stress.

The results are showing that through the axial feed thickness strain of approximately zero is possible. This effect was discovered in [6] but reached through the friction between tube and medium. One aim in this work is to reduce the media friction so that longer profile products are possible. Through the active feed, minimizing thickness strain while reducing media friction is possible.

With increasing feed, the error between simulation and experiment is increasing. It ranges from +17% to +96% depending on the feeding ratio. A reason for this could be that through the axial feed a bending moment on the tube bulge is initiated. This bending moment may lead to a localization of the strain. Additionally, the number of elements in the simulation is limited. Through the strain localization, the number of elements in the FEM simulation might be too low to accurately predict the strains caused by the bending effects, leading to the error in maximum strain for the high feed cases. While the error is high when measuring the thickness in high feed cases, the failure mode of the tube also changes. In high feed cases, accurately predicting the thickness strain becomes secondary to predicting the actual material failure through wrinkling which is successfully achieved through the model (Fig. 6).

The process window shows the process limits for insufficient forming, excessive thinning and wrinkling of the tube material, and the pressure limit in the medium through the consolidation pressure. The limits from the simulation and from the process tests are depicted. For the tests, the lines are extrapolated from the results of three tests without failure, which consists of three specimens each. To compare to the successful tests, the tests for the first material failure during the forming process are illustrated too.

Insufficient forming occurs when the distance between tube and die is higher than 5 mm. The consolidation pressure limit is the pressure at which the medium forms into a green body, resulting in a case where no more pressure can be transferred through the medium [1]. As can be seen in contrast to Fig. 5, the simulation is in good accordance with the experiments for the process window.

There are two mechanisms leading to the reduction of maximum complexity of profile parts produced by this process. First, the pressure drops over the length of the

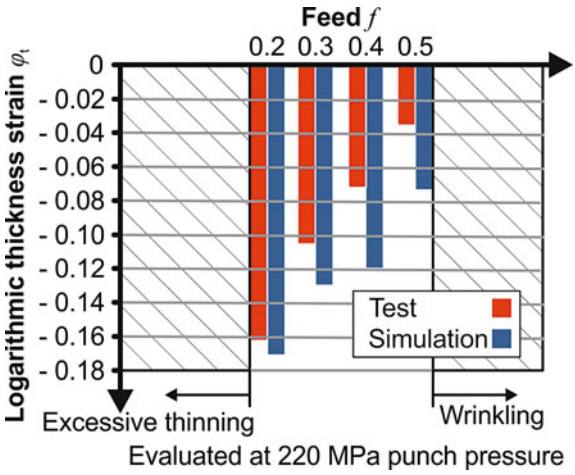

Fig. 5 Influence of axial feed on profile thickness strain. (Color figure online)

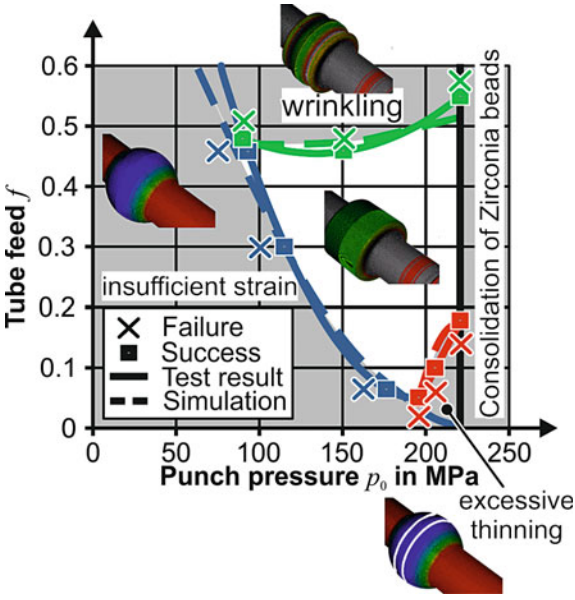

Fig. 6 Process window for zirconia beads as forming medium. (Color figure online)

media pillar due to friction [10]. Second, the maximum pressure transferred by the medium is limited by its consolidation pressure. Thus, to increase profile complexity, a reduction of medium friction is necessary.

4.2 *Influence of Media Friction*

To reduce media friction, the zirconia beads were mixed with different fractions of boron nitride. The boron nitride is evenly distributed in the mixture. Boron nitride is a ceramic material, giving it the high-temperature stability necessary for the press hardening process. The lubrication mechanism of this material is comparable to graphite [11] but as a carbon-based lubricant graphite is not usable as lubrication for steel materials at high temperatures. Even low fractions of boron nitride have a huge influence on forming success (Fig. 7). Depicted is the cross-sectional geometry of the tubes after the forming process and the die geometry as desired geometry. All profiles are evaluated at the feed of $f = 0.2$ and a punch pressure of $p_0 = 150$ MPa. Mean geometry out of three tests is used for each curve. The difference is the mass fraction of boron nitride mixed with the granular medium. As illustrated, a mass fraction of 1% boron nitride (red curve) leads to a reduction of friction and thus an increase in tube formability for the same punch pressure compared to zirconia beads without boron nitride (green curve). Lower fractions of boron nitride reduce the formability.

A higher mass fraction than 1% of boron nitride influences the formability negatively. The reason for this might be the density disparity between the two medium materials. While the zirconium dioxide manifests a density of 6200 kg/m^3, the density for boron nitride is 2250 kg/m^3. This difference leads to the medium mixture consisting of a high volume fraction of boron nitride. Additionally, for the plastic deformation of a volume of granular material, it is necessary for the particles to fill the cavities in the medium pillar meaning the smaller the medium grains, the more force is necessary for the pillar to deform. The high volume of the smaller boron

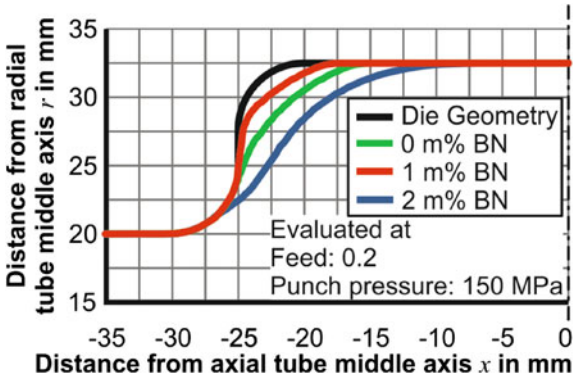

Fig. 7 Geometrical results of the forming process for different mass fractions of boron nitride. (Color figure online)

nitride particles is now filling the cavities influencing the mechanical properties of the medium for mass fractions higher than 1 m%.

5 Conclusion

The objectives of this work were to investigate the influence of axial feed and the influence of media friction on the process. The FEM analysis has proven to predict the failure modes of the tube material during the forming process correctly. While there are still issues in predicting the thickness strains for high feeds and the surface indentations, the model covers typical process errors such as wrinkling and can correctly predict the thinning in low feed cases.

An active feed mechanism was successfully applied in the granular media-based press hardening process. Through the use of the active feed tube, thinning can be prevented. These results grant the basis for increasing the product complexity of the process through the reduction of media friction and thus increasing the transferable forces through the medium.

Lastly, the reduction of friction through using additives such as boron nitride in the medium was shown to improve the formability of the tube at same pressures compared to pure zirconia beads. The amount of additive used may not surpass a certain threshold to achieve a positive effect. With these first results on the reduction of media friction during the granular media-based press hardening process a foundation has been laid for further improvements in product complexity in the process.

Finite Element Simulation and Punch Design for Tube Hydro-Piercing

Yeong-Maw Hwang, Wei-Han Dai, and Pin-Chen Lin

Abstract This study is focused on punch shape design in tube hydro-piercing processes of aluminum alloy A6005 tubes. The flow stresses of the aluminum alloy tubes obtained by tensile tests are used in the finite element simulations of tube hydro-piercing process with software "DEFORM 3D." The ductile fracture criterion of normalized Cockcroft and Latham is used during the FE simulations. The critical damage values for the criterion are obtained by comparing simulation results and tensile test data. The effects of various parameters such as the stroke, internal pressure, etc., on hydro-piercing processes and deformation mechanism are discussed. Experiments are conducted and the experimental shearing surface heights are compared with the simulation results to verify the validity of the analytical models. The effects of various parameters on shearing surface heights are also discussed by hydro-piercing experiments.

Keywords Tube hydroforming · Hydro-piercing · Finite element analysis · Punch shape design

1 Introduction

The hydroforming processes have been widely applied to manufacturing parts in various fields, such as automobile, aircraft and aerospace, shipbuilding industry, etc., due to the increasing demands for lightweight parts. Hydraulic punching or piercing is combined with hydroforming processes to save manufacturing costs and raise positional accuracy [1]. Generally, hydro-piercing can be conducted in two ways: outward piercing and inward piercing. In an outward piercing process, a counterpunch moves backward as high internal pressure is reached. The process formability and the hole section characteristics are affected by the internal pressure and the corner shape of the die. The punched scrap is removed out of the tube after the process. In an inward piercing process, a punch moves forward to pierce the tube material and

make the scrap drop into the tube. The hole section characteristics are affected by the internal pressure and punch shapes. The pierced hole section characteristics are different with inward and outward hydro-piercing processes.

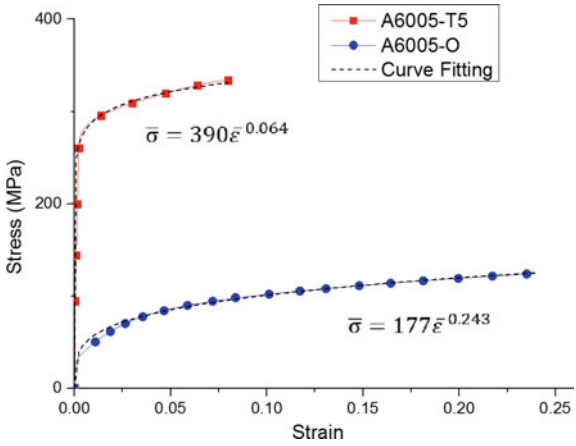
In order to improve the dimensional accuracy of the hole shape in a sheet hydro-piercing process, Shiomi et al. [2] used a hydrostatic pressure to support the sheet. The effects of punch movement types on pierced section surface quality were discussed. Wu et al. [3] used the finite element software ABAQUS with six ductile criteria to predict crack initiation and propagation in the hydro-piercing process of tubes. Some comparisons among the results obtained by simulations using different ductile criteria and the experimental results were also discussed. The model using Rice and Tracey criterion showed good agreement with the experimental data at loading pressure of 60 MPa. Mizumura et al. [4] proposed a nut-inlaying method to join a bolt on a thin-walled tube, in which hydro-piercing and hydro-burring were conducted sequentially. Uchida and Tomsawa [5] investigated the fundamental characteristics of outward hydro-piercing by an internal hydraulic pressure experimentally. The effects of hydraulic pressure, tensile strength, and wall thickness of the tube on the pierced surface shape and shearing resistance during hydro-piercing were discussed. Choi et al. [6] investigated the effects of tube material properties, punch diameter, tube wall thickness, and internal pressure within the tube during hydro-piercing on the deformation behavior experimentally. From the experimental results, empirical equations were developed to predict roll-over height and deformation radius of the punched tube prior to shear fracture in the hydro-piercing process. Korkmaz et al. [7] investigated the effects of the punch movement on the burr formation in a hydro-piercing process of 304 stainless steels using finite element software LS-Dyna and Jonson–Cook hardening and damage model. Their simulation results showed that the burr formation can be eliminated by a two-step movement of the punch through the piercing operation.

Up to now, most researches concerning pierced hole sections after hydro-piercing were experimental works. Few literature investigated the characteristics of the pierced hole sections analytically with different punch shape design during hydro-piercing processes. This paper investigates the effects of the punch shape on the characteristics of the pierced hole section of the tube and discusses the effects of the internal pressure on the residual thickness during hydro-piercing processes of aluminum alloy tubes.

2 Finite Element Modeling

2.1 Tube Material

Aluminum alloys were used as the tube specimens. The flow stresses or the true stress–strain curves of the tube material obtained by tensile tests with an average strain rate of 0.006 s^{-1} are shown in Fig. 1. The corresponding equation best fitted with the flow stress is also shown in the figure. The yield stress is obtained by the



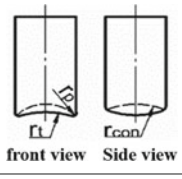


Fig. 1 Flow stress curve of tube materials A6005-T5 and A6005-O. (Color figure online)

0.2% offset method. The obtained yield stress σ_y, for A6005-T5 and A6005-O, are 278 and 69 MPa, respectively.

2.2 Punch Shape Design

Two types of punch shapes were designed as shown in Table 1. (1) Plane punch (PP) exhibits a flat plane at the bottom of the punch. (2) Concave tube surface punch (CTSP) is so designed that the peripheral corner is in contact with the tube surface, whereas the inside is a spherically concave surface. These two types of punches have an identical corner radius of rp at the peripheral corner. The intersection curves or the contact configurations between the punch and tube for type CTSP are shown in Fig. 2.

Table 1 Punch types and corresponding shapes

Punch type	Punch shape
Plane punch (PP)	
Concave tube surface punch (CTSP)	

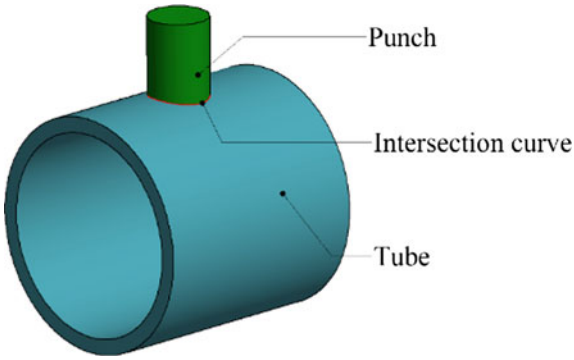

Fig. 2 Contact configurations between punch type CTSP and tube. (Color figure online)

2.3 Forming Conditions

The contact configurations between the punch and tube before and after hydro-piercing are shown in Fig. 3. Initially, a high pressure is imposed on the inner surface of the tube. The punch moves inward with a speed of V. After a stroke of S, the tube exhibits a roll-over height Hr on its top surface and a residual thickness tr at the bottom of the hole section. The scrap does not separate completely with the tube at this moment. If the scrap separates completely with the tube, the scrap will be kept inside the tube and eventually will drop into the oil tank, which is not good for further processes. There is no die or other support structure inside the tube to support the tube, and it is difficult to control the hole quality. Thus, in this paper, a high internal pressure is adopted to improve the characteristics of the pierced hole surface.

The outer diameter and thicknesses of the aluminum alloy tubes are 70 mm and 3.75 mm, respectively. A finite element software "Deform 3D" was used to simulate the tube material deformation and fracture behavior in the hydro-piecing process. The punch diameter Dp is 6.5 mm and the punch speed is set as 1 mm/sec. The punch corner radius rp is 0.2 mm and the spherical radius rcon for type CTSP is 5 mm. The

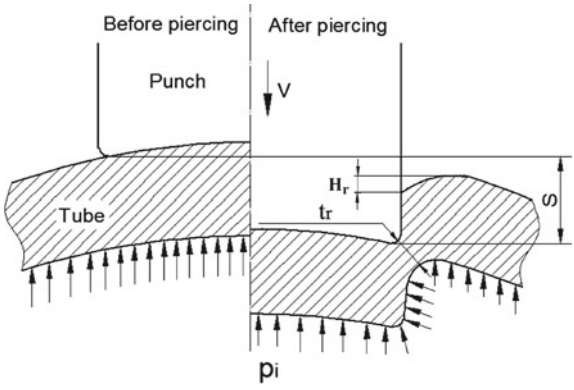

Fig. 3 Contact configurations between punch and tube before and after hydro-piercing

Table 2 Forming parameters used in FE simulations

Material	A6005	Internal pressure	20, 40, 60, 100 MPa
Material model	Rigid-plastic body	Spherical radius r_{con}	5 mm
Tube diameter Dt	70 mm	Punch corner radius rp	0.2 mm
Thickness t0	2.0, 3.75 mm	Temperature T	20 °C
Punch diameter Dp	6.5 mm	Step increment	0.01 mm
Punch velocity V	1 mm/sec	Mesh number	157,000
Coulomb friction coefficient μ	0.1	Minimum element length	0.08 mm

other parameters used in the finite element simulations are summarized in Table 2. The Normalized Cockcroft and Latham (NCL) ductile fracture criterion [8] given in Eq. (1) was used to determine if the tube material reaches the fracture condition and the corresponding element is removed.

$$c = \int_0^{\bar{\varepsilon}_f} \frac{\sigma_1}{\bar{\sigma}} d\bar{\varepsilon} \tag{1}$$

where, $\tilde{\sigma}$ is the effective stress, σ_1 is the maximum tensile stress, $\bar{\varepsilon}_f$ is the effective strain at the fracture point, $\bar{\varepsilon}$ is the effective strain, and c is the critical damage or fracture value. Tensile test simulations with the NCL criterion and real tensile tests were conducted. The critical damage value c is obtained by comparing the elongation and loading curve between the FE simulations and the real tensile tests. The obtained critical damage value for A6005T5 and A6005-O are 0.219and 0.618, respectively.

3 Simulation Results and Discussion

3.1 Punch Load

Figure 4 shows the load variations with punch type CTSP during the hydro-piercing process. The whole process can be divided into three stages: (A) Elastic stage, (B) Plastic stage, and (c) Fracture stage. In stage (A), the tube undergoes elastic deformation and only slight roll-over deformation occurs. In stage (B), the load increases

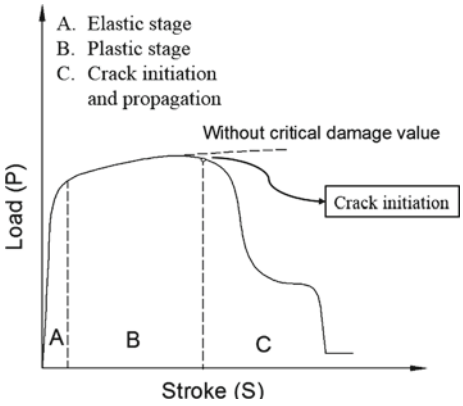

Fig. 4 Punch load variations during hydro-piercing process

monotonically with the stroke, in which the tube undergoes elasto-plastic deformation, the roll-over region expands, and a burnished surface or a slip surface generates. In stage (C), the load drops drastically, in which material fracture initiates and a fracture surface starts to generate. If no critical damage value is set in the FE simulations, the load will continue to increase as showen in Fig. 4.

Figure 5 shows the load variations with different internal pressures during the hydro-piercing process. Clearly, the load increases with the internal pressure, whereas the whole stroke range decreases with the increase in internal pressure. That is because the fracture surface region decreases under a higher hydro-static stress state, however, the roll-over and burr parts are not influenced significantly by the hydro-static stress state.

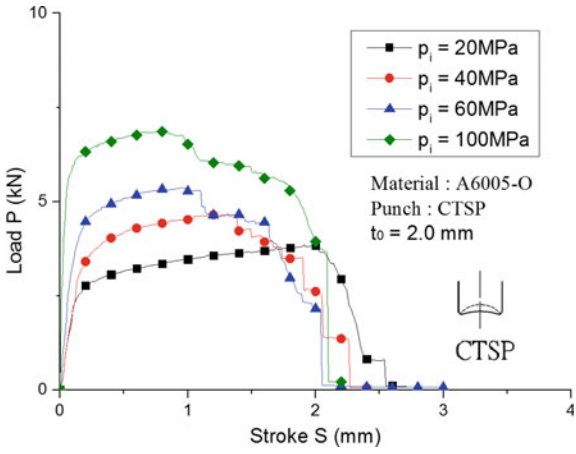

Fig. 5 Punch load variations with different internal pressures during hydro-piercing process. (Color figure online)

3.2 Characteristics at Pierced Hole Section

Figure 6 shows the schematic diagram at the pierced hole section, which is constituted by a roll-over, a burnished surface, a fractured surface, and a burr. The roll-over region results from an inward deflection of the tube in contact with the die. There are shear and tensile stresses existing at the burnished and fracture zones. The burnished surfaces result mainly from shear stresses and fracture surfaces result mainly from tearing of the tube material due to tensile stresses. The burr part results at the free inner surface of the tube. Some simulation results of the extent or quality of each zone affected by punch shapes are discussed in the following figures.

Figure 7 shows the effects of punch shapes on the surface characteristics of the pierced hole section. The forming conditions are internal pressure $P_i = 40$ MPa, initial tube thickness $t_0 = 3.75$ mm, and punch diameter $D_p = 6.5$ mm. From the figure, it is known that a smaller roll-over height Hr can be obtained with punch type of CTSP. For tube material of A5005-O, a smaller burnished surface height is obtained with punch type of CTSP.

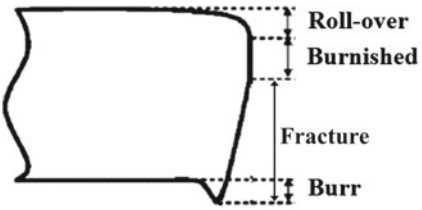

Fig. 6 Schematic at pierced hole section

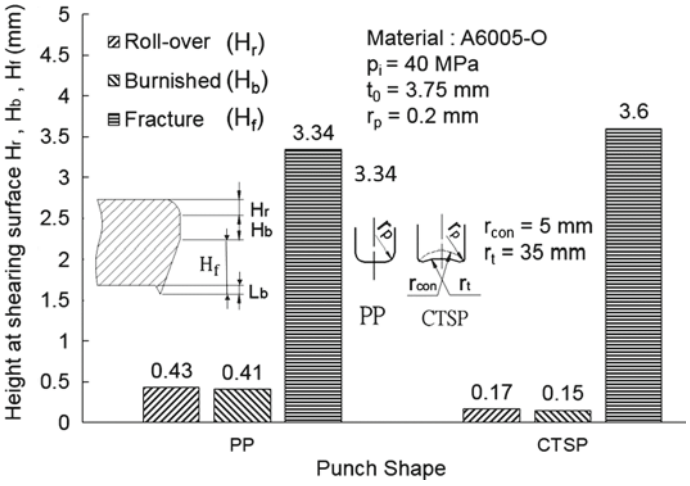

Fig. 7 Effects of punch shapes on characteristics of pierced hole section

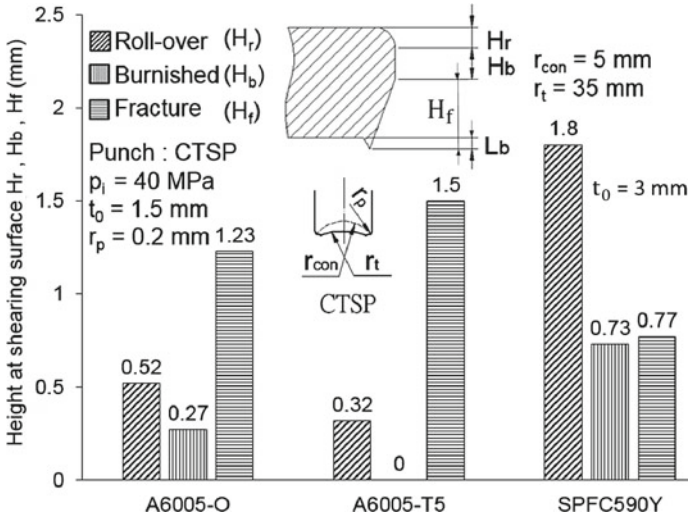

Fig. 8 Effects of different materials on characteristics of pierced hole section

Figure 8 shows the effects of different materials on the heights of roll-over, burnished surface, and fracture surface at the pierced hole section. The initial tube thickness is $t_o = 1.5$ mm and the internal pressure is $p_i = 40$ MPa. Clearly, for tube material of carbon steel SPFC590Y, a larger roll-over was obtained. Because carbon steel SPFC590Y ($t_o = 3$ mm) has a larger critical damage value, a larger burnished surface height and a smaller fracture surface height are obtained. Because of a quite small damage value for aluminum alloy A6005-T5, a quite small burnished surface height was obtained.

3.3 Residual Thickness

In a hydro-piecing process, sometimes the scrap is not pierced off completely because the scrap dropping into the oil tank probably results in some blockage of the oil loop and make the hydraulic system not function normally. A small residual thickness (see Fig. 3) makes the scrap remain on the tube and the scrap is removed manually afterward. Figure 9 shows the effects of internal pressure on the residual thickness with an initial tube thickness of $t_i = 2.0$ mm. Clearly, the residual thickness decreases with the stroke. In other words, as the punch moves forward, the residual thickness decreases from the initial value of 2.0 mm to 0 mm. On the other hand, as the internal pressure increases, the residual thickness decreases. The turning point of the slops of the curves indicates the initiation of the fracture surface. A higher internal pressure can decrease the fracture surface fraction, accordingly, the residual thickness decreases as the internal pressure increases.

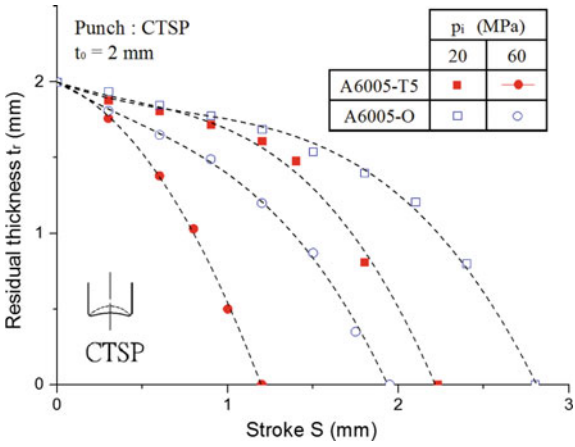

Fig. 9 Effects of internal pressure on residual thickness. (Color figure online)

4 Hydro-Piercing Experiments

4.1 Experimental Apparatus

An experimental apparatus was designed and manufactured by the present authors. The appearance of the die set used in hydro-piercing experiments is shown in Fig. 10. A tube would be placed at the cavity of the bottom die. Two pushing rods move forward for oil sealing at the two ends of the tube. A hydraulic cylinder at the back is used to push the punch forward to implement the hydro-piercing process. A fine-tuning pitch control mechanism is designed to control the stroke of punch accurately. Accordingly, the goal of the residual thickness of the tube can be set easily and accurately. After the top die moves downward to clamp the tube, the left and right pushing rods move forward for oil sealing and then the hydraulic pressure inside the tube is adjusted to the set value. Finally, the hydraulic cylinder combined with the designed punch head moves forward to carry out the hydro-piercing experiments.

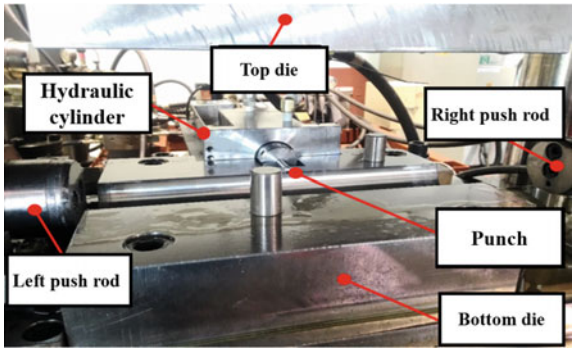

Fig. 10 Appearance of die set and punch used in hydro-piercing experiments. (Color figure online)

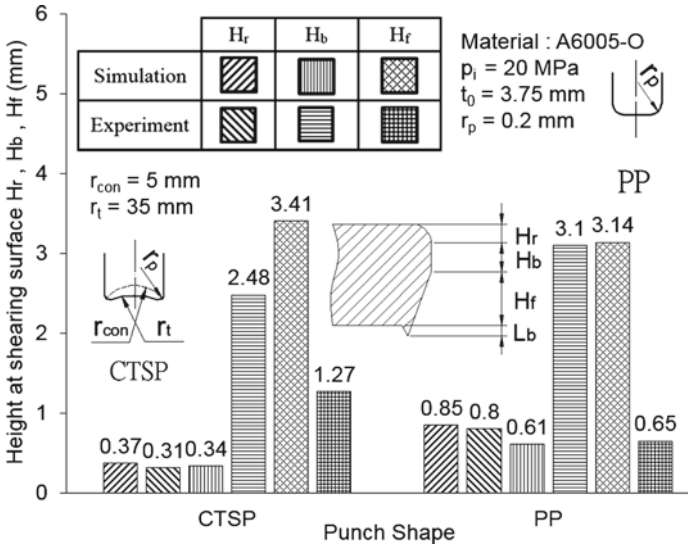

Fig. 11 Effects of punch shape on characteristics of hydro-pierced hole section

4.2 Experimental Results

Figure 11 shows the effects of punch shapes on the characteristics of the hydro-pierced hole section. Clearly, a larger roll-over height, a larger burnished surface height, and a smaller fracture surface height are obtained using punch type of PP compared with those using punch type of CTSP for both simulation and experimental results, which means a better-pierced hole section can be obtained using punch type of PP for tube material of A6005-O. A larger stroke is required using punch type of PP, thus a larger roll-over height is obtained. Generally, the simulation results of roll-over height are coincident with the experimental data. In Fig. 11, there is some discrepancy between simulative and experimental burnished surface heights. That is because the critical damage values in the NCL ductile fracture criterion, which influences greatly the burnished surface height, is difficult to obtain accurately from tensile tests.

Figure 12 shows the effects of punch shapes on the burr length of the hydro-pierced hole section. Clearly, a smaller burr length is obtained using punch type of CTSP compared with those using punch type of PP for both tube materials of A6005-O and A6005-T5, which means a better-pierced hole section can be obtained using punch type of CTSP. A larger stroke is required using punch type of PP, thus a larger burr length is obtained. On the other hand, the burr length for an aluminum alloy of A6005T5 is smaller than that for A6005-O, because A6005T5 is harder than A6005-O.

Figure 13 shows the comparisons of residual thickness between simulation and experimental results with tube thickness of $t_i = 3.75$ mm using punch type of CTSP

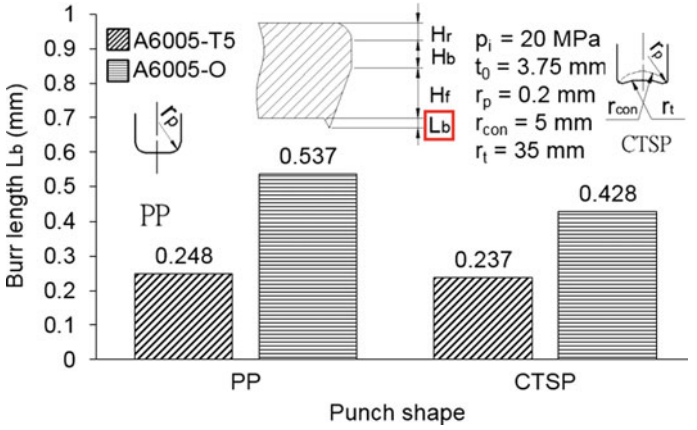

Fig. 12 Effects of punch shape on burr length of hydro-pierced hole section. (Color figure online)

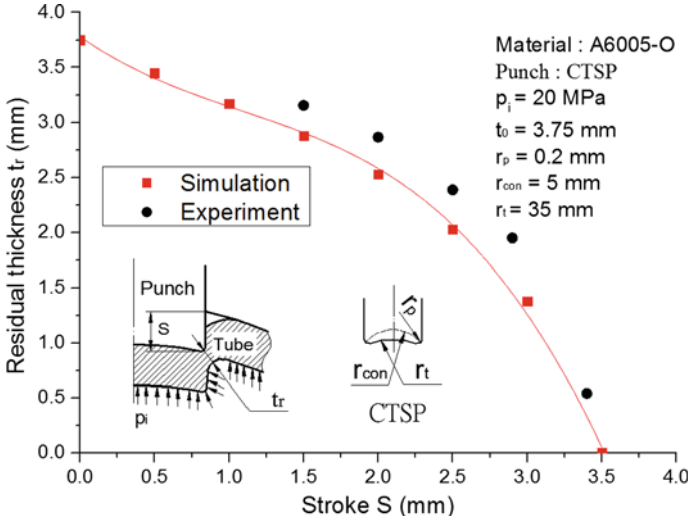

Fig. 13 Comparisons of residual thickness between simulation and experimental results. (Color figure online)

and internal pressure of 20 MPa. Clearly, the residual thickness decreases with the stroke. In other words, as the punch moves forward, the residual thickness decreases from the initial value of 3.75 mm to 0 mm. Generally, the simulation results are quite coincident with the experimental data. The final strokes at tr = 0 mm for simulation and experimental values are 3.50 and 3.60 mm, respectively. Generally, the errors between the simulation and experimental results are about 10%.

5 Conclusions

The finite element software "Deform 3D" was used to analyze the plastic deformation and fracture behavior in tube hydro-piercing processes of aluminum alloys A6005-O and A6005-T5. The effects of various parameters, such as the punch shape, internal pressure, etc., on the characteristics of the pierced hole section after hydro-piercing processes were discussed. Hydro-piercing experiments of aluminum alloys A6005-O and A6005-T5 tubes were conducted. From the simulation and experimental results, it is known that the punch shape of concave tube surface punch (CTSP) is a better design for obtaining a smaller roll-over height and a smaller burr length. Higher internal pressures could reduce the roll-over height and increase the burnished surface fraction on the pierced hole section. The simulation results are generally coincident with the experimental data.

Novel Roll-Bonded Stainless Steel/Boron-Steel Multilayer Under Hot Stamping Conditions

Mike Kamaliev, Marco Teller, Christian Löbbe, Gerhard Hirt, and A. Erman Tekkaya

Abstract Aluminum-silicon-coated (AlSi-) boron-steels are regarded as standard material in direct hot stamping processes. Nevertheless, the material brings along some disadvantages such as the requirement of a long dwell time in the furnace for the generation of a resistant diffusion layer. In this paper, a multilayer steel sheet with a boron-steel core-layer and stainless steel outer-layers is introduced and the manufacturing process by hot roll-bonding is described. Due to the stainless steel surfaces, a coating for hot stamping is no longer necessary. The multilayer is characterized by hot tensile tests and compared with the monolithic multilayer-partners. Hot stamping experiments are conducted on a laboratory scale. Corresponding hardness measurements show that the core-layer is hardened while the outer-layers remain ductile. The new multilayer sheets offer the potential to deliver components with higher formability due to tailored properties along the sheet thickness and the use of rapid heating methods.

Keywords Roll-bonding · Hot stamping · Multilayer

1 Introduction

Due to the high component strengths and the design freedom, hot stamping is an established manufacturing process for safety-relevant components in the automotive industry [1]. Boron-steels with AlSi-coating are still considered as standard materials for this process, with 22MnB5 is the most common alloy [2]. Due to the low melting temperature of the AlSi-layer, the formation of stable Fe/Al/Si diffusion layers is necessary [3]. The required temperature treatment takes place within narrow specifications so that sufficient time is available for the safe development of the protective

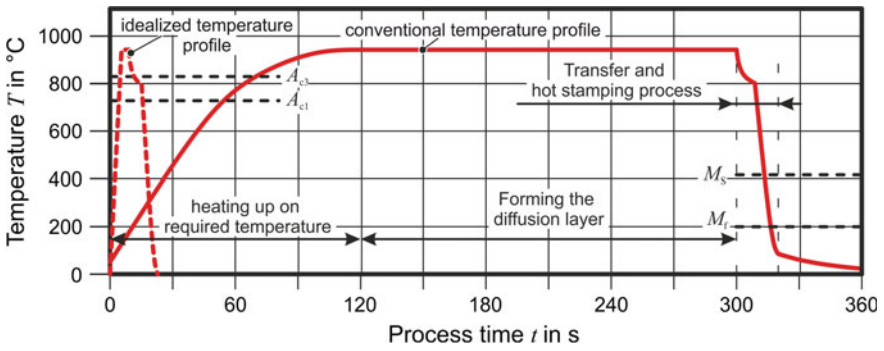

Fig. 1 Typical temperature profile during conventional hot stamping and idealized profile representing processes with rapid heating methods. (Color figure online)

diffusion layers. Like exemplary shown in Fig. 1, a large part of the total process time is attributable to the defined temperature profile. Processes which use rapid heating methods like resistance or induction heating allow temperature profiles from less than 20 s (compare: idealized temperature profile—Fig. 1), shown exemplarily in [4]. With such high heating rates, the use of coating is difficult. On the other hand, the use of uncoated material leads to thin oxide layers which has to be removed after the process—e. g., through blasting or ultrasonic cleaning [5].

A recent developed boron-steel for hot stamping is the roll-bonded three-layer material composite Tribond® from thyssenkrupp Steel Europe AG. The combination of conventional 22MnB5 as core-layer and a microalloyed steel as outer-layers allow for tailored properties over the sheet thickness. AlSi-coatings are still required for this composite in order to protect the material from corrosion [6].

One potential solution to avoid coatings like AlSi is the use of chromium-steels which are offered by different companies (e. g., Aperam—[7]) On the other hand, depended on the exact alloy, an additional thermal treatment is required for these materials. Also the mechanical properties are homogenous over the sheet thickness and the material costs are higher.

The main challenge when plating composite materials is to break-up passivating oxide layers and impurities on the surfaces to be joined so that metallic contact can arise between the composite partners. For this purpose, the surfaces are prepared before the actual plating process [8]. A renewed oxidation of the joining zone must be prevented, especially in hot roll bonding. Therefore, the outer edges of the stacked sheets are often welded [9].

The use of roll-bonded boron-chromium-composites for hot stamping represents a new approach that combines the specific advantages of each alloy. Using a boron-steel as core material and a ductile austenitic stainless steel as outer-layers would lead to tailored products which don't need an AlSi-coating. In order to assess the potential of this composite for hot stamping, the basics of roll-bonding manufacturing, the forming behavior, and the final product properties need to be investigated. This paper will first describe the roll-bonding process to produce such a composite.

Furthermore, the flow stress at elevated temperatures and in the hot-stamped state is investigated. Finally, analytical methods are applied to predict the flow stress, using the characterized separate materials.

2 Experimental Procedure

As core material an industrially produced 27MnCrB5-2 (precidur HLB27, 1.7182) is chosen, which provides the desired strength in the hot-stamped state. For the outer-layers an industrially produced X5CrNi18-10 (1.4301) is used, which brings the required resistance against cinder and corrosion. Furthermore, this austenitic steel is not hardening during hot stamping, whereby the desired tailored properties over the sheet thickness can be reached.

An initial layer ratio of 1:8:1 is chosen, resulting in a core-layer of $s_C = 12$ mm thickness and outer-layers of $s_L/2 = 1.5$ mm thickness (1.5 mm on each site). Different formats with 100 × 250 mm^2 and 175 × 250 mm^2 are cut from the materials. The surfaces are then cleaned by sandblasting and the package is stacked. Due to the low initial thickness of the package and therefore low possible height reduction as well as surface enlargement within rolling, a melter (brazing powder) is applied into the gaps to improve the break-up of the oxide layers. The composite packs, with a total thickness of 15 mm, are welded all around the side faces and on the end faces, leaving a small free space at the head end. The free space allows the melter and the broken oxide layers to leave the contact zones during rolling. The prepared packages are heated in the furnace to 1200 °C within 30 min and afterwards hot-rolled within four passes. After each pass a reheating in the furnace took place and after selected passes, due to the excessive elongation of the semi-finished products, an intermediate cross-cutting after cooling took place. Figure 2 shows the different process steps and the rolling schedule used. After a final cutting, roll-bonded sheets with a length of 1200 mm and a good surface quality are achieved.

In order to characterize the material behavior during the forming process, hot tensile tests with an initial gauge length of $l_0 = 30$ mm are conducted in a Zwick Z250. The complete experimental setup is shown in Fig. 3a. The specimens are heated inductively, using a single-strip face inductor. The traverse velocity of the test is defined as $v = 1$ mm/s. The temperature is measured by a pyrometer Metis M318 and controlled by a PID-controller (co. Sensortherm). The elongation is measured by a high-temperature extensometer PMA-12/V7 with ceramic measurement roods (co. Maytec). The temperature profile is based on a conventional hot stamping process (Fig. 1) with an austenitization temperature of $T_A = 950$ °C and an austenitization time of $t_A = 300$ s (consisting of 120 s heating up and 180 s dwell time). The specimens are cooled for 10 s on forming temperatures T_F between 700 °C and 800 °C, to simulate the transfer during a hot stamping process, before starting the tensile test. In order to be able to compare the flow behavior of the composite material with the individual partners, these are also investigated with the same conditions.

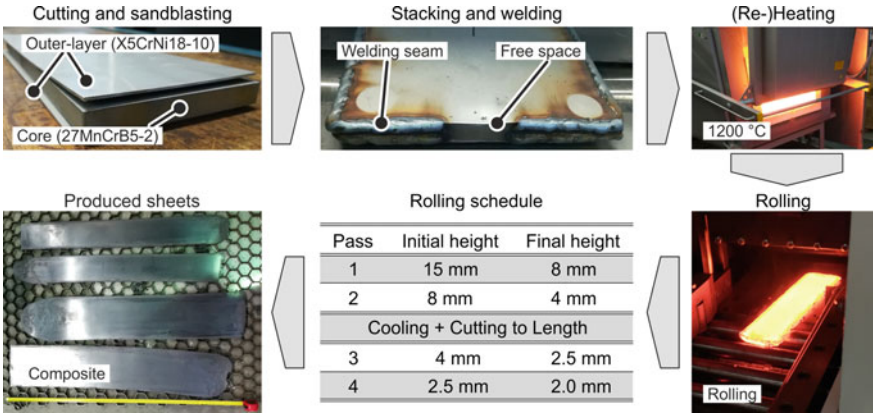

Fig. 2 Process chain and rolling schedule for the production of roll-bonded sheets including the preparation of sheet stacks. (Color figure online)

To estimate the mechanical properties from the roll-bonded composites after the process, sheets are hot stamped without deformation between two cooled plates. The experimental setup is shown in Fig. 4a. Therefore, the specimens are austenitized in a furnace N161 (co. Nabertherm) $T_A = 950$ °C for $t_A = 300$ s. After a manual transfer with the time of $t_T = 10$ s, the specimens are quenched through two cooled plates with a contact pressure of $p_Q = 6$ MPa for $t_Q = 10$ s. For further investigations, specimens for hardness measurements and tensile tests are cut out from the sheets. Tensile tests are conducted in a Zwick Z250 regarding DIN EN ISO 6892–1 with a gauge length of $l_0 = 50$ mm. Microhardness measurements (HV0.1) are conducted over the sheet thickness to determine the hardness and the extent of a boundary layer. Again, the monolithic composite partners are also examined for comparability.

3 Mechanical and Analytical Findings

Sections 3.1 and 3.2 describe the experimental results. These are fundamental for an analytical description in Sect. 3.3 to predict the flow stress of the composite. Various approaches are tested to predict the flow stress of the multilayer at elevated temperatures and after hot stamping.

3.1 Flow Behavior at Elevated Temperatures

The true stress σ as function over the true plastic strain ε_{pl} at temperatures of 700, 750, and 800 °C are shown in Fig. 3b. Table 1 shows the resulting yield points k_{f0} and strain hardening coefficients n. The outer-layers (X5CrNi18-10) have the highest

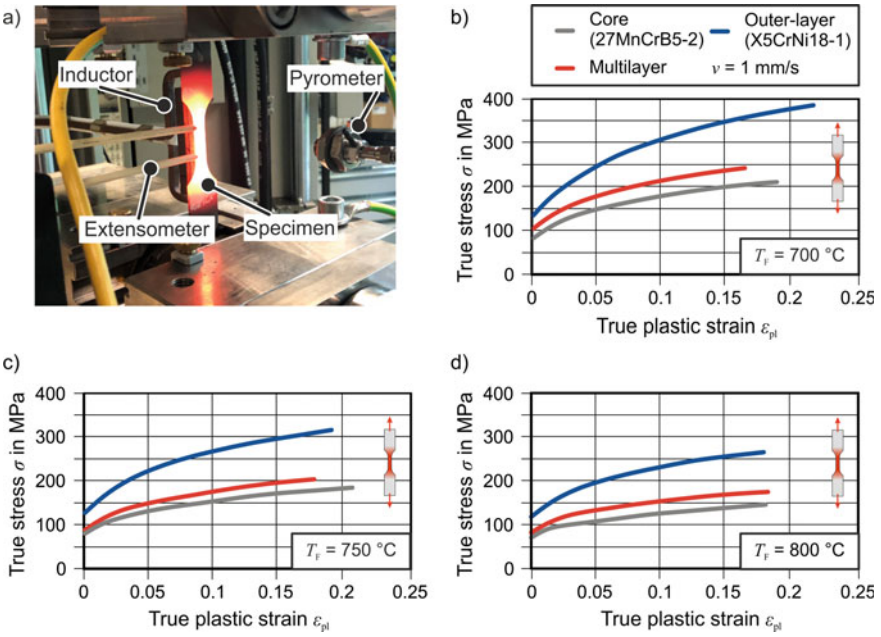

Fig. 3 **a** Experimental setup for tensile tests at elevated temperatures as well as the flow curves of the monolithic steels and the multilayer at **b** 700 °C, **c** 750 °C, and **d** 800 °C. (Color figure online)

Table 1 Results from the tensile tests at elevated temperatures for the monolithic steels and the multilayer

Temperature	700 °C		750 °C		800 °C	
Parameter	k_{f0} in MPa	n	k_{f0} in MPa	n	k_{f0} in MPa	n
Outer-layer (X5CrNi18-10)	130.5	0.31	127.0	0.26	123.7	0.24
Core-layer (27MnCrB5-2)	80.9	0.26	85.3	0.22	83.9	0.18
Multilayer	100.4	0.26	91.0	0.23	86.1	0.20

yield stress at all temperatures. The yield point k_{f0} is on average 43 MPa higher than that of the core material (27MnCrB5-2). Also the measured hardening coefficients are higher. This can be traced back to the alloy elements chrome and nickel.

The flow curves of the multilayer lie between the monolithic partners. The qualitative tendency toward the core material is explained by the layer ratio. This also causes the values for the yield points k_{f0} and the strain hardening coefficients n.

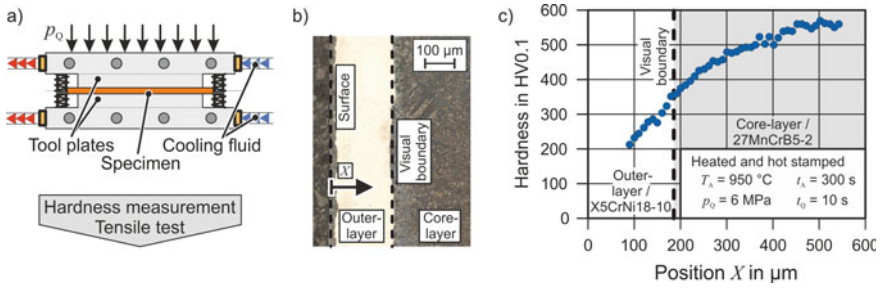

Fig. 4 **a** Experimental setup for hot stamping, **b** optical microscopy of the hot stamped multilayer steel, and **c** hardness in HV0.1 over the visual boundary-layer after hot stamping. (Color figure online)

3.2 Mechanical Properties Under Hot Stamped Conditions

In order to investigate the three different materials after hot stamping, samples were cut out, prepared and microhardness measurements in HV0.1 were carried out. Average values of $HV_L = 186.0$ HV0.1 for the outer-layers and $HV_C = 544.1$ HV0.1 for the core-layer were determined.

In order to investigate the geometrical dimensions of the different composite layers, microhardness measurements are carried out with a distance of $X = 10$ µm. Figure 4c shows the values depending on the distance to the surface. A pronounced transition zone can be recognized, which is probably the result of diffusion processes during the manufacturing process and is regarded as an extra layer. The dimensions from outer-layers and core-layer result from a comparison with the hardness values of the monolithic materials. Due to the required minimum distance to the material surface, the first valid measured values could be determined at $X = 100$ µm. Although a higher hardness compared to 186.0 HV0.1 of approx. 200 HV is determined, the boundary to the outer-layer is defined here. It is assumed that this will have a negligible influence on the following investigations.

The results from the tensile test after hot stamping are shown in Fig. 5. The yield points $R_{p0.2}$ and ultimate tensile strength R_m of the multilayer lie between the values from the monolithic partners. The uniform elongation A_G of the multilayer should

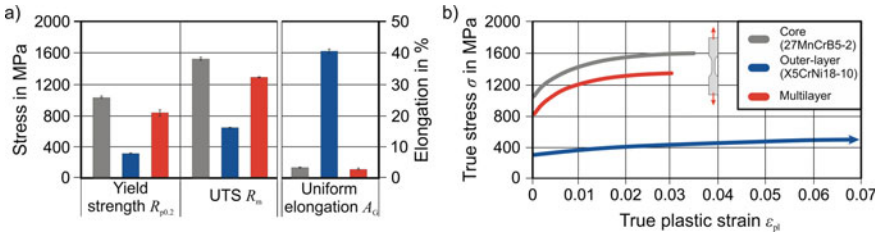

Fig. 5 **a** Parameters from the tensile test regarding DIN EN ISO 6892–1 and **b** Flow curve of the multilayer and the monolithic partners after hot stamping. (Color figure online)

be specified by the brittle partner and is slightly less than expected. The courses of the flow curves are shown in Fig. 5b. While the outer-layers still have high ductility and low strength, the core-layer exhibits a level as expected in hot stamping. The composite material is in terms of strength between the two partners.

3.3 *Analytical Empiric Prediction of Composite Properties*

After the experiments have shown an intermediate flow stress of the bounded material, this section examines different analytical approaches to predict the flow stress of the multilayer material at elevated temperatures and after hot stamping. The aim is to describe the material behavior, although only the separated partners are characterized or to transfer the flow stress to varying layer ratios. In this way, e. g., a required strength of the material after hot stamping can be designed and the flow curve at elevated temperatures can be defined for numerical simulations, without roll-bonding the composite. The experimental results are used to validate the analytics.

Firstly, the dimension of the different layers has to be defined, based on the hardness measurements from Fig. 4c. The values show a clear transition zone where other properties have to be assumed. It follows that the layer ratio before roll-bonding (index 0) and after the roll-bonding together with hot stamping (index 1) must be considered separately, like shown in Fig. 6. While the initial layer ratio is a combination of outer-layer and core-layer

$$\frac{s_{C,0}}{s_0}+\frac{s_{L,0}}{s_0}=R_{L,0}+R_{C,0}=1, \tag{1}$$

the roll-bond and hot-stamped multilayer has to be described with an extra transition zone

$$\frac{s_{C,1}}{s_1}+\frac{s_{B,1}}{s_1}+\frac{s_{L,1}}{s_1}=R_{L,1}+R_{B,1}+R_{C,1}=1 \tag{2}$$

where s is the thickness of the associated layer (C: Core; B: Boundary-layers; L: Outer-layers) and R stands for the ratio to the total composite thickness s_1. The flow

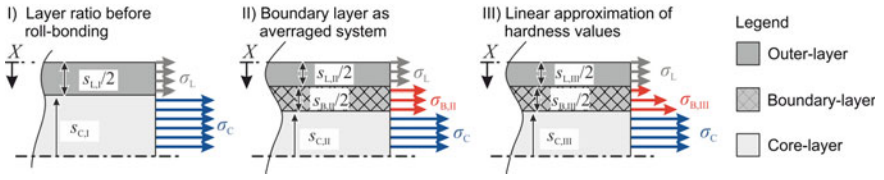

Fig. 6 Different efforts to describe the analytical flow behavior of the multilayer under various conditions. (Color figure online)

stress of the multilayer $\sigma_M(\varepsilon_{pl})$ is assumed to be the sum of these individual parts

$$\sigma_M(\varepsilon_{pl}) = \sigma_L(\varepsilon_{pl}) \cdot R_L + \sigma_B(\varepsilon_{pl}) \cdot R_B + \sigma_C(\varepsilon_{pl}) \cdot R_C \tag{3}$$

where $\sigma_L(\varepsilon_{pl}) \cdot R_L$ stands for the outer-layers, $\sigma_B(\varepsilon_{pl}) \cdot R_B$ for the boundary-layers and $\sigma_C(\varepsilon_{pl}) \cdot R_C$ for core-layer. While the specific flow stress of the outer-layer $\sigma_L(\varepsilon_{pl})$ and core-layer $\sigma_C(\varepsilon_{pl})$ are known from previous experiments, the behavior and dimension from the boundary-layer $\sigma_B(\varepsilon_{pl}) \cdot R_B$ is unknown. This also makes the ratios R_L, R_B, and R_C undefined. Therefore, three approaches I, II, and III are examined with different efforts—visualized in Fig. 6:

I. The ratios $R_{L,0}$ and $R_{C,0}$ before roll-bonding are used. Through this approach, there is no boundary-layer and

$$\sigma_{B,I}(\varepsilon_{pl}) = 0 \tag{4}$$

is valid. The ratios before roll-bonding are used so that $R_{L,I} = R_{L,0}$ and $R_{C,I} = R_{C,0}$ are valid. For this approach, only the flow behavior of the separated partners has to be characterized in advance. In the following, it is checked whether the prediction is sufficiently accurate to give an initial estimate of the properties.

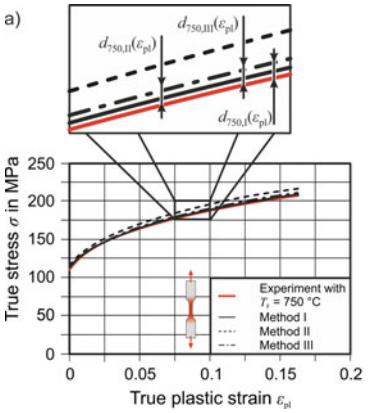
II. The boundaries between the core-layer and the outer-layers are averaged and regarded as homogeneous. Taking into account the hardness measurements, the dimension of the boundary-layer is set between $X = 100$ and 450 µm. The ratios $R_{L,II}$, $R_{B,II}$, and $R_{L,II}$ can now be calculated. The flow behavior of the boundary-layer $\sigma_{B,II}(\varepsilon_{pl})$ is assumed to be the average between the core-layer $\sigma_C(\varepsilon_{pl})$ and the outer-layer $\sigma_L(\varepsilon_{pl})$.

$$\sigma_{B,II}(\varepsilon_{pl}) = \frac{\sigma_C(\varepsilon_{pl}) + \sigma_L(\varepsilon_{pl})}{2}. \tag{5}$$

Hot stamping of the composite and microhardness measurements are required to define the thickness and allow the calculation of the ratios. Transferability to different layer ratios is assumed here.

III. The dimension of the boundary-layers will be defined between $X = 100$ and 450 µm, like in method II. Assuming that the flow behavior is proportional to the hardness, a linear approximation is carried out for each measured value after hot stamping. The number of the increments is defined by the number of hardness measurements n_H in the defined boundary-layer. In this way, the flow stress of each geometric increment is defined as the mixed function of the separated partners. Similar to [10], the relationship between the hardness defines the flow curve of the boundary-layer $\sigma_{B,III}(\varepsilon_{pl})$

$$\sigma_{B,III}(\varepsilon_{pl}) = \sum_{i=1}^{n_H} \frac{1}{n_H} \cdot \left[\left(\frac{HV - HV_L}{HV_C - HV_L} \right) \cdot \sigma_C(\varepsilon_{pl}) + \left(\frac{HV_C - HV}{HV_C - HV_L} \right) \cdot \sigma_L(\varepsilon_{pl}) \right], \tag{6}$$



where HV_C is the average hardness of the core, HV_L the average hardness of the outer-layers, and HV the hardness of the associated increment. In this way, each hardness measurement is considered as a separate layer. For this approach, the multilayer has to be hot stamped, hardness measurements have to be conducted and a linear approximation must be performed. Like in method II, a transferability to other layer ratios is assumed.

The approaches are assessed on the basis of the average $|\overline{d}_P|$ and the maximum deviation $|d_{P,max}|$ from the experimental results, where the index P stands for specific material conditions (700, 750, and 800 for elevated temperature at the listed value; HS for hot stamped). For this, the amount of the average deviation for defined process parameters $|\overline{d}_P|$ in every plastic strain increment (here 0.001) is determined

$$|\overline{d}_P| = \left[\frac{1}{n_\varepsilon} \cdot \sum_{i=1}^{n_\varepsilon} \left|d_P(\varepsilon_{pl})\right|\right] \cdot 100\% = \left[\frac{1}{n_\varepsilon} \cdot \sum_{i=1}^{n_\varepsilon} \frac{\left|\sigma_{P,M}(\varepsilon_{pl}) - \sigma_{P,E}(\varepsilon_{pl})\right|}{\left|\sigma_{P,E}(\varepsilon_{pl})\right|}\right] \cdot 100\%, \tag{7}$$

where n_ε is the total amount of plastic strain increments, $\sigma_{P,M}(\varepsilon_{pl})$ is the analytical true stress, and $\sigma_{P,E}(\varepsilon_{pl})$ is the experimental true stress for the associated increment (the index M stands here for the considered analytical method I, II, or III). Figure 7a shows one example at defined process parameters. Furthermore the maximum deviations $|d_{P,max}|$ are listed, which defines the maximum deviation between analytical and experimental true stresses σ at specific plastic strains ε_{pl} for each method. The results for the calculated layer ratios (with $s_1 = 2.04$ mm) and different deviations for various process parameters (700, 750, and 800: tensile tests at elevated temperatures; HS: tensile tests with hot-stamped material) are shown in Fig. 7b.

a)

b)

Parameter			Method I	Method II	Method III
layer ratios	R_L	-	0.2	0.10	0.10
	R_B		0	0.34	0.34
	R_C		0.8	0.56	0.56
700 °C	$\lvert\overline{d}_{700}\rvert$	%	5.00	1.52	3.98
	$\lvert d_{700,max}\rvert$		9.93	3.52	7.70
750 °C	$\lvert\overline{d}_{750}\rvert$	%	0.84	4.87	1.77
	$\lvert d_{750,max}\rvert$		3.52	6.65	4.33

	$\lvert d_{HS,max}\rvert$		7.88	5.55	6.32
Average	$\lvert\overline{d}_{P,Av}\rvert$	%	3.00	3.00	2.62
	$\lvert d_{P,max,Av}\rvert$		7.26	6.46	6.67

Fig. 7 **a** Example: Experimental and analytical flow curves of the multilayer at 750 °C and **b** resulting layer ratios and deviations, based on the methods I, II, and III. (Color figure online)

Comparing the three methods for different material conditions, no clear tendency can be determined. The mean deviations fluctuate between 0.84% and 5.00% while the maximum deviation at defined true plastic strain between 1.10 and 9.93%. To be able to assess the accuracy of the three analytical approaches regardless of the process parameters, $|\overline{d}_{\mathrm{P,Av}}|$ and $|\overline{d}_{\mathrm{P,max,Av}}|$ show the average values of all deviations. Only minor differences between the individual analytical approaches are determined here.

4 Conclusion and Outlook

A multilayer material made of boron-steel precidur HLB 27 (27MnCrB5-2) as core-layer and a chromium-steel (X5CrNi18-10) as outer-layers were successfully manufactured using hot roll-bonding. The flow behavior of the multilayer and the separated partners were characterized at elevated temperatures from 700 to 800 °C through tensile tests. Conventional direct hot stamping processes were conducted with two cooled flat tools. Hardness measurements show that the core-layer hardened by martensitic transformation with 544.1 HV0.1, while the outer-layer with 186.0 HV0.1 stays softer. Tensile tests after hot stamping of the multilayer shows an averaged UTS of 1297 MPa. The uniform elongation of the composite is with averaged 3.1% lower than from the core-layer. This can be attributed to insufficient bond strength of the separated partners [11]. For comparability and analytical approaches, experiments with the monolithic partners have also been conducted. Three different methods were investigated, which should predict the flow stress of the multilayer material, based on an analysis of the separated partners. All three approaches show average deviations of 3% or less, whereby every analytical procedures can be considered suitable. Method I is qualified for providing an estimate of the material properties to be expected before the multilayer is manufactured. Method II and III in combination with hardness measurements provide another option for carrying out the appraisal.

In the following, the manufacturing process of the composites by roll-bonding will be examined further and supplemented by subsequent steps like diffusion annealing. Also different layer ratios and outer-layer materials have to be taken into account to investigate the transferability of the analytical methods. Furthermore, an empirical prediction for the boundary-layer dimension is sensible. This would enable the use of all methods without prior roll-bonding a composite. Forming processes next to tensile tests has to be conducted to investigate the adhesive strength of the multilayer material at different strain states. A combination with rapid heating methods like induction would also reflect the potential reductions in process time. If the roll-bonding of boron-chromium-steels is mastered robustly, an expansion to tailored sheet metal is also possible. One potential design is shown in Fig. 8. Such a material with variable layer ratios over the width would allow the hot stamping of tailored products in conventional process routes.

Effect of Machining Induced Microstructure Changes on the Edge Formability of Titanium Alloys at Room Temperature

J. S. Kwame, E. Yakushina, and P. Blackwell

Abstract The challenges in forming titanium alloys at room temperature are well researched and are linked both to the limitations imposed by the basic crystal structure and their ability to form texture during plastic deformation. One major issue of concern for the sheet forming of titanium alloys is their high sensitivity to surface inhomogeneity. Various machining processes are utilised in preparing sheet hole edges for edge flanging applications. However, the response of edge forming tendencies of titanium to different edge surface finishes is not well investigated. The hole expansion test is used in this project to elucidate the impact of Abrasive Water Jet (AWJ) and Electro-discharge machining (EDM) cutting techniques on the edge formability of CP-Ti (Grade 2) and Ti-3Al-2.5 V alloys at room temperature. The results show that the quality of the edge surface finish has major effect on the edge formability of the materials. The work also found that the variations in the edge forming performance are mainly the result of the influence of machining induced edge surface defects.

Keywords Titanium alloys · Hole expansion test · Edge formability · Non-conventional machining

1 Introduction

Titanium and its alloys have been widely used in the aerospace industry mainly due to their excellent properties such as high temperature strength compared to aluminium, their good strength to weight ratio compared to steels and their good corrosion resistance [1]. However, various issues have been identified to have limited their use. One such is their low formability at room temperature due to limited slip

systems caused by their crystallographic structure and their tendency to develop strong textures with concomitant planar anisotropy [2]. Another limiting factor is their high sensitivity to surface inhomogeneity resulting in reduced fatigue life [3]. These surface inhomogeneities are sometimes introduced during machining processes. Considering the poor machinability of titanium [4], issues relating to the extent of edge defects produced during machining become a major area of research interest. Low heat conductivity coupled with chemical reactivity of titanium are some of the reasons contributing to their poor machinability [5]. Depending on the method used to machine titanium, certain levels of edge surface defects may be introduced onto the part surface. The common edge surface defects produced during machining of titanium include carbide cracking induced cracks, microstructure alteration, white layer formation, and residual stress [6]. Normally, conventional and non-conventional machining methods are adopted in cutting titanium and other metals. Non-conventional machining methods are non-contact techniques widely adopted in industry since they eliminate tool-part contact related issues [7]. Abrasive water jet (AWJ) cutting and Electro-discharge machining (EDM) are used in this work. A standard hole expansion test (HET) is used in this research to examine the hole edge formability of the materials. The extent of edge formability is defined by the hole expansion ratio (HER). The higher the HER value, the higher the edge forming performance of the material. The HER is enumerated by finding the percentage of the ratio of the difference between the final and initial hole diameter to the initial hole diameter [8];

$$HER = \frac{d_f - d_0}{d_0} \times 100\% \tag{1}$$

where d_f—final hole diameter, d_0—initial hole diameter.

Since areas around the hole edge are regions of high stress concentration, the integrity of the fabricated edge becomes a significant factor during HET. However, the impact on forming performance of edge surface micro-features and defects introduced into titanium alloys during machining has not been extensively researched. This work is directed at ascertaining the impact of EDM and AWJ induced edge microstructure alterations on the edge formability of titanium alloys deformed at room temperature. The work seeks to understand how the cutting techniques examined alter the edge related failure modes and failure nucleation process in titanium alloys.

2 Experimental Procedure

2.1 The Materials

The materials studied in this work are commercially pure titanium (CP-Ti) Grade 2 and Ti-3Al-2.5 V alloys. Ti-3Al-2.5 V alloys have intermediate strength and good cold workability. This alloy is mainly utilised in aerospace applications such as hydraulic tubing and light weight honeycomb structures. CP-Ti (Grade 2) possesses a good strength to weight ratio and also has the ability to maintain its strength appreciably during deformation. They are also largely employed in airframe skin applications [9].

2.2 Material Preparation

The edge surface roughness values and micrographs were characterised using an Alicona 3D microscope. The edge surface topography and crack surface fractographs were also examined using a Quanta FEG 250 microscope. AWJ cut edges were prepared with a Calypso water jet machine, operated at 70HP and at a feed rate of 400 g/min. The transverse cutting speed was varied to attain two different edge surface finishes for both materials (250 mm/min: finished edge surface and 600 mm/min: unfinished edge surface). Both materials showed higher edge surface micro-ridge distribution for the unfinished AWJ edges compared to the finished parts. The ratio of the edge surface micro-grooves to micro-ridges was also fairly even for the finished AWJ cut edges compared to the unfinished parts for both materials; Fig. 1a, b, e, f. The EDM cut edges were machined using a GF FI 440 CCS machine fitted with a 0.25 mm diameter brass cutting wire. The EDM cutting parameters were varied to attain two distinct edge surface finishes (1. wire tension ~2 $\times$ 10^1 N, pulse on time

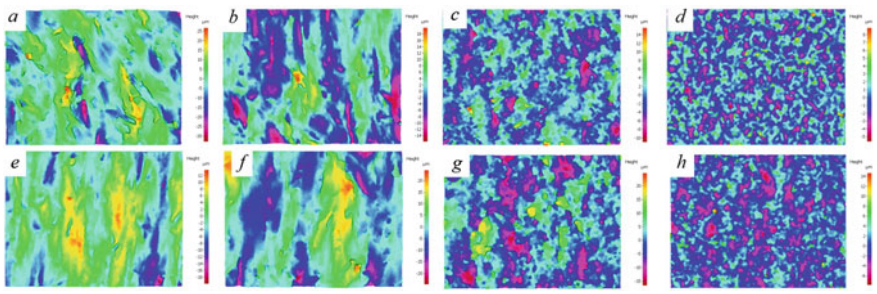

Fig. 1 Alicona micrograph of surface topography and roughness after EDM and AWJ cutting. **a** Unfinished (Ra~5.2 μm) and **b** Finished (Ra~3.2 μm) AWJ for CP-Ti; **c** Unfinished (Ra~2.7 μm) and **d** Finished (Ra~0.8 μm) EDM for CP-Ti; **e** Unfinished (Ra~5.7 μm) and **f** Finished (Ra~3.8) AWJ for Ti-3Al-2.5 V; **g** Unfinished (Ra~2.9 μm) and **h** Finished (Ra~1 μm) EDM for Ti-3Al-2.5 V. (Color figure online)

Table 1 Room temperature tensile properties

Material	Type	Yield strength (0°, 45°, 90°), MPa	Tensile strength (0°, 45°, 90°), MPa
CP-Ti (Grade 2)	α	197.99, 218.19, 250.05	550.31, 489.43, 513.25
Ti-3Al-2.5 V	α/near α	165.97, 188.75, 168.99	605.44, 504.38, 529.42

~0.05 ms, pulse off time ~20 ms: for finished edges and 2. wire tension ~1.3×10^1 N, pulse on time ~0.7 ms pulse off time ~2 ms: for unfinished edges). Both materials showed a finer distribution of surface micro-grooves for the finished EDM edges compared to the unfinished edges; Fig. 1c, d, g, h. The attained surface micro-groove size and distribution for the finished EDM edges for CP-Ti are finer compared to those observed for Ti-3Al-2.5 V; Fig. 1d, h.

2.3 Hole Expansion Test

Hole expansion testing was performed on a Zwick/ Roell BUP 1000 testing machine controlled by testXpert II software. A 60° head conical punch with a die set design consistent with ISO 16,630:2017 was used to deform a 10 mm diameter hole produced with either AWJ or EDM cutting methods. The test trials were done for the two cutting methods as well as their two distinct edge surface finish qualities. A blankholder force of 150 kN was used to prevent the material from drawing-in during the test. The punch was driven at a speed of 1 mm/s through the fabricated hole until an edge crack occurred.

2.4 Mechanical Properties

A Zwick/ Roell Z150 tensile testing machine was used to perform a standard room temperature uniaxial tensile test consistent with ISO 6892–1:2016. The tests were conducted at a constant strain rate of 0.001/s. Both materials exhibited anisotropic behaviour when examined in three sheet processing directions, Table 1.

3 Results and Discussion

3.1 Machined Edge Surface Topography and Defects

The edge surfaces after AWJ machining were characterised by surface mechanical erosion features, produced by the tracks travelled by the abrasive particles during the

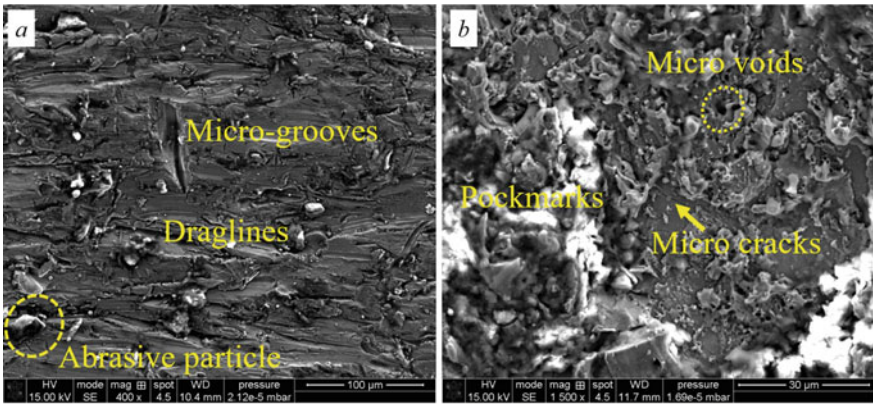

Fig. 2 Surface topography of machined edges. **a** AWJ cut edge surface, **b** EDM cut edge surface. (Color figure online)

cutting process. The surface draglines, micro-grooves, and dents observed are also due to the areas occupied and/or vacated by the abrasive particles during the cutting process, Fig. 2a.

The surface after EDM cutting showed features consistent with its heat erosion attributes. The surface featured micro-voids, micro-cracks, craters, ridges, and pockmarks as the main edge defects, Fig. 2b. The extent of surface pockmarks produced is a function of the ability of the dielectric fluid to wash away debris during the cutting process in the quest to minimise melt solidification.

3.2 Hole Edge Formability

Figure 3 shows the hole edge forming performance of both materials tested for two different edge cutting methods and edge surface finish qualities.

The EDM cut edges showed highest edge formability (CP-Ti: ~195.86% and Ti-3Al-2.5 V: ~78.16%) compared to AWJ cut edges (CP-Ti: ~140.38% and Ti-3Al-2.5 V: ~49.84%). Both materials showed better edge formability for the finished cut edges (CP-Ti: EDM ~195.86%, AWJ ~140.38%, and Ti-3Al-2.5 V: EDM ~78.16%, AWJ ~49.84%) compared to the unfinished edges (CP-Ti: EDM ~148.4%, AWJ ~100.9%, and Ti-3Al-2.5 V: EDM ~69.73%, AWJ ~42.48%) for both cutting techniques. Overall, CP-Ti showed better edge formability compared to Ti-3Al-2.5 V alloy. This trend could be attributed to the nature of the edge microstructures produced after machining of both materials. Generally, the edge micro-features attained for both materials are varied after EDM and AWJ machining. CP-Ti after AWJ cutting showed lower levels of edge surface micro-grooves and defects compared to Ti-3Al-2.5 V, Fig. 4a, b. The EDM microstructure also showed a high volume fraction of machining induced micro-cracks in CP-Ti compared to Ti-3Al-2.5 V, Fig. 4c, d. Pure titanium is predominantly alpha phased alloys and is relatively soft and easier to

machine compared to alloyed titanium [10]. Heat conductivity also plays a massive role in titanium machinability in terms material and heat removal rate. Pure titanium generally exhibits stable heat conductivity with rising temperature during machining compared to its alloyed counterparts [11]. The severity of defects produced during machining is a function of the ease of machinability of the components.

3.3 Failure Nucleation

The edge surface defects observed after AWJ machining are mainly due to the action of the abrasive particles. The severity of the edge defects is a function of the machining parameters and the material's machinability. The surface defects produced on the material surface after AWJ machining act as stress concentration sites (yellow arrow) during HET, Fig. 5a. These defects sites serve as areas of high energy concentration where the cracks begin to grow. The rate of the crack growth is dependent on the defect depth, distribution, and size.

The AWJ fracture surface is characterised by micro-void nucleation sites with dimpled surface at spherical inclusions, Fig. 5b. The growth of these micro-voids around the spherical inclusions (by virtue of interface decohesion) is mainly due to the action of plastic strain and hydrostatic stress which results in major flaws and subsequent failure upon coalescence. Generally, the trajectory of the crack is a function of the stress state at the hole edge. The stress state around the hole edge during HET is pure uniaxial tension [12]. Since the hole edge is subjected to plane strain mode I loading, the optimum plastic strain is obtained at an angle of 45° to the crack axis. From a localised point of view, this angle becomes the favoured trajectory for micro-void growth and coalescence. However, global constraints like edge defects (surface draglines and grooves) have the tendency of redirecting the crack plane path. The zigzag patterns seen at the AWJ cut edge fracture tip is as a result of the corrections made to the deviation by global constraints, reverting back to the optimum plastic strain angle, Fig. 6.

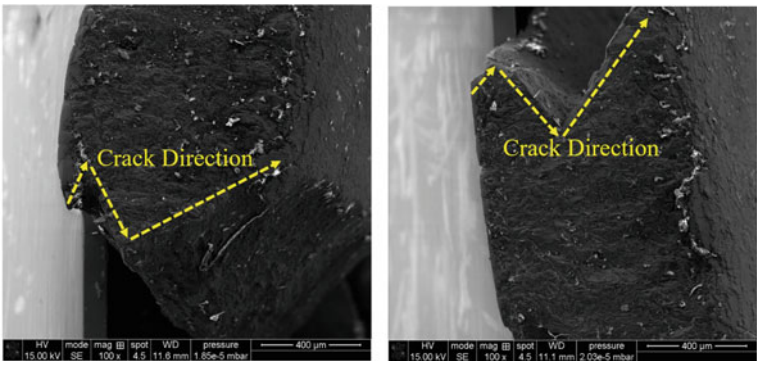

Fig. 6 AWJ edge crack orientation. (Color figure online)

On the other hand, the thermal stresses produced during EDM machining due to plastic deformation or during the cooling process are manifested on the machined surface as micro-cracks. These surface micro-cracks are responsible for distributing the imposed stresses homogenously around the hole edge during HET. This phenomenon delays early failure of the material by preventing the cracks from developing towards the thickness direction of the sheet, Fig. 7a. CP-Ti exhibited higher volume fraction of EDM machining induced surface micro-cracks compared to Ti-3Al-2.5 V cut edge, Fig. 4c, d, hence the higher edge performance. The higher the EDM induced surface micro-cracks, the higher the edge formability of the material. Hasegawa et al. [13] in their research also reported the influence of stress induced surface micro-cracks produced after punching of martensite single phase steels and their role in the restriction of crack extension towards the sheet thickness direction with an accompanying increase in the material's HER performance.

The differences in the attained EDM edge performance observed for CP-Ti and Ti-3Al-2.5 V alloys could also be attributed to the variation in EDM induced residual stress. Normally, metallurgical alterations and thermal gradients produced during EDM machining induce residual stresses [14]. As a consequence, the attained strains

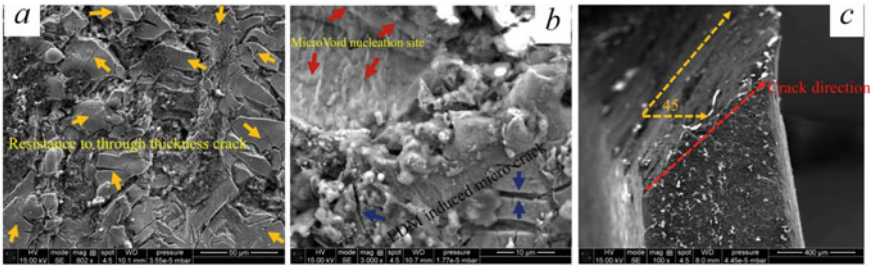

Fig. 7 EDM cut edge failure initiation process during HET. **a** Resistance to through-thickness cracking by EDM induced surface micro-cracks (yellow arrows), **b** free surface formation (red arrow), **c** edge crack orientation. (Color figure online)

result in the inception of tensile residual stresses, which are deleterious in terms of shortened fatigue life and enhanced fatigue crack growth. Fatigue generally emanates from the surface, hence the integrity of component surface is of significant essence. The residual stress values attained after EDM cutting are linked to the attained surface topography and the material yield strength [15].

The crack tip of the EDM samples after HET showed localised necking with ductile shear failure, Fig. 7c. The crack occurred just after the formation of micro-voids on the free surface, Fig. 7b. The shear stresses acting during plastic deformation become highest for a plane of maximum plastic shear strain at 45°. Through-thickness disparity in triaxiality could also be responsible for the shear deformation governed by fracture trajectory at the crack tip orienting at 45° to the optimum principal stress. In such cases, the triaxiality at the crack tip offers an adequate upgrade for micro-void nucleation reminiscent of ductile fracture [16].

4 Conclusions

Varied machining methods are used to cut titanium alloys and these introduce edge surface defects and microstructure alteration into the material. This project sought to examine the impact of AWJ and EDM induced microstructure changes on the edge formability of CP-Ti (Grade 2) and Ti-3Al-2.5 V alloys. The research also examined the nature of the edge surface related failure modes and failure nucleation processes linked to these cutting methods. It was found that

- EDM machined test samples showed higher edge forming performance compared to AWJ cut edges for both materials.
- The high edge formability of the EDM machined edges for CP-Ti was due to the high volume fraction of cutting induced surface micro-cracks compared to those observed in Ti-3Al-2.5 V. CP-Ti also showed a lower volume fraction of edge surface micro-grooves after AWJ cutting compared to Ti-3Al-2.5 V.
- The quality of the edge surface finish has a significant impact on the edge formability of the materials (1. CP-Ti: AWJ finished ~140.38%, unfinished ~100.9%; EDM finished ~195.86%, unfinished ~148.4%, and 2. Ti-3Al-2.5 V: AWJ finished ~49.84%, unfinished ~42.48%; EDM finished ~78.16%, unfinished ~69.73%
- The nature of defects introduced onto the edge surface by virtue of the machining process governs the crack nucleation, growth rate, and orientation in the material
- The failure mechanism in both materials is ductile fracture with the associated growth of micro-voids around spherical inclusions upon increase in plastic strain and hydrostatic stress.

Investigation on Springback Behavior of Multi-intersecting High Stiffened Structure in Die Forming

Qiyuan He, Weidong Li, Min Wan, Cailing Li, and Chao Cui

Abstract Multi-intersecting high stiffened structures have potential application in aerospace components, which are the main load-bearing structure of manned space station. However, its springback behavior is very complicated due to the interaction of multi-intersected ribbons and intersecting patterns during die forming. In this study, for typical spherical shaped multi-intersecting stiffened structures, a new approach is proposed to quantize the influence on flexural neutral layer of multi-intersected ribs. The strain distribution along the thickness at different radial positions of ribs is derived theoretically. Reverse loading method is used to calculate springback radius of each position assisted by Matlab software and the radial profile of the panel after springback is obtained by numerical integration algorithm. To verify the accuracy and effectiveness of the new approach, finite element simulations based on ABAQUS software and experiments were both implemented. Comparison shows that the results are of good agreement, proving the approach is capable of predicting springback of multi-intersecting stiffened structures.

Keywords Multi-intersecting high stiffened integral panel · Neutral layer · Springback prediction

1 Introduction

Spherical integral panel with multi-intersecting high stiffeners is the major load-bearing structure of manned space stations. It has many advantages such as low weight, high structure efficiency, and large rigidity [1, 2]. Because of large curvature of the panel component, die forming is used as the main forming method for its good flexibility and forming ability. However, due to the unevenness of the size and distribution of the stiffened ribs and the interaction between the multi-directional ribs,

https://doi.org/10.1007/978-3-030-75381-8_224

the springback behavior of the panel is especially complicated, affecting the product manufacturing accuracy. Therefore, accurate and efficient prediction of springback is necessary to obtain the final desired shape.

The investigations on springback prediction were mostly focused on 2-D springback of stiffener and 3-D springback of plate. Li [3] derived the shift and rotation of the bending neutral layer with linear hardening model and deduced the springback amounts of single stiffeners with symmetric and asymmetric section in press bending. Wang [4] improved the springback prediction accuracy for Z-section profiles by taking neutral layer shift and power-law hardening model into account. Li and Wu et al. [5] used a cubic non-uniform B-spline to interpolate the die profile with varied curvature, calculated bending moments more accurately by a new formulas of stress and strain, and obtained the final shape of the sheet after springback by proper connecting technologies. As for the 3-D springback problem, in the early stage, Yu and Johnson [6] analyzed the strain distribution of rigid-perfectly plastic circular plates deformed in hemispherical dies, whereby deriving the approximate ratio of the radii of the plate before and after springback according to the edge displacement led by the strain release. An improved approach was proposed by Xue [7–9] who divided the circular plate in stamping into many segments along the meridional direction, each of which had constant strain that was calculated by energy method, then the final profile of the plate was constructed because of the strain release of each segment and the approach was extended to predict springback of a square plate and an unequal double-curvature plate.

Owing to the limitations of theoretical analysis, the finite element method (FEM) was introduced and numerical simulation was applied widely to predict springback of stiffened structures during the forming process. Several researchers had studied the influence of process parameters on the integral panel with FEM models to guide the technology design [10, 11]. But the accuracy and efficiency of simulation were the necessarily concerned problems. The principal factors affecting accuracy were unloading modulus, Bauschinger effect, transient behavior, and permanent softening, which should be modeled more accurately. Zang and Lee [12] evaluated the significance of hardening behavior and unloading modulus in springback prediction for U bending, indicating that unloading modulus is most important but the traditional isotropic hardening scheme with constant initial elastic modulus might be able to predict springback within reasonable accuracy. To improve the efficiency, Li [13] and Yan [14] proposed and built the plastic equivalent FEM models, respectively, achieving acceptable accuracy as well as reducing the simulation time by 70%–80%. Nevertheless, as the integral panels become larger and more complex, the excessive simulation time is still a severe problem.

The present paper proposes an efficient theoretical analysis and numerical approach to predict springback for a typical intersecting high stiffened integral panel in spherical die forming. The approach quantifies the effect between ribs and gets the 3-D springback problem simplified, having excellent efficiency and good reference value in springback prediction.

2 Theoretical Analysis

The typical "*" shaped intersecting stiffened integral panel is shown in Fig. 1. As the panel deforms in spherical die forming (Fig. 2a), its shape can be represented by the bending and springback profiles of the three ribs at the center intersection (Fig. 2b). Define the three ribs as the main ribs whose deformation behavior is affected by others. The effect, when the panel is bent, is reflected in different bending neutral layers at different locations. Such as at the intersection of ribs, the neutral layer is farther away from the skin, suggesting the bending neutral layer can be used to quantize the influence between the ribs. Hence, the complex 3-D springback of the panel is transformed into the 2-D springback of the main ribs.

The main ribs flow with the skin into the die during forming process, so the cross-sectional strain is not only composed of the pure bending component, but also of the component from the deformation of the skin. The deformations proceed simultaneously, superimposed to obtain the total strain. The neutral layer coordinates are required for the bending strain, and the skin deformation displacement is required for the skin strain.

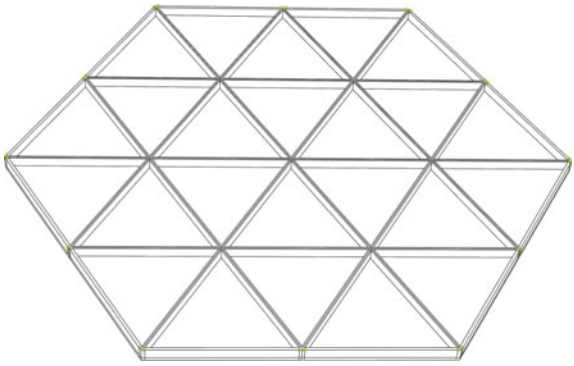

Fig. 1 Typical panel structure. (Color figure online)

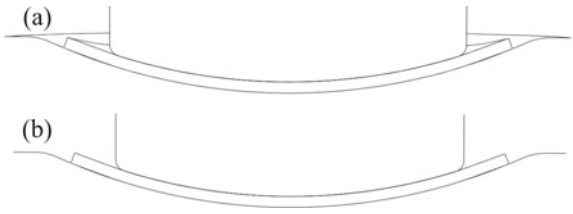

Fig. 2 Deformation of **a** panel and **b** main rib

2.1 Calculation of Bending Neutral Layer

The difference in the coordinates of the neutral layer on the panel is basically caused by the complex geometry. Hereby we define the coordinate of the bending neutral layer at one point as the average value of the neutral layer coordinates of all cross sections passing the point, without considering the shift of the neutral layer during bending. The specific calculation algorithm is as follows.

For any point (x_0, y_0) on the plate and given angle $\theta(0 \leq \theta < \pi)$, the cut line, projected line of the section and depicted in Fig. 3, can be expressed as a parameter form, $x = x_0 + l\cos\theta$, $y = y_0 + l\sin\theta$, in which l is the parameter, and the cross section is shown as the A-A section in Fig. 3 with some rib sections represented by dash lines.

To obtain the section width b and rib width s_i:

(1) Find the boundary of the cut line. Calculate the intersection parameters between cut line and edge line of the panel to obtain the boundary parameters that are marked as l_s and l_e, and $b = l_e - l_s$.
(2) Find the intersection parameters with the rib lines. Calculate the intersection parameters between cut line and projection line of ribs. Put the parameters inside the interval of (l_s, l_e) into a sequence.
(3) Sort the sequence in ascending order. Traverse sorted sequence and calculate the width of each cross section of rib s_i.
(4) Calculate the y-coordinate of the neutral axis of the section. Regarding bottom edge as the reference axis, y-coordinate of the neutral axis satisfies Eq. (1).

$$-bt\left(y_c - \frac{t}{2}\right) + \left(\frac{h}{2} + t - y_c\right)h\sum s_i = 0. \tag{1}$$

Let $s = \sum s_i$, then we obtain

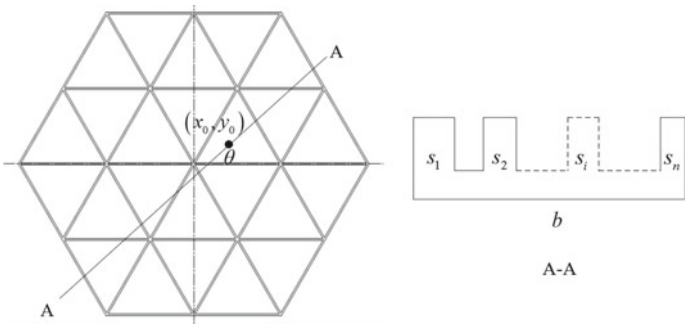

Fig. 3 Schematic diagram of cross section of cut line

$$y_c(\theta) = \frac{bt^2 + sh^2 + 2ths}{2(bt + hs)}. \tag{2}$$

(5) Change the angle θ and repeat steps 1–4.
Then the neutral layer height of the point is

$$\overline{y}_c = \frac{1}{n_d} \sum_{i=1}^{n_d} y_c(\theta_i), \tag{3}$$

in which n_d is the number of θ, that is, the number of the cut lines passing the point, which should be reasonable in accuracy and efficiency. The step size of θ used by the present approach is $\pi/12$, thus n_d is 12. Based on the bending neutral layer, the bending strain can be calculated according to the Kirchhoff assumption.

2.2 Deformation of Skin Component

In die forming, material flowing of the panel's skin can lead to deflection ω and radial displacement u. Adopting finite deformation theory, meridian strain and circumference strain of skin are expressed as:

$$\varepsilon_r = \frac{\partial u}{\partial r} + \frac{1}{2}\left(\frac{\partial \omega}{\partial r}\right)^2, \ \varepsilon_\theta = \frac{u}{r}. \tag{4}$$

When the plate forms a partly spherical surface, $\omega(r) = (r_d^2 - r^2)/2r_p$, where r_d takes the smaller value between the circumferential radius of die and the radius of panel's inscribed circle, r is the radial coordinate, and r_p is radius of the die. The derivation of u is based on the energy method. In axisymmetric die forming of thin plates, there are two energy components presented as follows:

(1) Bending strain energy

$$U_w = \frac{D}{2} \int_0^{2\pi} \int_0^{rd} \left[\left(\frac{\partial^2 \omega}{\partial r^2}\right)^2 + \frac{1}{r^2}\left(\frac{\partial \omega}{\partial r}\right)^2 + \frac{2\nu}{r}\frac{\partial \omega}{\partial r}\frac{\partial^2 \omega}{\partial r^2} \right] r dr d\theta, \tag{5}$$

(2) Membrane strain energy

$$U_m = \frac{\pi E t}{1 - \nu^2} \int_0^{rd} \left(\varepsilon_r^2 + \varepsilon_\theta^2 + 2\nu \varepsilon_r \varepsilon_\theta\right) r dr, \tag{6}$$

in which $D = Et^3/[12(1-v^2)]$ is the bending rigidity of the plate, E is the elastic modulus, t is the plate thickness, and v is the Poisson ratio.

According to variation principle, the real u should lead to the minimum strain energy. The trial function method is used to solve the variation problem. To simplify the answer form, u is approximated by polynomial function of three terms at least. In die forming, due to central radial displacement being zero, assume $u = r(C_1 + C_2 r + C_3 r^2)$ to satisfy the displacement boundary conditions.

Note that only U_m is relative with u; by substituting ω and u into Eq. (6) and solving minimum condition $\partial U_m/\partial C_i = 0 (i = 1, 2, 3)$, u is solved and expressed as

$$u = \frac{1}{16r_p^2} r\left[(1-\upsilon)r_d^2 - (3-\upsilon)r^2\right]. \tag{7}$$

Then the strain distribution function is derived as in Eqs. (8) and (9) by Eq. (4).

$$\varepsilon_r = \frac{1}{16r_p^2}\left[(1-\upsilon)r_d^2 - 3(3-\upsilon)r^2\right] + \frac{r^2}{2r_p^2} \tag{8}$$

$$\varepsilon_\theta = \frac{u}{r} = \frac{1}{16r_p^2}\left[(1-\upsilon)r_d^2 - (3-\upsilon)r^2\right]. \tag{9}$$

When v is 0.33, a typical value for aluminum alloys, ε_r is approximately a constant that is equal to $(1-v)r_d^2/16r_p^2$. The final strain distribution is combined by the bending strain and the meridian strain of the skin.

2.3 Calculation of Springback

Before calculating springback of the main rib, take the springback caused by the release of circumference strain into consideration, which is a relatively small value. The relation between spherical radius r_p and r_d is $r_p = (d^2 + r_d^2)/2d$, derived by arc geometry, where $d = r_p - \sqrt{{r_p}^2 - {r_d}^2}$ is the height of the arc. The differential of r_p with respect to r_d is $\Delta r_p = \Delta r_d \cdot r_d/d$. With the release of circumferential strain, increment of edge radius is $\Delta r_d = r_d|\varepsilon_{\theta r_d}|$, so radius of panel shape is of small variation that is

$$\Delta r_p = \frac{r_d^2}{r_p - \sqrt{r_p^2 - r_d^2}}\left|\varepsilon_{\theta r_d}\right|. \tag{10}$$

Then the springback of the main rib is calculated by the reverse loading method. The rib is divided into n_s segments along the radial direction by Δr; the neutral layer within each segment is regarded as fixed. For the segment with larger rigidity,

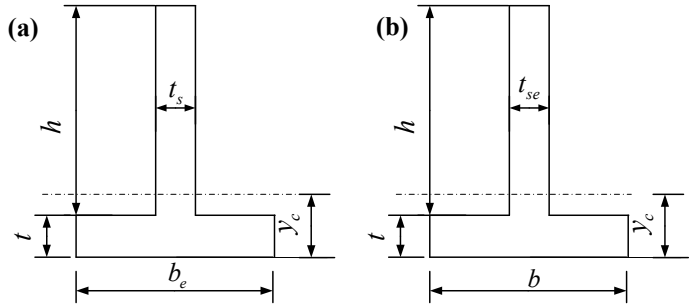

Fig. 4 **a** Equivalent cross section for moment, **b** Equivalent cross section for inertia

its springback amount is smaller for its lower load moment and higher inertia; two equivalent cross sections are devised to calculate equivalent load moment and inertia, respectively.

The equivalent cross section for moment calculation is shown in Fig. 4a, in which b_e can be calculated by Eq. (11).

$$b_e = \left(\frac{h}{2} + t - y_c\right) h t_s \Big/ t\left(y_c - \frac{t}{2}\right). \tag{11}$$

The power-law strain hardening model developed by Wagoner [15] is adopted to consider nonlinear strain hardening, expressed as in Eq. (12).

$$\sigma = \begin{cases} E|\varepsilon|, |\sigma| \le \sigma_s \\ \sigma_s + K\left|\varepsilon_p\right|^n, |\sigma| > \sigma_s \end{cases}, \tag{12}$$

in which σ is the true stress, ε is the true elastic strain, σ_s is the initial yield stress, ε_p is the true plastic strain, K is the hardening coefficient, and n is the hardening exponent.

The coordinate of the elastic–plastic transition point is $y_p = \rho(\varepsilon_e + \varepsilon_r)$, where ε_e is the maximum elastic strain. If$\varepsilon_e > \varepsilon_r$, y_p is on the outer side of the neutral layer; the equivalent load moment on the equivalent section can be calculated by Eq. (13).

$$\begin{aligned} M_e = & t_s \int_{y_p}^{h-\overline{y}_c} \left[\sigma_s + K\left(\varepsilon_r + \frac{y}{\rho} - \varepsilon_e\right)^n\right] y dy + b_e E \int_{-\overline{y}_c}^{-\overline{y}_c+t} \left(\varepsilon_r + \frac{y}{\rho}\right) y dy \\ & + t_s E \int_{-\overline{y}_c}^{y_p} \left(\varepsilon_r + \frac{y}{\rho}\right) y dy. \end{aligned} \tag{13}$$

Otherwise, all of outer sides of the section enter plasticity, y_p is on the inner side, and the M_e is calculated by

$$M_e = t_s \int_0^{h-\bar{y}_c} \left[\sigma_s + K\left(\varepsilon_r + \frac{y}{\rho} - \varepsilon_e\right)^n\right] y dy + b_e E \int_{-\bar{y}_c}^{y_p} \left(\varepsilon_r + \frac{y}{\rho}\right) y dy + b_e E \int_{y_p}^{0} \left[\sigma_s + K\left(\varepsilon_r + \frac{y}{\rho} - \varepsilon_e\right)^n\right] y dy \tag{14}$$

where $\rho = r_p + \Delta r_p + \bar{y}_c$ is the curvature radius of the neutral layer.

Another equivalent section shown in Fig. 4b is to calculate equivalent t_s by Eq. (15) with fixed b that is the maximum value of b_e among all segments.

$$t_{se} = bt\left(y_c - \frac{t}{2}\right) \Big/ \left(\frac{h}{2} + t - y_c\right) h. \tag{15}$$

Then the section is applied to obtain equivalent inertia with the following equation:

$$I_e = \frac{1}{12} b t^3 + bt\left(y_c - \frac{t}{2}\right)^2 + \frac{1}{12} t_{se} h^3 + t_{se} h \left(\frac{h}{2} + t - y_c\right)^2. \tag{16}$$

According to the elastic unloading rule, the springback radius ρ_0 is easily obtained by

$$\frac{1}{\rho} - \frac{1}{\rho_0} = \frac{M_e}{E I_e}. \tag{16}$$

Because the curvature is equal to the second derivative of ω, twice numerical integrations are used to calculate the points on the final profile of the main rib after springback with the boundary conditions presented as $\omega(0) = 0$ and $\omega'(0) = 0$. The formula is

$$\begin{cases} \omega'(i) = \omega'(i-1) + \dfrac{\Delta r}{2}\left(\dfrac{1}{\rho_0(i-1)} + \dfrac{1}{\rho_0(i)}\right) \\ \omega(i) = \omega(i-1) + \dfrac{\Delta r}{2}\left(\omega'(i-1) + \omega'(i)\right) \end{cases} i = 2, 3, \ldots\ldots, n_s. \tag{17}$$

3 FEM Simulations and Experiments

3.1 FEM Simulation Modeling

Material of the integral panel is the H-state 5A06 aluminum alloy and the material properties are shown in Table 1.

ABAQUS software is used to model the die forming process. The contact between the panel and the die is a complex nonlinear problem, so two nonlinear static analysis steps are adopted for the simulation of pressing and springback, in which the loading approach adopts displacement loading. The simulation model consists of an integral panel and upper and lower tools, as shown in Fig. 5. The panel is modeled with solid elements C3D8R, with the plate thickness of 5 mm, the rib height of 15 mm, the rib thickness of 4 mm, and the side length of 400 mm. The global seed size is 5 mm, while the number of the element layers is 3 along the thickness direction of the skin and 4 for the ribs. The tools are discretely rigid with the face radius of 1000 mm, 1200 mm, and 1405 mm, respectively, and the circumference radius of the upper tool being 310 mm. A path is created for acquiring the profile of the panel along the main rib, as depicted in Fig. 6.

Table 1 Material properties of H-state 5A06 aluminum alloy

E(MPa)	σ_s(MPa)	σ_b(MPa)	n	K
72,000	161	420	0.70	1065

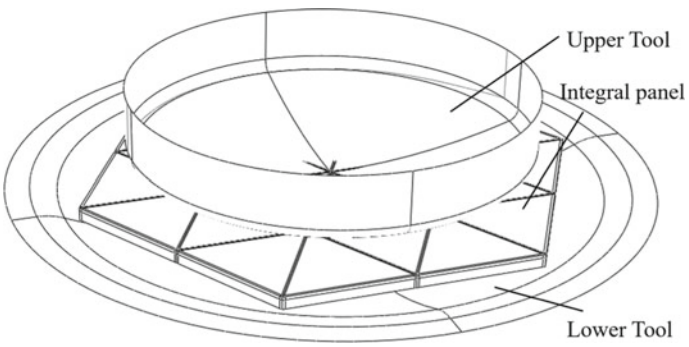

Fig. 5 Simulation model

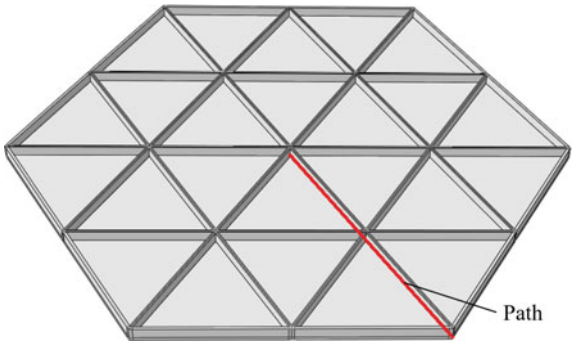

Fig. 6 Path along the main rib. (Color figure online)

3.2 Experiments

Figure 7 is the photo of experimental setup, in which a dial indicator is used to measure the depression height of the punch and the paper clamped by the upper tool and the specimen is to determine the initial contact between them. The experiments with a die radius of 1000, 1200, and 1405 mm are all implemented. Due to the panel not being able to be accurately placed in the center of the tool, the deformation of the adjacent sides of the panel during the forming process is not the same, but the sealing between the sides and the die is better when the punch is fully pressed. After the panel is released, the string length of the main rib is measured with a ruler and the string height with a vernier caliper, through which the springback height is calculated. An experiment specimen after forming is shown in Fig. 8.

Fig. 7 Experimental setup. (Color figure online)

Fig. 8 Experiment specimen after forming. (Color figure online)

4 Results and Discussion

4.1 Simulation Results

For the simulation model, the panel is placed in the center of the die ideally, thus all sides are in the same deformation state during the simulation process and fit the die well after being fully pressed. Figure 9 shows the Mises stress contour and the equivalent plastic strain contour of the simulation results with the die radius of 1000 mm at the end of the pressing step. In Fig. 9a, the maximum stress happens at the rib intersections of the sides that are of intense contact with the die surface. In Fig. 9 b, the whole skin of the panel is almost in elastic state, while the plastic deformation is mainly due to the ribs, which demonstrates the forming principle of the integral panel components. The meridian strain distribution of the main rib is shown in Fig. 10; it can be seen obviously that the neutral layer of the rib intersections is higher than other positons, proving the difference in neutral layers on the panel that is quantitatively considered by the present approach.

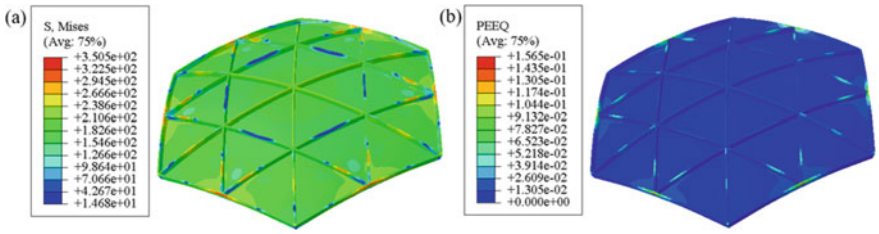

Fig. 9 **a** Mises stress contour **b** Equivalent plastic strain contour of the simulation results with die radius of 1000 mm. (Color figure online)

Fig. 10 The meridian strain distribution of the main rib. (Color figure online)

4.2 Verification of the New Approach

Compare experimental results with corresponding simulation and theoretical calculation results to verify the validity of the simulation model and the numerical approach. The Δr used to divide the main rib is 5 mm. As is shown in Table 2, the finite element model can well simulate the real springback situation. The theoretical calculations, with better computational efficiency, predict slightly larger springback amounts but have relatively small error from the experimental results, proving the effectiveness of the present approach. The calculated and simulated final profiles of the panels are depicted in Fig. 11, where the endpoints of the main ribs on the specimens after springback are also drawn. Great agreement is seen among theoretical predictions, simulation results, and experimental measurements.

Note that the die radius is smaller, and the springback amount is smaller for the reason of the smaller bending radius, which matches the tendency of the springback results of pure bending. Besides, according to the present approach, ε_r is proportional to the square of r_d/r_p, for the certain r_d; ε_r is bigger when r_p is smaller, leading to the bending-tension effect that can further reduce the springback.

Table 2 Comparison of springback amounts among the theoretical predictions and the simulations and experiments results

Die radius/mm	Loading height/mm	Springback amount/mm		
		Calculation	Simulation	Experiment
1000	78.60	9.41	8.59	9.01
1200	68.20	12.17	11.28	11.87
1405	56.20	14.21	13.06	13.72

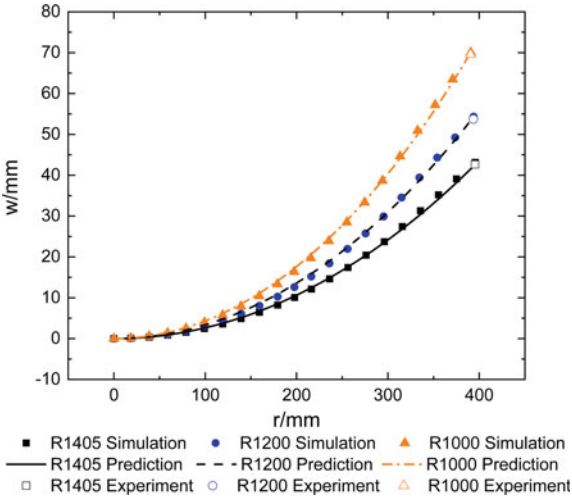

Fig. 11 Comparison of final profiles between theoretical predictions and simulation results. (Color figure online)

5 Conclusions

The paper proposed a theoretical analysis and numerical calculation approach to predict springback for intersecting high-stiffened integral panel in spherical die forming. By comparing with the simulation and experimental results, the present approach is capable of predicting springback accurately and efficiently. The specific conclusions are as follows:

(1) Quantize the influence of the intersecting ribs on the bending and springback behavior by defining neutral layer on the panel and designing algorithm, with which the multi-direction springback problem is transformed into a 2-D springback problem. The difference in bending neutral layer is proved by simulations.

(2) With the consideration of the skin deformation, the power-law hardening model and different elastic–plastic divisions for moment calculation, the approach can accurately describe the springback behavior of the panel in spherical die forming.

(3) Computational results indicate that the r_p is smaller, ε_r is bigger, causing smaller springback amount, which agrees well with simulation and experimental results but is of great calculation efficiency.

Size Effect on Cyclic Deformation Behavior and Springback Prediction of Ultrathin Superalloy Sheet

Weilin He, Bao Meng, Bingyi Song, Rui Zhao, Li Zhang, and Min Wan

Abstract Springback is a challenging issue in the processing of ultrathin superalloy components whose thickness are usually in the range of 0.1 ~ 0.3 mm, and its prediction is affected by the size effect. In this research, the cyclic shearing tests of superalloy sheets with different grain sizes were performed to clarify the relation between size effect and cyclic deformation behavior. The experimental results indicated that it is affected by the geometrical and grain size effects. To explore how the size effect affects the springback of ultrathin superalloy sheet, U-bending tests were performed on specimens with different grain sizes and thicknesses. In addition, different hardening models were compared by multiscale U-bending tests. The results showed that the Yoshida–Uemori (YU) model can well describe the cyclic deformation of superalloy sheet at various scales.

Keywords Size effect · Cyclic deformation behavior · Springback prediction · Superalloy sheet

1 Introduction

In the process of plastic deformation, the metal sheet will produce wrinkling, cracking, springback and other defects. Especially the springback problem is the most difficult to solve. In recent years, the extensive application of high-strength materials such as high-strength steel, superalloy, and titanium alloy has brought more and more challenges to the prediction of forming springback. Especially thin-walled micro-components made of superalloys play an irreplaceable role in reducing the weight and improving the performance of aircraft engine and carrier rocket. In order to study the springback of such ultrathin superalloys, it is essential to investigate the cyclic plastic behavior.

The Bauschinger effect which refers to the phenomenon that the yield stress in the reverse deformation of a material is smaller than the yield stress in the initial

https://doi.org/10.1007/978-3-030-75381-8_225

direction during cyclic plastic deformation is one of the important characteristics of cyclic plastic deformation. It is caused by residual stress between grain boundaries of polycrystalline materials which reflects the influence of deformation history on material properties. Song et al. [1] investigated the effects of different pre-strains under different loading modes on the Bauschinger effect of AZ31B magnesium alloy. The results revealed that the Bauschinger effect is sensitive to strain rate and pre-strain in tension-unloading-reverse compression loading mode, but not to strain rate in c-u-t loading mode. Mahato et al. [2] explored the effects of forward deformation mode, monotonic and cyclic asymmetry on the Bauschinger phenomenon of annealed polycrystalline copper with different Bauschinger parameters under different uniaxial tensile strains. The results provided that the Bauschinger effect is not obvious under asymmetric cyclic loading compared with uniaxial loading. Kato et al. [3] studied the Bauschinger effect in 1-mm-thick plates by tensile test and four-point bending test. The results showed that this effect does not exist when the pre-strain is less than 4% and exists when the pre-strain is higher than 4%. Unfortunately, there are not sufficient investigation on the influence of the size effect on the Bauschinger effect.

Accurate springback prediction not only needs investigation of the factors influencing cyclic deformation behavior but also of the error sources of springback prediction. U-bending test is considered as the general method to test the springback phenomenon, because the material at the side wall undergoes bending, unloading, and reverse bending and unloading during the forming process with the bending punch and die, which is very suitable for analyzing the factors influencing springback. Among them, the size effect is one of the factors that affects the U-bending test results. There are two size effects existing in micro-scale materials, grain size effect and geometry size effect. The geometry effect is usually reflected in the thickness of the specimen. Wang et al. [4] used copper alloy sheet samples with thickness of 0.1, 0.2, and 0.4 mm to conduct pure micro-bending experiments. The results showed that the springback angle caused by size effect decreases with the increase of sheet thickness and the decrease of grain size. Diehl et al. [5] proposed with the help of bending tests that with the increase of surface grain proportion, the increase of strain gradient, and the decrease of scale factor, the springback behavior of a thin film features different effects.

There are many researches based on the Bauschinger effect and U-bending. However, due to the existence of the size effect, there is a great difference in mechanical properties and forming characteristics of a macroscopic sheet metal and an ultrathin superalloy sheet. Therefore, the superalloy GH4169 was used to perform experimental forming tests in this study. Cyclic shearing and U-bending tests were carried out on samples with different grain sizes. The first aim was to investigate the effect of sample geometry and grain size on the Bauschinger effect and to summarize the influence of grain size on the Bauschinger effect. The second aim was to determine the effect of grain size on the springback parameters in U-bending test. The last aim was to discuss the accuracy of different hardening models in predicting the springback in U-bending of ultrathin sheets.

	0.2	1050	70.8	2.82

2 Materials and Methods

2.1 Material Processing and Grain Size Characterization

Ultrathin GH4169 has high-temperature performance, corrosion resistance, pressure resistance, and molding performance. For these reasons, it is widely used in aerospace, nuclear energy, and petroleum industry as well as for extrusion dies. Therefore, GH4169 nickel-based superalloy is selected as the research object whose chemical composition is shown in Table 1.

In order to obtain samples with different grain sizes, the vacuum heat treatment with various temperatures was performed. The holding time was 30 minutes. The grain size of the samples was obtained by metallographic analysis. First, the polished samples were etched in a mixture of HCl solution and H_2O_2 solution with a ratio of 1:1. Then, metallographic pictures were obtained under the Leica microscope. Finally, Image-pro software and the truncation method were used to obtain the average grain size. The results show that the grain size increases with the increase of heat treatment temperature. The different sheet thickness and grain sizes of the material are shown in Table 2, where t represents the thickness of the specimen and d represents the grain size.

2.2 Cyclic Shearing Test

Cyclic shearing tests were performed by installing the shearing test fixture in the uniaxial tensile machine. The experimental equipment is shown in Fig. 1a. The left and right parts of the testing device are symmetrical in the center. During the test, the left part was fixed, and the right part was driven by the testing machine. The relative

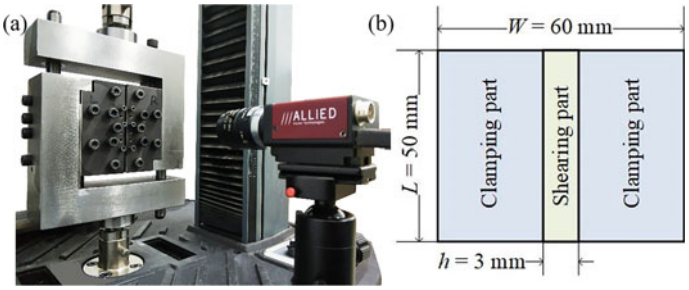

Fig. 1 **a** Cyclic shearing test device; **b** Cyclic shearing test sample. (Color figure online)

motion of the two parts causes forward and reverse shearing strain in the center of the specimen. The DIC system was used to measure the strain of the sample and the output frequency is 2 Hz. Lock nuts were utilized to eliminate device clearance. Compression screws on both sides of the deformation zone were set to avoid slipping and to ensure strain uniformity. The tightening torque of the first-stage compression screw was determined to be 35 Nm and the tightening torque of the second-stage compression screw was determined to be 5 Nm. The shear stress–shear strain curves under cyclic loading were obtained from the testing results of DIC and the load curves of the machine.

In this paper, rectangular samples were selected as shown in Fig. 1b. The length (W) and width (L) of the specimen are 60 mm and 50 mm, respectively. The width (h) of the shearing part is 3 mm. Reducing width of the shearing part can prevent premature wrinkling. But if the width of the deformation zone is too narrow, the recording area of DIC camera is too small and the strain cannot be measured accurately. Therefore, the width of the shearing part was designed to be 3 mm. At the same time, the overall width of the sample was determined to be 60 mm by combining the width of the clamping block. L/h determines the uniformity of stress distribution in shear deformation zone. As L/h increases, the distribution uniformity of shear stress increases. When $L/h \geq 10$, relatively uniform distribution of shear stress and shear strain can be obtained. Therefore, the height of deformation zone L was determined to be 50 mm.

2.3 U-bending Test

The material thickness selected for this test was 0.2 mm. Due to the small sheet thickness, the sample geometry had to be adapted in comparison to samples of larger sheet thicknesses to ensure usable testing results. Therefore, the optimal sample size was determined to be 110 mm and 30 mm (length direction was the rolling direction). The radii of the punch and die were 3 mm. The bending stroke was 28 mm. The bending speed was 10 mm/min. The blank holder force was constant 5 kN. The

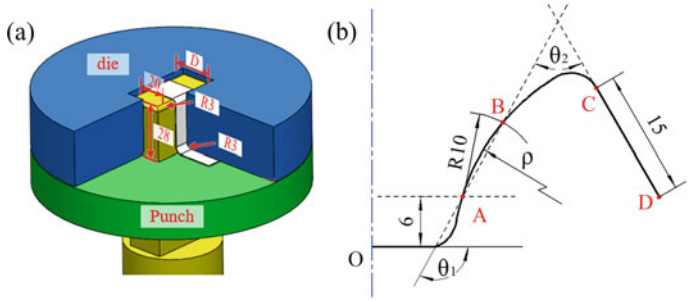

Fig. 2 **a** U-bending test device; **b** Definition of springback parameters in U-bending test. (Color figure online)

punch width was 20 mm and the width of the die was selected 20.5 mm. The test was carried out on the universal sheet metal forming testing machine and the U-bending device is shown in Fig. 2a. After being formed, the U-shaped part was removed from the die and immediately pressed into a printing pad to ink the side. The side outline was then printed on a paper. The method for determining the springback parameters is shown in Fig. 2b. Springback parameters include angle θ_1 between x-axis and AB, angle θ_2 between AB and CD, radius ρ of the circle through A and B.

3 Results and Discussion

3.1 Grain Size and Sheet Thickness Effects on the Bauschinger Effect

The Bauschinger effect can be described with a stress reduction $\Delta\sigma$ due to reverse loading. It is defined as

$$\Delta\sigma = \sigma_{fs} - \sigma_{rs} \tag{1}$$

where σ_{fs} is initial yield stress and σ_{rs} is the reverse yield stress. According to the cyclic shearing test curves of the samples with three grain sizes under different pre-strain conditions, $\Delta\sigma$ was calculated, as shown in Table 3. The relationship between grain size and $\Delta\sigma$ is shown in Fig. 3.

As it can be seen from Fig. 3, softening amount increases with the decrease of grain size, which reveals that the Bauschinger effect becomes more obvious with a decrease of grain size. This can be explained by the Kocks–Mecking dislocation density theory [6]. According to this theory, grain boundaries act as an obstacle for the dislocation movement in the material. This can lead to the generation of a reverse stress opposite to the dislocation movement. Therefore, less stress is needed to start dislocation movement during reverse loading. Smaller grain sizes lead to higher

Table 3 Results for the Bauschinger parameters

Grain size/μm	Pre-strain	σ_{fs}/MPa	σ_{rs}/MPa	σΔ/MPa
24.2	0.02	840.6	449.6	391.0

densities of grain boundaries, dislocations, and higher reverse stress. Therefore, the Bauschinger effect becomes more obvious.

3.2 Grain Size and Thickness Effect on Springback in U-bending Test

Two analytical theories for springback in sheet metal forming are the Ludwik engineering analytical theory and the Hill precise analytical theory. Due to a relative

bending radius R and material thickness, in this test of $R/t \geq 10$, the state in this test can be considered plane strain. The influence of the inner shift of the neutral layer was ignored to meet the assumption of a flat section. Therefore, the adoption of Ludwik engineering theory can meet the requirements of qualitative analysis. According to the hypothesis, the springback angel $\Delta\alpha$ is calculated with:

$$\Delta\alpha = \left(\frac{3\sigma_c}{E} \cdot \frac{\rho}{t} + \frac{D}{E}\right)\alpha \tag{2}$$

where σ_c is the yield strength of the material, E is the elastic modulus, ρ is the curvature radius of the neutral layer, t is the thickness of the sheet metal, D is the strengthening modulus, and α is the pre-unloading angle.

The U-bending test results for different sheet thicknesses and grain sizes are shown in Fig. 4.

The springback increases with the increase of θ_1 and the decrease of θ_2 and ρ. In all the test results, θ_2, ρ, and θ_1 always show an opposite trend, that is, θ_2 and ρ decrease with the increase of θ_1, while θ_2 and ρ increase with the decrease of θ_1. Therefore, the effects of these three parameters on springback remain consistent.

It can be seen from Fig. 4a that for the same sheet thickness and deformation state, the springback decreases with the increase of the average grain size. This can be explained by the surface layer model and the K-M dislocation density model. With the increase of grain size, the number of grains in sheet thickness direction decreases. The decrease of grain boundary in thickness direction leads to the decrease of dislocation density, which eventually leads to the decline of yield strength and flow stress. According to Eq. (2), the decrease of yield strength and elastic modulus will lead to the decrease of springback. The decrease in yield strength causes a smaller portion of elastic deformation and springback is less obvious.

In addition, it can be seen from Fig. 4b that the springback decreases with the increase of sheet thickness, which is consistent with the conclusion of Eq. (2). On

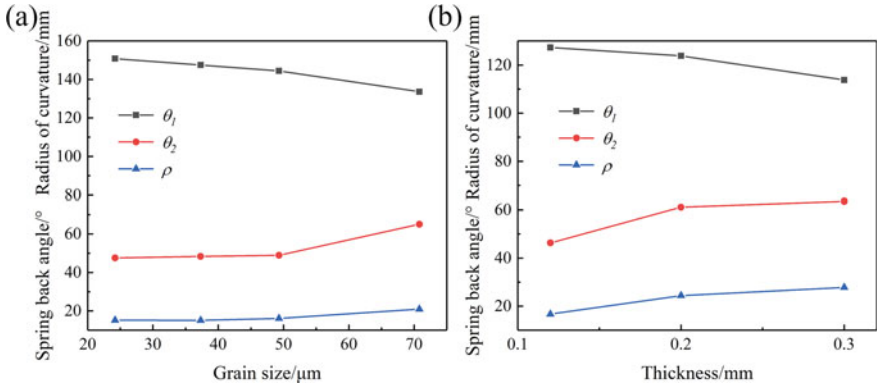

Fig. 4 Influence of **a** grain size and **b** thickness on springback of parameters. (Color figure online)

the other hand, the t/d ratio of the three samples gradually increases as shown in Table 2, which leads to the increase of yield strength and flow stress and thus the springback increases. However, this effect has less influence on springback than the sheet thickness leading to a decrease of springback.

The results of the test indicate that the t/d ratio should be utilized only when the surface layer model and the dislocation density model are characterized simultaneously for the same sheet thickness. This is because the increase of grain size and thickness will lead to the decrease of springback at the same time. If the grain size and thickness are combined as t/d ratio, it is assumed that the two factors have the opposite effect on the springback. This is inconsistent with the test results and caused various contradictory results [7] and the anomaly at the experimental point [8].

3.3 Prediction of Springback with Different Hardening Models

For FE simulation, the special software of dynaform sheet metal forming based on ls-dyna solver was selected for finite element simulation of the springback. Yoshida and Uemori hardening model (Y-U model), isotropic hardening model, and Armstrong and Frederic hardening model (A-F model) were used to predict the springback of a 0.2-mm-thick superalloy sheet. The yield criterion used for three hardening models was Hill48. These three hardening models corresponded to the three material models #125, #37, and #165 in ls-dyna, respectively. The mold mesh size is 1 mm. The mesh size of the specimen is 0.5 mm. Contact definition is FORMING-ONE-WAY-SURFACE-TO-SURFACE. Element formulation is unit 16. Friction coefficient is 0.125. The profiles of the U-bending test samples obtained from simulation and experiment are shown in Fig. 5. The springback parameters obtained from the profiles are shown in Fig. 6.

As it can be seen from Fig. 5b, the predicted profile of Y-U model has the best coincidence degree with the profile obtained from experiment. The prediction accuracy of the isotropic hardening model is worst. Although the prediction accuracy of the A-F model is not as good as that of the Y-U model, it has been improved compared to the isotropic hardening model. The above results are quantified in Fig. 6. It can be seen that the prediction results by the three models are not significantly different and the Y-U model shows the best results in comparison to the experimental values.

Furthermore, the cyclic plastic curves calculated with the three hardening models are shown in Fig. 7. The isotropic hardening model does not take into account the Bauschinger effect, which causes the reverse stress and the stress gradient to be larger, thus overestimating the springback. The A-F model shows significant differences from the experimental curve at the beginning of the reverse loading stage, resulting in deviation of springback prediction. The springback prediction results of the Y-U model are in good agreement with the experimental test results, indicating that it can accurately describe the cyclic loading behavior of materials.

4 Summary

In this research, the effect of sheet thickness and grain size on the Bauschinger effect for ultrathin superalloy sheet in cyclic shearing test was investigated. Furthermore the relationship between the effect of sheet thickness and grain size and springback for U-bending was discussed. In addition, different hardening models were compared by multiscale U-bending simulations. The following conclusions are drawn:

(1) Due to the effect of grain size on reverse stress, the Bauschinger effect of ultrathin superalloy sheet becomes more obvious with the increase of grain size.

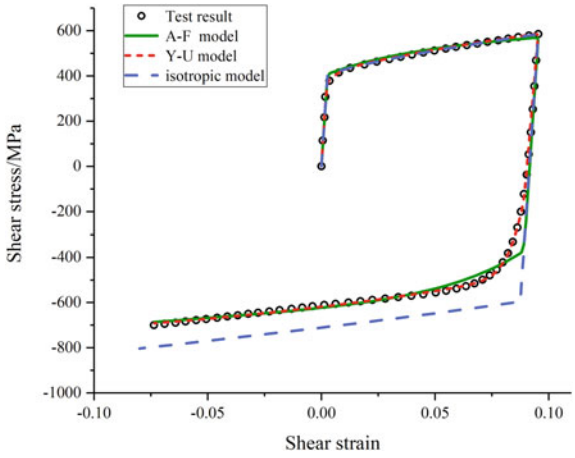

Fig. 7 Cyclic plastic shear curves obtained from experiment and FE simulation. (Color figure online)

(2) With the increase of grain size and the decrease of sheet thickness, the springback is more obvious in U-bending. These results can be explained by surface layer model and K-M dislocation density model.

(3) The Y-U hardening model should be used for the FE simulation of cyclic deformation of ultrathin superalloy sheet at various scales being in good agreement with the experimental results.

Hydro-Mechanical Deep Drawing of Locally Solution-Treated Aluminum Alloy Sheets

Takeshi Nishiwaki, Ryota Sako, and Hideo Tsutamori

Abstract Improvement of formability of aluminum alloy sheets is desired because of their lower drawability than mild steel. Therefore, the special sheet forming methods such as a hydro-mechanical forming and a tailor heat treated blank have been developed for aluminum alloy sheets. In this study, we combined both the methods and investigated the limit of drawing ratio of tailor heat treated blanks in a hydro-mechanical forming process. Tailor heat treated blanks of A6061-T6 sheets were produced by the local solution treatment which was conducted by heat transfer from metal plates heated to a high temperature. Hydro-mechanical deep drawing tests were performed using a cylindrical punch. The limit of drawing ratio of tailor heat treated blanks in a hydro-mechanical forming process was higher than that of simple hydro-mechanical forming and that of simple tailor heat treated blanks.

Keywords Hydro-mechanical deep drawing · Deep drawing · Tailor heat treated blank · Aluminum alloy sheets

1 Introduction

An aluminum alloy sheet has less deep drawability than steel sheet, and it is difficult to form deep cups by conventional deep drawing method (DD). Therefore, the hydro-mechanical deep drawing method (HDD) has been developed and used for manufacturing parts of aircraft and railway vehicles. HDD uses specific dies to apply fluid pressure, therefore multi-stage forming is difficult. It is desired to develop the method of improving deep drawability in one process for complicated products which cannot be produced by conventional HDD.

As one of the ways to improve the drawability of aluminum sheets, the deep drawing of strength graded blanks has been investigated. Tozawa reported the periphery annealing method [1] as strength graded blanks. The periphery over aging

https://doi.org/10.1007/978-3-030-75381-8_226

method [2] and the center aging method [3] have been already examined to make strength graded blanks.

As a method of local heat treatment to produce strength distribution in an aluminum alloy sheet, a steady temperature distribution which was made by contacts with metal heating blocks and cooling blocks was used. A unsteady heat treatment method has also been developed in which metal blocks heated to a high temperature are brought into contact with an aluminum alloy sheet for a short period to give strength distribution [4]. In recent years, laser heat treatment to give strength distribution have been examined mainly. These deep drawing methods of the strength graded blanks are called Tailored Heat Treated Blanks (THTB) [5–9].

The THTB method is a technology for modifying the mechanical property before forming unlike other special forming methods. Therefore, the THTB can be combined with other forming methods. The THTB has been applied for the conventional DD process and could be applied for the HDD process. It is reported that a combination of the THTB and the HDD improves the drawability in numerical analysis [10]. However, there are a few reports that the formability is actually improved in a combination of the THTB and the HDD. In the present work, the improvement of drawability was experimentally examined by the forming method combining both the methods.

2 Experimental Procedure

2.1 Test Material

As a starting material to make the strength graded blanks, the A6061 alloy sheet (1.0 mm thickness) was prepared in T6 heat treated condition. Chemical composition and mechanical properties of A6061 alloy are shown in Tables 1 and 2. Table 2 also shows mechanical properties of A6061-W which is solution-treated in the whole area by the method described later.

Table 1 Chemical composition of A6061 alloy (in wt%)

Si	Fe	Cu	Mn	Mg	Cr	Zn	Ti
0.63	0.3	0.27	0.06	1.0	0.18	0.06	0.03

Table 2 Mechanical properties of A6061 alloy

	YS /MPa	TS /MPa	Elongation / %
A6061-T6	292	315	10.6
A6061-W	99	188	20.3

2.2 Local Solution Treatment

As the method of local solution treatment, the heat transfer by the contact between heating dies and an aluminum sheet was used. Figure 1 shows a schematic diagram of the local solution treatment apparatus. The local solution treatment of the blanks was performed under the condition of heating temperature at 500 °C. The blanks were clamped at 25 kN between heating dies which contained cartridge heaters, held for 0.8 s, and quenched with water. In the center of heating dies, circular grooves were machined to produce a non-contact area. By exchanging these dies, the non-contact area with an aluminum sheet was changed, and it was possible to make various designs of THTB. Four sets of heating dies were prepared in which the ratios between the circular groove diameter D_{in} to the punch diameter D_p were 1.2, 1.4, 1.6, and 1.8. A set of non-grooved heating dies was also prepared for comparison, and the blanks used in this set were solution-treated in the whole area as A6061-W.

Distributions of Vickers hardness in the local solution-treated blanks are shown in Fig. 2. In any distribution, maximum value of hardness is about 110 HV 2 at

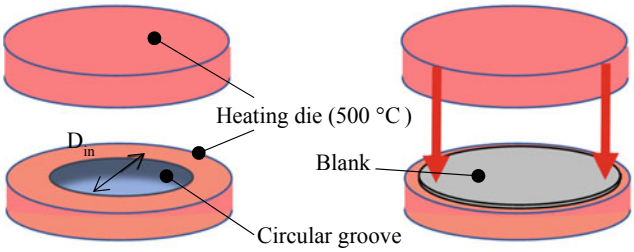

Fig. 1 Schematic diagram of the local solution treatment apparatus. (Color figure online)

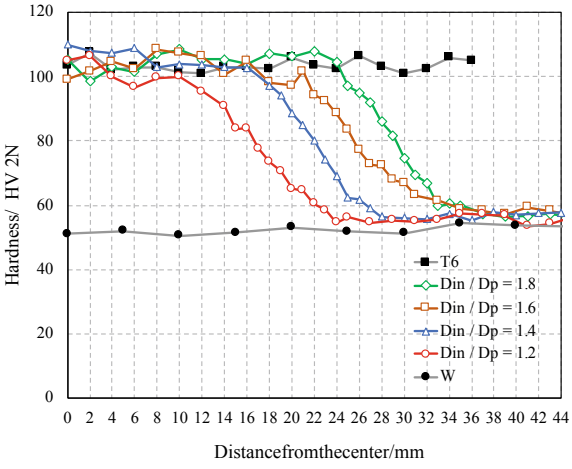

Fig. 2 Hardness distributions of strength graded blanks. (Color figure online)

non-contact area and minimum value of hardness is about 60 HV 2 at contact area. The hardness of the softened part was reduced by over 40%. In addition, a transition region was confirmed around the contact end, where the hardness was continuously reduced by heat conduction from the contact area.

2.3 Forming Test Procedure

2.3.1 Hydro-Mechanical Deep Drawing Process

Our HDD equipment consists of a forming die set, a hydraulic pressure control unit, and a tensile test machine as a driving source. The hydraulic pressure control unit has a relief valve to keep the pressure constant and a hand pump to positively apply hydraulic pressure. Hydraulic pressure increases naturally due to a decrease in the volume of the hydraulic chamber, and extra pressure is added by the pump. Figure 3 shows the hydraulic pressure–punch stroke curve at the condition where holding pressure P_H is 15 MPa and the pressure rise ratio P_H/S_H is 1.0 MPa/mm. Here, S_H is of the holding start stroke. HDD was performed under relatively low blank hold force. Therefore, water leakage was prevented by moving the punch and wrapping the sheet around the die shoulder. Extra pressure is added until 10 MPa which is maximum ability of the pump. In the HDD process, the parameters of the holding pressure P_H and the pressure rise ratio P_H/S_H were controlled.

2.3.2 Hydro-Mechanical Deep Drawing Condition

Cylindrical cups were deeply drawn with tools shown in Table 3. For the drawing test, various strength graded blanks (Hard area ratio D_{in}/D_p is from 1.2 to 1.8) were

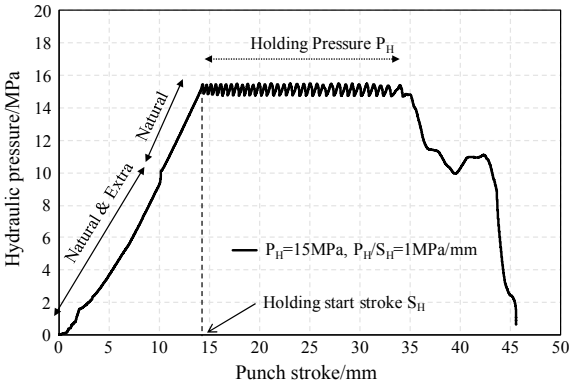

Fig. 3 Hydraulic pressure–punch stroke curve and controlled parameters

Table 3 Dimensions of drawing tools and blanks

Punch	Diameter D_p/mm	33.0
	Profile radius R_p/mm	10.0
Die	Diameter D_d/mm	37.1
	Profile radius R_d/mm	5.0
Blanks	Diameter D_0/mm	ϕ62–85
	Hard area ratio D_{in}/D_p	1.2, 1.4, 1.6, 1.8

used. They were cut into ϕ62 ~ 85 mm circle blanks so that the center of the solution-treated area coincided with the center of the blank. Uniform strength blanks, T6-and W-treated blanks were also drawn as a comparison.

Punch speed of drawing was 6 mm/min. Blank hold forces were 1.3 kN when the blank diameter was less than 66 mm, and 2.4 kN when the blank diameter was more than 68 mm. As a hydraulic condition, the holding pressure P_H was controlled to 4 levels: 5, 10, 15, 20 MPa, and the pressure rise ratio P_H/S_H is controlled to 4 levels: 0.83, 1.0, 1.43, 2.0 MPa/mm. Conventional DD process without hydraulic pressure were also conducted as a comparison.

2.4 Hardness Measurement of Formed Cups

Hardness distribution of cups formed by the DD process and the HDD of the THTB process were measured at a test load of 2.0 N using micro Vickers hardness tester. The cups of THTB were artificially aged at 433 K for 18 h.

3 Results and Discussion

3.1 Effect of the Forming Method

Formability of the DD, the HDD, the THTB, and the HDD of the THTB method are compared in Fig. 4. Figure 5 shows the limit of drawing ratio (LDR) of these forming methods. In the THTB and the HDD of the THTB process, blanks of hard area ratio ($D_{in}/D_p = 1.4$) were used. Common conditions ($P_H = 10$ MPa, $P_H/S_H = 1.0$ MPa/mm) were applied in this HDD process. The formability of A6061-T6 in conventional HDD method is not much improved compared to the DD. However, it was confirmed that the LDR in the HDD of the THTB process was significantly improved by 0.54 compared to the DD.

Figure 6 shows the punch load–stroke curve in the various forming processes of the same blank size. The LDR in the HDD of THTB showed the highest value even though the maximum punch load was higher than the DD and the THTB. This is

	Conventional DD	Conventional HDD	THTB (D_{in}/D_p =1.4)	HDD of THTB (D_{in}/D_p =1.4)

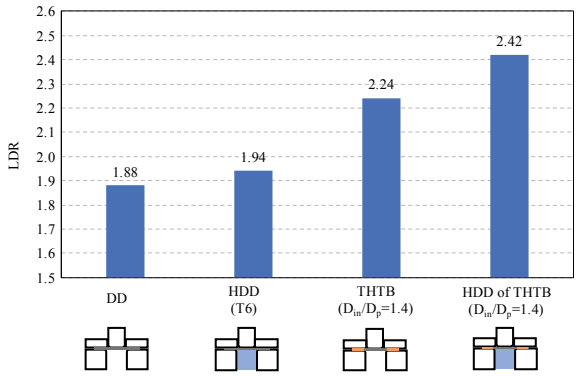

Fig. 5 LDR of various forming methods. (Color figure online)

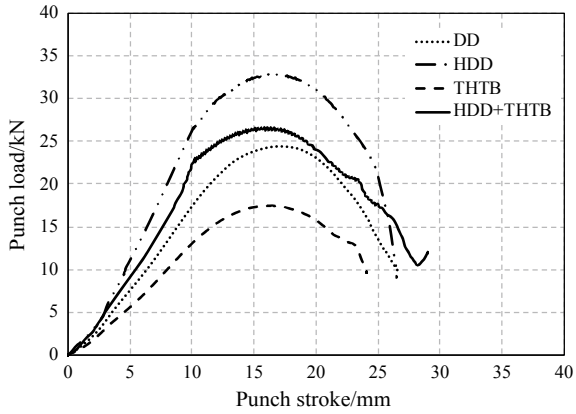

Fig. 6 Punch load–stroke curve in various forming process ($D_0 = \phi 64$)

the reason that the presence of the counter pressure applies a force to the top of the punch. A large maximum load in the HDD does not mean that the deformation resistance of the flange part is large. On the other hand, when results of the HDD and the HDD of THTB were compared, the maximum punch load of the HDD of THTB was lower than the HDD. It is considered that the presence of the softened material reduced the deformation resistance of the flange part.

These results indicate that the HDD of THTB obtained both the counter pressure effect and the periphery softening effect. The former effect reduces the radial stress and friction in the flange area, and the latter one reduces the deformation resistance of the flange part, thereby the formability was greatly improved.

3.2 *Effect of the Local Solution-Treated Region*

The HDD of THTB ($D_{in}/D_p = 1.2, 1.4, 1.6, 1.8$) and the HDD of uniform blanks (T6, W) were conducted to investigate the effect of the locally solution-treated region. Figure 7 shows the LDR of various blanks in the HDD where P_H is 10 MPa and P_H/S_H is 1.0 MPa/mm. It was confirmed that the formability was most improved when THTB ($D_{in}/D_p = 1.4$) was formed by the HDD process, and the LDR was improved by 0.48 compared to the HDD using T6 blanks. However, in the case of narrow softened blank such as THTB ($D_{in}/D_p = 1.8$), the formability is not much improved compared to the DD using T6.

Figure 8 shows the punch load–punch stroke curves for various hard area ratio blanks. As the solution-treated region becomes wider, the punch load decreases, and it is considered that the formability is improved due to the decrease in the deformation resistance of the flange part.

The HDD of the THTB process had two types of fractures as shown in Fig. 9. In the case of hard area ratio of 1.6 and 1.8, fractures occurred at the punch shoulder as the conventional DD or HDD. On the other hand, fractures occurred at the punch side wall in the case of hard area ratio of 1.2 and 1.4. The fracture at the side wall occurred near the boundary between the hard and the softened regions of the blanks.

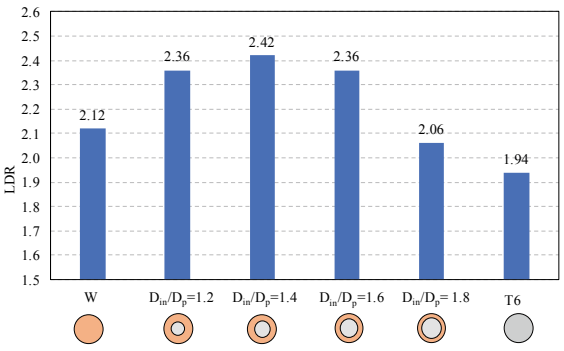

Fig. 7 LDR of various hard area ratio blanks in the HDD ($P_H = 10$ MPa, $P_H/S_H = 1.0$ MPa/mm). (Color figure online)

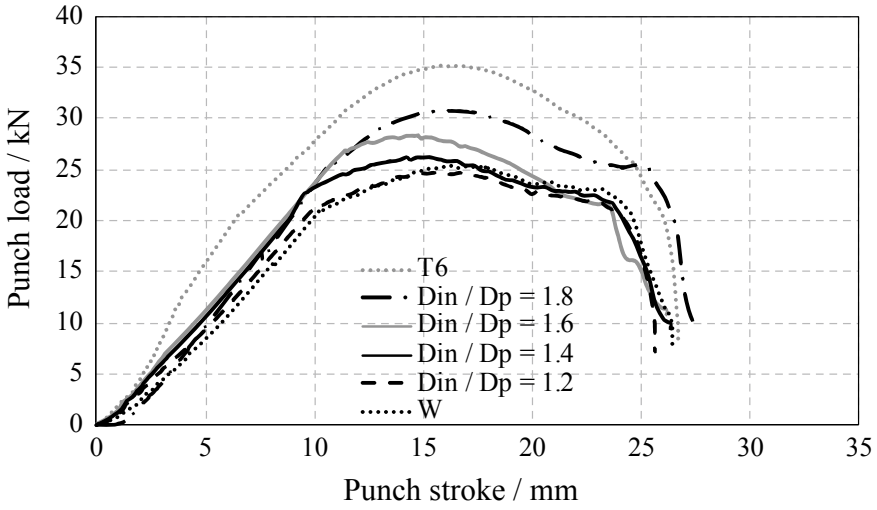

Fig. 8 Punch load–punch stroke curves of the various blanks ($D_0 = \phi 64$)

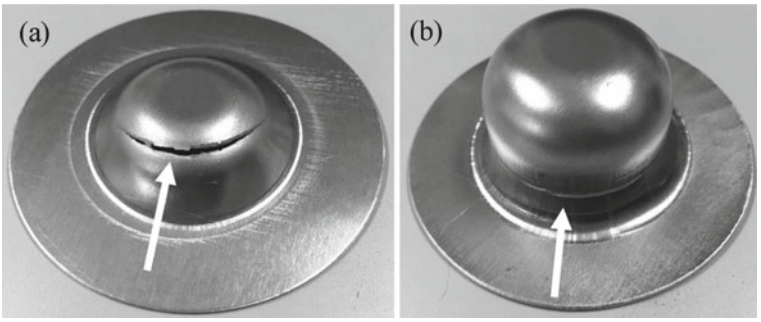

Fig. 9 Two types of fractures **a** fracture at the punch shoulder ($D_{in}/D_p = 1.6$, $D_0 = \phi 80$), **b** fracture at the side wall ($D_{in}/D_p = 1.4$, $D_0 = \phi 82$)

It is considered that the fracture is caused by a decrease in the strength of the wall due to solution treatment. When the softened region is wide, fractures occur at the side wall, and when it is narrow, fractures occur at the punch shoulder. Therefore, the hard area ratio of 1.4, where the softened region is not too wide, was optimal and had the best formability. These two types of fractures occur also in the single THTB process.

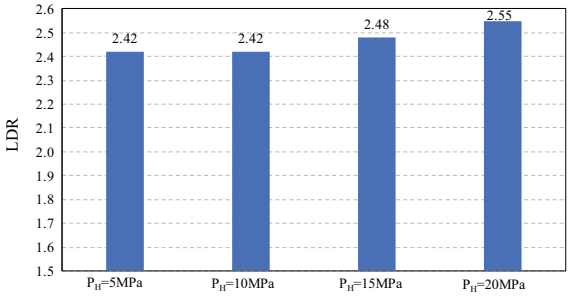

Fig. 10 LDR in various holding pressure of HDD ($P_H/S_H = 1.0$ MPa/mm, $D_{in}/D_p = 1.4$). (Color figure online)

3.3 *Effect of the Holding Pressure*

Figure 10 shows the LDR of the various holding pressure where P_H/S_H is 1.0 MPa/mm and D_{in}/D_p=1.4 in the HDD of the THTB process. The formability was gradually improved by increasing the holding pressure, and it was confirmed that the LDR was improved by 0.13 at 20 MPa compared to 5 MPa. In general, the formability deteriorates when the hydraulic pressure is too high, but no decrease in the LDR was observed at hydraulic pressure up to 20 MPa. The upper limit of LDR was not confirmed.

Although fractures of the THTB ($D_{in}/D_p = 1.4$) occurred at the side wall in low hydraulic pressure, increasing the holding pressure suppressed the side-wall fracture and improved the formability. It is considered that high pressure not only on the punch shoulders, but also on the side walls, activates the friction holding effect, reduces the radial stress, and suppresses fractures.

3.4 *Effect of the Pressure Rise Ratio*

The HDD of THTB tests were performed with the pressure rise rate controlled at 0.83 to 2.0 MPa/mm to investigate the effect on formability. Figure 11 shows the LDR at various pressure rise ratios where P_H is 15 MPa and the hard area ratio of THTB is 1.6. As the pressure rise ratio increased, the LDR gradually improved. It was confirmed that the LDR was improved by 0.12 at 2.0 MPa/mm compared to 0.83 MPa/mm. On the other hand, the pressure rise ratio had no effect on the LDR of the THTB ($D_{in}/D_p = 1.4$).

Holding start stroke S_H depends on pressure rise ratio, and high pressure rise ratio means that S_H is small. The friction holding effect is activated in the early stage of the HDD process and suppresses the deformation of sheets at the punch shoulder. Therefore, it is considered that the LDR was improved at the hard region ratio of 1.6, which reached the forming limit due to the punch shoulder fracture. On the other hand, the pressure rise ratio is independent of the pressure in the middle stage of the

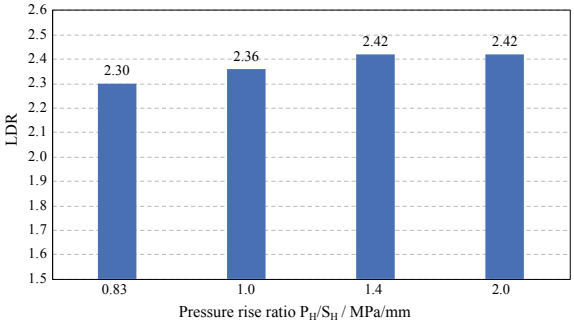

Fig. 11 LDR at various pressure rise ratios of HDD (P_H 15 MPa, $D_{in}/D_p = 1.6$). (Color figure online)

HDD and does not affect the side-wall fracture which occurs in the middle stage. Therefore, the LDR of the THTB ($D_{in}/D_p = 1.4$) was not improved.

3.5 *Hardness Distribution of Formed Cups*

Figure 12 shows the hardness distribution of the formed cups of T6 and the THTB. The hardness of formed cups increased due to strain hardening. Although the initial hardness of the softened periphery region of the blank was low, the hardness after forming increased to 100 HV 2 as well as the original hardness of T6 blank.

The hardness distribution after artificially aging is also shown in Fig. 12. Hardness of softened region and transfer region had increased.

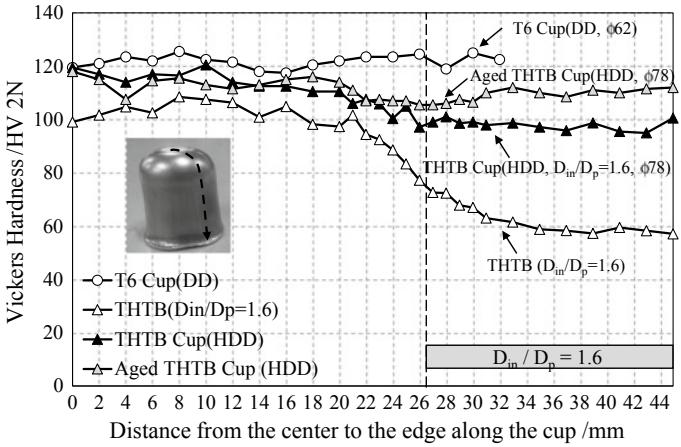

Fig. 12 The hardness distribution of formed cups

4 Conclusions

Combination of the HDD and the THTB methods for 6061-T6 alloy sheets was conducted and improved the LDR compared to a single method. Formability of various hard area ratios of THTB were investigated, and the optimal softened region was found. Fractures occurred at the punch shoulder when the hard region is large, and side-wall fractures occurred when the softened region is large. In addition, it was confirmed that high holding pressure suppressed the wall failure and high pressure rise ration prevented the early fracture at the punch shoulder.

Development of Adhesion Preventing Method During Deep Drawing of Titanium Alloy Sheets

Yusuke Okude, Taku Iwaoka, and Isao Nakamura

Abstract It is necessary to prevent the surface oxide film peeling caused by sliding between workpiece and die material with high surface pressure for reducing punch load and preventing fracture. Hence, we have focused on the method to prevent the titanium surface oxide film peeling during press forming to prevent the adhesion. The workpieces with surface oxide film by atmospheric oxidation were utilized to demonstrate the effect of titanium surface oxide film on formability in deep drawing process. Additionally, the method to prevent adhesion during deep drawing process was developed. In this study, the compressed air was applied to the die and the blank holder force (BHF) with vibration technique was utilized during circular-cup deep-drawing of TP340 sheets. As a result, the occurrence of adhesion was prevented significantly by the application of developed methods.

Keywords Sheet metal working · Deep drawing process · TP340 titanium sheets · Adhesion preventing method

1 Introduction

In recent years, pure titanium has utilized various areas, for example, medical devices and aerospace fields [1]. However, the adhesion easily occurs during press forming. By the occurrence of adhesion, punch load increased and fracture occurs during deep drawing process of pure titanium sheet. So, it is necessary to develop the adhesion preventing method in dry press processing for the global environment. To prevent the adhesion during dry press processing, diamond-like carbon (DLC)-coated die was utilized, but it is difficult to prevent adhesion by using only DLC-coated die. Hence, DLC-coated die and lubrication were applied and 600 times deep drawing process without adhesion were achieved [2]. On the other hand, the ultrasonic vibration was applied to the die during deep drawing process to prevent the adhesion, but it is difficult to prevent the adhesion only by the application of the ultrasonic vibration

[3, 4]. Then, the development of adhesion preventing method for titanium alloy sheets in deep drawing process is necessary. Adhesion occurs easily because the clean metal surface comes in contact with the die due to the peeling off of the oxide film due to the high surface pressure state during deep drawing processing. Therefore, to reduce the adhesion during deep drawing process the TP340 pure titanium with oxide film was utilized [5, 6]. And the effect of the processing conditions on the oxide film was investigated. In this study, the compressed air was applied to the die and the blank holder force (BHF) with vibration technique was utilized during circular-cup deep drawing of TP340 sheets for the reducing of frictional heat and contact between die and blank. As a result, the occurrence of adhesion was prevented significantly by the application of developed methods.

2 Low-Frequency Vibration Applied Crease Suppression-Assisted Cylinder Deep Drawing Test Condition Setting and Adhesion Suppression Method

As the workpiece of experiment, TP340 pure titanium sheet, thickness $t_0 = 0.5$ mm, diameter $\phi = 19.5, 19.95$ mm (Drawing ratio, $DR = 2.0, 2.1$) was utilized. We have focused on the method to prevent the titanium surface oxide film from peeling during press forming to prevent adhesion. Hence, the oxide film was formed on the blank surface by using atmospheric oxidation before deep drawing process. Atmospheric oxidation was maintained for 2 hours at 500 and 600°C using muffle furnace. Figure 1 shows the schematic of experimental apparatus of the cylindrical deep drawing process. Table 1 indicates the dimensions of dies and SKD11 material for die. BHF was loaded in the range of 120–580 N, and the frequency was 0–8 Hz by servo motor control. Punch speed conditions of 1.2, 12, and 120 mm/min were applied. Compressed air was applied in the range of 0–0.8 MPa. After the deep drawing, the die was observed in order to confirm the effect of the peeling of the oxide film on the surface on the adhesion. Figure 2 shows the method of adhesion measurement on die and measurement sample of adhesion after deep drawing of pure titanium sheet. For observation, digital microscope was utilized and adhesion amount was measured at the die shoulder where the most adhesion occurs after deep drawing of TP340 with oxide film.

3 Formability in Cylindrical Deep Drawing of Oxide-Coated TP340 Pure Titanium Sheet

Figure 3 shows the effect of conditions on the peeling of surface oxide film at 500 °C. At the punch speed of 1.2 mm/min, the maximum punch load decreased about 12% compared to 120 mm/min. But the surface oxide film peeling occurs in all punch

speed conditions. Figure 4 shows the effect of conditions on peeling of surface oxide film at 600 °C. The maximum punch load of punch speed 1.2 mm/min decreased 6.7% in comparison with 120 mm/min. However, the surface film peeling occurs at the conditions of 1.2 mm/min punch speed as shown in Fig. 4. In the deep drawing of TP340 alloy sheets at held 600 °C, peeling of the surface oxide film was prevented in the conditions of 12 and 120 mm/min. Figure 5 shows the photographs of die and maximum adhesion area after deep drawing of TP340 sheets with oxide film (600 °C). As increasing punch speed, the adhesion of die decreased as shown in the photograph. Hence, the adhesion occurrence was affected by punch speed.

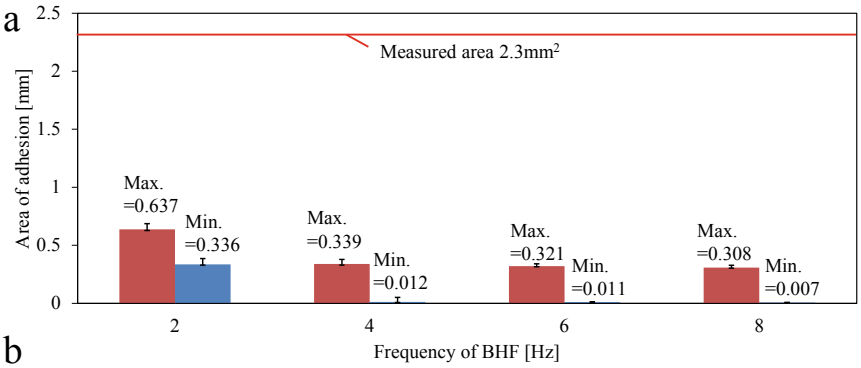
4 Development of Preventing Adhesion Method in Deep Drawing Processing

In this study, the compressed air was applied to die and BHF with vibration technique was utilized during deep drawing of TP340 sheets. First of all, to clarify the effect of compressed air on preventing oxide surface film peeling, the deep drawing test with compressed air was carried out for blanks held at 500 °C. Figure 6 indicates the effect of compressed air pressure on peeling of surface oxide film and adhesion on die at TP340 with oxide film at 500 °C. In the 0.4 MPa of compressed air pressure, the measured area of maximum adhesion was 0.308 mm^2 and area minimum adhesion 0.004 mm^2. On the other hand, from a value of 0.4 MPa, the maximum punch load, adhesion of die, and surface film peeling increased as the compressed air increase. From these results, it is considered that a value more than 0.4 MPa has exerted the effect of pressing the workpiece for the punch direction, and thus increased the punch load and increased adhesion. So, 0.4 MPa is a suitable condition of compressed air pressur for decreasing the peeling of surface oxide film and adhesion on die for the reducing of frictional heat during deep drawing process in this experiment.

The low-frequency vibration is applied to the BHF as follows:



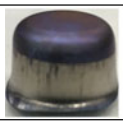
a

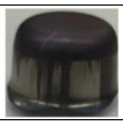
b

Condition	0.2MPa	0.4MPa	0.8MPa
Photograph of drawn cup			
Max. punch load [kN]	3.16	3.12	3.21

Fig. 6 Effect of compressed air pressure on peeling of surface oxide film and adhesion on die (500 °C), **a** comparison of max. and min. adhesion area on die, **b** photographs of drawn cup samples. (Color figure online)

b





Condition	2Hz	4Hz	8Hz
Photograph of drawn cup			
Max. punch load [kN]	3.76	3.28	3.08

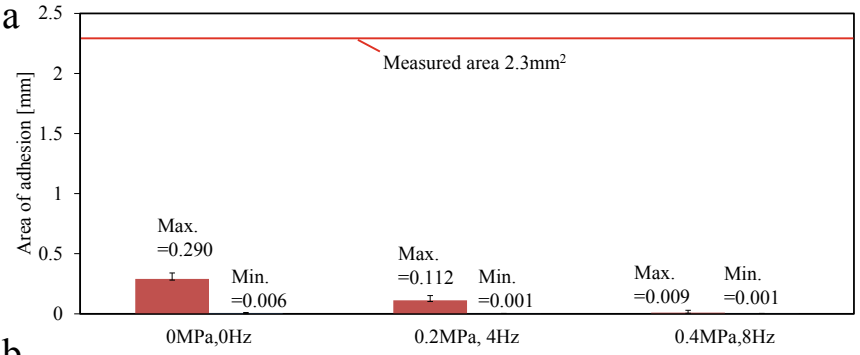


Fig. 7 Effect of frequency of BHF with low-frequency vibration on peeling of surface oxide film and adhesion on die (500 °C), **a** comparison of max. and min. adhesion areas on die, **b** photographs of drawn cup samples. (Color figure online)

$$BHF = A\cos\left(2\pi t\frac{1}{T}\right) = A\cos(2\pi tf) \tag{1}$$

where A is the amplitude of BHF(A is selected from the range of 120 to 580 N), T is the period, t is the time during deep drawing process, and f is the frequency calculated by $1/T$. Hence, in the case of BHF without low-frequency vibration, BHF indicates the value of A. Figure 7 indicates the effect of low-frequency vibration on the peeling of surface oxide film and adhesion on die at TP340 with oxide film at 500 °C. As the frequency of BHF is increased with low-frequency vibration, the area of maximum and minimum adhesions decreased. Because, in the case of frequency less than or equal to 4 Hz, it is considered the surface oxide film peeling occurred by the effect of striking surface oxide film by the die vibration. For frequency of 8 Hz, the effect of reducing of contact time between die and blank has appeared. Hence, the suitable value of frequency BHF with low-frequency vibration prevents the delamination of surface oxide film.

Figure 8 indicates the effect of compressed air and BHF with low-frequency vibration on peeling of surface oxide film and adhesion on die at TP340 with oxide film at 600 °C. By the application of a combination of compressed air and BHF with low-frequency vibration, the surface film peeling and adhesion on die was decrease dramatically as shown in Fig. 8. As the result, the surface film peeling was prevented completely and the area of minimum adhesion decreased to the value 0.009 mm^2 in the compressed air pressure 0.4 MPa and BHF with 8 Hz low-frequency vibration.

a

b

Condition	0MPa,0Hz	0.2MPa, 4Hz	0.4MPa,8Hz
Photograph of drawn cup			
Max. punch load [kN]	3.76	3.42	3.08

Fig. 8 Effect of compressed air and BHF with low-frequency vibration on peeling of surface oxide film and adhesion on die (600 °C), **a** comparison of max. and min. adhesion areas on die, **b** photographs of drawn cup samples. (Color figure online)

5 Conclusion

(1) In the deep drawing process of TP340 sheets with oxide film (600°C), the adhesion of die decreases as increasing punch speed. Hence, the surface film peeling was affected by the punch speed on each thickness of oxide film.

(2) By the application of compressed air pressure during deep drawing process, the surface oxide film peeling of TP340 was decreased. And the measured area of maximum adhesion was 0.308mm^2 and area minimum adhesion 0.004mm^2 in the 0.4 MPa of compressed air pressure.

(3) By the application of BHF with low-frequency vibration during deep drawing process, the surface oxide film peeling of TP340 was decreased. As the frequency of BHF is increased with low-frequency vibration, the area of maximum and minimum adhesions is decreased in the range of 2–8 Hz.

(4) By the application of a combination of compressed air pressure and BHF with low-frequency vibration during deep drawing process, the adhesion of die decreased exponentially. The surface film peeling was prevented completely and the area of minimum adhesion decreased to the value 0.009 mm^2 per measured area 2.3/mm^2 in the compressed air pressure 0.4 MPa and BHF with 8 Hz low-frequency vibration. As a result, the preventing of adhesion was

achieved by the application of a combination of compressed air pressure and BHF with low-frequency vibration without coating dies and lubrication.

Development of Warm Press Forming Process Method of Ti–6Al–4 V Alloy Sheet

Yusuke Okude, Taku Iwaoka, Isao Nakamura, and Takashi Katagiri

Abstract Because of the low ductility of Ti–6Al–4V alloy at the temperatures between room temperature and 600 °C, fracture easily occurs during press forming. Hence, a method of press forming of Ti–6Al–4V alloy sheets at 300 °C was developed. In this method, the punch motion and blank holding force were applied separately to prevent fracture at the punch radius until the maximum punch load was reached, and the deep drawing process was demonstrated from the maximum punch load until finish forming to prevent the fracture at end of the flange. In addition, by applying the developed method, we were able to prevent the decrease in wall thickness at the punch shoulder, compared with that in press forming. As a result, warm press forming of Ti–6Al–4V alloy sheets at 300 °C was achieved without fracture of the formed cup or local decrease in the wall thickness by applying the developed method.

Keywords Sheet metal working · Warm forming · Ti–6Al–4V alloy · Incremental press forming · Deep drawing process

1 Introduction

Ti–6Al–4V titanium alloy has been actively used in medical equipment and aerospace due to its characteristics of light weight, corrosion resistance, and high specific strength [1]. In general, Ti–6Al–4V alloy sheets are formed by incremental press forming in the temperature range between 600 and 900 °C [2–4]. In this temperature range, the ductility of Ti–6Al–4V alloy is improved, and it has been applied as hot stamping of titanium alloys for aircraft parts in the temperature range of 800–900 °C [5]. Due to the principle of electric heating, the blank material is limited to a rectangular shape. In addition, for high-strength materials with poor formability, continuous resistance heating has been applied to bar rolling, and bar forming of Ti–6Al–4V alloy has been successfully performed with a reduced fracture [6]. Because

of the low ductility of Ti–6Al–4V alloy at the temperatures between room temperature and 600 °C, fracture easily occurs during press forming. Hence, a method of press forming of Ti–6Al–4V alloy sheets at 300 °C was developed. In this method, the punch motion and blank holding force were applied separately to prevent fracture at the punch radius until the maximum punch load was reached. As the result, warm press forming of Ti–6Al–4V alloy sheets at 300 °C was achieved without fracture of the formed cup or local decrease in the wall thickness by applying the developed method.

2 Experimental Apparatus and Formability of Ti–6Al–4 V Alloy Sheet at Warm Temperature of Deep Drawing Test

In order to understand the basic formability of circular-cup deep drawing of Ti–6Al–4V alloy sheet, circular-cup deep drawing with a general blank holding force (BHF) was first performed. Figure 1 shows a schematic of deep drawing process, and Table 1 the dimensions of the dies of deep drawing process. The die material used was SKH51. Ti–6Al–4V alloy plate and a blank with a thickness of $t_0 = 0.5$ mm were

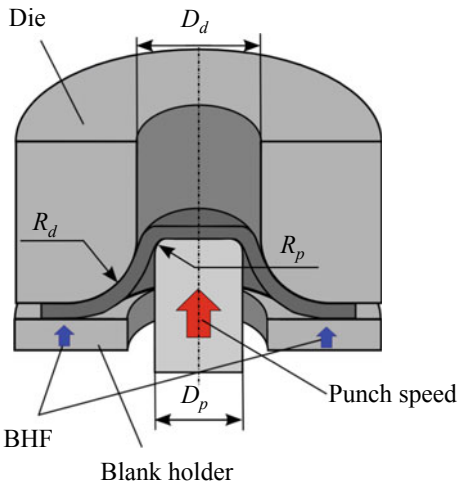

Fig. 1 Schematic of deep drawing process

Table 1 Dimension of dies of deep drawing process

Die	Diameter: D_d/mm	35.0
	Shoulder radius: R_d/mm	3.0
Punch	Diameter: D_p/mm	32.5
	Shoulder radius: R_p/mm	5.0

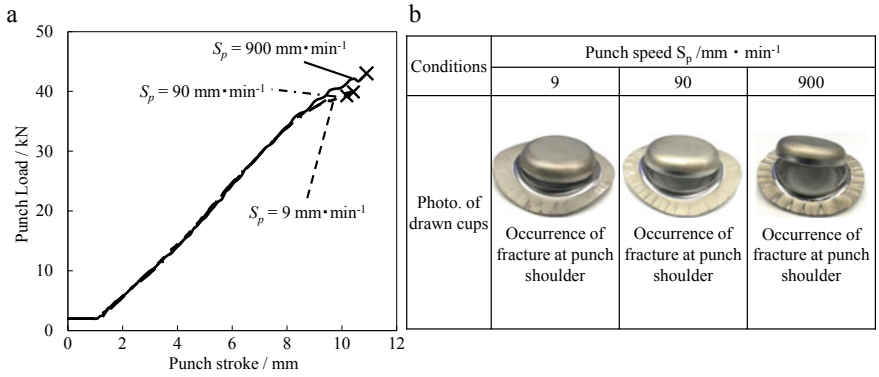

Fig. 2 Effects of punch speed on deformation behavior of Ti–6Al–4V alloy sheet at 300 °C, **a** Punch load–punch stroke curve, **b** Photographs of cups drawn under each set of conditions. (Color figure online)

used as test materials. The test was performed with a blank diameter of $\phi = 60$ mm (Drawing ratio, $DR = 1.85$).

Circular-cup deep drawing was carried out at the condition of 300 °C forming temperature. Test was performed at the same temperature as the blank for the drawing die and the blank holder. The punch was kept at room temperature under all conditions. The punch speed S_p was set to three conditions of 9, 90, and 900 mm/min, and the constant blank holding force BHF_{const} was applied at 4 kN. Figure 2 shows the punch load–punch stroke curve and photographs of cups drawn under each set of conditions. In each condition, fracture occurred at punch shoulder. Therefore, the low formability of Ti–6Al–4V alloy sheet was confirmed.

3 Incremental Press Forming Method and Formability of Ti–6Al–4V Alloy Sheet

In circular-cup deep drawing with constant blank holding force, fracture occurred at the punch shoulder at any punch speed at a forming temperature of 300 °C. In this study, we focused on the fact that in normal cylindrical drawing, wall thinning progressed due to tension due to blank holding force from the start of the punch until the maximum punch load was reached. When the material is pressed into the die with a punch under the condition of applying wrinkle suppressing force, the thickness of the punch shoulder is significantly reduced. Therefore, in order to perform press forming in the incremental forming developed in this study, two processes were separated: a punch motion process and BHF without blank holding force process. Figure 3 shows the schematic of incremental press forming. FORMKOTE T-50 was applied as a lubricant between the blank and the mold. In the incremental forming, press forming was performed under the conditions of $S_{pi} = 9$ mm/min, $P_{si} = 0.2$ mm, and $BHF_i =$

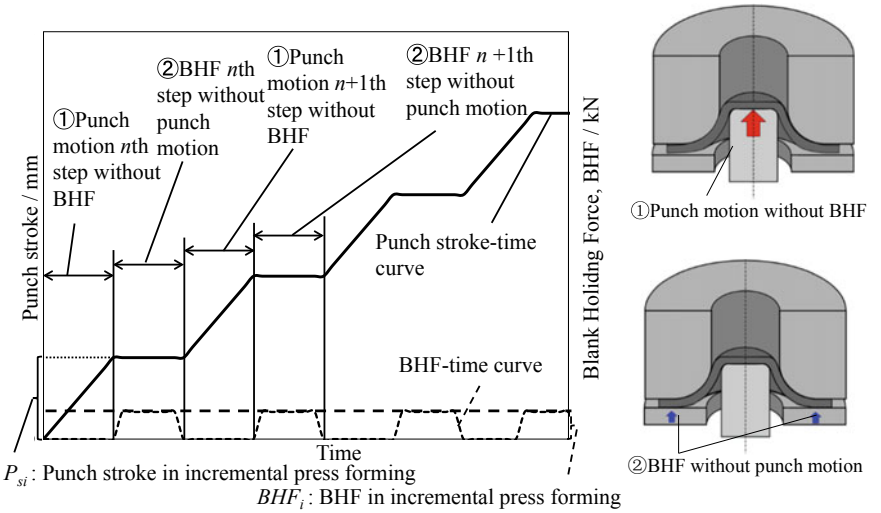

Fig. 3 Schematic of incremental press forming. (Color figure online)

20kN. For comparison, the circular-cup deep drawing was carried out under the same lubricating conditions with a punch speed of 9 mm/min and a blank holding force of 4 kN. Figure 4 shows the effect of incremental forming on formability. However, the fracture occurred at the flange as shown in the figure caused by the compressive deformation of the flange. In addition, the effect of punch feed on the formability was investigated by forming under three conditions of $P_{si} = 0.2$, 0.4, and 0.8 mm,

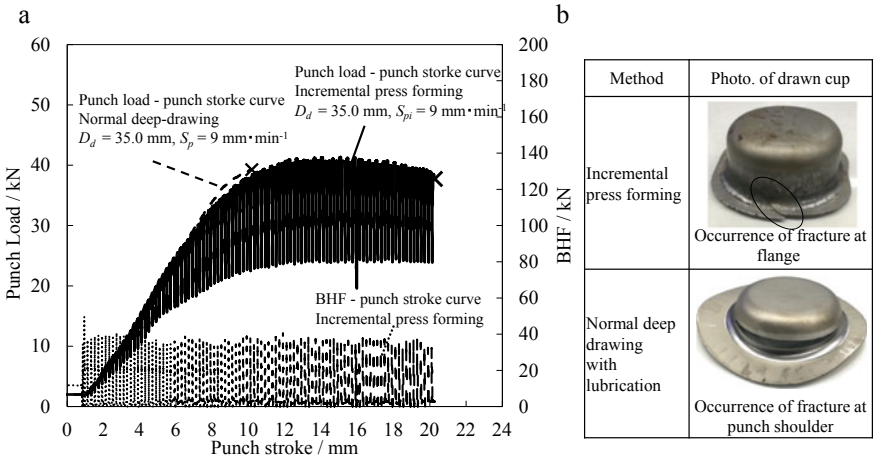

Fig. 4 Effect of incremental forming on deformation behavior at 300 °C, **a** Punch load–punch stroke curve, **b** Photographs of cups drawn under each set of conditions. (Color figure online)

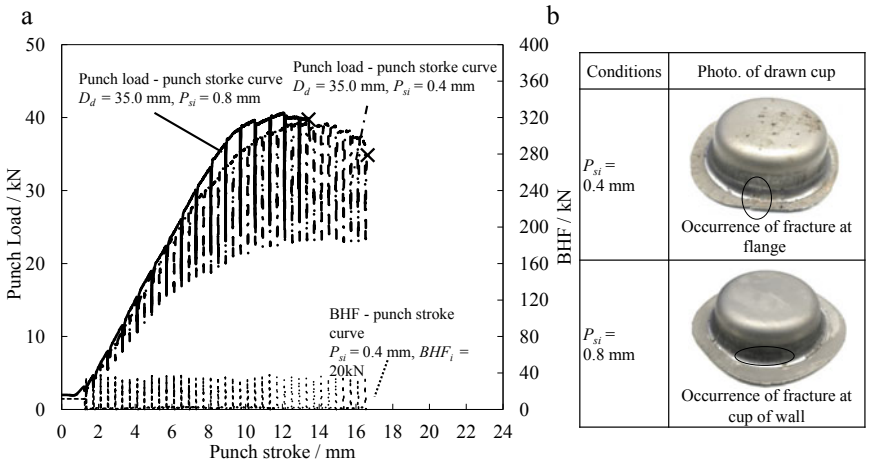

Fig. 5 Effect of punch stroke on deformation behavior during incremental forming at 300 °C, **a** Punch load-punch stroke curve, **b** Photographs of cups drawn under each set of conditions. (Color figure online)

with the punch speed fixed at the condition of $S_{pi} = 9$ mm/min. As in the case of the punch speed, the formability was different depending on the feed amount of the punch. Figure 5 shows the effect of punch feed on formability. As the punch feed increased, the formability decreased, and at a feed of 0.8 mm, the cup wall fractured. The amount of blank flowing into the die increased, as the amount of punch feed increased.

4 Development of Warm Press Forming Process Method for Ti–6Al–4V Alloy Sheet

From the experimental results of incremental press forming, it was difficult to prevent fracture caused by shearing force at the flange, or breaking at the cup wall. For this reason, we developed the method of forming vertical fracture without irregular deformation by combining incremental forming and drawing forming, based on the prediction that fracture by shearing force at the flange is caused by compressive force on the flange part. Concretely, in order to form the cup head where the thin wall progresses especially at the shoulder of the punch, the molding is performed incrementally in the initial stage to the middle stage. In addition, when the blank flows into the mold to form the cup wall, significant compression deformation is applied to the flange part. In the middle to late stages, drawing is performed to reduce the compression deformation. Figure 6 shows the schematic of developed press forming method. In this method, the punch load increment dL for each punch stroke P_{si} was

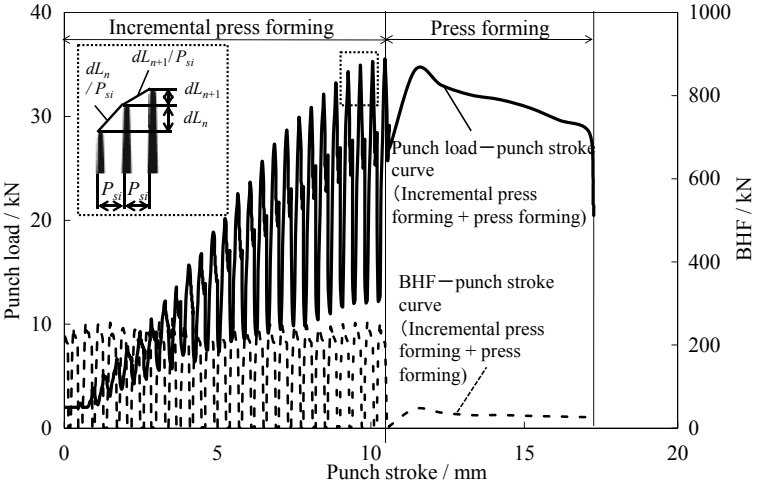

Fig. 6 Schematic of developed press forming method

calculated during incremental forming, and after the value of dL/P_{si} reached 0.2 or less, the process was shifted to drawing.

To achieve press forming of Ti–6Al–4V alloy sheet at 300 °C. $S_{pi} = 9$ mm/min, $P_{si} = 0.2$ mm, $BHF_i = 200$kN in the incremental forming process using FORMKOTE T-50 as the lubrication condition, and $S_{pi} = 900$ mm/min and $BHF = 20$kN in the draw forming. Figure 7 shows the effect of developed forming method on deformation behavior at 300 °C. By application of developed forming method, the press forming

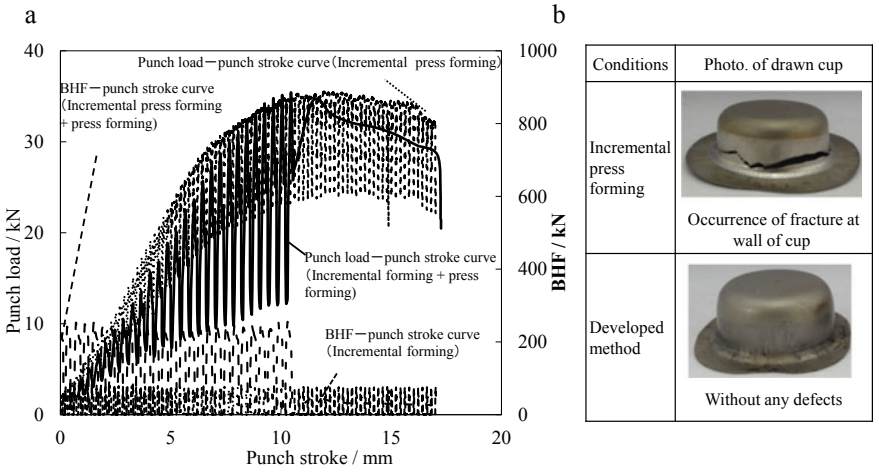

Fig. 7 Effect of developed forming method on deformation behavior at 300 °C, **a** Punch load–punch stroke curve, **b** Photographs of cups drawn under each set of conditions. (Color figure online)

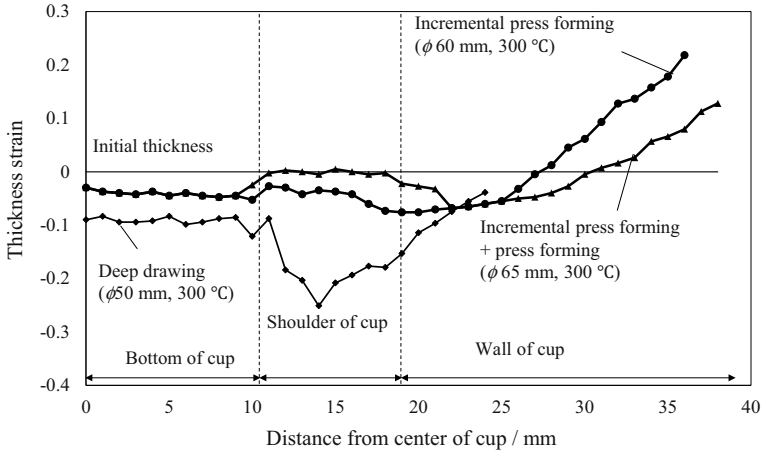

Fig. 8 Effect of developed forming method on thickness strain of drawn cup

of Ti–6Al–4V alloy sheet in the conditions of $DR = 2.0$ at the forming temperature of 300 °C was achieved without fracture and Fig. 8 shows the effect of the forming method on the wall thickness distribution.

5 Conclusion

(1) By applying incremental forming, it was possible to form the Ti–6Al–4V titanium alloy without cracking after reaching the maximum punch load at 300° C, compared to drawing, but drawing was possible. Shortly, before the end of die, fracture caused by shearing force occurred in the flange.

(2) By developing the method of combination of incremental forming and draw forming to prevent the fracture caused by shearing force at the flange part, and the press forming at the condition of $DR = 2.0$ of Ti–6Al–4V alloy was achieved.

(3) With the developed incremental forming and drawing methods, the reduction of the wall thickness distribution was suppressed compared to the constant blank forming force, and the result was that the entire forming cup had a uniform wall thickness.

Research on New Hot Stamping Tool with Low-Cost and High-Efficiency Cooling

Shixin Peng, Jie Zhou, Mengmeng Zhang, Kemin Zhang, and Jie Liu

Abstract Hot stamping technology is widely used to produce car body components with more complex shape, higher strength, and less springback. A pair of optimal hot stamping tool should have a long service life, low manufacturing cost, and good cooling performance simultaneously. Consequently, a new manufacturing method of hot stamping tool with CCC (conformal cooling channels) is introduced in this study. Besides, CuCrZr and Fe-based alloy were welded on the specimens as intermediate layer and surface layer respectively, high-temperature compressive yield strength, the heat conductivity, and thermal expansion coefficient of welding materials were measured. The whole stamping process of the new hot stamping tool is simulated and discussed. The simulation results indicate the maximum stress in each area of the new tool was less than the yield strength of the corresponding welding materials, which demonstrated that the new tool manufactured by surfacing technology could meet the strength requirement and deserve further research.

Keywords Hot stamping tool · Surfacing technology · Surface layer · Intermediate layer · Numerical simulation

1 Introduction

To meet the dual requirement of automotive lightweight and safety improvement, the hot stamping technology of ultra-high-strength steel is widely applied in the automotive industry [1–3]. Hot stamping tools play a key role in the whole stamping process [4]. A set of satisfied hot stamping tools should have three characteristics with long service life and low manufacturing cost and excellent cooling performance simultaneously. However, traditional hot stamping tools with straight holes were integrally manufactured by homogeneous tool materials with high cost, and the partial tool failure would lead to a whole scrap or difficult repair [5–7].

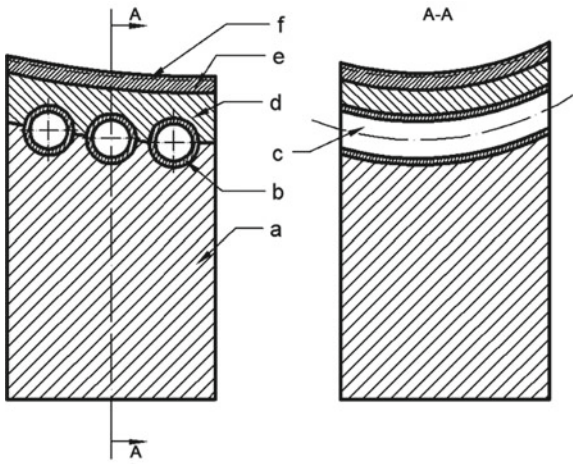

Fig. 1 2D Section diagram of new hot stamping tool insert **a** Matrix; **b**, **c** Copper pipe; **d** Intermediate layer; **e** Surface layer; **f** tool surface

In this paper, a novel design of hot stamping tool with conformal cooling channels (CCC) manufactured by surfacing technology is put forward, as shown in Fig. 1. Firstly, the matrix with a lower half of CCC shape is machined, and then the pre-bended copper pipes are embedded into the cooling channels of the matrix material, so the top half of copper pipes is exposed in the air. Then again, the welding materials with high thermal conductivity are welded on the surface of matrix and copper pipes to form intermediate layer. And then the heat-resisting welding materials are welded on the surface of the intermediate layer to obtain surface layer. Finally, the tool must be heat-treated and machined in order to satisfy the requirements of shape and size and performance. By this method, material properties of the new hot stamping tool can reach the allocation of materials on demand. In other words, the surface layer will withstand severe condition such as high temperature and high stress, and the intermediate layer can improve the cooling efficiency, and the 45 steel matrix will greatly reduce the use of expensive tool materials under the premise of the meeting working conditions.

2 Materials and Methods

In this study, quenched and tempered 45 steel was chosen as the matrix material, Fe-based and CuCrZr alloy were preselected as the surface layer and the intermediate layer, respectively.

The matrix specimens were firstly cleaned and preheated to 400 °C and then the surfacing process was carried out by using an HRWS-3250-type welding machine according to test design requirement. Finally, the specimen was tempered to 500 °C after welding. The 3D model and finished specimens are shown in Fig. 2.

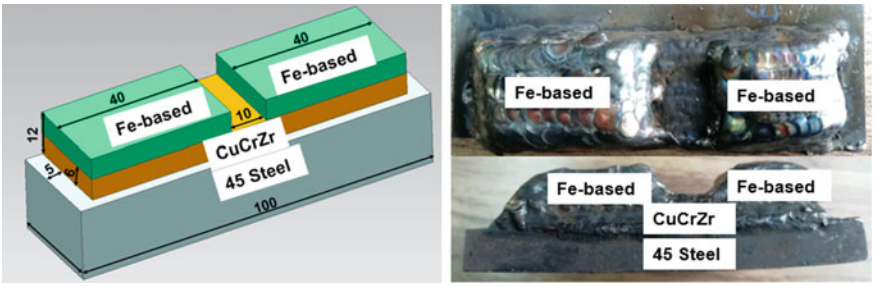

Fig. 2 The surfacing samples. (Color figure online)

3 Performance Test of Surfacing Materials

3.1 Mechanical Properties of Surfacing Materials

The high-temperature compressive yield strength of two single welding materials and two interfaces are shown in Fig. 3. It can be concluded that the yield strength has a downward trend with increasing temperature, but the interface of CuZrCu + Fe-Based exhibits a higher yield strength above 150 °C. The yield strength of Fe-based alloy reduced from 1608 to 1198 Mpa, the yield strength of Cu–Cr–Zr fell from 135 to 90 Mpa, the interface yield strength of 45 + CuCrZr changed from 383 to 361 Mpa, and the interface yield strength of CuCrZr + Fe-Based fluctuated from 343 to 379 Mpa.

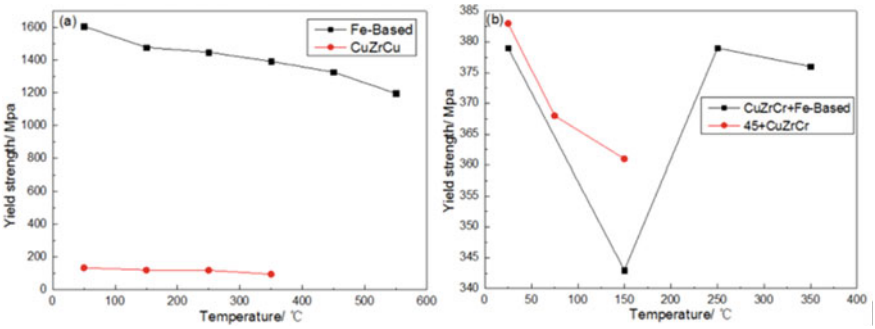

Fig. 3 The high-temperature compressive yield strength of surfacing materials. (Color figure online)

Table 1 Thermal expansion coefficient of two alloy materials (unit in/°C)

Temperature/°C	50	150	250	350	450
Fe-Based	1.50E-5	1.36E-5	1.36E-5	1.34E-5	1.32E-5
CuCrZr	1.63E-5	1.67E-5	1.77E-5	1.76E-5	1.74E-5

Table 2 Heat conductivity of two alloy materials (unit in W/m•°C)

Temperature/°C	25	100	200	300	400
Fe-Based	39	43	48	51	54
CuCrZr	166	154	145	138	134

3.2 Heat Conductivity and Thermal Expansion Coefficient of Surfacing Materials

The heat conductivity and thermal expansion coefficient of Fe-based and CuCrZr are displayed in Tables 1 and 2, respectively. These thermal parameters which directly influence the stress and temperature contribution will be input into ABAQUS software for process simulation.

4 Numerical Simulation of Traditional and New Hot Stamping Tools

4.1 FE Model Establishment

Traditional tools of automotive rear side member were chosen as research object as shown in Fig. 4. Figure 5 presents the structures of traditional and new hot stamping

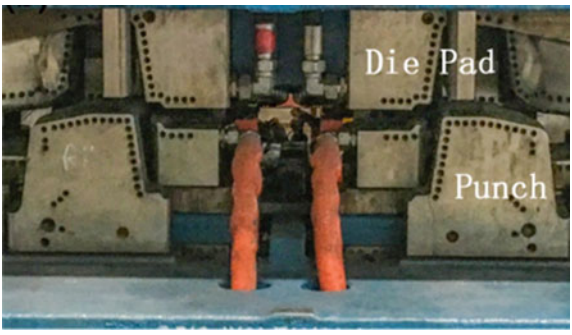

Fig. 4 Traditional hot stamping tool. (Color figure online)

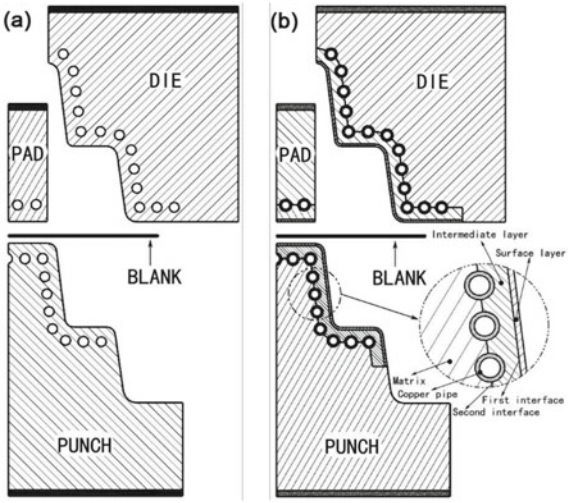

Fig. 5 Two hot stamping tools structures **a** Traditional tool; **b** New tool

tools which both contain die, punch, pad, and rigid tool base; however, the new hot stamping die is divided into surface layer, intermediate layer, matrix, and cooper pipe.

4.2 Temperature Filed Comparison of Traditional and New Tools

In the continuous stamping process, the temperature field of tool will reach dynamic balance after approximately fourth and fifth stamping circles according to trial and error. For both traditional and new tools, the temperature field at the end of pressure holding stage is presented in Figs. 6 and 7. As can be seen from Figs. 6 and 7, the maximum temperature of the traditional tool (TT) is within the range of 110–121 °C, the maximum temperature of the new tool (NT) varies from 70 °C to 74 °C, which indicates that new tool has a higher cooling efficiency due to intermediate layer with high thermal conductivity.

4.3 Stress Filed Comparison of Traditional and New Tools

Figure 8 shows the stress field distribution of traditional and new tools at the end of stamping. The simulation result indicated that new tool will be subjected to lower stress than traditional tool, which is attributed to high heat conductivity and low elastic modulus of intermediate layer. According to the simulation results, the maximum stress of the new tool was less than yield strength under corresponding

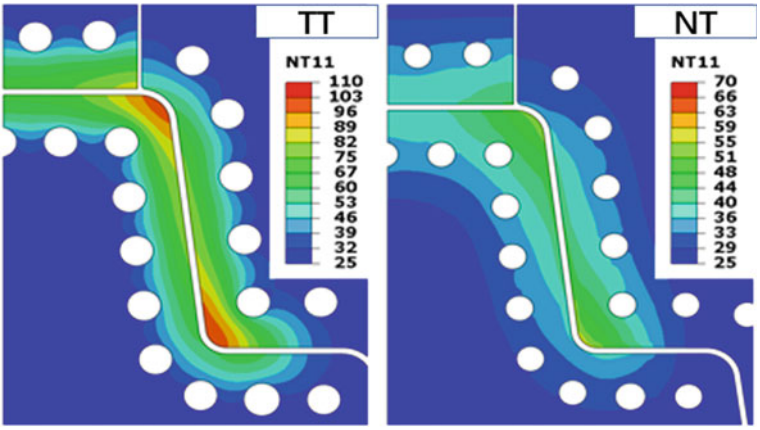

Fig. 6 Temperature field at the end of the pressure holding (the first stamping). (Color figure online)

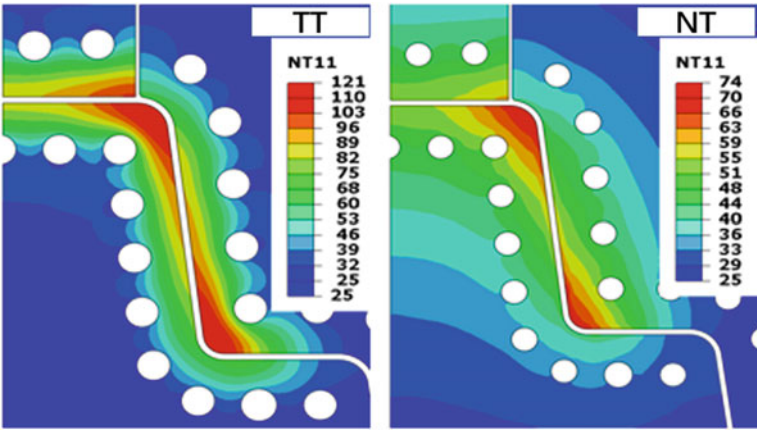

Fig. 7 Temperature field at the end of pressure holding (the sixth stamping). (Color figure online)

temperature, which demonstrated that the new tool manufactured by surfacing technology can satisfy the strength requirement of hot stamping process.

4.4 Cooling Rate Comparison of Traditional and New Tools

Cooling rate above 27 °C/s [8] will lead to hot-stamped part with a fully martensitic structure, a higher cooling rate can improve the production efficiency. Cooling rate comparison of traditional and new tools in the martensitic phase region is shown in Fig. 9. The average cooling rate of the blank in traditional and new tools is about

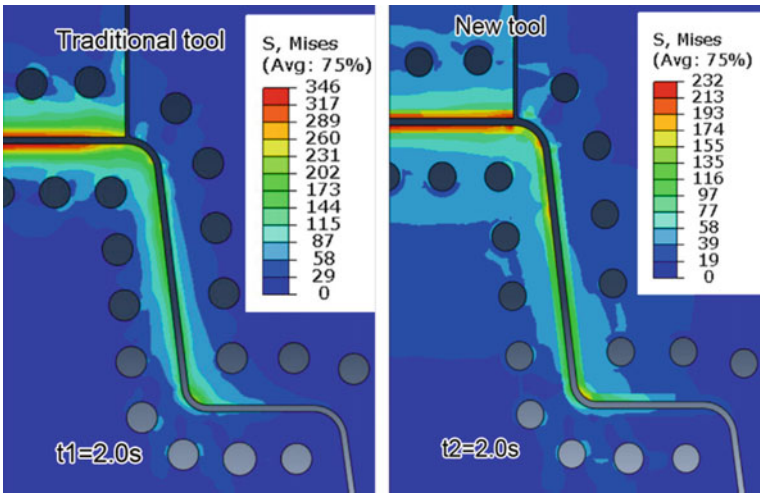

Fig. 8 Stress field comparison of traditional and new tools (the sixth stamping). (Color figure online)

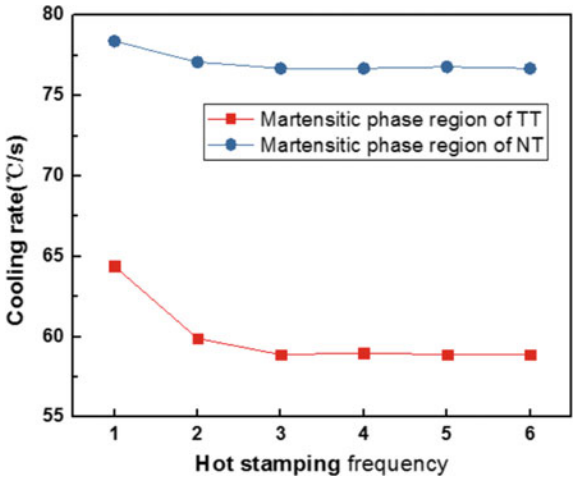

Fig. 9 Cooling rate comparison of traditional and new tools. (Color figure online)

59 °C/s and 77 °C/s, respectively.

5 Conclusions

1. A new manufacturing method of hot stamping tool with CCC is proposed in this study. The temperature of traditional and new tools reached dynamic thermal equilibrium after 4 and 5 stamping circles, respectively.
2. The temperature and stress of new tool were always lower than traditional tool. The maximum stress of new tool was less than the yield strength of the corresponding welding materials, which demonstrated that new tool manufactured by surfacing technology could satisfy the strength requirement and deserve further research.

Formability Analysis of a Local Heat-Treated Aluminium Alloy Thin-Walled Tube

A. Piccininni, J. P. Magrinho, M. B. Silva, and G. Palumbo

Abstract The environmental concerns to save energy are currently driving the attention toward alternative ways to produce lightweight components, matching the most promising light alloys (as in the case of aluminium alloys) with new and innovative manufacturing trends. To address these new requirements the use of tubular structures has increased as a solution to reduce weight. Parallel to the need to increase the material formability local heat treatment of metal sheets has gained some relevance in the last years. The present work is focused on the evaluation of the formability at room temperature of thin-walled aluminium alloy tubes previously overaged in specific zones by laser. The formability limits of the thin-walled tube material in the 'as-received' condition were preliminarily determined by means of tensile tests and tube expansion with elastomer. An initial numerical analysis was performed in order to define laser heating parameters to effectively overage the material. The experimental work (tensile and tube expansion tests) was assisted by the Digital Image Correlation (DIC). On the other hand, the laser treatment to obtain Locally Overaged Tubes (LOTs) was investigated according to the results of the preliminary numerical simulations and such LOTs were subjected to experimental tensile and tube expansion tests. The strain paths and failure strains obtained on LOTs were assessed and compared to the formability limits of the 'as-received' tube, thus allowing to evaluate the effect of the local modification of the material properties on the formability of the tube.

1 Introduction

Environmental problems have increased in recent years the interest of the research toward energy saving which can be obtained, as discussed in [1], using different approaches such as (i) the design of lightweight components maintaining their mechanical requirements, (ii) the adoption of alternative manufacturing processes, and (iii) materials selection. One of the solutions that has a significant impact on weight and energy reduction is the use of thin-walled tubular structures [2], and this fact might be one of the causes promoting in the last years the increase of tube forming as manufacturing process. Additionally, the use of aluminium (Al) alloys can ensure good mechanical properties combined with low density; however, they are characterized by poor formability at room temperature, when compared to low carbon steel.

Recently, to overcome such a limitation, the scientific community has been developing innovative solutions, among which the local modification of the material properties via short-term heat treatments [3]. These local heat treatments can be performed by laser radiation, conductive [4] or inducting devices according to the complexity of the component as well as the number of parts to be manufactured. Laser heat treatment is therefore highly suitable for complex heating strategies on small series (prototypes) production thanks to its flexibility. The research in this area has been mainly focused on sheet metal parts, whereas only few examples are available in literature regarding the tube properties modification via laser treatment [5].

Under these circumstances, the main contribution of this paper is to provide a systematic methodology to evaluate the effect of laser treatments on the formability of AA6063 tubular samples purchased in the T6 condition. Preliminary numerical simulations were performed to define the process parameters to evaluate the temperature distribution during the laser heating of the tube. According to the numerical results, preliminary experimental laser treatments were carried out on tubular samples; the Locally Overaged Tubes (LOTs) were subsequently subjected to hardness measurements to assess the effectiveness of the laser heating; after the tuning of the treatment to be used for changing the material condition into ‘overaged’, the formability was assessed by means of tensile tests and tube expansion with elastomer.

2 Material and Methodologies

The experimental work was performed on AA6063-T6 Al alloy tubes with an external diameter of 40 mm and an average initial thickness of 1.85 mm. Table 1 presents the chemical composition of the alloy under investigation.

As previously mentioned, the aim of the present work is the evaluation of the effect of a local modification of the material properties on the overall formability at room temperature. In the case of the investigated age-hardenable alloy, the local laser treatment was designed to bring the material in a more formable condition without triggering the natural ageing, i.e. aiming at the overaged condition.

According to what was reported in literature, a fast hardenable Al alloy reaches a more formable condition after being irradiated for few seconds at a temperature between 400 and 450 °C [6–8]. Laser treatments were experimentally carried out using the experimental setup shown in Fig. 1a, mainly composed of an Al cylindrical support on which the tubular sample was mounted; all the tubular samples were preliminarily painted in black to increase the absorption coefficient. Laser heat treatments were carried out adopting a 20 mm square spot.

To properly define the laser heating parameters, the experimental equipment was modelled using the Finite Element (FE) code Abaqus. The tube (initial length:100 mm) and the support were modelled as deformable bodies; the heat exchange between them was considered as conductive whereas a convective heat exchange was considered with the surrounding environment. The laser heating was designed according to a linear path parallel to the tube axis (a DFLUX user subroutine was used to model the laser spot movement). Four different Feed Rate (FR) levels were considered to investigate the effect of the interaction time and the laser

Table 1 Chemical composition (wt%) of the AA6063-T6

Si	Fe	Cu	Mn	Mg	Cr	Zn	Ti	Al
0.2–0.6	< 0.35	< 0.1	< 0.1	0.45–0.9	< 0.1	< 0.1	< 0.1	Bal

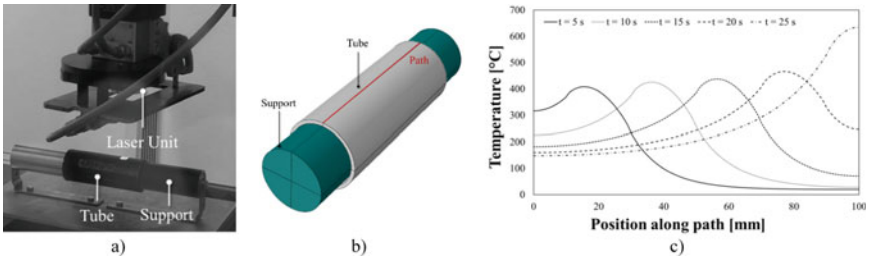

Fig. 1 Tube laser heating: **a** experimental set-up; **b** modelled assembly for the preliminary simulations; **c** distribution of temperature along the longitudinal path. (Color figure online)

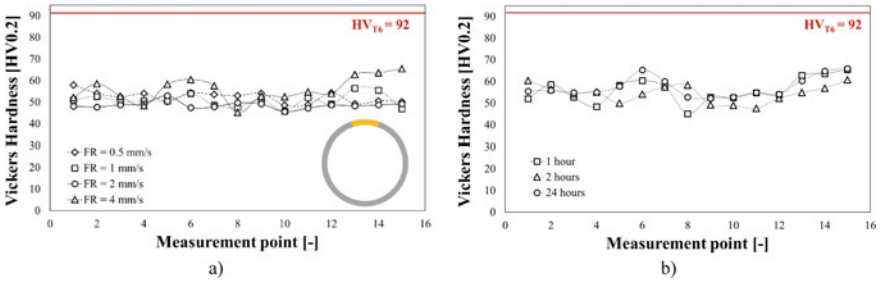

Fig. 2 Hardness measurement: **a** effect of the feed rate, **b** evolution of hardness with time. (Color figure online)

power (LP) was changed accordingly in order to subject the material to the above-mentioned range of temperatures. Results of the thermal simulations were analysed in terms of temperature distribution along a longitudinal path, as shown in Fig. 1b.

Figure 1c, regarding the laser heating setting the LP at 1050 W and the FR at 4 mm/s, shows that, once the initial transient heating was over, most of the tube was subjected to a temperature ranging from 400 to 450 °C. Additionally, as the laser approached the end of the tube, the temperature sensibly increased due to the limited quantity of material available to dissipate the heat.

To evaluate the effectiveness of the laser treatment, a ring sample was extracted from the middle part of the tube; the portion subjected to the laser heating (highlighted in yellow in Fig. 2a) was mounted, grinded, polished, and subjected to Vickers microhardness tests (Qness microhardness tester Q10 A + , setting a load of 200 g and a dwell time of 15 s) at regular interval of time. The hardness of the alloy in the as-received condition (T6) was also measured and resulted equal to 92 HV.

Hardness profiles in Fig. 2a show that all the investigated FR levels were effective in bringing the material to a more formable (and stable) condition: in fact, if focusing the attention on the hardness evolution with time (FR = 2 mm/s) in Fig. 2b, even after 24 h from the heat treatment there was a negligible variation of the hardness. This result confirms that the investigated laser parameters were effective in bringing the material to the overaged condition.

The laser heating for the experimental plan was designed to locally modify the tube properties without affecting the rest of the tube. For this reason, the subsequent treatments, on 200-mm tube samples, were carried out setting the FR at 2 mm/s (material/radiation interaction times equal to 10 s) and, consequently, LP at 800 W. In order to avoid the excessive increase of the temperature in the last part of the laser heating, as previously shown in Fig. 1c, the beam power was reduced by 50% after having completed 75% of the linear track.

Table 2 Summary of the experimental work plan of the tensile tests

Material condition	Geometry dimensions					Number of specimens
	Outer radius (mm)	Thickness (mm)	Gauge length (mm)	Length of the reduced section (mm)	Width (mm)	
T6	20	1.85	50	80	12.5	3
LOT						3

Table 3 Summary of the experimental work plan of the tube expansion with elastomer

Material condition	Geometry dimensions			Operation conditions			Number of specimens
	Outer radius (mm)	Thickness (mm)	Length (mm)	Free length, l_{free} (mm)	Fixing condition	Velocity (mm/min)	
T6	20	1.85	150	20	blocked	5	3
LOT							3

3 Experimentation

The experimental work consisted of (i) the conduction of tensile tests extracted in the longitudinal direction from the tubes and (ii) tube expansion tests using an elastomer. Both the tests were carried out at room temperature condition. The AA6063-T6 tube formability limits by necking and by fracture were determined by the authors in a previous work [9].

3.1 Tensile Tests

The longitudinal tensile test specimens were prepared in accordance to the ASTM E8/E8M standard [10], with a 50 mm gauge length and 12.5 mm of width. The specimens were wire electro-discharge cut and the tensile tests were performed using a universal testing machine (Instron 4507). The experimental work plan for the tensile tests is summarized Table 2 (Table 3).

3.2 Tube Expansion Tests

The elastomer compression was used to expand the tube up to failure. The adopted equipment was assembled on a hydraulic testing machine (Instron Satec 1200) and it is presented in Fig. 3. The main components of the equipment are: punch, dies, rubber plug, and clamping system. The operation of the process is the following: the

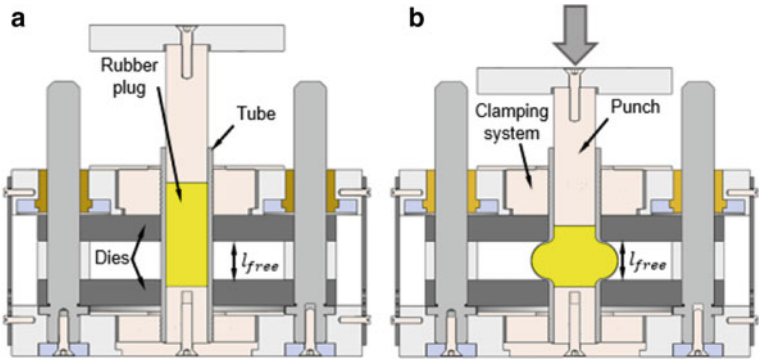

Fig. 3 Schematic representation of the tube expansion tests with elastomer equipment in the **a** initial and **b** final positions [9]. (Color figure online)

tube ends were clamped and the cylindrical rubber plug was placed inside the tube without lubricant and compressed by the punch; the expansion of the tube occurred in the free length, l_{free} between the two dies.

The experimental work plan for the tube expansion tests with elastomer is summarized in Table 2.

3.3 Strain Measurements

The strain distribution on the fracture zone in both tensile and tube expansion with elastomer tests were measured by means of a digital image correlation (DIC) system (Dantec Dynamics model Q-400 3D) equipped with two cameras with 6 megapixels of resolution and 50.2 mm of focal length (aperture: f/11). The frequency of image acquisition was set to ten frames per second and the correlation algorithm was performed with the INSTRA 4D software.

The fracture strains were obtained by measuring the thickness at the cracking (thus calculating the thickness strain ε_3) and combining it with the ε_2 from the last stage of the DIC analysis in order to calculate the major strain ε_1 by the incompressibility condition. The thickness measurements were performed with a stereoscopic microscope Nikon AZ100M with a magnification of 20 $\times$ using the Imaging Software NIS-Elements D 3.21.03.

4 Results and Discussion

The experimental work revealed to be highly replicable thus, to improve the quality of the present section, only results per one condition have been presented.

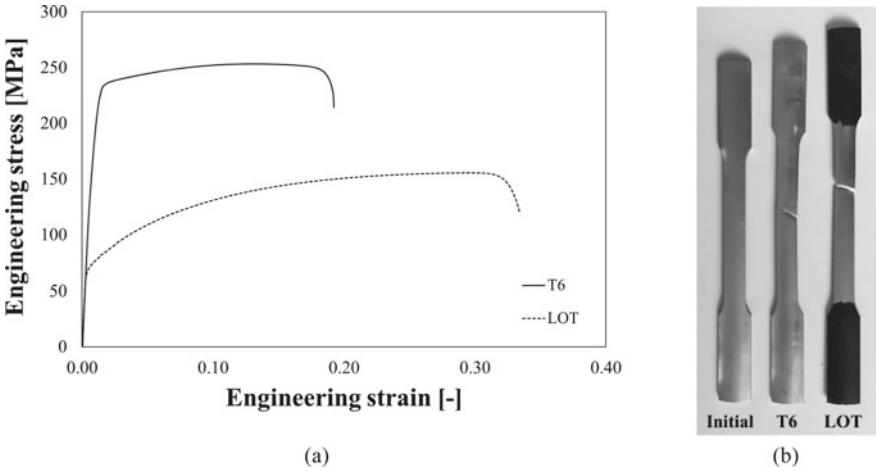

Fig. 4 Tensile tests results: **a** engineering stress–strain curves for the as-received and locally overaged treatment and **b** photograph of the specimens

The stress–strain curves from the tensile tests performed on both the investigated conditions (T6 and LOT) are presented in Fig. 4a, confirming that the overaged condition (characterized by a lower yield point and a remarkable increase in the elongation at failure) was obtained.

The improvement in the material formability was also evident comparing at the end of the tensile test of the undeformed sample with the ones in the T6 and the LOT conditions (please refer to Fig. 4b).

Figure 5 presents the strain loading paths for both experimental tests (tensile and tube expansion) for the two analysed material conditions (T6 and LOT) along with the Fracture Forming Line (FFL) previously determined by the authors [9] for the T6 condition.

The tensile strain loading path, for both conditions, starts from the uniaxial strain condition (slope of −0.5) and the LOT specimen presents a localization in the deformation (plane strain condition, slope 0) before the T6 specimen.

The fracture strain for the T6 condition (labelled as UT T6 in Fig. 5) presents a value in the proximity of the FFL (T6 condition). On the other hand, the fracture strain of the LOT specimen (indicated by the blue square marker in Fig. 5) is characterized by a major strain value which is twice higher than the T6. The difference between the last point of the strain path and the fracture point in all cases is related to localization phenomena [11], which occur in a very short period of time; for this reason, according to the maximum frequency of data acquisition in the DIC system, the number of measurements can differ from case to case. The localization is higher for the LOT specimen because of the more pronounced thickness reduction (as it can be seen in the fractographies detailed in Fig. 5).

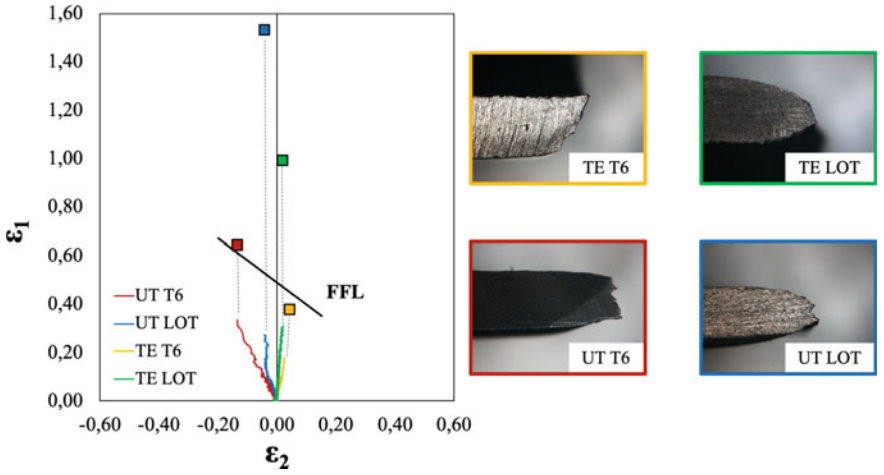

Fig. 5 Strain loading paths, fracture strains, and fractographies for aluminium tube AA6063 in T6 and LOT conditions. (Color figure online)

Similar results were obtained from the tube expansion tests, in particular showing that the local treatment had an influence on the slope of the stain path, moving from the biaxial deformation (slope higher than 0) to an almost plane strain condition.

The results are in accordance with the presented fractographies in Fig. 5 which reveal a more strained condition till fracture for the LOT specimens when compared with the fractographies in the T6 condition.

5 Conclusions

In the present work, a systematic methodology to evaluate the effect of local laser treatments on the formability of AA6063 tube samples has been presented. The designed laser treatment by FE simulations was effective in bringing locally the material in the overaged condition as confirmed by the hardness measurement. Moreover, the stress–strain curve obtained from the tensile tests confirmed these results since the material in the overaged condition showed a remarkable increase of the elongation at fracture along with a reduced yield point.

On the other hand, regarding the formability investigation, the presented fractographies demonstrated that the thinning was much more severe in the LOT samples than the samples in the as-received condition (T6). Consequently, the fracture strains in the principal strain space resulted to be significantly higher for both the experimental tests performed in the LOT conditions.

Analysis of Material Work Hardening and Fracture Strains for Sheet Metal Stamping Processes

Sergey Golovashchenko, Srecko Zdravkovic, Natalia Reinberg, Saeid Nasheralahkami, and Weitian Zhou

Abstract Experimental study of sheet material flow curves was performed using combined methods of cold rolling for prestraining material to targeted strain and then tensile testing. Experimental studies revealed that aluminum alloys show a tendency for flow curves saturation which substantially lowers work hardening of the sheet material. Performed numerical simulations of cup drawing illustrated that this effect leads to earlier material wrinkling compared to power law approximation of the flow curve. Examples of numerical simulation with Autoform software comparing the result of cup drawing for various cases of flow curve approximation are discussed in this paper. Analysis of fracture strains was performed by combined gridding and paint spraying on the sheet surface. This approach enabled measurements of local strains in the area closely adjacent to fracture without having continuous access to this area by video camera. This approach was used for sheet hole expansion, sheared edge stretchability along straight cut, hemming, and self-piercing riveting for high-strength steels and aluminum alloys.

1 Introduction

In order to achieve successful prediction of metal forming and joining processes, it is necessary to have knowledge of adequate stress–strain curves and fracture strains, especially where plastic strains substantially exceed those in a traditional tensile test. The risks of trying to define all the parameters via finite element analysis using reverse engineering are associated with a lack of knowledge not only in stress–strain behavior and fracture strains but also in friction behavior which represents an even more significant challenge.

In engineering practice, modelers are often using the power law approximation of stress–strain curves: $\sigma = K\varepsilon^n$. In early studies of diffuse necking by Considere

[1], this approximation quantified the initiation of diffuse necking when true strain is reaching the n-value. Power law approximation, according to Hollomon and Jaffe [2], worked well for mild steels up to true strains of 0.4. Swift [2] discussed the power law approximation with initial prestrain which provided an additional parameter assisting in more accurate approximation:

$$\sigma = K(\varepsilon_0 + \varepsilon)^n$$

According to Keeler and Kimchi [3] and Davis [4], mild steels and HSLA steels have n-values that are constant with deformation in the tensile test while AHSS steels have n-values that change with deformation. Xu et al. [5] demonstrated that stress–strain curve for AA5754 needs three sets of parameters to achieve a good correlation with experimental stress–strain data obtained from the tensile test where the maximum true strain slightly exceeded 0.2.

Defining the stress–strain behavior beyond uniform elongation in a tensile test represents a challenge. Tensile test experiments performed by Dan et al. [6] for Al alloy extended the stress–strain curve from 0.2 true strain in a standard test to 0.37 by employing Digital Image Correlation. However, it should be indicated that the Lode parameter is substantially different during uniform deformation and necking phases of the tensile test.

Hecker et al. [7] indicated that uniaxial tension with necking correction, biaxial sheet or tube bulging, compression, torsion, wire drawing followed by tension, and rolling followed by tensile testing methodologies are able to extend the range of stress–strain curves substantially. Potential errors during bulging tests were discussed by Ranta-Eskola et al. [8] and by Smith et al. [9].

The compression test does not have the issues of geometric weakening, but it is complicated by friction. Mohebbi et al. [10] studied plane strain compression and observed a change of coefficient of friction (COF) of approximately a factor of four, which serves as an indication that assumptions on constant friction between the tool and the sample may significantly affect the stress–strain results.

A numerical approach to determine the stress–strain curve based upon cold rolling process was developed by Byon et al. [11] using the equation for the roll force and forward slip. However, significant variations of COF admitted by Mohebbi et al. [10] make the stress–strain results less reliable.

Based on the performed review of previous work, the rolling prestrain followed by the uniaxial tensile testing of samples fabricated from prestrained strips was considered the most convenient for the manufacturing processes working with sheet metals and selected for the material testing in this paper.

Defining the fracture strain for sheet metals is also a challenging problem. Bao and Wiezbicki [11] studied fracture strain as a function of hydrostatic pressure. Bai and Wierzbicki [12] emphasized the importance of both hydrostatic pressure and Lode parameter on fracture strains using gridding method. Sriram et al. [14] employed through-thickness strain as a fracture criterion for DP780 and DP980 steels which does not take into account the ratio between two other principal strains. Therefore, gridding method remains the most popular for fracture strain measurements since

early studies of strip compression and extrusion by Nadai [13]. For sheet metal forming applications, the localization of strains was measured by Gensamer [14] where he discovered that the value of maximum strain at localization varies with the strain ratio. The concept of Forming Limit Diagram was developed by Keeler [15] and Goodwin [16] using circular grid analysis for measuring safe and localized strains. The practice of using square grids for material flow analysis was discussed by Wilson [17]. Smith [18] described circular grid analysis as a major experimental tool to define the distribution of strains in stamped sheet metal parts.

The early results on measurement of strain distribution in deformed plane sample using Digital Image Correlation were discussed by Sutton et al. [19]. Garcia et al. [20] discussed strain measurement for Forming Limit Diagram applications. Sutton et al. [21] illustrated DIC capabilities for fracture strain measurement in high-speed plastic deformation. Overall, the DIC method is a powerful tool capable of high resolution of strains which can be employed for measurements of fracture strains. However, the major requirement is to have access for the video camera to the surface of a sheet metal blank and record speckle motions during the deformation process. Due to this circumstance, the grid analysis remains a major tool for measurements of the strain distribution in stamped parts after over 90 years of its initial usage.

The spatial resolution of grid analysis is limited by the size of the applied grid as well as by the quality of the grid pattern (uniform dimensions of individual squares of the applied grid, as well as thickness of lines). Measurement of fracture strain is usually problematic with grid analysis because of cracks propagating through a sequence of grids and not through their boundaries. In this case, the fracture strain is measured as a strain of the nearest grid. When sheared edge stretchability, local strains in processes like hemming, flanging, or self-piercing riveting are of interest, this resolution makes a significant difference. A new method suitable for such applications was proposed by Golovashchenko [22]. The idea of this method is to apply the speckle on top of the etched grid which provides a coordinate system to identify the sprayed dots. The picture of the grid with applied dots is taken before and after the forming process, and finite strains can be calculated based upon the analysis of individual dots stretching. This concept provides the ability to measure the strains in close vicinity to the crack initiation for traditional stamping processes. The applications of this method will be further discussed in this paper.

2 Stress–Strain Curves for Extended Range of Strains and Discussion of Their Effect in Sheet Metal Forming

Stress–strain curve obtained from tensile testing parallel to the initial rolling direction of as-received and prestrained (via cold rolling) AA6111-T4 specimens was compared with Power Law ($\sigma = K(\varepsilon_0 + \varepsilon)^n$) stress–strain curve that is broadly used in numerical simulation of metal forming processes. The chemical composition of AA6111-T4 includes the following elements: Si 0.7–1.1%, Mg 0.5–1%, Fe 0.4%

max, Mn 0.15–0.45%, Zn 0.15% max, Cr 0.1% max, Ti 0.1% max, Other (each) 0.05% max, Al—remainder. The tensile samples were fabricated using wire EDM technology from the strips of AA6111-T4 rolled step-by-step with successive thickness reduction. The geometry of the specimens was selected following ASTM E8 standard [23]. The tensile direction was parallel to the multistep rolling direction, which was parallel to the rolling direction of the as-received AA6111-T4 sheet. The rolled strips were stacked together and clamped between two steel plates 12.7 mm thick, which guided the wire during the EDM process. For AA6111-T4, the results of the tensile test can be approximated using the following parameters: K = 513.92 MPa, $\varepsilon_0 = 0.0001$, and n = 0.24 [26]. These parameters provide the approximation which fits very well the experimental tensile curve obtained in this study. Comparison of stress–strain curves obtained from the tensile testing parallel to the initial rolling direction of prestrained AA6111-T4 with the power law approximation is shown in Fig. 1. From this comparison, it is obvious that both curves are very close to each other up to the true strain of 0.2. For the strains exceeding this level, the rate of work hardening in the experimental curve becomes much slower compared to the power law approximation.

Below is the discussion of manufacturing processes where the difference in material behavior can lead to a visible difference in simulation results if the power law approximation is employed instead of using the extended range curve obtained through rolling tensile testing.

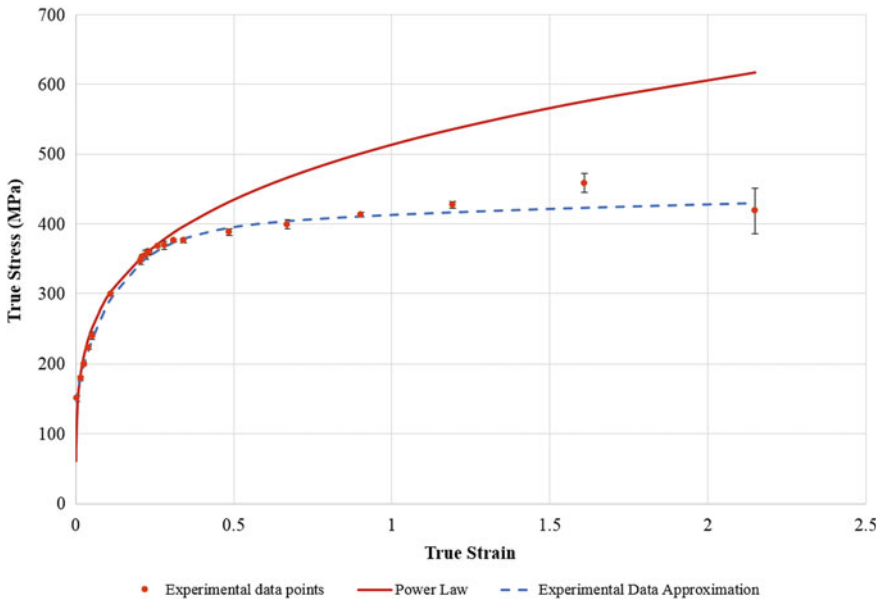

Fig. 1 Comparison of the experimental curve obtained by tensile testing parallel to the initial rolling direction of as-received and prestrained (via cold rolling) AA6111-T4 and power law true stress–true strain curve (K = 513.92 MPa, $\varepsilon_0 = 0.0001$ and n = 0.24). (Color figure online)

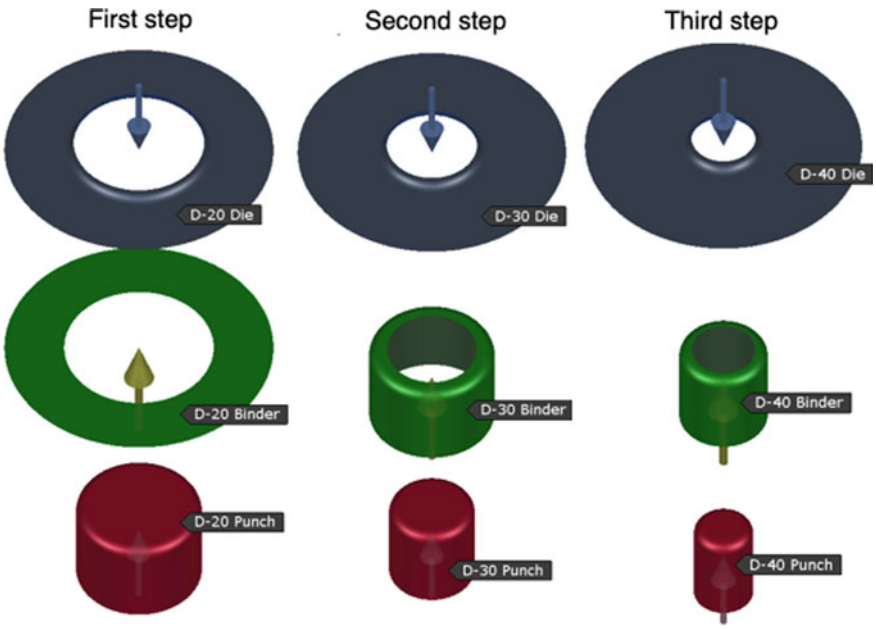

Fig. 2 Multiple-step drawing tool design. (Color figure online)

Deep drawing is the major operation of sheet metal forming technology. In order to illustrate the effect of work hardening on quality of sheet metal drawing, a simple example, drawing of a cylindrical cup, was employed. Computer experiment was performed by using the AutoForm software where the stress–strain curve was varied and the rest of the parameters were kept the same. Multiple-step drawing tools that were used are shown in Fig. 2. At the first step of drawing, the punch of 150 mm in diameter had 33.5 mm displacement for full cup drawing from a flat circular blank 200 mm in diameter and 0.93 mm thick. At the second step of drawing, the punch of 101 mm in diameter made 70 mm displacement to further form the cup initially drawn during the first step from the flat round blank. At the third step of drawing, the punch of 67 mm in diameter mm made 45 mm displacement.

In the analysis, mill oil characteristics were employed for the multistep cup drawing process. The coefficient of friction (COF) used for the contact of the blank with the die and the binder was 0.05 while for the contact with the punch, it was assumed to be 0.5. Higher COF on the punch helps to avoid the material flow from the bottom of the cup. The results of numerical simulation shown in Fig. 3 illustrated that a significant area with wrinkles takes place in case when the experimental stress–strain curve was used for the simulation, and smooth shape without any wrinkles was observed when the power law stress–strain curve was used for the simulation. In case when the experimental curve was used for the analysis, plastic strain value is up to 35% higher than in case when the power law curve was used for the simulation. In the previous studies, Shofman [24] performed analytical derivations indicating

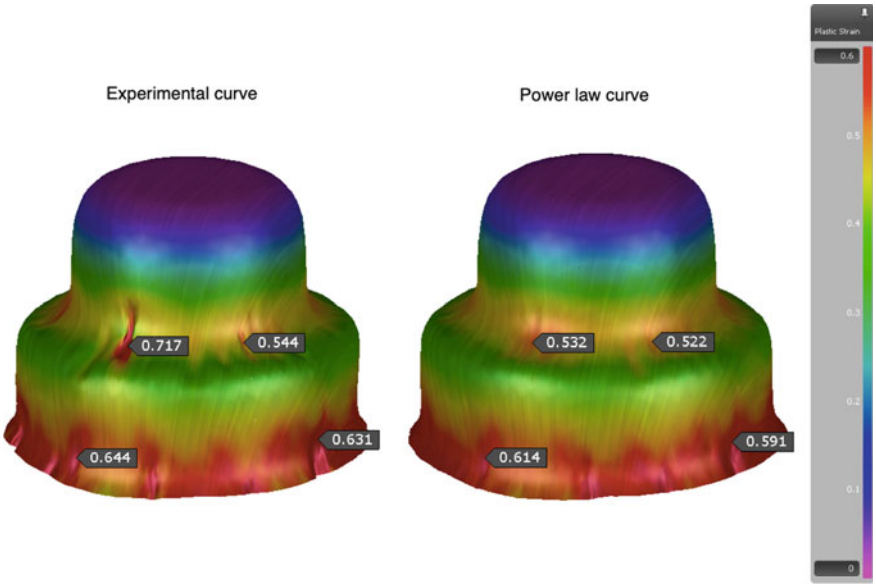

Fig. 3 Plastic strain and wrinkles in multiple-step drawing when experimental stress–strain curve was used for simulation and power law stress–strain curve was used for simulation. (Color figure online)

that materials with lower work hardening exponent n-value have a higher tendency for wrinkling. Later on, Moshnin [25] performed the analysis based upon the sheet buckling being compressed between two rigid surfaces and obtained very similar results: increased work hardening exponent provides better resistance to wrinkling. Cup drawing analysis was studied numerically by Kim et al. [26] where the same trend was confirmed: wrinkling occurs earlier for the materials with lower n-value.

Even though wrinkling is usually suppressed by the binder force, it could be indicated that overestimating work hardening condition might provide misleading information regarding wrinkling. Therefore, while designing the multistep drawing process, it is important to take into account the actual stress–strain curve. It is known from the reference literature [27] that in multistep drawing the drawing ratio can increase up to 6.5 which corresponds to true strain of 1.87. Employment of the power law for the analysis of such a stamping process would lead to substantial overestimation of work hardening and potential errors in the design of the stamping die.

Another important consideration should be taken into account: Hosford and Caddell [28] indicated that the limiting redraw ratio is greater for materials with lower n-value (cold rolled sheets) than for those with higher n-value (annealed sheets). This circumstance is driven by the limitation of the cup drawing process when the stress in the wall of the cup achieves plastic instability limit. It happens earlier for materials with higher n-value because the bottom of the cup wall, which must carry the redrawing force, is not getting work hardened. From this perspective, it becomes

clear that the material work hardening puts two different limitations on the drawing process, and, therefore, should be considered for the processes where the strain level substantially exceeds the range of initial approximation with the power law (n-value).

One more area of sheet metal stamping where knowledge of actual flow stresses is critical is springback prediction and compensation. Even though, a lot of practical efforts illustrate the successful application of springback compensation technology achieved via numerical simulation of the sheet metal blank unloading process, for example, as indicated by Cheng et al. [29]. However, multiple recent studies, for example Xue et al. [30], indicate that the elastic modulus has a tendency to decrease with the increase of plastic deformation, but then stabilize after a certain threshold. This effect partially compensates for the overestimation of the flow stress. However, the discrepancies should tend to grow for a larger level of effective plastic strain, which typically takes place in filling trihedral corners.

3 Fracture Strain Measurements

The examples of fracture strain measurements are provided in this section. In Fig. 4, the results of stretching of the sheared edge are illustrated for the strip sample of DP980 1.45 mm thick sheet. The sample was 127 mm long (in the transverse direction) and 12.7 mm wide (in rolling direction). It was initially sheared with 20% cutting clearance and then subjected to the tensile test to identify the elongation at which fracture initiates on the surface of the edge. The sheared edge had no significant burrs which would be positioned outside the lower plane boundary of the material. However, it can be seen that the burr was initially formed at the bottom, but then broken during the cutting process. During tensile testing, the crack originated from the broken burr. In the observed test of the sheared edge stretching, progression from hairline crack to final failure was rather slow, especially in the tensile test. Cracks could open up to the width nearly a third of the material thickness before

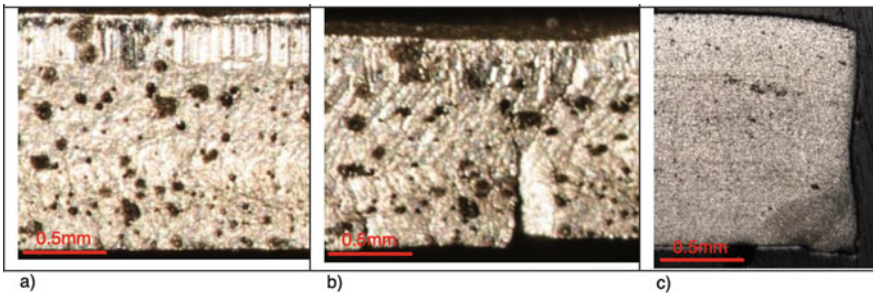

Fig. 4 The views of sheared edge of the trimmed sample: **a** the view of the sheared edge with the dots of paint before the beginning of the tensile test; **b** the view of the sheared edge when fracture crack was propagating; **c** cross section of the sample DP980 sample after cutting with 20% clearance. (Color figure online)

complete failure was detected. The tensile test showed diffuse necking before fracture, but localized necking did not advance before the crack penetrated throughout the thickness. The hairline crack progression was the factor that led to the failure. The fracture strain for the illustrated sample was measured as 0.091 true strain at the initial moment of fracture initiation in the burr area.

The process of fracture strain measurement by bending process is illustrated in Fig. 5. In bending experiment, strain measurement of fifteen samples of DP980 sheet was performed. The experimental procedure included the following steps: (1) cut the samples 76.2 mm in length and 50.8 mm in width to fit the slots on the bending die; (2) draw the lines in the area where fracture occurs; (3) spray black dots on the surface of the sample; (4) take pictures of the selected dots before bending (use a microscope with 20X magnification); (5) clamp the sample in the die positioned in 100 ton hydraulic press; (6) run the press to bend the sample to its final shape shown in Fig. 6; (7) post-process the picture using the software 'ImageJ' to measure the selected dots before and after bending; (8) calculate the local true strain. According to the results, the effective fracture strain is 0.42, which was the average data of the measured results. The standard deviation of the measured fracture strain was 0.08.

The next example was the hole expansion test which was applicable to the self-piercing riveting process (SPR). In order to simulate the SPR process, it was necessary

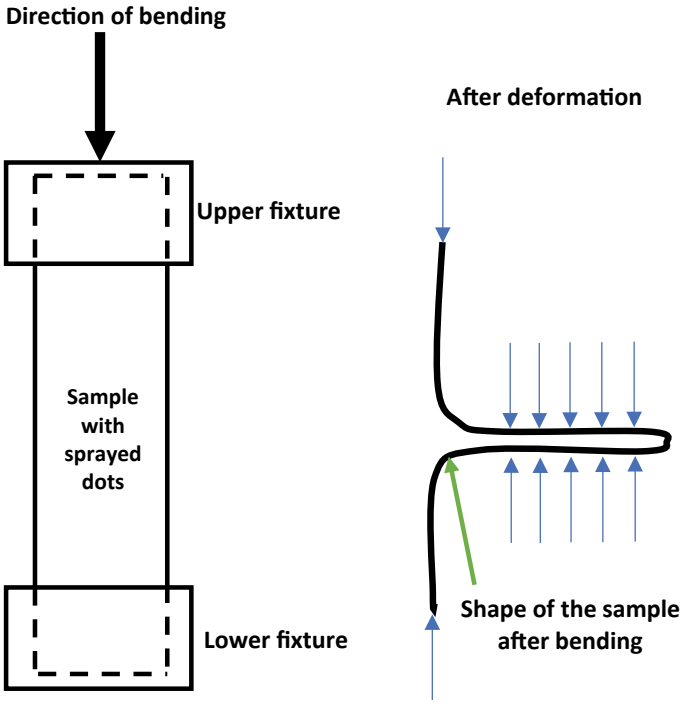

Fig. 5 Schematic of the experiment and the final shape of the sample after bending. (Color figure online)

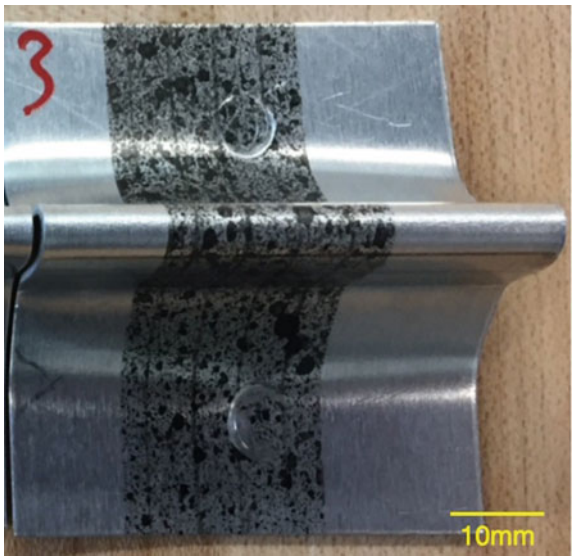

Fig. 6 Pictures of the sample after bending. (Color figure online)

to have a fracture strain for the fracture criterion applicable to the material fracture of joined sheets. The experiment was performed by expanding the hole 5 mm in diameter using hemispherical punch 20 mm in diameter. The selection of the initial hole diameter was dictated by the actual diameter of the rivet. The sequence of steps in the experiment was similar to described above for the folding experiment. The deformed sample of DP590 1 mm steel sheet with the dots of paint is illustrated in Fig. 7, where four quadrants are marked to make it easier to compare the dots before and after fracture. The fracture strains were measured along the perimeter of the hole.

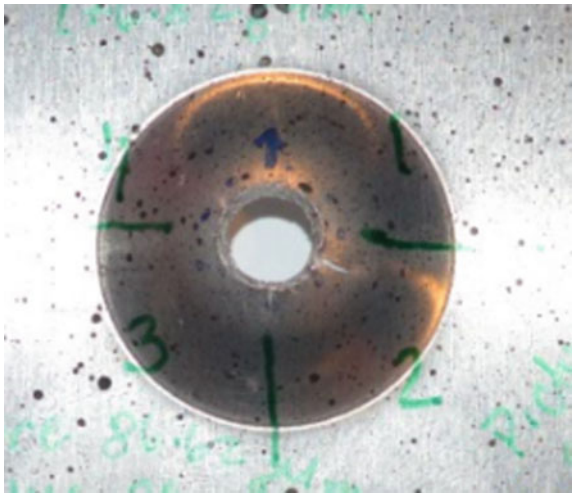

Fig. 7 The sample after hole expansion test using 20 mm in diameter hemispherical punch. (Color figure online)

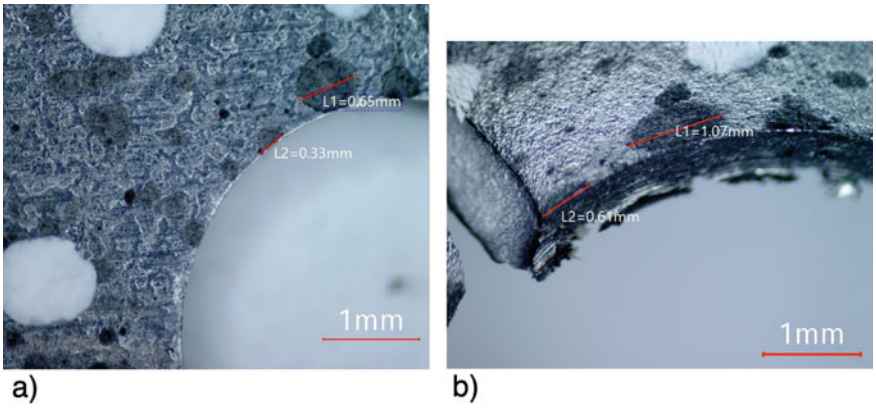

Fig. 8 The tested sample of DP590 steel before **a** and after **b** the hole expansion test. (Color figure online)

The illustration of the sample from DP590 1 mm thick steel sheet with dots before and after the hole expansion process is shown in Fig. 8. The white lines and white dots served to help correlation between the dots at the beginning and at the end of the process. Fracture happened in the area of the white dot, and the white line is used to correlate this area with the initial one. The measured true strain was 0.614 in close vicinity to the crack, while, in some distance from the crack, the true strain was 0.498. Establishing this correlation helped to avoid the necessity to use video camera through the whole process. Instead of a video camera used in traditional digital image correlation measurements, the microscope was utilized in this experiment allowing more accurate measurements of local strains at the very edge of the sample.

4 Conclusions

1. The experimental study of aluminum stress–strain behavior for extended range of strains for aluminum alloy 6111-T4 indicated that power law approximation substantially overestimates the material work hardening outside the range of strains in the tensile test.
2. The performed analysis based upon numerical simulation of cup drawing from sheet metal illustrated that employing power law approximation will likely underestimate potential wrinkling of the blank. In case, when the experimental curve was used for the analysis, the plastic strain value is up to 35% higher than in case, when the power law curve was used for the simulation.
3. Performed measurements of local strains by measurements of changes in the dimensions of the dots of paint provided the capability to measure the fracture strains in close vicinity to fracture initiation without the necessity to have continuous visual access to the surface of the blank.

A New Approach for the Production of Burr-Free Sheet Metal Components Having Significantly Increased Residual Formability

Sergei Senn and Mathias Liewald

Abstract Shear cutting induces high strains and work hardening into the shear-affected zone, thus reducing the formability of the sheet metal material during subsequent forming operations. A common method for increasing the residual formability of shear-cut component edges is to shave the surfaces. The shaving process allows for the removal of highly hardened areas from a pre-cut contour, resulting in a comparatively high residual formability of the cutting surface. However, as known from conventional cutting, a burr remains on the shear surface when shaving. Such burr formation is undesirable and therefore usually has to be removed afterward. For this reason, a new process has been developed which combines two processes within the same stroke of punch, the counter-cutting, and shaving process, enabling the production of burr-free shear surfaces showing a high portion of clean-cut proportions and significantly 1.6 times higher hole expansion ratios than conventional cutting surfaces. The present paper deals with numerical and experimental investigations carried out in the course of the process development with the high-strength sheet metal material DP600.

Keywords Shear cutting · Edge crack sensitivity · Work hardening · Counter-shaving · Hole expansion test · Burr-free cutting · Progressive die

1 Introduction

Shear-cut edges can be found at almost every sheet metal component manufactured by sheet metal forming technology. However, shearing induces high strain values onto the cutting edge and thus reduces the residual forming capacity of sheet metal materials with regard to subsequent forming processes [1, 2]. This effect is also

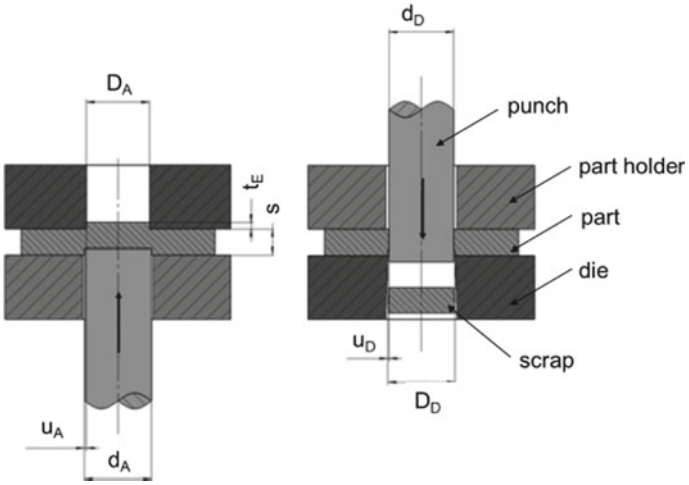
known as "edge crack sensitivity" and may lead to spontaneous crack initiation and premature failure [3]. A perspective approach for reducing the edge hardening effect of sheared sheet metal components is provided by two-stage shaving [4, 5]. However, this shaving process does not prevent the formation of a shaving burr, which can become detached in subsequent machining processes or during product life cycle and thus leads to pressure marks on the component or on the die surface in case of processing sheet metal components further by subsequent progressive dies. Therefore, shaving is usually followed by a downstream process (e.g., vibratory grinding, troweling, etc.), in which the burr is removed. Due to this processing deficit, methods such as counter-punching [6] or embossing-shearing [7] have been developed in recent research work, which enables burr-free cutting of sheet metal materials. In addition to these processes, the present paper is focusing on the newly developed two-stage counter-shaving process. In particular, the influence of this process on edge hardening effects and edge crack sensitivity of sheet metal materials is numerically and experimentally investigated.

2 Two-Stage Counter-Punching and Shaving

Counter-punching is defined as a shearing process being performed in several stages with at least one reversal of cutting direction. This reversal of cutting direction allows burr formation to be avoided [8]. The counter-punching process was developed by Liebig at the Institute for Metal Forming Technology (IFU), University of Stuttgart, in 1979 as a three-stage process and has been continuously improved during recent years [6, 9–11]. In addition to three-stage counter-punching, [12] and [13] examined a two-stage counter-punching process and showed that robust counter-punching can also be performed by only two tooling operations. In the first stage of two-stage counter-punching, the sheet metal material is embossed from the lower side to a depth t_E by a punch, causing a rollover at the lower side of the sheet metal material to be formed (see Fig. 1). In the second stage, counter-punching is performed in the opposite direction and complete material separation is achieved.

The so-called shaving process belongs to the group of cutting processes with high accuracy, which allow economical production of rectangular cut surfaces with a very high burnish depth. The shaving process is frequently used in industry to significantly improve the cutting surface quality of shear-cut components and thus to enable fitting punching, for example. During shaving, the sheet metal is pre-punched with a smaller cutting diameter in the first stage and cut to size in the same cutting direction with the final contour punch by adding a shaving addition z in the second stage [15–17]. Principle of the second shaving stage is shown in Fig. 2. The separation of a narrow contour (additional shaving) results in changed stress conditions since material separation takes place much later. The shaving process is mainly influenced by the geometric process variables clearance u and shaving addition z, which have been extensively investigated for different materials in [4]. The sensitivity to edge cracking of two-stage recut edges has been tested in [5]. The investigations carried out

by means of hole expansion tests and hole tensile tests clearly show the high potential of recut shaving strategies to reduce edge hardening of shear cut components [5, 18]. Compared to conventionally sheared edges, the sensitivity is significantly lower and the residual forming capacity is higher.



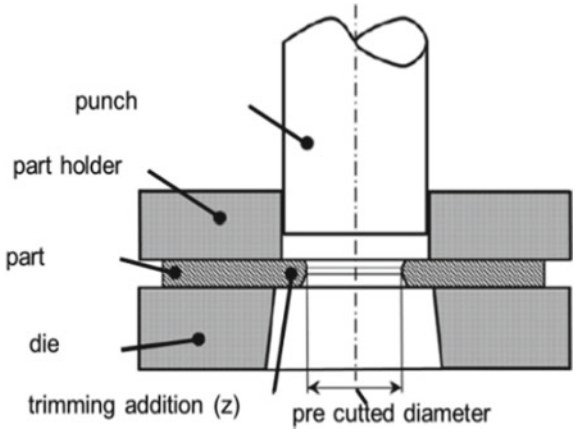


Fig. 1 Principle of two-stage counter-punching [14]

Fig. 2 Principle of a shaving process [18]

Senn and Liewald [27] further developed both cutting processes described above further to achieve a combined counter-shaving process. Counter-shaving leads to an increase in residual formability, a reduction in crack sensitivity, and to a good cutting surface with high clean-cut portions and freedom from burrs, as all advantages of

counter-punching and conventional shaving are combined in this two-stage process (see Fig. 3). Here, pre-piercing and embossing are performed in one stroke. For this purpose, a punch with a step in the diameter is used, which fulfills the function of these two processes. In the second stroke, the shaving step is performed in the counter-direction.

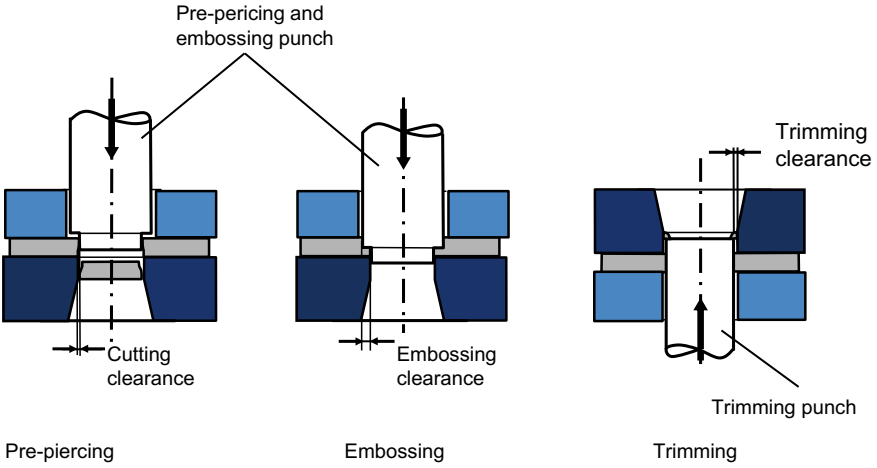

Fig. 3 Functional principle of two-stage counter-shaving [27]. (Color figure online)

3 Simulation Setup and Modeling

For the numerical investigations on the two-stage counter-shaving process, a basic simulation for the first process step with a stepped pre-piercing punch was initially set up using the software environment DEFORM 2D. This simulation provided the basis for all subsequent simulations and for the design of experiments. On this basis, all simulation parameters and boundary conditions were first defined, which were defined as fixed during the investigations and remained constant throughout. The main simulation parameters are listed in the following table (Table 1).

In addition to these basic settings, the punch and die geometries were varied in order to examine the process parameters cutting clearance u_v, embossing clearance u_p, and embossing depth t shown in Fig. 4. This examination was performed by means of a full factorial simulation strategy. For each factor combination, the corresponding geometry of punch and die were created in Dassault Systems Catia, implemented individually in DEFORM, and assigned to each other. The geometric parameters investigated are listed in Table 2 which means that a total of 84 parameter

combinations were examined. The values given in percent refer to the sheet thickness. In this study, the piercing of a diameter of D = 10 mm was investigated during counter-shaving process.

The following Figs. 5 and 6 show an exemplary complete simulation of an ideal process cycle in 11 images. In picture 1, the punch with the pre-piercing diameter just engages into the metal sheet. In picture 3, the metal sheet has just been separated. The engagement of the embossing diameter of the punch can be seen in picture 5. After reaching the defined embossing depth t, which is adjusted by the punch stroke, the metal sheet is completely embossed (Picture 6). Immediately afterward, the engagement of the shaving punch is shown on the bottom side of the metal sheet (Picture 7). Pictures 8–10 show the shaving process and the last picture shows the completely trimmed cut surface with the final cut surface shape.

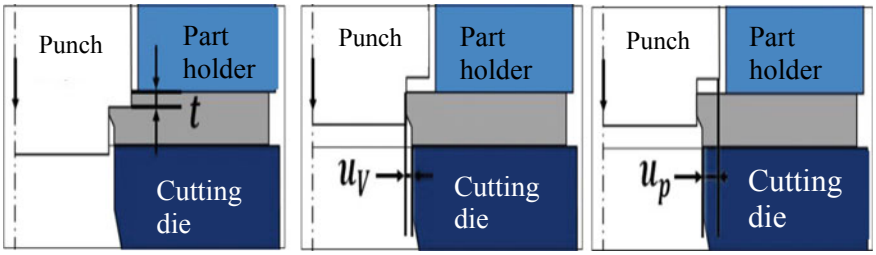

Fig. 4 Explanation of the punching parameters. (Color figure online)

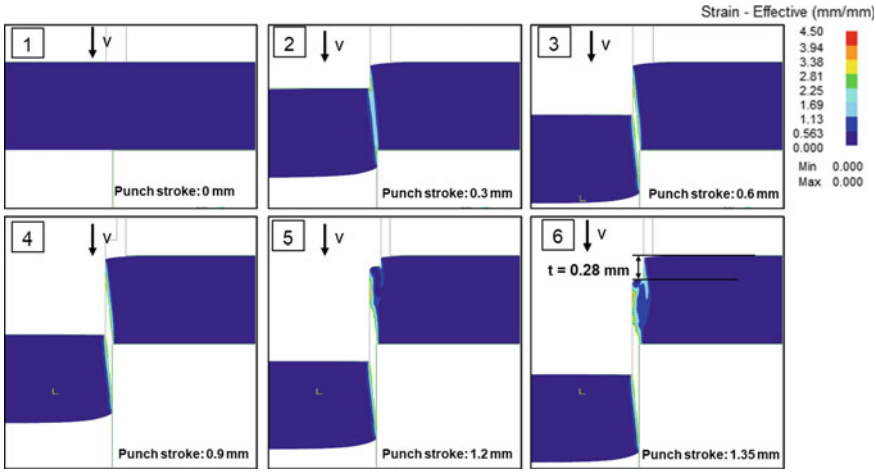

Fig. 5 First stroke: Pre-piercing and embossing, (t = 28%, cutting clearance $u_v = 7.5\%$, embossing clearance $u_p = |-5\%|$). (Color figure online)

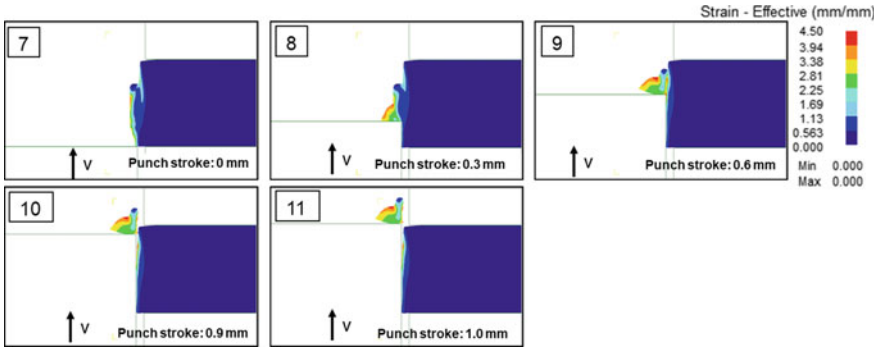

Fig. 6 Second stroke: shaving,; (t = 28%, cutting clearance $u_v = 7.5\%$, embossing clearance $u_p = |-5\%|$. (Color figure online)

After simulating all 84 parameter combinations in sequence, the requested data of the simulation results (after pre-piercing, embossing, and shaving) could be extracted or measured using the measurement tool of the simulation program. The data was collected in tables and subsequently evaluated. All measured data refer to the cutting surface because this is where the highest material load occurs during a cutting process. For the evaluation of the "Strain Effective" as a comparison value between the various simulations, the maximum value occurring at the cut surface was considered. To get this maximum value, 500 measuring points were positioned along the cutting surface. As a result, a sufficiently small distance between the single measuring points could be ensured, which is approximately 1/3 of the smallest element edge length. Figure 7 (left) shows an example of such a punctured cut surface from P0 to P500. For evaluation, the lengths of the two smooth cut portions were measured with the measurement tool which is integrated into DEFORM. The upper clean-cut portion is formed by embossing, the lower clean-cut portion is formed by shaving. The size of the fracture surface could be determined approximately from the data of the clean-cut portions. The areas described are shown in Fig. 7 on the right. In the evaluation, all results of all simulations that were performed for the individual factor combinations were compared with each other according to the full factorial DOE, shown in Table 2.

4 Results and Discussion

The counter-shaving process presented in this paper must comply with two main objectives. The first essential objective consists of the production of burr-free component surfaces. The freedom of burrs thereby depends on the cutting parameters embossing depth, embossing clearance, pre-punch clearance, and shaving clearance. The optimum adjustment of these parameters as well as the process limits regarding the production of burr-free components were investigated as part of the research work reported in this paper. The second essential objective of the counter-shaving process is to reduce edge hardening on cutting surfaces. In this respect, the potential of counter-shaving could be demonstrated by means of hole expansion tests.

4.1 Numerical Results

4.1.1 Identifying the Process Limits for Burr-Free Cutting

To determine the numerical limiting process parameters of the counter-shaving process, schematic images of the cutting surface at some intermediate steps of the cutting process are considered. For some parameter combinations, critical process runs occur already during embossing or at the beginning of the shaving process. In this respect, the three main limiting parameters are described in more detail in the following.

1. If embossing is carried out with a depth of more than $t = 64\%$, the sheet metal material flows into the cutting clearance between punch and cutting die, and a material ring is formed on the bottom side of the sheet. On the one hand, this can lead to damage to the surface of the punch and, on the other hand, prevents the shaving punch from touching the sheet metal in a defined way. Thus, the shaving punch does not engage on the underside of the sheet metal but instead folds the material ring. If the material ring breaks, a swarf ring is produced. Furthermore, folding up the material ring hinders the formation of the edge draw-in. Figure 8 shows an example of the formation of the material ring.

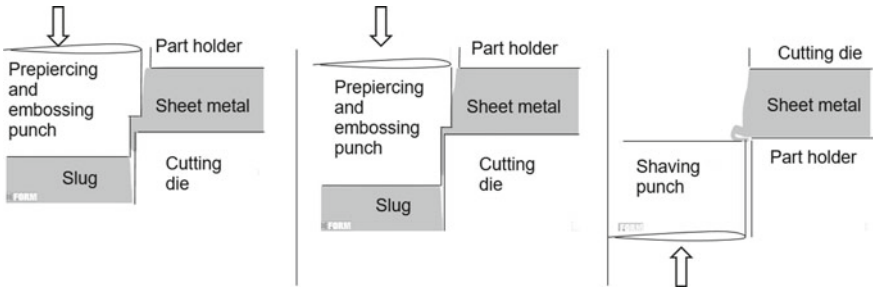

Fig. 8 Material ring formation during embossing and folding during shaving

2. The following Fig. 9 illustrates positioning of the shaving punch on a sheet metal pre-pierced and embossed in the previous step. In the case shown, the previously chosen embossing clearance was too small because the shaving punch does not engage on the bottom side of the sheet metal, but rather on the fracture surface created during pre-piercing. This prevents edge draw-in on the bottom side of the sheet metal and may lead to burrs. This problem does not occur when using larger embossing clearances of over $|-2.5\%|$.
3. Figure 10 shows a counter-shaved sheet metal material. The embossing depth was $t = 16\%$. Due to this low embossing depth, the crack initiation only occurs after a high punch stroke during shaving. As a result, the clean-cut surface due to embossing and the edge draw-in on the top of the sheet metal is lost and a

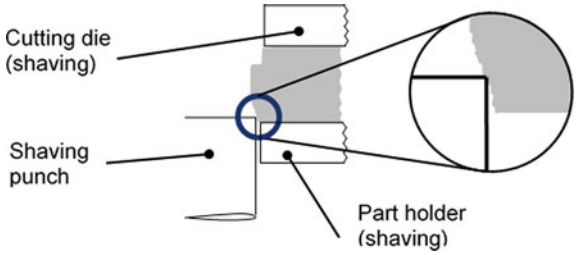

Fig. 9 Shaving punch engagement on the fracture surface. (Color figure online)

cutting burr typically created by normal shaving is formed. For burr-free cutting surfaces, the embossing depth must be at least $t = 28\%$.

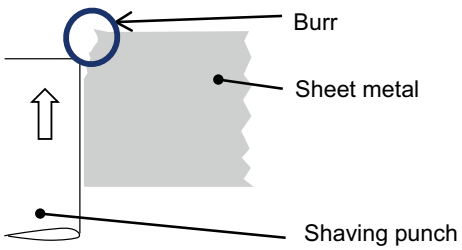

Fig. 10 Burr formation during shaving. (Color figure online)

4.1.2 Effect of Process Parameters on Clean-Cut Portion and Strain Effective

The following sections describe the results of numerical investigations on the combined counter-shaving process with regard to the influence of various process parameters on the cutting result and the occurring interactions. For these investigations, the sheet metal material DP600 with a sheet thickness of 1 mm was used. The following scatter diagrams (Fig. 11 and Fig. 12) do show the influences of the process parameters and the effects of interactions. It can be noticed that the embossing depth affects both the Strain Effective and the clean-cut portions (CCP).

Figure 11 shows the CCP caused only by shaving in relation to the Strain Effective. It can be seen that the CCP correlates with the Strain Effective value and that due to lower embossing depths t, higher clean-cut portions and at the same time lower Strain Effective values can be achieved. So, the investigation on the embossing depths reveals that low embossing depths have a positive effect on both the remaining formability and the geometric cut surface: The smaller the embossing depth, the lower the deformation, and the larger the clean-cut surface created during shaving. This also indicates that there is a correlation between the geometry of the cut surface

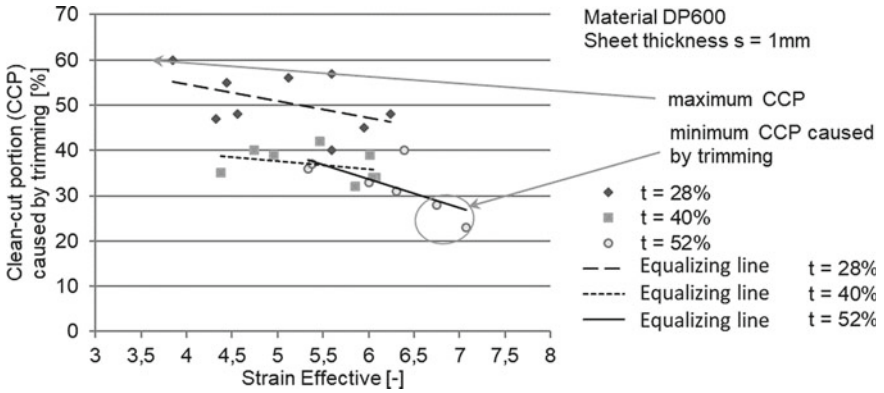

Fig. 11 CCP caused by shaving versus strain effective

and the degree of deformation. Further, the Strain Effective value is influenced by the cutting clearance and the embossing clearance. In the following, only the embossing depth $t = 28\%$ is considered since this embossing depth showed the greatest potential for low Strain Effective values. Figure 12 shows the total CCP (i.e., the sum of the clean-cut portions caused by embossing and shaving) and that the maximum clean-cut portions do not immediately correlate with the Strain Effective, as maximum possible CCP does not correlate with the lowest Strain Effective value.

In Fig. 13, the simulated Strain Effective values are plotted on the ordinate axis and visualized as bars. The considered cutting clearances u_v and the embossing clearances u_p are plotted on the abscissa axis in combination. Neither the increase in the cutting clearance u_v nor the increase in the embossing clearance u_p shows a correlating increase/reduction in the Strain Effective value. Nevertheless, a considerable influence of these process parameters on the result can principally be observed:

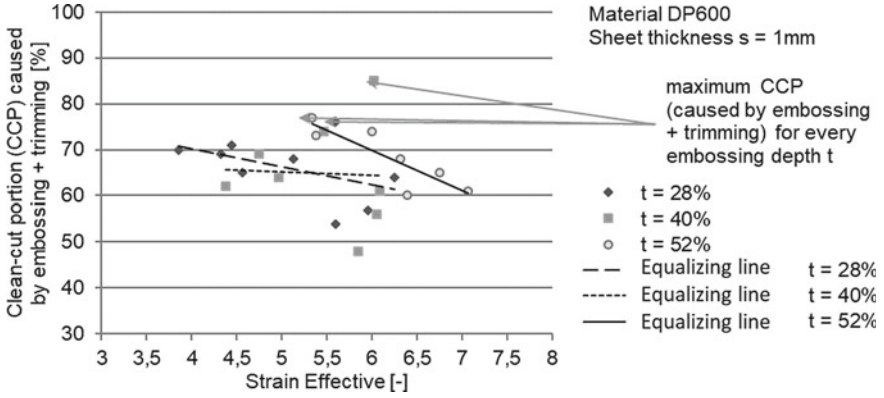

Fig. 12 CCP caused by embossing and shaving

between the largest ($\overline{\varepsilon} = 6.25$) and the lowest Strain Effective value ($\overline{\varepsilon} = 3.85$) is a difference of $\Delta\overline{\varepsilon} = 2.4$, which corresponds to a range of 38%. Based on these investigation results, it is assumed that the influence of cutting clearances and embossing clearances is impaired by varying strengths caused by the further deformation of the cutting surface during shaving. The following combination of parameters can be considered as the best result for achieving low edge crack sensitivity and a suitable cutting surface inside the robust process window: For combined counter-shaving, an embossing depth of $t = 28\%$ with an embossing clearance of $= u_p$|-5%| and a cutting clearance of $= u_v 5\%$ shows the best results.

4.2 Experimental Results

4.2.1 Work Hardening of Shear Cut Edges

In order to quantify edge hardening due to work hardening during the shearing process considered, the hardness test method according to Vickers [19] was used. Vickers hardness testing is standardized in DIN EN ISO 6507–1 and is usually used for small sheet thicknesses such as those considered here. For a microhardness measurement, low test loads (HV0.01) are used. In order to gain meaningful results concerning the hardening of cutting edges, it is important to carry out a hardness gradient measurement with a sufficient number of measuring points. The starting points of the measurement should be close to the cutting edge and extend over the entire sheet thickness. The measuring section must run through the entire solidified area down to the unsolidified one. Thus, it can be determined how deep the influenced cutting edge zone reaches into the material. In addition, it is possible to measure the degree of hardening by comparing the hardness after shearing (HV_1) with the initial hardness of the material (HV_0). Material hardness in that sense can be used as a characteristic value that correlates with the structural change of material. By means of a hardness measurement, conclusions can be drawn about changes in the microstructure caused by the work hardening described above [19]. Figure 14 shows the cutting edge of conventional shearing process according to VDI guideline 2906 with additions for edge hardening. In the influenced marginal zone b_{RZ}, the HV_1/HV_0 ratio is higher than 1, because the hardness after the cutting process (HV_1) is higher than the hardness of the initial material (HV_0). Afterward, when enlarging the distance to the cutting edge, the unaffected area in which HV_1 equals HV_0 follows. The ratio is thus calculated to the value 1 since only the initial hardness of the sheet metal material is available in this area. In order to gain meaningful results, a sufficient number of measuring points must be generated when measuring spatial hardness distribution [19] has illustrated the arrangement of measuring points in a small sketch, which is shown in Fig. 15. The sketch is an example of the arrangement of the measuring points of a sheet thickness of 1 mm. Here, the entire measuring range extends over a width of 0.500 mm. The measuring points are arranged offset over the complete thickness of the sheet metal. The first three vertical measurement

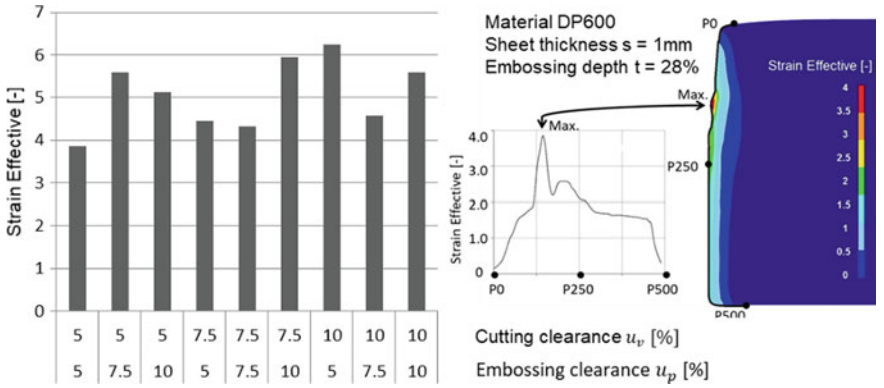

Fig. 13 Effect of cutting clearance $\mathbf{u_v}$ and embossing clearance $\mathbf{u_p}$ on the Strain Effective at embossing depth t = 28%. (Color figure online)

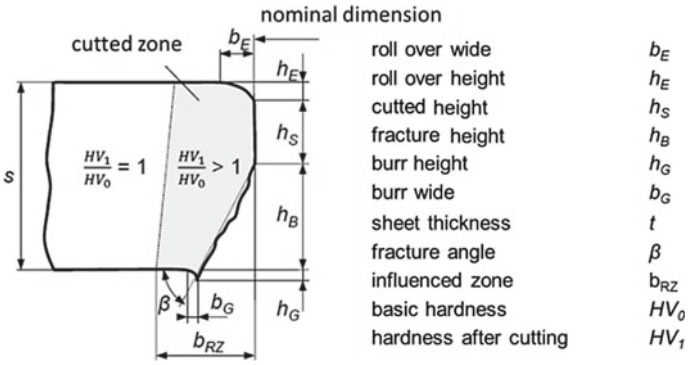

Fig. 14 Hardening of cut edges [20]

series with distances of 0.070 mm, 0.145 mm, and 0.250 mm are used to measure edge hardening. The fourth column, which has a larger distance than the others, is intended for measuring the initial hardness of sheet metal. The distances between the points and rows are selected according to [19] in such a way that the distance rules for hardness indentations according to DIN EN ISO 6507–1 are adhered to.

Figure 16 shows measured microhardness distribution of the conventionally sheared edge of sheet metal material DP600 with thickness s = 1 mm. Cutting clearance was u = 10%. Cutting parameters and cutting process are visualized in the figure. In addition, the small picture of the cut edge shows the distance direction of distances l and d. Distance d indicates the distance of the hardness indentations in the direction of sheet thickness. Distance l shows the distance between the measurement series and the cutting edge. The ratio HV1/HV0 is plotted on the abscissa. This can be used to indicate the degree of hardness. The measuring series in sheet metal thickness direction having a distance of 0.9 mm to hole perimeter represents

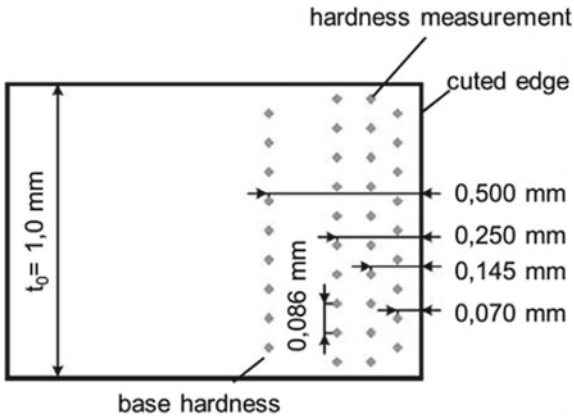

Fig. 15 Arrangement of the measuring points to determine the hardening of an idealized cutting edge [19]

initial material hardness. However, the ratio HV1/HV0 does not correspond exactly to 1.0, as the hardness values of the initial material microstructure also are scattering. The dark blue line, which is the closest to the cutting edge, shows a maximum ratio of 1.65. The following measurement series with a greater distance to the cutting edge (light blue and light gray) cover the whole sheet thickness. The maximum hardening of the edges ranges around 1.65 and all series of measurements, except for the initial material hardness, show an increase in hardening from the starting point. This phenomenon can be justified as follows: The deeper the punch penetrating through the sheet metal during the cutting process, the greater the stress value that emerges in the shearing zone. The material starts to flow plastically as soon as the shear yield point of the material is reached. With progressive deformation, the stresses reach the material-dependent shear fracture limit. No more material can be deformed any further at that stage, the first cracks are formed and therefore the slug breaks through. The stresses are linked with work hardening effects, whereby the cutting edge hardens, too. The work hardening increases with increasing stress, which also increases the hardness at the cutting edge. Thus, the material also shows the greatest edge hardening in the area of the fracture surface.

Figure 17 shows the work hardening of counter-shaving with an embossing clearance of $u_p = -0.5\%$, a precutting clearance of $u_v = 10\%$, and an embossing depth of $t = 0.2$ mm. Similar to shear cutting, the initial material hardness values are 1. Measuring closer to sheared edge shows an increasing hardness distribution. Edge hardening continues to level out over a longer area in a certain scatter band until it finally falls back to the basic level. When shearing, however, edge hardening increases continuously up to the maximum (see Fig. 12). The differences can be explained by [4]. When pre-punching, the first step in the counter-shaving process corresponds to conventional shearing. In the second stage, the actual shaving, the cutting edge of the pre-cut contour is scraped off. This removes the remaining shaving allowance. This process corresponds to machining because a thin chip is unrolled from the upper side of the sheet metal until it breaks off. In [4] it is reported that the cutting forces decrease with declining shaving addition. This is due to the lower stiffness of smaller

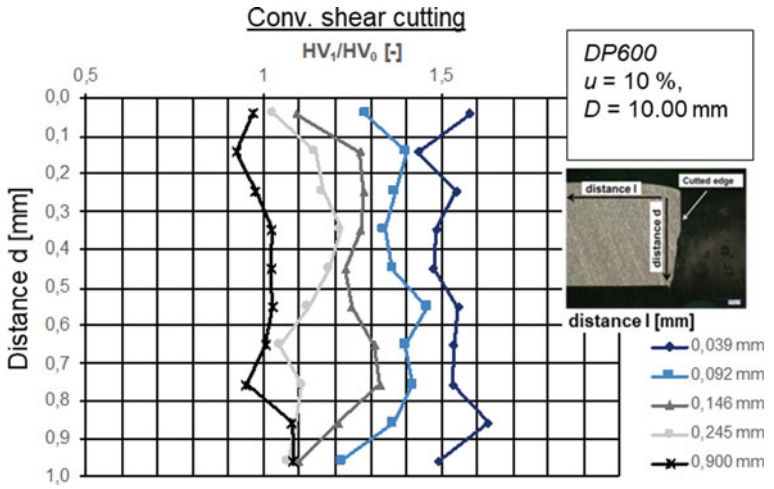

Fig. 16 Measurement of microhardness distribution of shear cut edge. (Color figure online)

shaving addition. The forces and therefore also the tension stress in the cutting edge can be positively influenced by a reduced shaving addition. This correlation also has a positive effect on edge hardening. The maximum measured microhardness distribution values around 1.35, i.e., similar to recut edges. All measurement series show a lower work hardening of counter-shaved edges compared to conventional cut edges.

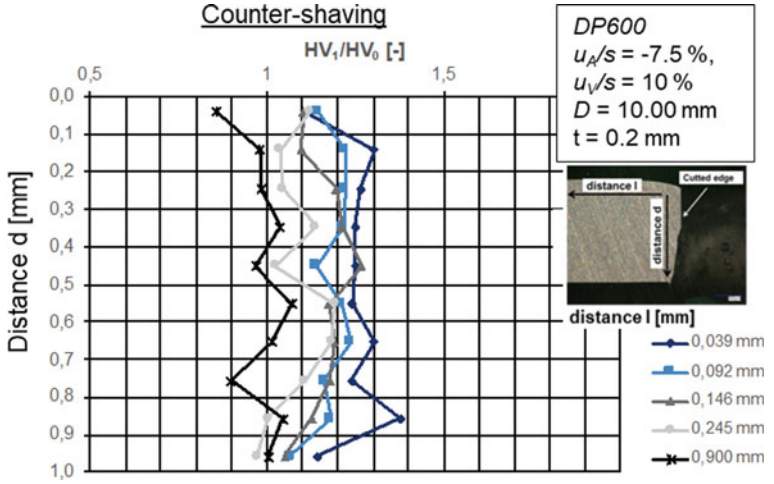

Fig. 17 Measurement of microhardness distribution of counter-shaved edge. (Color figure online)

4.2.2 Crack Edge Sensitivity of Shear Cut Edges

Hardening of cut edges can be measured by spatial hardness measurement strategies as described above. However, the hardness values cannot be used directly to determine the residual formability of the cutting edge [21]. Several methods for determining the sensitivity to edge cracking can be found in literature. For the open cutting line, the diabolo test is usually used [22]. This paper, however, only deals with closed-cutting line conditions. At present, the hole expansion test according to ISO 16,630 is the only standardized test method for determining the sensitivity to edge cracking of closed cutting lines. Prior to the test, a hole with a diameter of 10 mm is punched into a blank. For hole expansion tests according to ISO 16,630, at least three samples should be tested per sample variant. First of all, the sample is placed on a die with the burr pointing upward and centered ahead the punch. A part holder fixes the sample firmly in place thus preventing it from slipping or flowing. A conical punch having a 60° head taper angle moves upwards and expands the hole. The expansion is stopped as soon as a crack has formed through the complete sheet thickness. In [5], the crack detection is carried out visually by the operator. Due to his subjectivity, however, this leads to a range of results. The determination of component failure due to cracks depends very much on the reaction speed and the experience of the operator. In [19], GOM Aramis system is used for crack detection. The exact point of crack initiation can be determined by the system's digital images. This eliminates the influence of the operator's subjectivity. Figure 18 shows the experimental setup of the hole expansion test according to ISO 16,630. Here, the two most important characteristic values are the diameter of punched hole before the test D_0 and the hole diameter after test D_h. Both values are used to calculate hole expansion ratio (HER) by means of the following:

$$\lambda = {(D_h - D_0)}/{D_0} \times 100\%$$

If the cutting edge has a low widening ratio, the material is highly sensitive to edge cracking. Conversely, a high hole expansion ratio indicates a low edge crack sensitivity. According to [24], the hole expansion capability correlates with the tensile strength of the material.

The results of the hole expansion tests carried out for conventionally shear cut and for counter-shaved edges are shown in Fig. 19. For the sheet metal material DP600 having a sheet thickness of t = 2 mm, the hole expansion ratio of conventionally cut edges is 65%. This value is used as a reference value and is compared to the value of the counter-shaved specimens. For this purpose, several specimens counter-shaved with different embossing depths (from t = 40% to t = 70%) were investigated. The results show that the hole expansion ratio can be significantly increased with decreasing depth of embossing. At an embossing depth of t = 60%, the HER is the same as with conventionally shear cutting. However, if the embossing depth is reduced to t = 40%, the HER increases to 104% and thus is significantly higher compared to conventional shear cutting. Fig. 20 presents the influence of the pre-

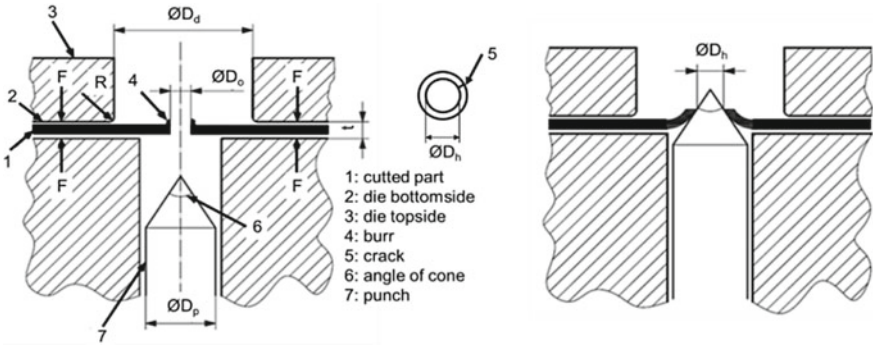

Fig. 18 Experimental setup of the hole expansion test [23]

piercing clearance during counter-shaving. It can be seen that a higher clearance in pre-piercing, here up to 10%, shows better results than a pre-piercing clearance of 5%.

Specimens for counter-shaving were tested in both orientations, as no burr occurs, but according to ISO 16,630 standard the burr should always be directed upwards when testing. Compared to conventional shearing, counter-shaving can be increased the HER by 59%. Thus, it has been demonstrated that counter-shaved components show a lower sensitivity to edge cracking than conventional shear cut edges.

5 Conclusion

This paper shows the great potential of the newly developed counter-shaving with regard to the production of burr-free shear cut surfaces having reduced edge hardening and high residual formability compared to conventional shear cutting. Based on the hole expansion test, it could be demonstrated that counter-shaved components are less sensitive to edge cracking than shear cut components. However, when correlating the hole expansion test to edge hardening, it was found that cutting edges achieve different hole widening ratios for comparable edge hardening. As reported in [25, 26], the cut surface quality has an influence on the hole expansion ratio. Thus, a large smooth cut surface increases the forming capacity of a cutting edge. In contrast, microcracks and rough surfaces lead to a large fracture area, which impairs the forming capacity. This means that cutting edges with a lower edge hardening rate in conjunction with a larger smooth cutting surface also have a larger hole expansion ratio. In this respect, shear cutting has the greatest edge hardening and the smallest smooth cut, resulting in the lowest hole expansion ratio of all processes. Furthermore, the results presented in this paper show that counter shaved-components are 59% less sensitive to edge cracking than conventional shear cut components, which enables a significantly higher degree of forming capacity in subsequent forming operations.

Fine-Piercing of Electrical Steel Sheets by Edge-Sharpened Diamond Punch

Tatsuhiko Aizawa and Tomomi Shiratori

Abstract Femtosecond laser trimming procedure was optimized to reduce the edge curvature of diamond-coated WC (Co) punch as possible and to decrease the maximum roughness of diamond coatings. Bare diamond-coated WC (Co) punches with normal grain size were prepared to have an original film thickness of 9 μm. Through two laser machining steps, the edge width of diamond coating was reduced down to 2 μm. By using the core die with the clearance of 4%, fine piercing experiments were performed to measure the load–stroke relationship and to describe the affected zone formation by shearing. The affected zone area as well as the fractured surface ratio significantly decreased with a reduction of the edge width down to 2 μm.

Keywords Piercing · Electrical steels · Nanostructured diamond punch

1 Introduction

The diamond-coated WC (Co) punches and dies have been developed to put the dry technology of plasticity into practice [1]. Due to the three-dimensional growth of diamond crystals on the WC (Co) tool surface, the normal diamond film has high surface roughness in its maximum up to 3–5 μm [2]. This high maximum surface roughness is not allowed in the precise stamping and forging; a post-treatment of as-coated diamond films is needed to adjust the surface roughness as well as the dimensional inaccuracy in geometry into the tailored surfaces of tools [3]. Plasma oxidation processing was utilized not only to ash the used DLC (Diamond-Like Carbon) films coated onto the tools and dies [4] but also to etch and polish the rough diamond films [5]. Although this process is effective to remove a part of coated films

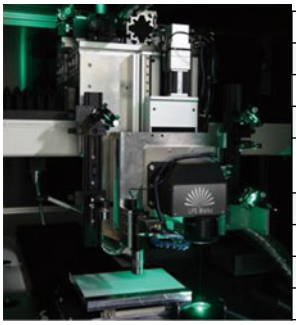
and to reduce the surface roughness, it is difficult to adjust the geometric inaccuracies within the tolerance of dimensions required for fine embossing and piercing punches of lead frames and fuel-cell separators [6, 7].

High silicon electrical steel sheets as well as amorphous magnetic films were developed to produce the motor cores with a variety of size, geometry, and alignment [8]. The key items common to them are low iron and hysteresis losses and geometric accuracy [9]; how to reduce those losses and how to sustain the dimensional accuracy stand on the high qualification in fine piercing of electrical steel sheets and films into the tailored core component. In particular, the affected zones into cores by piercing must be reduced as possible to lower the core loss [10]. Furthermore, the tool life of piercing punch and die has to be prolonged as possible for significant reduction of production cost [11]. As had been studied in [12, 13], bare WC (Co) punch was easy to be chipped at its edge only after piercing 100 times in continuous. CVD-diamond-coated tools as well as plasma nitrided tools were recognized to prolong the punch and die life in continuous piercing even under nearly zero clearance [14, 15]. The reduction of affected zones in pierced sheets was left as an engineering issue to be solved by trimming these diamond-coated and nitrided tool surfaces.

Authors reconsidered the previous trimming method with the use of the excimer laser processing [16] and proposed the femtosecond laser trimming process to adjust the CVD-diamond-coating geometry and to reduce the edge curvature of diamond-coated punch [17]. In fact, the edge curvature was reduced from 12. 5 μm down to 2.5 μm by this laser trimming. After embossing the AISI304 sheet with a thickness of 0.1 mm, EBSD (Electron Back-Scattering Diffraction) analysis revealed that the affected zone area was significantly reduced by using the trimmed, diamond-coated punch [18].



In the present paper, this femtosecond laser trimming procedure is optimized to reduce the edge curvature of diamond-coated WC (Co) punch as possible and to decrease the maximum roughness of diamond coatings. Bare diamond-coated WC (Co) punches with normal WC-grain size are prepared to have an original film thickness of 9 μm. Through two laser machining steps, the edge width of diamond coating was reduced down to 2 μm. With use of the core die with the clearance of 4%, fine piercing experiments are performed to measure the load–stroke relationship and to describe the affected zone formation by shearing. The affected zone area as well as the fractured surface ratio significantly decrease with the reduction of edge width down to 2 μm.

2 Experimental Procedure

Femtosecond laser machining system as well as laser trimming procedure are first stated to explain how to reduce the edge with and surface roughness of diamond coating. CNC (Computer Numerical Control) stamper is used to make fine piercing of electromagnetic steel sheets.

Femtosecond Laser Machining System. Femtosecond or sub-picosecond lasers are developed for innovative research and development; most industrial applications stand on this laser machining in the order of 100 femtoseconds. Since the focused spot of work materials is subjected to ultra-high power irradiation, how to scan the beam spot becomes more important when using this laser machining system. Higher repetition frequency of laser beams as well as higher scanning speed result in fast-rate, dimensionally accurate machining. Our developed system and its configuration are shown in Fig. 1. In the following experiments, the repetition rate was fixed by 400 kHz.

Laser Trimming Program. The laser-trimming and polishing process is instrumented into an experimental setup with notes on the uniform machining and ray pass control. Figure 2 depicts a standard setup for present trimming experiments. The side surface of punch head is first trimmed by using the laser beam controlling mode-1 where the laser is scanned along the central axis of WC (Co)-punch till the total reduction in thickness reaches to 2 μm. The top surface is secondly processed by using mode-2. The laser beam is moved from the center to the end of punch head. In both modes of experiment, the end of punch is held in jig to rotate with the constant velocity; e.g., $\omega = 20$ rps. The fluence (ϕ) for laser irradiation was also fixed to be different between control-I and control-II. In the control-I, $\phi = 0.6$ J/cm^2, while $\phi = 0.265$ J/cm^2.

Wave length	515nm
Pulse duration	180fs～190fs
Average power	8.2W
Repetition	MAX600kHz
Beam spot size	MIN:10μm using Galvanometer MIN:1μm using fixed lens
Stage area	300mm×300mm
Scanning speed	MAX 3000mm/s
Scanning area	MAX 30㎜×30㎜
Sample weight	< 30kg

Fig. 1 A femtosecond laser trimming system with the details on its capacity. (Color figure online)

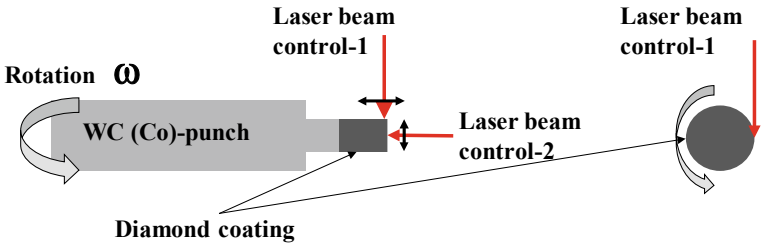


Fig. 2 Two-step laser trimming procedure. (Color figure online)

CNC Fine-Stamper for Piercing. The diamond-coated WC (Co) punch with and without trimming was fixed into a cassette die set for piercing experiment. Figure 3 depicts a typical experimental setup where the stroke is controllable by every 1 μm with in situ measurement of piercing load and punch stroke.

Observation and Measurement. SEM (Scanning Electron Microscopy), EBSD (Electron Back-Scattering Diffraction), and three-dimensional profilometer were employed to make an observation on the untrimmed and trimmed diamond-coated punches as well as the pierced electrical steel sheets and to measure the edge width of punch.

Tooling and Work materials. Bare CVD-diamond-coated WC (Co) punches were prepared in this experiment. The diamond film thickness was constant by 9 μm. Figure 4 shows the SEM image of diamond film prepared for trimming experiments.

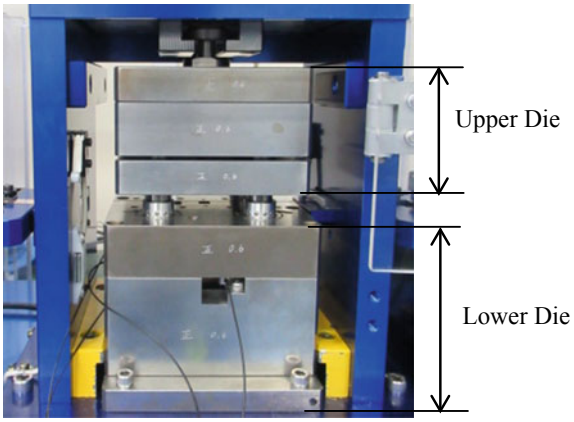

Fig. 3 Precise piercing experiment of electromagnetic steel sheets by using the CNC stamping system. (Color figure online)

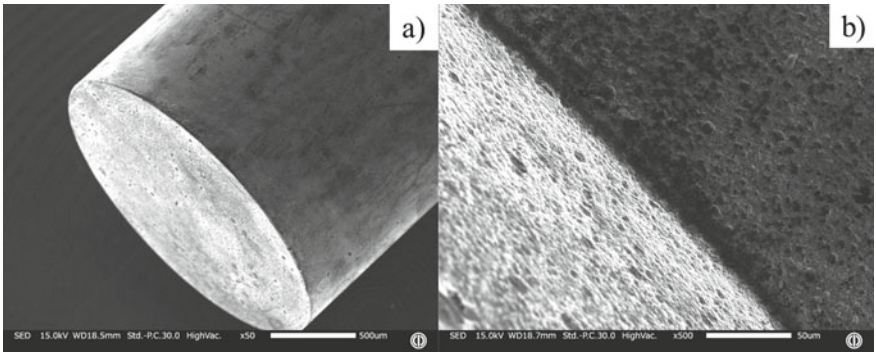

Fig. 4 SEM image on the bare CVD-diamond-coated WC (Co) punch surface. **a** Cylindrical punch with the diameter of 2 mm and **b** rough surface of diamond coating

The diamond film coated the WC (Co) punch surface uniformly. However, the top and side surfaces have high maximum roughness up to 3 μm. In particular, the punch edge becomes an intersection of two diamond films growing respectively on the top and side surfaces of WC (Co) head. As shown in Fig. 4b, the diamond film surface becomes dull at this punch edge.

3 Experimental Results

The diamond-coated WC (Co) punch with the head diameter of 2 mm and head height of 5 mm was laser-trimmed by reduction of diamond from a thickness from 9 μm down to 5 μm. Instead of the curvature radius at the edge of punch, the edge width was measured by SEM and employed as a targeting parameter to optimize the laser trimming conditions. Piercing process was utilized to describe the shearing behavior by using the diamond-coated WC (Co) punch with and without laser trimming.

Femtosecond Laser Trimming. Figure 5 shows the SEM images of trimmed diamond coatings. The top periphery of side surface with a width of 150 μm was trimmed to reduce the diamond film thickness by 5 μm. Comparing the trimmed surface in Fig. 5b with the surface of bare diamond coating in Fig. 4b, the surface condition and roughness are much improved by this laser trimming. Figure 6 shows the enlarged view from the punch head to the punch shoulder surface across the edge of punch. The curvature radius at the punch edge is much reduced from the original radius of 15 μm in the bare diamond-coated punch. Let us precisely describe the geometric configuration across the punch edge.

Optical microscopy is utilized to measure the edge width between the trimmed punch head and side shoulder surface. The laser beam is gradually focused onto the punch edge by changing the position. Figure 6 shows the focused image just on the punch edge; both the punch head and side shoulder surfaces become vague due to

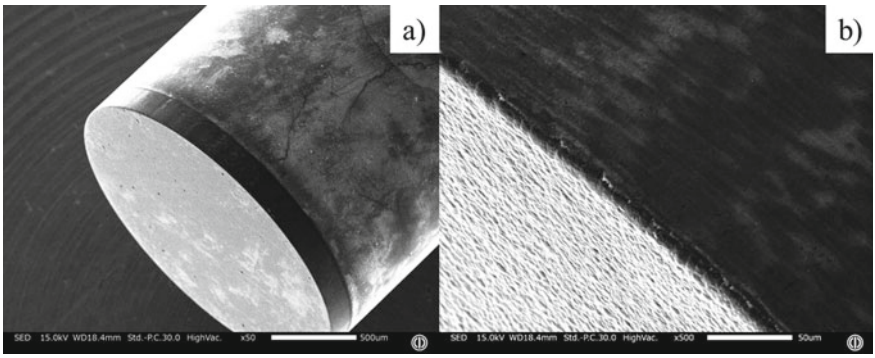

Fig. 5 Trimming results of the CVD-diamond-coated WC (Co) punch. **a** Trimming of diamond coating from surface up to the width of 150 μm, **b** Enlarged punch head and side surface

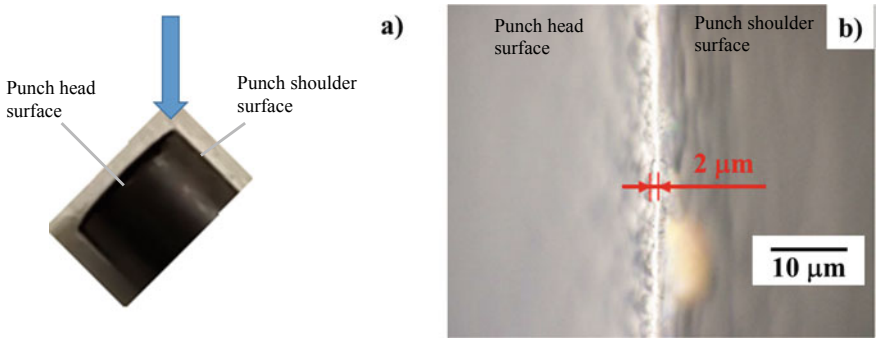

Fig. 6 Optical microscopic image from the punch head to the punch shoulder across the punch edge. **a** Observation field of view, **b** Enlarged punch edge and edge length. (Color figure online)

the focus depth in this laser microscopy. From the focused line width, the edge width is determined to be 2 μm.

Piercing Experiments. Two types of piercing experiments were performed by using the electrical steel sheets with the thickness of 0.5 mm; half and full piercing experiments. In the former, the shearing behavior is mainly governed by indentation of the edge-sharpened punch into worksheet with less influence from the core-die.

As shown in Fig. 7, the fine, fresh surface without local fractures is formed by this

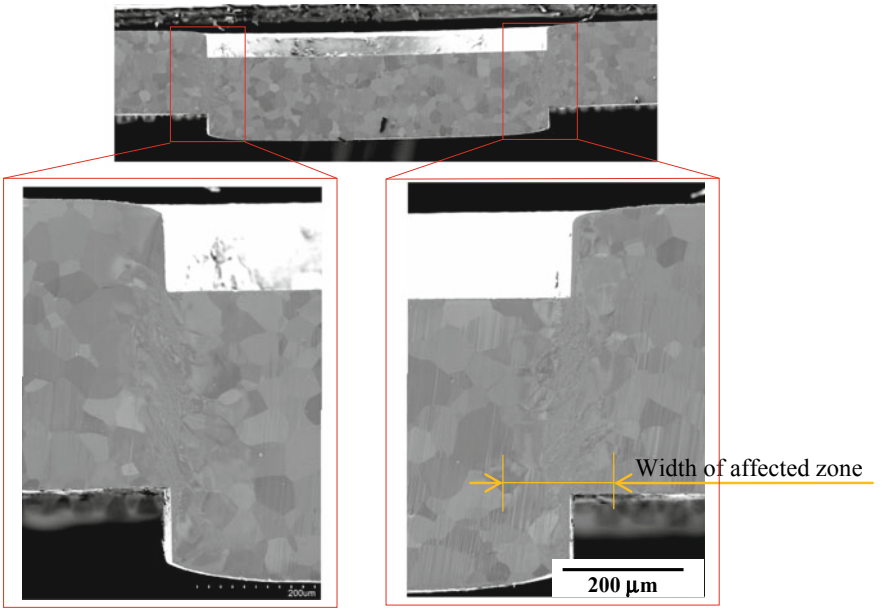

Fig. 7 Plastic flow by shearing process in the half-piercing experiment. (Color figure online)

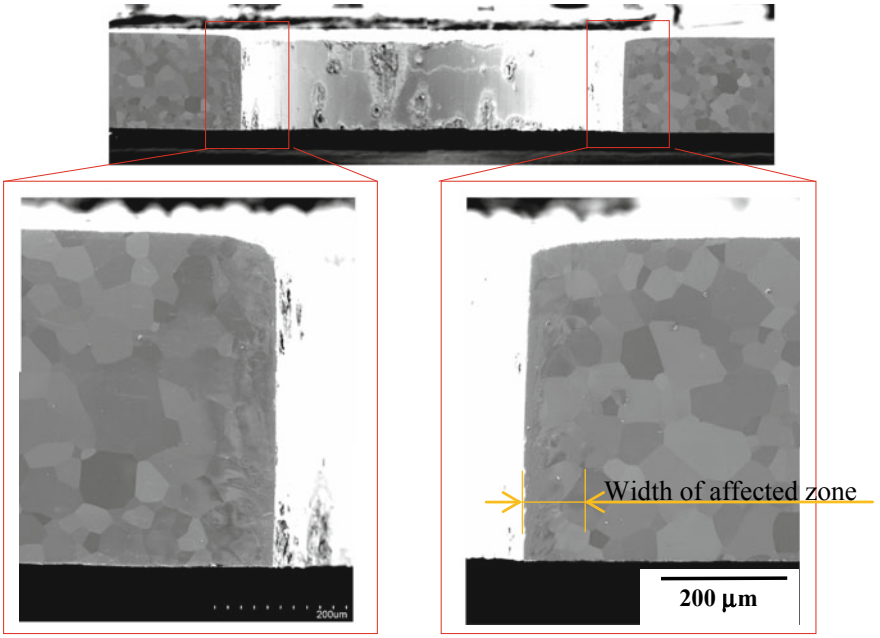

Fig. 8 Plastic flow by shearing process in the full-piercing experiment. (Color figure online)

half-piercing indentation of the trimmed diamond-coated punch. From this SEM observation, the electrical steel grains are severely deformed along the shearing plane. The affected zone width in the circumferential direction of the hole was up to about 180 µm. In case of full-piercing experiments, as shown in Fig. 8, the process affected zone width in the circumferential direction of the hole was decreasing from half-piercing result of 180 µm to full-piercing result of 90 µm. The affected zone width in the circumferential direction of the hole was suppressed to 20% or less of the plate thickness

Figure 9 shows the comparison of the load–stroke relationship in piercing process between the normal WC (Co) punch and the trimmed diamond-coated punch. When changing the punch from the normal WC (Co) punch to the trimmed diamond-coated punch, the maximum punching load was changed from 1765 N to 1654 N. There is 6.3% decreasing of maximum punch load.

Evaluation on Affected Zones in Pierced Sheet by EBSD. Figure 10 shows the EBSD (Electron backscatter diffraction) analysis results of cross section of full-piercing hole that shown in Fig. 8. Figure 10a shows inverse pole figure map. Figure 10b shows the KAM (Kernel Average Misorientation) angle. The measured KAM angle corresponds to equivalent plastic strain [20]. From Fig. 10a, there is a process-affected zone where crystal grains have been refined on the side surfaces of the hole. From Fig. 10b, this process-affected zone was mainly displayed by the

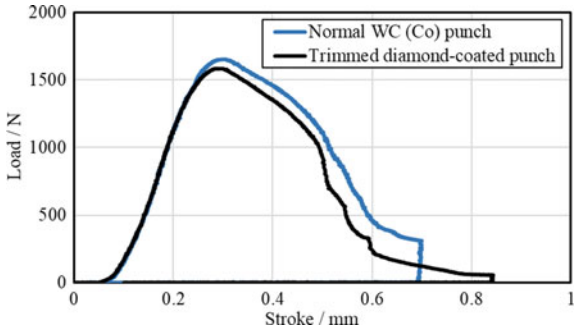

Fig. 9 Comparison of the load–stroke relationship in piercing process between the normal WC (Co) punch and the trimmed diamond-coated punch. (Color figure online)

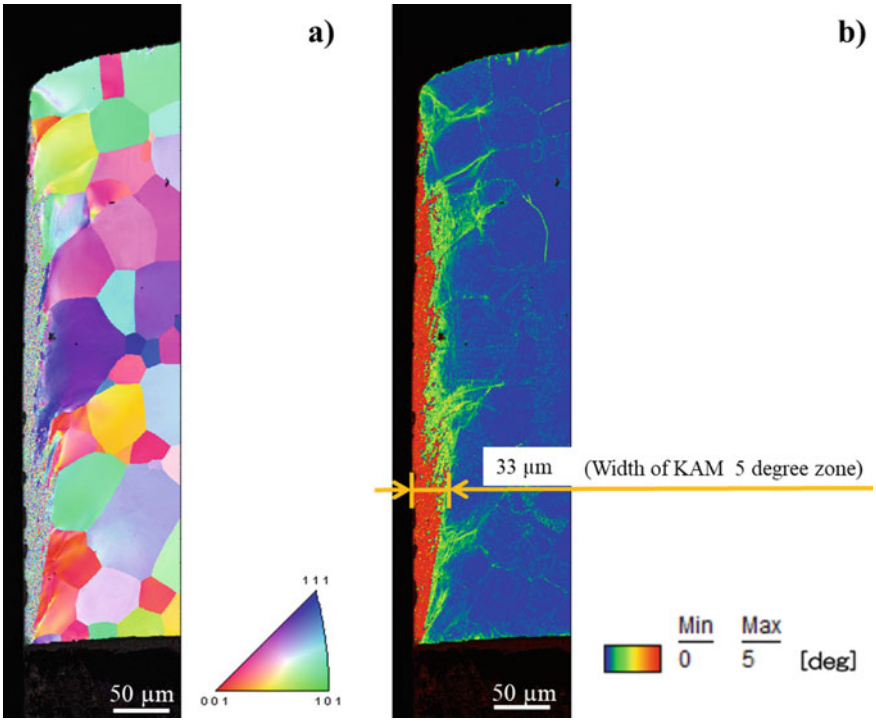

Fig. 10 EBSD analysis on the cross-section of full-pierced electromagnetic steel sheet. **a** Inverse pole figure map, and **b** KAM distribution. (Color figure online)

regions colored in red region with higher KAM degrees than 5. This region was identified as the part with high spin rotation of grains as well as high equivalent plastic strains. The width of this region in the circumferential direction around the hole was 33 μm. The process-affected zone in Fig. 8 was 90 μm. This difference reveals that the highly affected zone with spin rotation and high KAM degrees in Fig. 10 narrows in the plastically strained regions in Fig. 8 [21].

4 Discussion

The edge width or the edge curvature radius could be less than 1 μm if the punch head and side shoulder surfaces were independently trimmed by the femtosecond laser beam. In practice, the laser beam has a finite focusing eye for ablation of work materials, and its energy profile is shaped in Gaussian; there must be mutual interaction between laser trimming processes in control-I and -II in Fig. 2. How to minimize this interaction, becomes a practical issue to significantly reduce the edge width. As suggested by [19], the sacrifice film might be effective to suppress the diffusive beam from the machined surface to its neighboring ones. On the other hand, the edge width of trimmed diamond-coated punch must be tailored to be free from severe damage even after long usage in piercing process. Tool life test by piercing is also necessary to determine the optimum edge width in practice.

The process-affected zone into electrical steel sheets by piercing is observed and measured by various methods. In the above, the process-affected zone width (W) is determined by SEM analysis to have plastically deformed grains; e.g., W = 90 μm. After EBSD analysis, this process-affected zone is redefined to have higher misorientation angles among the neighboring grains in KAM distribution; e.g., W = 33 μm. Furthermore, the detection of local magnetization direction by the Kurr-effect microscopy also becomes a preferable tool to describe the disturbance to spatial magnetization distribution by piercing. As reported in [22], the elastic recovery in the elastoplastically strained grains as well as the affected zones have an influence on this disturbance to increase the iron and hysteresis losses. Mutual comparison among those methods are useful to find a way to minimize these losses by piercing.

In addition to the reduction of the edge width by laser trimming the diamond-coated punch, several approaches must be taken into account to minimize the affected zone width. The friction on the laser-trimmed punch edge and side surface is noticed as the first item. Due to the stress concentration at concentrates the punch edge during piercing, the maximum punching load becomes lower by 6.3% than using the normal WC (Co) punch. The clearance between punch and core-die diameters is the second item. As had been studied in [12–15], nearly zero clearance is effective to narrow the sheared plane in fine piercing. The loading sequence by CNC stamping as well as the loading speed has an influence on the plastic localization along the shearing plane in piercing. A loading program including the high-speed indentation mode might be preferable to narrow the affected zone width.

5 Summary

Femtosecond laser trimming process is effective to reduce the edge width of CVD-diamond-coated WC (Co) punch down to 2 μm. Due to the stress concentration at the edge during piercing, the maximum punching load is significantly decreased together with the reduction of process affected zone width. This edge-sharpened punch as well as the core die with the clearance of 4% is employed for piercing of the electrical steel sheet with a thickness of 0.5 mm.

An Investigation on Formability of Ti6Al4V Alloy in the Three-Layer Sheet Hot Stamping Process

Xiaoming Yang, Baoyu Wang, and Chuanbao Zhu

Abstract In the hot stamping process, the sheet will lose a lot of heat which results in poor formability of the sheet. So, a novel hot stamping process for the three-layer sheet is proposed in this paper, which uses two steel sheets to clamp the titanium alloy sheet for transferring and stamping. In this paper, the hot stamping depth is studied by experiments and simulation under the single/three-layer sheet hot stamping condition. The results show that the temperature of the titanium alloy sheet can be controlled effectively by using the three-layer sheet hot stamping process, and the stamping depth can be improved. Compared with the single-layer sheet hot stamping process, the depth of the titanium alloy parts can be increased by 135.7% under the three-layer sheet hot stamping process at 900 °C, and the thickness distribution of titanium alloy parts obtained by three-layer sheet hot stamping process is more uniform. The finite element analysis results show that the temperature and stress distribution of titanium alloy sheet by three-layer sheet stamping process is more uniform, and the temperature difference is small through the sheet. The distribution of thickness obtained by simulation has good consistency with the experimental results. Under the three-layer sheet hot stamping process, the titanium alloy sheet has good deep drawing.

1 Introduction

Titanium alloy is widely used in aerospace due to its high strength, corrosion resistance, and high temperature resistance [1]. Titanium alloy needs high temperature to improve its formability due to its poor plasticity at room temperature [2].

At present, there are many articles about the formability of titanium alloy at high temperature. In order to study the high temperature mechanical properties of titanium alloy, the stress-strain curves and grain growth of Ti6Al4V alloy were studied at the temperature of 650–870 °C and strain rate of 10^{-4}–$10^{-2}s^{-1}$ by Velay et al. [3]. The microstructure of Ti6Al4V titanium alloy under different deformation conditions was observed by Sun et al. [4]. It was found that work hardening occurred mainly at lower deformation temperature, and dynamic recrystallization and dynamic recovery dominated with the increase of deformation temperature. According to the experimental results from Lai et al. [5], the plasticity of Ti6Al4V titanium alloy could be improved at high temperature due to the reduction of yield strength. Li et al. [6]. Used the M-K model to predict the forming limit curves of Ti6Al4V titanium alloy at 700 °C, and then verified the correctness of the model by the hemispherical dome tests at elevated temperature.

The traditional hot forming methods of the titanium alloy sheet include superplastic forming [7], hot creep forming [8] and isothermal forming [9]. However, the forming efficiency of traditional forming method is low, and the tool has a high temperature to protect the heat loss of the sheet. The heating time of the tool is approximately 3 h which reduces the production efficiency. The formability of Ti6Al4V alloy is studied by Kopec et al. [10]. Under the hot stamping and cold die quenching process in order to improve the production efficiency. The results show that Ti6Al4V alloy sheet has a lot heat loss in the transferring and stamping process reducing its formability. Aghchai et al. [11]. Studies the forming limit of Al1100/ST12 composite sheet, and the forming limit curves of double-layer sheet are predicted by the M-K model. The results show that the forming performance of double-layer sheet is better than that of component metal sheet. Therefore, this paper presents a multi-layer sheet hot stamping process to meet the production requirements. The multi-layer sheet hot stamping process is proposed based on the hot stamping and cold die quenching process. In this process, a titanium alloy sheet is clamped by two steel sheets (the sandwich structure) for transferring and stamping to reduce the heat loss of the titanium alloy sheet.

In this paper, the formability of titanium alloy is studied by multi-layer sheet hot stamping process. Both the single-layer and three-layer sheet hot stamping of deep drawing tests were performed and compared for investigating the formability of titanium alloy. The finite element simulation model of titanium alloy multi-layer sheet hot stamping process is established. The distribution of thickness is analyzed and compared by experiment and simulation. The temperature and stress distributions of titanium alloy sheet are analyzed by simulation.

Parameters	Values
Sheet temperature/°C	900
Tool temperature/°C	25
Blank holder force/kN	5
Diameter of sheet/mm	100
Stamping speed/mm·s^{-1}	40

2 Experimental Tests

The material used in the tests is the annealing Ti6Al4V titanium alloy with a thickness of 1.6 mm. And the auxiliary sheet is the HC1500HS steel produced by the Shougang steel group with a thickness of 1.4 mm. A 60-ton high speed press is used as the experimental equipment to study the deep drawing of the titanium alloy. The experimental tool and geometry size are shown in Fig. 1. During the tests, the titanium alloy sheet with a diameter of 100 mm is clamped by two steel sheets and put into the furnace for heating 30 min. Then, the three sheets are transferred and stamped when the temperature of the three sheets increases to the required. The process parameters are shown in Table 1.

3 Finite Element Simulation Model

The finite element simulation model shown in Fig. 2 is established to study the formability of titanium alloy by the simulation software Abaqus.

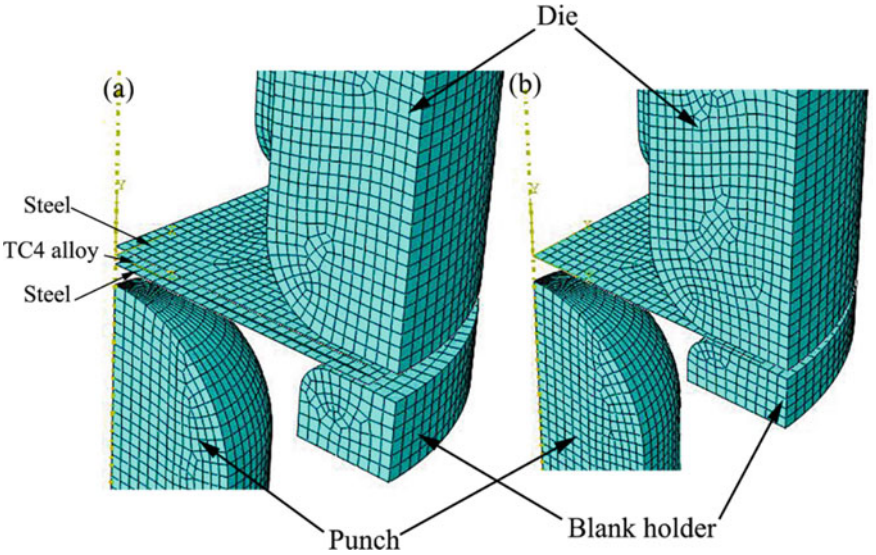

Fig. 2 The finite element simulation model **a** Three-layer sheet hot stamping model, **b** Single-layer sheet hot stamping model. (Color figure online)

In order to ensure the consistency between the simulation results and the experimental results, the material of tool in the simulation model is AISI-H13 which is consistent with the material used in the experiments. The physical parameters of the tool and sheets are shown in Table 2. The true stress-strain curves of the Ti6Al4V titanium alloy and HC1500HS steel are shown in Fig. 3 at a temperature of 900 °C. With the increase of strain rate, the flow stress of the Ti6Al4V titanium alloy and HC1500HS steel shows a rising trend. However, the plastic strain of the Ti6Al4V

Table 2 The physical parameters of the tool and sheets

titanium alloy and HC1500HS steel shows an opposite trend with the strain rate increasing.

Two types of interactions are defined in the simulation model. One is the contact friction, and the other is the interfacial heat transfer between metals. The interfacial heat transfer coefficient of titanium alloy measured by Bai [12] and HC1500HS steel measured by Huang [13] is used in this paper, which is shown in Fig. 4. The friction coefficient between the titanium alloy sheet and HC1500HS steel sheet is 0.1. The friction coefficient between the HC1500HS steel sheet and tool is 0.2. In addition, The friction coefficient between the titanium alloy sheet and tool is 0.12 in the single-layer sheet hot stamping process. The element type of sheet is S4RT coupled with temperature-displacement. And the tools are meshed into C3D8T.

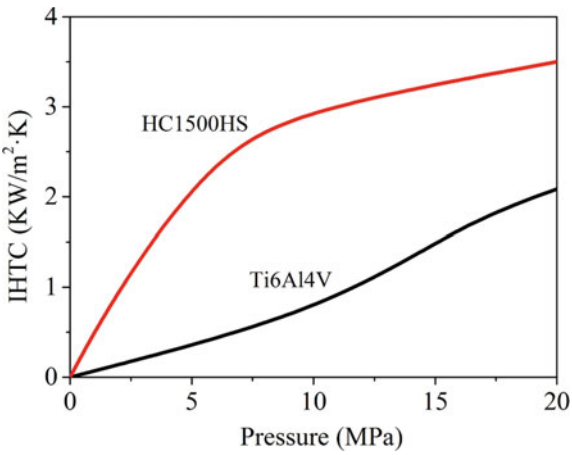

Fig. 4 The interfacial heat transfer coefficient of the Ti6Al4V titanium alloy and HC1500HS steel. (Color figure online)

4 Results and Discussion

4.1 Results of Tests

The titanium alloy parts obtained by different hot stamping methods are shown in Fig. 5. It can be seen that the stamping depth of the titanium alloy sheet increases obviously after the three-layer sheet hot stamping process. Compared with the single-layer sheet hot stamping process, the stamping depth of the titanium alloy parts is 33 mm increased by 135.7% in the three-layer sheet hot stamping process. This is because that the middle titanium alloy sheet clamped by two steel sheets is transferred and stamped, and the temperature of the titanium alloy sheet decreases slowly. In addition, the friction coefficient of the titanium alloy sheet is low, so the sheet is easy to be formed because the three sheets deform simultaneously.

The titanium alloy parts obtained by different stamping methods are cut along the diameter, and the distribution of the thickness is measured. The comparison results of thickness distribution between the simulation and experiments are shown in Fig. 6. The simulation results are in good agreement with the experimental results. The minimum thickness of the titanium alloy sheet is 1.2 mm when the stamping depth is 14 mm in the single-layer sheet hot stamping process. However, There is no thinning

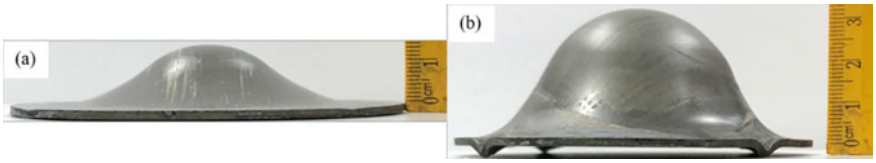

Fig. 5 Forming parts by different stamping processes at 900 °C **a** Single-layer sheet hot stamping process; **b** Three-layer sheet hot stamping process. (Color figure online)

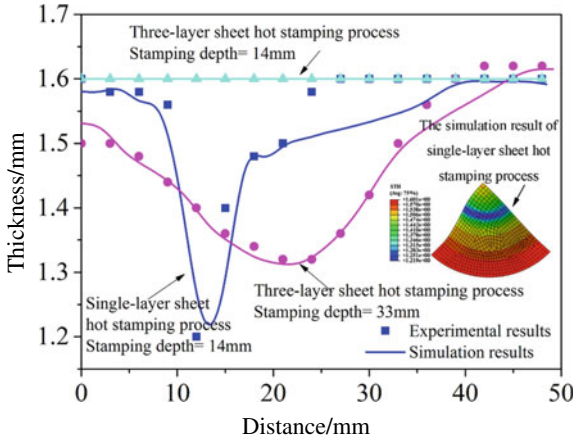

Fig. 6 The change of sheet thickness (Symbols represent experimental results, lines represent simulation results). (Color figure online)

in the three-layer sheet hot stamping process when the stamping depth is 14 mm. The minimum thickness of the titanium alloy parts is 1.32 mm when the stamping depth is 33 mm in the three-layer sheet hot stamping process. The better formability of the titanium alloy sheet can be obtained by using the novel three-layer sheet hot stamping process. It can be seen that the thickness decreases in the side wall region and increases in the blank holder region. The minimum thickness appears in the side wall area. The flow stress in the sidewall region is low because of the higher temperature, so the sheet is easy to be deformed. In the blank holder region, the circumferential compressive stress makes the sheet thickness increase. There is local thinning in the single-layer sheet hot stamping process. Compared with the single-layer sheet hot stamping process, the thickness distribution of the titanium alloy parts obtained by three-layer hot stamping process is more uniform.

4.2 Distribution of Sheet Temperature

The temperature distribution of the titanium alloy parts under different hot stamping conditions is shown in Fig. 7, which is calculated from the simulation results. The highest temperature of the sheet is 634.53 °C at the single-layer sheet hot stamping process and 640.56 °C at the three-layer sheet hot stamping process. Compared with the single-layer sheet hot stamping process, the distribution of temperature is uniform at the three-layer sheet hot stamping process. Under the condition of the single-layer sheet hot stamping, the temperature is 244.42 °C at the central region, which is 399.11 °C lower than the maximum temperature. The heat transfer between the titanium alloy sheet and tool occurs in the single-layer sheet hot stamping process. The cooling rates of the sheet at the contact position are higher than other positions. However, the titanium alloy sheet clamped by two steels is transferred and deformed,

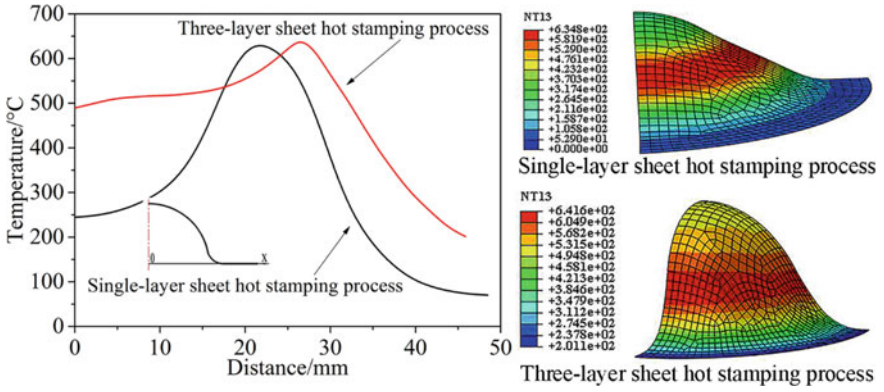

Fig. 7 The distribution of sheet temperature calculated from the FE simulation. (Color figure online)

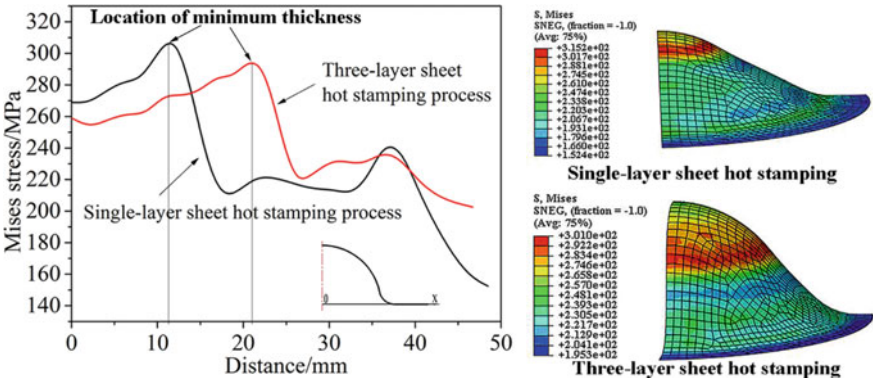

Fig. 8 The distribution of Mises stress calculated from the FE simulation. (Color figure online)

reducing the contact with air and tool in the three-layer sheet hot stamping process. Consequently, the temperature distribution of the titanium alloy parts obtained by the three-layer sheet hot stamping process is uniform.

4.3 Distribution of Mises Stress

The Mises stress distribution of the titanium alloy parts under different stamping conditions is shown in Fig. 8. Compared with the single-layer sheet hot stamping process, the stress distribution of the titanium alloy parts obtained by the three-layer sheet hot stamping process is more uniform. Under the single-layer sheet hot stamping condition, the stress decreased from 311.6 MPa to 208.35 MPa at the distance of 12 mm to 17 mm. And the stress decreased from 294.4 MPa to 218.3 MPa at the distance of 20 mm to 26 mm under the condition of three-layer hot stamping. The smaller stress difference can be obtained in the three-layer sheet hot stamping process. In addition, it can be seen that the position where the stress changes dramatically is the thinning one due to the change of the Mises stress.

5 Conclusion

In this paper, a three-layer sheet hot stamping process is proposed to reduce the heat loss of the titanium alloy sheet in the transferring and stamping process. The formability of Ti6Al4 V titanium alloy is studied by experiment and simulation under the multi-layer sheet hot stamping condition. It can be seen that the simulation results are in good agreement with the experimental results. Compared with the single-layer sheet hot stamping process, the distributions of thickness, temperature and stress are

uniform in the three-layer sheet hot stamping process. And there is deeper stamping depth of Ti6Al4 V alloy in the three-layer sheet hot stamping process.

The Effects of Servo Press Forming on Various Strain Path Failures

L. Zoller, T. Feister, and H. Kim

Abstract Utilizing a servo press for sheet metal forming provides benefits for users such as a fully adjustable slide motion and blank holder force control during the stroke. These allow users to program unique motion profiles of press slide and cushion based on position and velocity. This paper will discuss how unique servo press motion profiles can avoid various strain path failures that may occur in final formed parts. Standard crank motion, variable blank holder force, and attach-detach slide motion were used to evaluate biaxial and plane strain failures of 980GEN-3 steel. It was determined that different strain failure paths require different servo press programs to improve the overall part quality.

Keywords Servo press · Forming limit diagram · Simulation · 980Gen-3

1 Introduction

The stamping industry is currently increasing the use of servo presses in their production environments. A servo press uses an electric servo motor-driven slide and a hydraulic or pneumatic servo cushion system. The electric servo motor allows for a fully adjustable slide motion. The servo cushion system can be used to freely control the force during forming as well as program multi-drawing steps called attach-detach [1]. It is known that a servo press can be used to improve part quality however there is a lack of understanding how to determine the preferred servo press motion considering the deforming material strain path to avoid necking or wrinkling and the part design [2]. This lack of knowledge creates a need to fully understand how to accurately simulate the servo press motion attach-detach versus a standard crank press motion to study the strain [3].

The strain path-dependent failures are determined from the Forming Limit Diagram (FLD) as shown in Fig. 1 [4]. An FLD is used to evaluate formability with major and minor strains during different strain paths. Deep drawing includes both

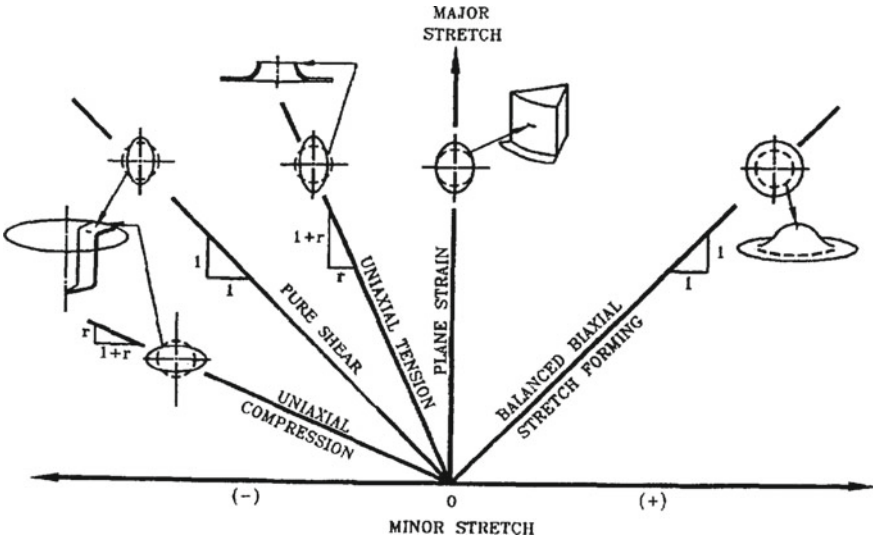

Fig. 1 Strain path failure modes plotted on true strain [M. Karima, N. Chandrasekaran, and W. Tse, Process singatures in metal stamping—basic concepts, J. Mat. Shaping Tech., 7 (3) (1989) 169–183.]

pure shear in the flange area and uniaxial compression in the flange edge. Therefore, thickening occurs in the drawn flange area. For the pure shear strain path, major and minor strain are equal with major strain in tension and minor strain in compression. Uniaxial tension is when major strain is in tension while minor strain is compressing in half the amount of strain as the major. Uniaxial tension behavior is similar to a standard tensile test. Plane strain is the lowest point on the FLD where minor strain is equal to zero. Equi-biaxial strain is when both major and minor strain are equal in tension.

2 Objective

The objective of this study is to determine how failure strain paths change by altering the press slide motion and blank holder force (BHF) profiles. Predicting critical strain paths using Finite Element Method (FEM) helps to identify and avoid any necking failures in the stamped part which is important to reduce scrap and improve productivity.

3 Approach

Two different lab scale die geometries were used in this study. The lab scale dies were chosen due to the type of failures seen in each die. The universal formability testing (UFT) die was designed to create biaxial strain dominant failure on the stamped part and the Crossform testing (CFT) die was designed to create the plane strain dominant failure.

The sheet material used for the both lab scale dies was 980GEN-3 (1.2-mm thick) steel. In order to accurately simulate the UFT and CFT tooling in PAM-STAMP two standard formability tests, uniaxial tensile testing for the flow stress and Limiting Dome Height (LDH) testing for FLD were completed to create the material card for simulations. The material card for each simulation was developed using ESI's material wizard. The hardening curve was developed using the uniaxial tensile test and the yield criteria used was Vegter yield locus as shown in Fig. 2. The coefficient of friction value used was 0.12. The press slide motion and blank holder force measured from experiments were defined in simulations as shown in Fig. 2, standard crank motion with a constant blank holder force, a standard crank motion with a variable blank holder force and an attach-detach motion.

During the attach-detach motion that slide "detaches" two times before completing the stroke. The die position for the first detach was at 15 mm from bottom dead center (BDC) and the die position for the second detach was at 5 mm from BDC and the third one corresponds to BDC. Therefore, the formed part is detached only from the stationary punch while the outer flange area is still constrained with both the upper

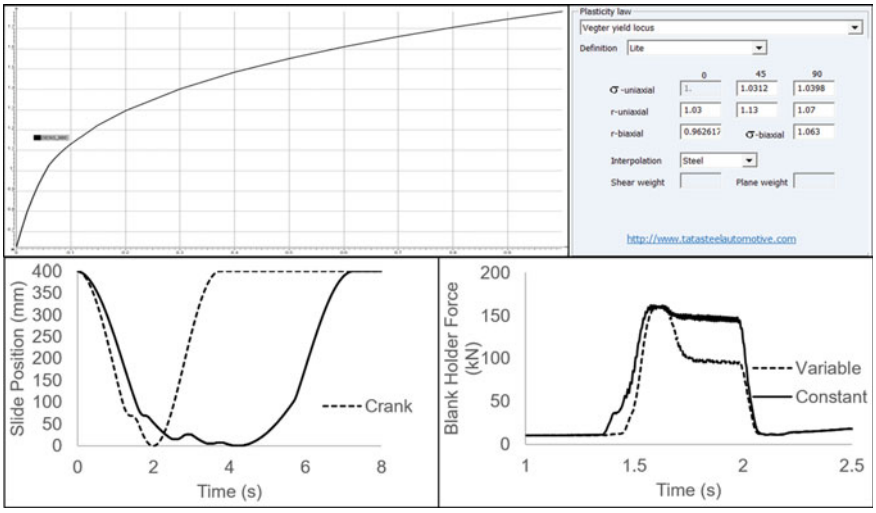

Fig. 2 Hardening curve (top left), yield criterion (top right), slide profile for crank motion and attach-detach (bottom left), and constant and variable blank holder force profiles (bottom right). (Color figure online)

die and blank holder. The crank motion slide profile has a silent deceleration feature that instantaneously slows down the slide speed during the initial contact between the upper die and a flat blank placed on the blank holder surface. The variable BHF profile was selected by preliminary FE simulations. The BHF profile selected is referenced as high-low because the force starts high and ramps down to lower force during forming. Adjusting the BHF is a commonly used method to improve part quality while maintaining the stroke per minute (SPM) in a production environment. Figure 2 shows that attach-detach has a slower SPM compared to crank motion due to the additional die travel during forming.

4 Results

The simulations began with crank motion. The goal for the simulation was to determine the failure stroke based on the FLD tested at EWI. For the UFT die the failure stroke was 68.7 mm for 980GEN-3 steels (Fig. 3). The failure location had a major true strain value of 0.315 and a minor true strain value of 0.168. The failure strain path for the UFT die crank motion was considered to be biaxial stretching conditions due to the positive major and minor strains.

The CFT die failure stroke was 65.5 mm for 980GEN-3 steel (Fig. 4). The failure location had a major true strain value of 0.207 and a minor true strain value of 0.022. The failure strain path location for the CFT die with 980GEN-3 was near plane strain.

With the failure stroke known for each die set, the high-low and attach-detach profile simulations were completed, starting with the high-low profile. The 980GEN-3 failure location (Fig. 5) had a major true strain value of 0.294 (6.6% strain decrease from crank) and a minor true strain value of 0.123 (26.8% strain decrease from crank) with the UFT die. Even though there was a little strain improvement with the 980GEN-3 material, the improvement was not enough to eliminate the failure based on the FLD.

The attach-detach motion with 980GEN-3 (Fig. 6) had a major true strain value

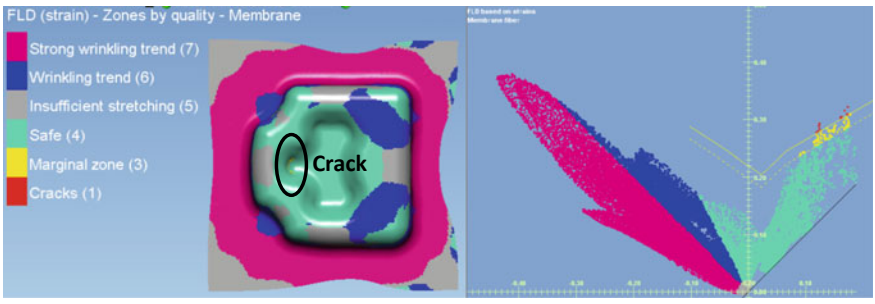

Fig. 3 980GEN-3 Crank Motion Failure using UFT die with Forming Limit Diagram at 68.7 mm die stroke. (Color figure online)

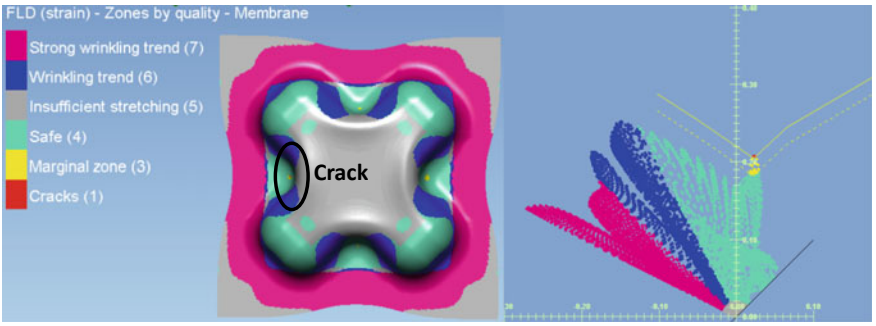

Fig. 4 980GEN-3 Crank Motion using CFT die with Forming Limit Diagram at 65.5 mm die stroke. (Color figure online)

of 0.282 (10.5% strain decrease from crank) and a minor true strain value of 0.146 (13.1% strain decrease from crank) with the UFT die. This strain improvement in both major and minor true strain predicted a final part with no failures based on the FLD.

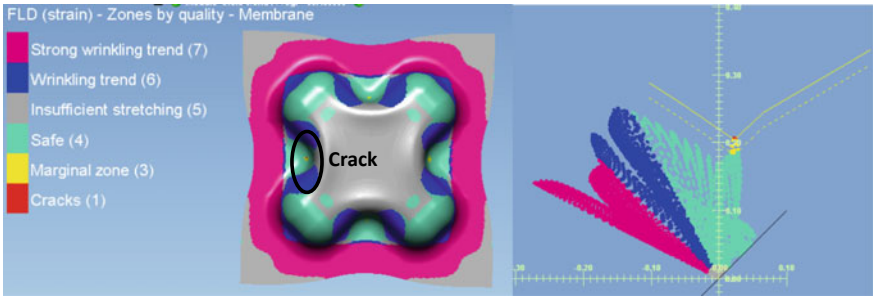

Fig. 7 980GEN-3 Variable Blank Holder Profile using CFT with Forming Limit Diagram at 65.5 mm die stroke. (Color figure online)

The CFT die with 980GEN-3 steel (Fig. 7) using the high-low profile still had the plane strain failure on the final part. The major true strain value was 0.207 (0% strain improvement from crank) and a minor true strain value was 0.024 (9.1% strain increase from crank).

The CFT die with 980GEN-3 steel (Fig. 8) using the attach-detach profile had the same failure location as the crank motion and high-low profiles major true strain value of 0.208 (0.5% strain increase from crank) and a minor true strain value of 0.022 (0% strain improvement from crank).

After the simulations were completed, EWI ran each test in a 300-Ton AIDA servo press. ARGUS strain analysis was also completed on the UFT parts to determine if the attach-detach motion was accurately simulated. The results are summarized in Table 1. The crank motion and the high-low BHF profile cases all failed, and the attach-detach motion improved the UFT part quality in the actual testing however it did not improve the CFT part quality. Figure 9 shows the ARGUS thickness reduction data for crank motion (failure) and attach-detach (good) parts. The ARGUS strain results had good correlation with the simulation results to confirm EWI's initial findings.

5 Summary of Major Findings and Conclusions

EWI found that selecting the effective servo press motion is dependent on the type of strain path failure found in the given die geometry based on the simulation and actual testing results. Specifically, the servo motion called attach-detach can improve the part formability of a biaxial part failure; however, it might be limited to improve the part formability of a plane strain failure for advanced high strength steels. Future work after this study will be to implement this process with an industry sized part as well as study different material types with material variation and various "detach" locations for the attach-detach profile.

Recent Advances on Modeling Plastic Deformation of Textured Metals with Applications to Metal Forming

Oana Cazacu and Benoit Revil-Baudard

Abstract Due to the ease in calibration from simple tests and the reliability of the parameter identification, generally von Mises isotropic criterion and Hill orthotropic criterion are used in industry. While more advanced 3-D yield criteria have been developed, generally such criteria are written in terms of eigenvalues of transformed stress tensors, and as such the anisotropy coefficients are not directly related to mechanical properties. Therefore, the quality of the F.E. simulations depends on the experience of the analyst in calibrating these parameters. Very recently, it was shown that all advanced non-quadratic yield criteria are in fact polynomials in terms of stress components (see [1]). Moreover, for the 3-D orthotropic criteria involving one linear transformation (e.g. Yld91), the anisotropy coefficients can be determined using analytical formulas, involving only four yield points or three Lankford coefficients, respectively (see [2, 3]). In this paper, the predictive capabilities of the orthotropic criteria of Hill [4], Yld91 [5], and Cazacu [6] calibrated using both analytical and numerical minimization procedures are discussed. Moreover, simulation results of deep drawing of steel alloy DC06 are presented. The influence of the choice of the criterion, the procedure used for identification (analytical vs. numerical), and the type/extent of the data used for identification are analyzed in detail.

Keywords Orthotropic yield criteria · Analytical identification · Cup drawing · DC06 steel

1 Introduction

Due to the fabrication process, most metallic plates and sheets display at the macroscopic scale anisotropy. For example, rolling leads to preferential orientations of the constituent grains (i.e. crystallographic texture), which in turn induces orthotropy of the mechanical properties in the plastic regime of behavior. Modeling of the effects of

orthotropy on the onset of plastic deformation (i.e. yielding) and subsequent evolution of plastic deformation has received a lot of attention. Orthotropy dictates that for 3-D loadings, the yield function should involve at least 6 anisotropy parameters. The most versatile orthotropic yield criteria involve up to 18 parameters (see [1]). For any forming process, the accuracy of the predictions obtained with any orthotropic criterion depends on the experimental database available for parameters identification, the calibration procedure used, as well as the performance of the numerical code. In particular, the identification procedure may strongly influence the quality of the finite-element (F.E.) simulation results (e.g. see discussion on the effects of the numerical identification procedures used for calibration of Hill [4] and Cazacu and Barlat [7] orthotropic criterion for DC06 steel on predictions of the material anisotropy and its behavior during forming presented in [8], and [9]-[10], respectively). Very recently, Cazacu et al. [1] derived new equivalent expressions in terms of stress components for all the 3-D non-quadratic orthotropic yield criteria. Furthermore, Cazacu [2, 3] has demonstrated that for the non-quadratic orthotropic yield criteria Yld91 and Karafillis and Boyce [11], which involve one linear transformation, the parameters identification can be done analytically using formulas involving only four experimental yield points or three Lankford coefficients, respectively. This makes the determination of the anisotropy parameters reliable even in the case when the mechanical data available for identification are limited. Also, it was demonstrated that the 6 anisotropy coefficients involved in either Yld91 or Karafillis and Boyce [11] criteria are not independent. Specifically, as it is the case of Hill [4] yield function, the mathematical form imposes very specific couplings between the yield stresses σ_0 and σ_{90} and the Lankford coefficients r_0 and r_{90} corresponding to the rolling direction (RD), and transverse direction (TD), respectively. Nevertheless, the new explicit expressions of Yld91 and Karafillis and Boyce yield criteria in terms of stress components enable a direct correlation between the anisotropy parameters and mechanical properties and lead to standardization of their use in numerical simulations.

In this paper, the benefits of having for Yld91 an explicit expression in terms of stresses and analytical identification procedures are demonstrated for a strongly anisotropic steel alloy, DC06. Specifically, the influence of the type of data used for identification of Yld91 (i.e. only experimental yield data or only experimental Lankford coefficients) the extent of the data set used for identification (i.e. reduced data set or extended data set), and the identification procedure (analytical vs. numerical) on the accuracy of cup forming predictions for the steel alloy DC06 are analyzed. Hill [4] and Cazacu [6] orthotropic criterion are also applied to DC06 and an in-depth analysis of the influence of the choice of the criterion used for modeling on the accuracy of the predictions is presented. We begin with a brief presentation of the cup drawing test setup for DC06 alloy reported in [8] and [12].

2 Cup Drawing Test Results for DC06 Steel

The geometry of the tools and blank are given in Table 1. The results of the cup

Table 1 Geometry of the tools and blank in the deep drawing test of the DC06 alloy (after [8])

Blank diameter	120 mm
Blank thickness	1 mm
Punch diameter	60 mm
Punch filet radius	5 mm
Die opening diameter	62.4 mm
Die filet radius	10 mm

drawing test were provided for all four quarters of the cup. Assuming that the material is orthotropic, in Fig. 1 is presented the experimental variation of the cup height averaged over the four quarters (i.e. $0 < \theta < 90^o$, with RD corresponding to $\theta = 0^o$). Thus, in Fig. 1 the reported height at θ is the average of the cup height at θ, $180^o - \theta$,$180^o + \theta$, and $360^o - \theta$. Note that this steel alloy exhibits four ears located at RD and TD, the largest height being observed at TD, and the minimum height being at 45^o to the RD.

Concerning the setup for the F.E. simulations, due to geometrical and material symmetries, only a quarter of the cup needs to be modeled. The blank is discretized with 17820 ABAQUS C3D8H elements (8 node brick elements with constant pressure). In all the simulations conducted, the friction coefficient between the blank and the tools is set to 0.03. The blank holder force is of 50 kN. This DC06 alloy is characterized by a Young modulus, E = 200 GPa and a Poisson coefficient $\upsilon = 0.3$. Hardening is considered isotropic. It is modeled with a Swift-type law $\sigma_0 = 529.5(0.0043 + \bar{\varepsilon}^p)^{0.268}$. As expected, if the anisotropy of the material

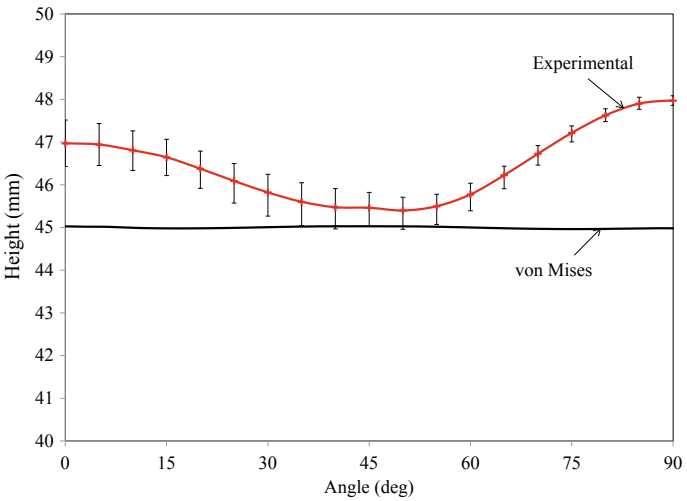

Fig. 1 Experimental cup height versus angle to RD and F. E. predictions according to the isotropic von Mises yield criterion for steel alloy DC06. The data points were averaged over the four quarters of the cup (after [8, 12]). (Color figure online)

is neglected, the earing profile cannot be captured (see Fig. 1). Nevertheless, the cup height according to the von Mises criterion, which is of 44.98 mm, is a good approximation of the experimental average height, $h_{avg}^{\exp} = 46.8$ mm.

3 Predictions of the Orthotropic Yield Criteria Yld91 and Hill Identified Analytically Using a Reduced Data Set

Yld91 yield function is an extension to orthotropy of the isotropic Hershey-Hosford yield function (see [5]). Its expression is given by:

$$\text{YLD91} = \left|\tilde{S}_1 - \tilde{S}_2\right|^m + \left|\tilde{S}_2 - \tilde{S}_3\right|^m + \left|\tilde{S}_3 - \tilde{S}_1\right|^m = 2\bar{\sigma}^m \tag{1}$$

In Eq. (1), $\tilde{S}_k$ are the eigenvalues of a transformed tensor $\tilde{\mathbf{S}}$, defined as

$$\tilde{\mathbf{S}} = \mathbf{C}\sigma \tag{2}$$

with the fourth-order tensor $\mathbf{C}$ being orthotropic, symmetric (i.e. $C_{ijkl} = C_{klij} = C_{jikl}$ for $i, j, k, l = 1\ldots3$), and deviatoric. Relative to the Cartesian coordinate system associated to the orthotropy axes (i.e. RD, TD, ND in the case of a rolled sheet), this tensor is represented by a 6×6 matrix with six non-zero components a, b,$\bar{c}$, f, g, h. For materials with the same behavior in tension and compression, the exponent m should be a positive even integer (see [11]). Specifically, Barlat et al. [5] recommends m =6 for BCC materials, and m =8 for FCC materials. Very recently, the explicit expression of Yld91 in terms of stresses was obtained. It was demonstrated that irrespective of the value of m, Yld91 is a homogeneous polynomial in the components of the Cauchy stress (see [1, 2]). In particular, for $m = 6$:

$$\text{YLD91} = \left(\tilde{S}_1 - \tilde{S}_2\right)^6 + \left(\tilde{S}_2 - \tilde{S}_3\right)^6 + \left(\tilde{S}_1 - \tilde{S}_3\right)^6 = 66\tilde{J}_2^3 - 81\tilde{J}_3^2, \tag{3}$$

where $\tilde{J}_2 = tr\left(\tilde{\mathbf{S}}^2\right)/2$ and $\tilde{J}_3 = tr\left(\tilde{\mathbf{S}}^3\right)/3$ are the second and third-invariant of the transformed stress tensor $\tilde{\mathbf{S}}$, respectively. The expressions of $\tilde{J}_2$ and $\tilde{J}_3$ can be easily obtained by making use of (2) and are given by

$$\tilde{J}_2 = f^2\sigma_{yz}^2 + g^2\sigma_{xz}^2 + h^2\sigma_{xy}^2 + \left[(b+\bar{c})\sigma_{xx} - \bar{c}\sigma_{yy} - b\sigma_{zz}\right]^2/18 + \left[-\bar{c}\sigma_{xx} + (\bar{c}+a)\sigma_{yy} - a\sigma_{zz}\right]^2/18 + \left[-b\sigma_{xx} - a\sigma_{yy} + (a+b)\sigma_{zz}\right]^2/18 \tag{4}$$

$$\tilde{J}_3 = 2(fgh)\,\sigma_{xy}\sigma_{xz}\sigma_{yz} + \frac{1}{27}\begin{bmatrix}\left[(b+\bar{c})\sigma_{xx} - \bar{c}\sigma_{yy} - b\sigma_{zz}\right]\cdot\left[-\bar{c}\sigma_{xx} + (\bar{c}+a)\sigma_{yy} - a\sigma_{zz}\right]\cdot \\ \left[-b\sigma_{xx} - a\sigma_{yy} + (a+b)\sigma_{zz}\right]\end{bmatrix} - \frac{f^2\sigma_{yz}^2}{3}\left[(b+\bar{c})\sigma_{xx} - \bar{c}\sigma_{yy} - b\sigma_{zz}\right] - \frac{g^2\sigma_{xz}^2}{3}\left[-\bar{c}\sigma_{xx} + (\bar{c}+a)\sigma_{yy} - a\sigma_{zz}\right]$$

$$-\frac{h^2\sigma_{xy}^2}{3}\left[-b\sigma_{xx}-a\sigma_{yy}+(a+b)\sigma_{zz}\right] \tag{5}$$

As mentioned, using the polynomial representation of Yld91 given by Eq. (3), Cazacu [2] demonstrated that the anisotropy coefficients are expressible only in terms of experimental yield stresses or experimental r-values. Specifically, it was shown that the anisotropy coefficients a, b, $\bar{c}$ are expressible only in terms of σ_0, σ_{90}, and σ_b the yield stress in equibiaxial tension. The in-plane coefficient h can be easily obtained using a simple formula involving the coefficients a, b, $\bar{c}$ and σ_{45}, the experimental value of the uniaxial yield stress at 45^0 to RD. It was also demonstrated that the same coefficients a, b, $\bar{c}$ can be expressible only in terms of the Lankford coefficients r_0 and r_{90}, while the coefficient h can be expressed in terms of a, b, $\bar{c}$ and r_{45}, the r-value at 45^0 to RD (for more details see [2]). For DC06, the values of the anisotropy coefficients of Yld91 criterion identified using these two analytical procedures are given in Table 2. In the same table are also reported the values of the coefficients involved in Hill criterion, which was also identified with analytical formulas involving only σ_0, σ_{45},σ_{90}, and σ_b (stress-based procedure) and r_0, r_{45} and r_{90} (r-values based procedure), respectively (for these formulas, e.g. see [1]).

3.1 Predictions of the Orthotropic Yield Criteria Yld91 and Hill [4] Identified Analytically Using Four Yield Points

Let us first discuss the predictions obtained with Hill and Yld91 criteria identified analytically using only σ_0, $\sigma_{45}\sigma_{90}$, and σ_b. Figure 2a–b show the theoretical evolution of the yield stress and Lankford coefficients in the plane of the sheet (i.e. (**x**,**y**) or (RD, TD) according to Hill and Yld91 criteria, respectively, in comparison with the experimental yield stresses for the DC06 alloy; the projection of the respective yield surfaces in the $(\sigma_{xx}, \sigma_{yy})$ plane are plotted in Fig. 2c. Note that the predictions of the anisotropy in yield stresses predicted with these criteria are practically the same while the yield surface according to Yld91 is a very slight upper bound of Hill's. Neither criterion captures nor the experimental trends in r-values (see Fig. 2). As concerns the cup drawing predictions, let us note that both models predict an average cup height close to the experimental one. Yld91 criterion predicts $h_{avg} = 45.94$ mm versus $h_{avg} = 45.31$ mm according to Hill, the experimental average height being of 46.08 mm.

However, the improvements in predictions with respect to von Mises criterion concern only average values of the cup height. While data show that the maximum cup height is at TD and the minimum at 45° to the RD, both Yld91 and Hill [4] criteria predict the maximum cup height around 45° to the RD and the minimum at TD. Also, the predicted amplitudes of the ears are much lower than the ones observed experimentally (see Fig. 3).

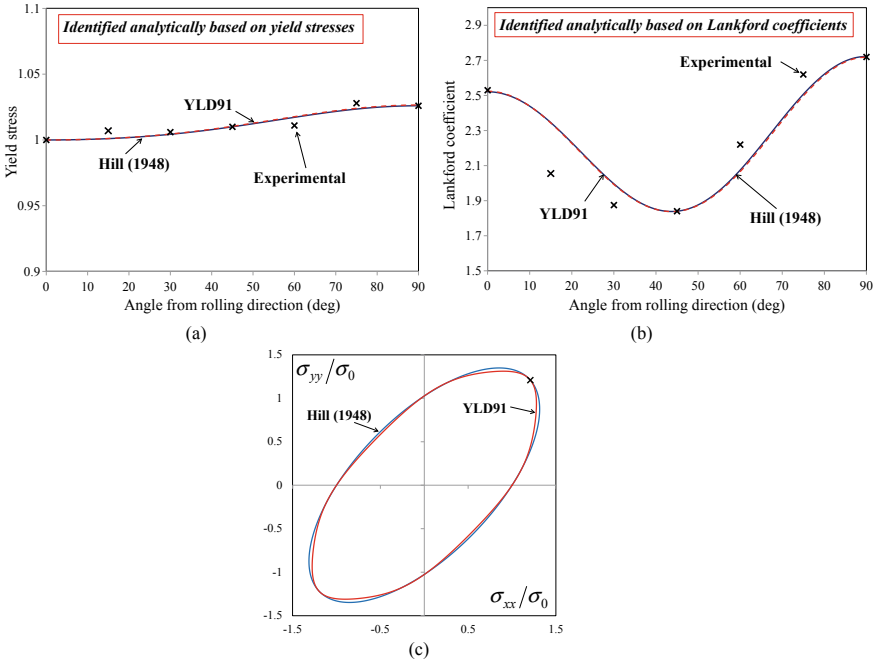

Fig. 2 **a** Evolution of the uniaxial yield stress versus the angle to RD; **b** Variation of the Lankford coefficients; **c** Yield surfaces in the biaxial plane $(\sigma_{xx}, \sigma_{yy})$ for DC06 according to Hill and Yld91. Data after [8, 13, 14]. (Color figure online)

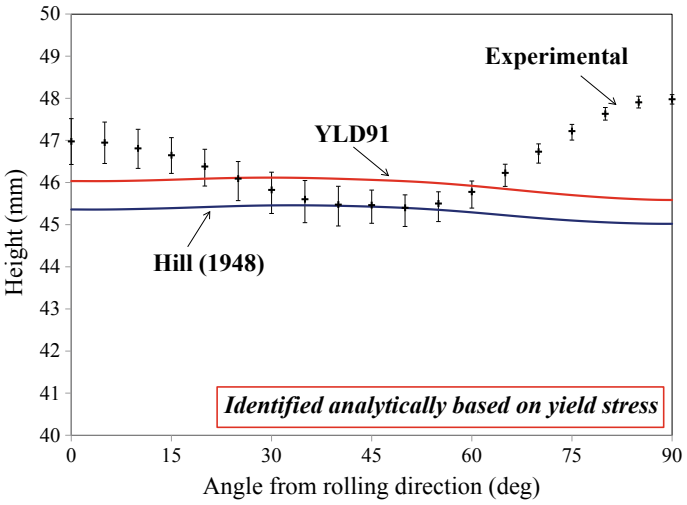

Fig. 3 Earing profile for the DC06 cup according to Yld91 and Hill [4] criteria. Both criteria were identified analytically using only the yield stresses. (Color figure online) σ_0, σ_{45}, σ_{90}, and σ_b. Data after [8, 12]

3.2 *Predictions of the Orthotropic Yield Criteria Yld91 and Hill Identified Analytically Using Only:r_0, r_{45},r_{90}*

The predictions obtained with Hill [4] and Yld91 criteria identified analytically using only the experimental r-values:r_0, r_{45},r_{90} are shown in Figs. 4 and 5.

Let us first note that the predictions of the anisotropy in Lankford coefficients of the steel alloy DC06 are practically the same. Both criteria predict the same variation of the yield stresses in the plane of the sheet, and both criteria greatly overestimate the experimental values. In the biaxial plane the projection of the yield surface according to the Yld91 criterion is interior to the one according to Hill, with Yld91 being in better agreement with the experimental equibiaxial tensile yield stress (see Fig. 4c). Both yield criteria predict the development of four ears at RD and TD, and a minimum height at 45° to the RD (see Fig. 5). In the experiment, the maximum height is at TD whereas either criterion predicts the maximum height at RD.

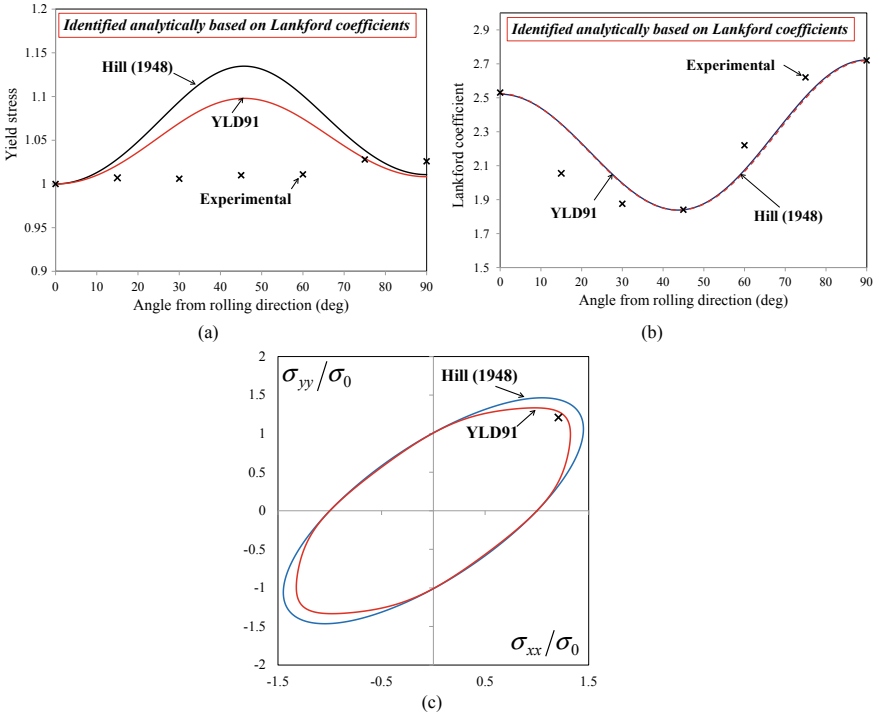

Fig. 4 Comparison between experimental and predicted plastic anisotropy of steel alloy DC06: **a** Evolution of the uniaxial yield stress versus the angle to RD; **b** Variation of the Lankford coefficients; **c** Projection of the yield surfaces in the biaxial plane according to Yld91 and Hill [4] yield criterion. Both criteria were identified analytically using only experimental Lankford coefficients r_0, r_{45},r_{90}. Data reported in [8, 13, 14]. Stresses are normalized by σ_0, the yield stress in uniaxial tension along RD. (Color figure online)

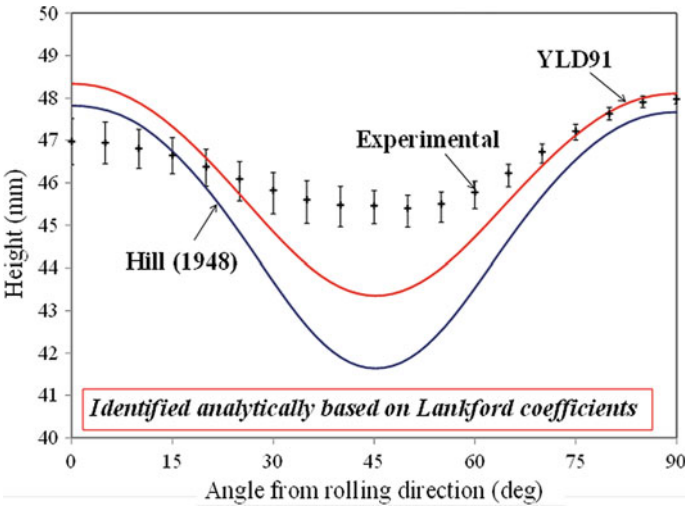

Fig. 5 Earing profile for the DC06 cup according to Yld91 and Hill [4]. Both criteria were identified analytically using experimental Lankford coefficients r_0, r_{45},r_{90}. Data after [8, 12]. (Color figure online)

Although both yield criteria predict the same variation in Lankford coefficients in the plane of the sheet (see Fig. 4b) and match exactly the average experimental r-values at 0^o, 45^o, 90^o to RD, the predictions of the average cup height are different, 44.98 mm according to Hill vs. 45.93 mm according to Yld91. In summary, it can be concluded that these yield criteria do not predict accurately the mechanical behavior of DC06 alloy in cup drawing.

4 Predictions Based on Yld91 and Cazacu [6] Orthotropic Yield Criteria Identified Using All Available Data

4.1 Predictions According to YLD 91 Criterion Calibrated Numerically Using All Available Data

Using the new mathematical results obtained recently in [1–3] for orthotropic yield criteria involving one linear transformation, it becomes now possible to compare the influence of the calibration method, namely, analytical vs. numerical, on the forming predictions. For this purpose, Yld91 was also calibrated numerically using all the available mechanical data for the steel alloy DC06, namely, the experimental r-values and uniaxial yield stresses in seven in-plane orientations, and the equibiaxial stress point. In the cost function all data points were given equal weights.

Note that the optimization algorithm leads to a better description of the experimental Lankford coefficients than that of the yield stresses in the plane of the DC06 sheet. Moreover, the predicted anisotropy in yield stresses and r-values obtained with the set of anisotropy coefficients determined with the numerical calibration procedure is similar to that obtained using the anisotropy coefficients evaluated using analytical formulas and the experimental r_0, r_{45},r_{90} (see Fig. 6b). This is because Yld91 cannot predict at the same time a very weak anisotropy in uniaxial yield stresses and a pronounced anisotropy in r-values. Note that the predicted earing profile obtained using the set of anisotropy coefficients determined with the optimization algorithm is very close to the one obtained using the r-values based identification strategy (see Fig. 6c). Practically, the same average height (45.96 mm vs. 45.93 mm), and the same locations and numbers of ears are obtained. Simulations were also done with Hill's criterion identified numerically using all available dataset. Same conclusions as for

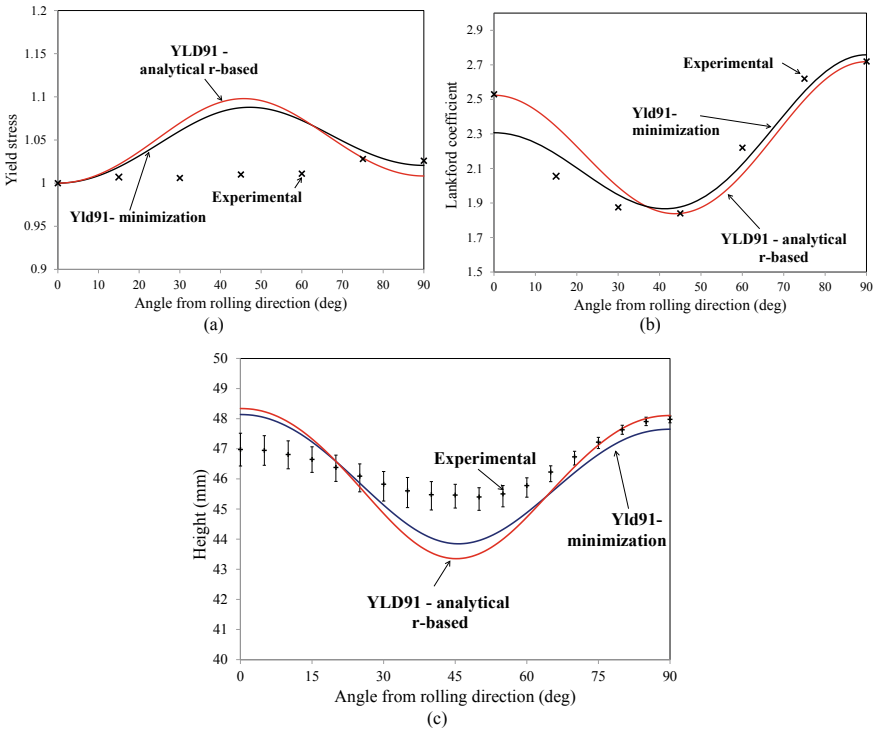

Fig. 6 **a** Evolution of the yield stress versus the angle to RD. **b** Evolution of the Lankford coefficient versus the angle to RD **c** Variation of the cup height versus the angle to RD according to Yld91 yield criterion for two sets of anisotropy coefficients: one determined analytically using only Lankford coefficients (red), and the other obtained by minimization in conjunction with all available data for steel alloy DC06 (black). Stresses are normalized by σ_0, the yield stress in uniaxial tension along RD. Data reported in [8, 13, 14]. (Color figure online)

Yld91 can be drawn concerning the accuracy of the predictions and the influence of the identification procedure and extent/type of data used for identification.

4.2 Predictions According to the Cazacu [6] Criterion

As seen previously the Hill or the Yld91 criteria cannot predict accurately the amplitude of the ears during the cup drawing application. One of the reasons is that the mathematical form of these criteria imposes very specific couplings between the r-values and yield stresses along RD and TD. In the following, the orthotropic criterion of Cazacu [6] will be applied to the same material. This yield criterion is expressed in terms of orthotropic invariants J_2^o, J_3^o as follows:

$$H\left(J_2^0, J_3^0\right) = \left(J_2^0\right)^4 - \alpha\left(J_3^0\right)^2\left(J_2^0\right) \tag{6}$$

where α is a parameter. These orthotropic invariants were developed based on rigorous representation theorems for tensor functions (for more details on the theorems used see Cazacu et al. [1], for the full mathematical proofs and the details concerning the derivation of Eq. (7) and Eq. (8) see Cazacu and Barlat [7]). As a consequence, it was ensured that the combinations of stress components that are involved in their expressions and the number of anisotropy coefficients are such as to fulfill the restrictions associated to orthotropic symmetries. Specifically, the orthotropic second-invariant J_2^o should involve exactly 6 anisotropy coefficients, a_i, $i = 1\ldots6$ and should be of the form:

$$\begin{aligned} J_2^o = {} & \frac{a_1}{6}\left(\sigma_{xx} - \sigma_{yy}\right)^2 + \frac{a_2}{6}\left(\sigma_{yy} - \sigma_{zz}\right)^2 + \frac{a_3}{6}\left(\sigma_{xx} - \sigma_{zz}\right)^2 + a_4\sigma_{xy}^2 \\ & + a_5\sigma_{xz}^2 + a_6\sigma_{yz}^2 \end{aligned} \tag{7}$$

while the third-order orthotropic invariant J_3^o should involve 11 anisotropy coefficients b_k, $k = 1\ldots11$and should be of the form:

$$\begin{aligned} J_3^o = {} & \frac{1}{27}(b_1 + b_2)\sigma_{xx}^3 + \frac{1}{27}(b_3 + b_4)\sigma_{yy}^3 + \frac{1}{27}[2(b_1 + b_4) - b_2 - b_3]\sigma_{zz}^3 \\ & - \frac{1}{9}\left(b_1\sigma_{yy} + b_2\sigma_{zz}\right)\sigma_{xx}^2 - \frac{1}{9}(b_3\sigma_{zz} + b_4\sigma_{xx})\sigma_{yy}^2 \\ & - \frac{1}{9}\left[(b_1 - b_2 + b_4)\sigma_{xx} + (b_1 - b_3 + b_4)\sigma_{yy}\right]\sigma_{zz}^2 + \frac{2}{9}(b_1 + b_4)\sigma_{xx}\sigma_{zz}\sigma_{yy} \\ & - \frac{\sigma_{xz}^2}{3}\left[2b_9\sigma_{yy} - b_8\sigma_{zz} - (2b_9 - b_8)\sigma_{xx}\right] - \frac{\sigma_{xy}^2}{3}\left[2b_{10}\sigma_{zz} - b_5\sigma_{yy} - (2b_{10} - b_5)\sigma_{xx}\right] \\ & - \frac{\sigma_{yz}^2}{3}\left[(b_6 + b_7)\sigma_{xx} - b_6\sigma_{yy} - b_7\sigma_{zz}\right] + 2b_{11}\sigma_{xy}\sigma_{xz}\sigma_{yz} \end{aligned} \tag{8}$$

Cazacu [6] criterion was calibrated numerically using all the available mechanical data for the steel alloy DC06, namely the experimental r-values and uniaxial yield

stresses in seven in-plane orientations and the equibiaxial yield stress point. The predictions according to this criterion are shown in Fig. 7. Note that the criterion describes reasonably well both the anisotropy in yield stresses and r-values in the plane of the sheet. Most importantly, it predicts correctly the earing profile (Fig. 7c). Specifically, it predicts that four ears develop at RD and TD, and that the minimum height is at 45° to the RD. In contrast to Yld91 and Hill criteria, this criterion predicts that the maximum cup height is at TD, as observed experimentally. Moreover, the predicted average height obtained is of 46.11 mm, i.e. very close to the experimental value of 46.8 mm.

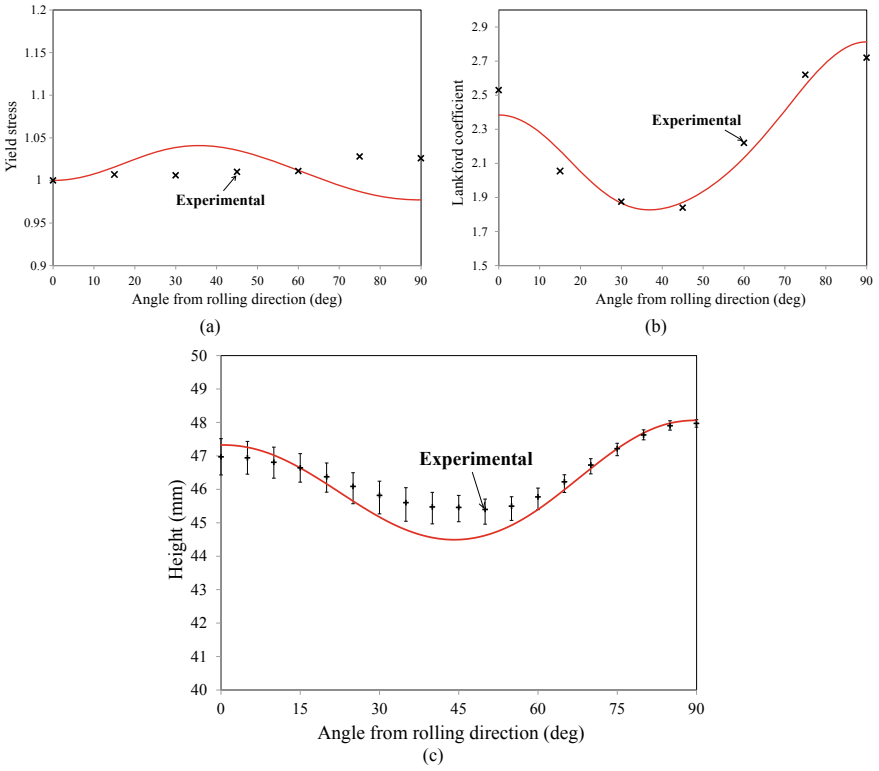

Fig. 7 Comparison between the experimental data and predictions according to Cazacu [6] orthotropic yield criterion for the steel alloy DC06: **a** Evolution of the yield stress vs. the angle to RD. **b** Evolution of the Lankford coefficient versus the angle to RD **c** Variation of the cup height vs. the angle to RD. Data from [8, 12, 14]. (Color figure online)

5 Conclusions

Using the new equivalent representation of Yld91 in terms of stresses (see Eq. (3)), this criterion can be identified analytically using four experimental yield stresses or three experimental Lankford coefficients, respectively (for more details, see [2]). This makes the parametrization of Yld91 very simple and reliable even if the mechanical characterization data set available is limited. Illustrations of the benefits of using the new explicit expression of Yld91 and the analytical identification procedures were presented for a strongly anisotropic steel alloy, DC06. Specifically, the influence of the type of data used for identification (i.e. only experimental yield data or only experimental Lankford coefficients) and the extent of the data set used for identification (i.e. limited data set or all available data set) on the accuracy of cup forming predictions were analyzed. Hill and Cazacu [6] criterion were also applied to DC06 and an in-depth analysis of the influence of the choice of the criterion used for modeling on the accuracy of the predictions was presented. If Yld91 and Hill criteria are identified using a stress-based analytical identification procedure, the predictions of the plastic anisotropy in r-values in the plane of the sheet and the predicted experimental earing profile are incorrect. Only the prediction of the average cup height is an improvement with respect to the von Mises yield criterion. Correct predictions in terms of number and location of ears and location of the minimum height are obtained with parametrizations obtained using analytical expressions involving the Lankford coefficients. It is worth mentioning that if the r-values based analytical identification strategy is used for Yld91, the predictions are slightly more accurate than those obtained with Hill [4]. Also, only a very slight improvement in accuracy is obtained if for the identification of the anisotropy coefficients of Yld91 all the available mechanical data are used. The most accurate predictions for DC06 are obtained using Cazacu [6] yield criterion, which can describe both the weak anisotropy in uniaxial yield stresses and the strong anisotropy in r-values of the material. In contrast to Yld91 [5] and Hill [4] criteria, Cazacu [6] yield criterion captures all the experimentally observed characteristics of the fully drawn cup of DC06 steel, i.e. the average height, the number and location of ears, the location of the maximum height of the fully drawn cup, and the amplitude.

Experimental Investigation of Different WAAM (Wire-Arc Additive Manufacturing) Processes and Their Influence on the Component Properties and Formability

Pascal Colditz, Marcel Graf, André Hälsig, Sebastian Härtel, Keval P. Prajadhiama, Yupiter P. Manurung, and Birgit Awiszus

Abstract Wire-arc additive manufacturing (WAAM) complex components can be built-up layer by layer from metallic construction materials. In this investigation two different WAAM processes with high built-up rates (CMT and pulsed GMAW) were compared in terms of geometry formation and component properties. The reference is a rectangular thin-walled geometry made of the austenitic stainless steel 316LSi (1.4430). During the welding process, the temperature development in the weld layer was measured. The experimental comparison of CMT (R_m = 630MPa) and pulsed GMAW (R_m = 605MPa) is completed by the determination of the mechanical properties using micro-tensile tests. Furthermore, the additive-manufactured walls were cold rolled with a subsequent heat treatment or hot rolled to provide proof of formability and forming induced property improvement.

Keywords WAAM · CMT · Pulsed GMAW · Additive manufacturing · Forming behavior

1 Introduction

Additive manufacturing processes have become much more popular in recent years. Due to various technological developments, metals and metallic composite materials can now also be processed. Additive Manufacturing base on the layer by layer

structure of components. For this purpose, the starting material is locally melted and solidified by an external energy supply and thus the individual layers are connected with each other. Accordingly, the additive manufacturing processes can be divided into solid, powder, or fluid based. For the processing of metallic materials, wire and powder-based processes are of primary importance. As energy sources, for example, laser technologies or arc processes can be used [1, 2].

With the wire-arc additive manufacturing (WAAM), the first step is to slice the previously created CAD model into layers. Afterward the individual layers are applied using a gas metal arc welding (GMAW) process. The handling of the welding torch to create the 2D contours can be carried out by robotic systems or computer numerical controlled gantries. Compared to powder-based processes, the WAAM is characterized by higher output rates, inexpensive materials, low investment costs, and easy handling. Disadvantages are the significantly lower surface quality and the geometrical accuracy of the components [2]. In addition, the process-related heat input can lead to high internal stresses and thus to component distortion. In order to reduce this heat input during the welding process considerably, corresponding process control variants have been developed from the classic GMAW process [3].

One possibility to reduce the heat input during welding is to use the *Cold Metal Transfer* (CMT) process from *Fronius International GmbH*. While conventional GMAW technologies feed the wire continuously, here the wire is fed oscillating in frequencies up to 130 Hz. The pull back of the wire supports the drop separation. As a result, the short-circuit current is very low and the material transfer takes place almost without electrical current. In addition, the short circuit does not happen in an uncontrolled manner but is timed by the pull back of the wire. These two properties result in a low heat input with nearly spatter-free welding seams. At the same time, the component quality, the build-up rate (1500 cm^3/h) and the output rate (99%) can be increased [4, 5].

Another method to reduce the heat input is to combine the GMAW with a pulsed arc. In this process, the power source is periodically switched between a low basic electrical current and a higher pulse elecrical current. The basic and pulse phases must be adapted to the wire feed. In the initial phase the wire is preheated by the arc. In the subsequent pulse phase the material is melted and afterward transferred. Thus the impulse arc process is a short-circuit free process. This reduces the heat input. In addition, similar high build-up rates can be achieved as with CMT and the macroscopic surface quality is even better. Disadvantages are the lower output and the higher spattering rate [4–6].

The aim of the investigation is to provide proof of formability and forming induced property improvement of the additive-manufactured walls and do compare the two different WAAM processes. Therefore, the components were cold rolled with a subsequent heat treatment or hot rolled, which will be discussed in the following chapters.

2 Experimental Investigation

In order to be able to compare both investigated WAAM processes, a rectangular, thin-walled component made of 316LSi (1.4430) was used as reference geometry with a length of 105mm, a width of 25mm and a height of approximately 42,5mm. (Figs. 1 and 2). This material is usually used as a welding filler for austenitic, stabilized, and unstabilised Cr-Ni-Mo steels. The material was applied to a base plate made of X5CrNi18-10 (1.4301) without pausing between the individual layers.

The following parameters were used for the component manufacturing:

- Wire diameter $d_W = 1,2$mm
- Welding speed $v_{CMT} = 40$cm/min, $v_{pulsed} = 42$cm/min,

Cu	<0,75%	0,90%	0,77%
Fe	bal	64,81%	65,53%

- Speed of the wire feed $v_{Wire} = 3$m/min
- Layer height $h_W = 1{,}7$mm
- Initial thickness of the walls $t_W = 6$mm
- Amperage $I_{CMT} = 110$A, $I_{pulsed} = 88$A
- Voltage $U_{CMT} = 13,5$V, $U_{pulsed} = 21$V
- Inert gas CMT 15 l/min; 97, 5% Argon and 2, 5% CO_2;
- Inert gas Pulsed 15l/min; 100% Argon.

In order to document the initial state of the material and to better understand the microstructural changes, the chemical composition of the material before and after the welding process was measured using EDX (Energy Dispersive X-ray Spectroscopy), see Table 1. A wire section was used to measure the material before and a specimen produced by pulsed arc welding to measure the material after welding.

The alloying elements carbon (C), phosphorus (P), and sulfur (S) cannot be reliably detected with the EDX method due to their low atomic mass. The EDX analysis shows a significant decrease in the alloy contents of silicon (Si), nickel (Ni), copper (Cu) due to the arc-related burn off. It can also be assumed that the titanium (Ti) content is reduced by the fusion with carbon to form titanium carbides. During the welding process, the floating of silicate islands can also be seen.

In order to be able to analyze the microstructural changes of the welding filler material during the additive manufacturing, the temperature level in the middle of the side wall were measured, see Fig. 2. For this purpose, a thermocouple type K was welded directly into the component on top of layer 10. The diagram for CMT shows a temperature peak of $\vartheta = 1330$ °C shortly after welding of the wire material and a subsequent cyclical reheating of the welded layer. In the pulsed arc process the temperature after melting is around $\vartheta = 1315$ °C. Both processes show a nearly

similar temperature curve with a low heat input for WAAM processes. In pulsed WAAM the material cools down marginally faster.

To be able to determine and compare the mechanical properties of the additive-manufactured components, hardness measurements, and tensile tests were carried out. For this purpose, the components were separated at the front sides. The respective long sides of the component were machined on both side to a thickness of 2mm, and micro-tensile specimen with an initial cross section of 4mm^2 and a measuring length of 6mm was taken by wire erosion (see Fig. 3). All of the corresponding tensile tests were carried out with the *Galdabini Quasar 50* test press, at a constant forming speed of $\dot{\varphi} = 0{,}1\text{s}^{-1}$ and at room temperature. During the tests, the pulling force and lengthening of the specimen were measured (Fig. 4). Taking into account the specimen geometry, a corresponding stress–strain diagram could then be calculated, see Fig. 5. The end faces were prepared for hardness measurements and microstructure

analysis (see Figs. 3 and 4).

The cyclical reheating during both WAAM processes, due to the further layer wise material application is similar to a repeated heat treatment of the material. While a cast structure is occurred immediately after the melting and the application of the wire material, the microstructure is influenced by the following heat treatment. During the investigation of WAAM with low-alloy (G4Si1, 1.5130) welding filler material, a cast structure was occurred after melting and application of the wire material. This structure was strongly globularly shaped by the subsequent repeated heat treatment. With the used material 316LSi no such clear microstructural differences between the individual layers could be detected. The entire specimen cross section shows a microstructure without pronounced grains (see Fig. 4). This indicates that the repeated application of temperature by the welding process does not cause any significant microstructural changes.

This is confirmed by the hardness measurements, which show an almost constant level over the height of the specimen. With the CMT process an average hardness of 209HV could be achieved. The hardness of the sample layer produced by means of the pulsed arc method at 207HV. According to standard ISO 18265 there is a direct relationship between hardness and tensile strength of a material [8]. Based on this relationship, the tensile strength of the two graphs should be significantly higher. The measured tensile strengths also fluctuate over the amount of micro-tensile samples tested. A possible reason for the difference between hardness measurements and tensile tests is the large number of pores in the material, which are created during the welding process (see Fig. 6). The pore creation is favored by the high silicon content in the material [9].

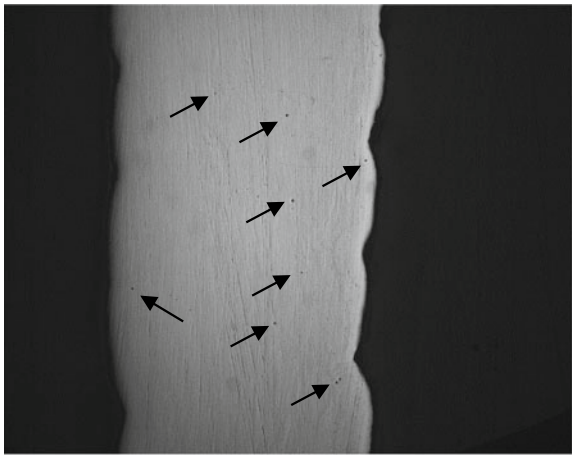

Fig. 6 Microsection specimen with clearly recognizable pores

2.1 Cold Forming and Subsequent Heat Treatment at 850 °C

In order to investigate the influence of cold forming on the additively manufactured components, a side wall was rolled to a thickness of 4mm before sampling. With a layer thickness of about 6mm this corresponds to a plastic strain of $\varphi = 0{,}4$. Afterward the walls were heat treated at 850 °C for one hour to induce static recrystallization effects. As already in the investigations of the initial states of the components, the micro-tensile samples were finally taken by means of machining and wire erosion. In addition, the microstructure was examined again, and hardness measurements were carried out.

Compared to the initial state, the specimen of both WAAM variants show a significantly changed microstructure (see Fig. 7). The cast-like microstructure could be transformed into a more globular structure by forming with subsequent heat treatment due to the static recrystallization.

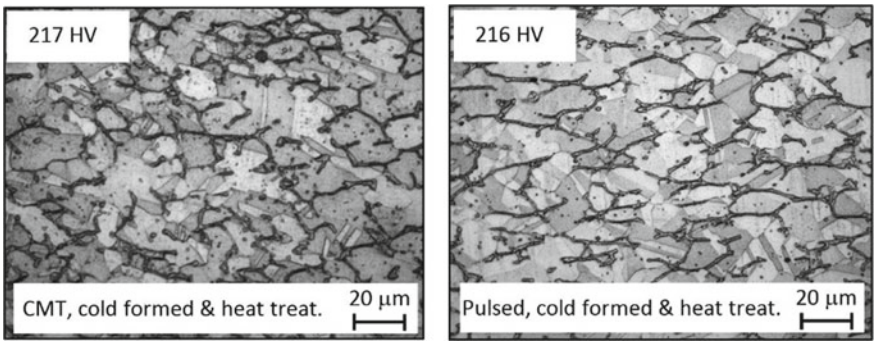

Fig. 7 Microstructure of cold rolled and heat treated (850 °C, 1 h) specimens; $\varphi = 0{,}4$

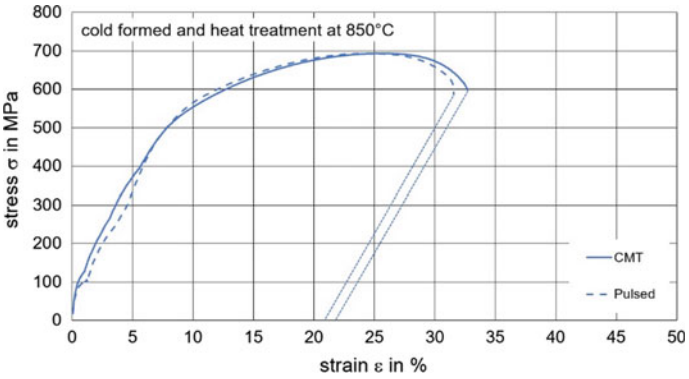

Fig. 8 Stress–strain diagram of the cold rolled $\varphi = 0, 4$ and heat-treated (850 °C, 1 h) specimen. (Color figure online)

It now shows a clearly recognizable grain structure and orientation. Both samples show that there is still a slight elongation of the grains. This indicates that recrystallization has not yet been completely finished. In addition, precipitates collect at the grain boundaries. These could be carbides or locally diffused delta ferrite [10]. The specimen manufactured by the CMT method shows a slightly finer microstructure. Otherwise, both microstructures are very similar. The same applies to the hardness measurements. Both samples achieve a hardness of about 215HV (see Fig. 7).

The stress–strain diagram shows a tensile strength of around $R_m = 690$MPa for both specimen (see Fig. 8). Furthermore, shows a very good agreement between CMT and pulsed WAAM. With the help of cold forming and subsequent recrystallization annealing it was possible to increase the strength of the specimen and to homogenize the mechanical properties. With an appropriately adapted heat treatment at higher temperatures, recrystallization in the material could probably be completed. This could further improve the mechanical properties with regard to higher elongation at break.

2.2 Heat Treatment at 850 °C

In order to be able to prove the influence of cold forming on the microstructural transformations taking place during heat treatment, comparative specimen without previous forming were examined. For this purpose, the additive walls were heat treated at 850 °C for one hour before sampling.

The micro-section specimens prepared for this purpose show clear differences in microstructure (see Fig. 9).

This differs very much from the cold formed and heat-treated specimens. While with these a clear grain structure and orientation was previously visible, the grains now can only be recognized by the precipitates at the grain boundaries. This clearly

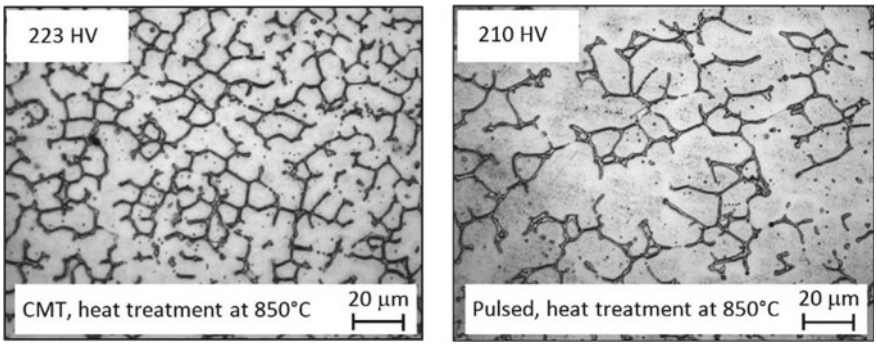

Fig. 9 Microstructure of heat treated (850 °C, 1 h) specimens; $\varphi = 0, 4$

shows that the microstructural transformations necessary for grain formation and growth are strongly dependent on the plastic strain previously introduced.

Here too, the CMT sample has a finer grain structure. Even though the microstructures differ more clearly, the mechanical properties are again almost the same. Due to the more fine-grained structure, the hardness value of the CMT sample at 223HV is slightly higher than that of the specimen produced by means of pulsed arcing (210HV). The curve profiles determined by means of a tensile test, however, are very similar again. As with specimen in their initial state, there is a clear difference between the hardness values and the associated measured tensile strengths (see Fig. 10). Here also the cause could be pores. At the same time, this allows the assumption that these pores could be partially eliminated by the preceding forming in Sect. 2.1.

Compared to the initial state, the mechanical properties of the specimens could not be significantly improved by the heat treatment, neither in terms of strength nor in terms of formability.

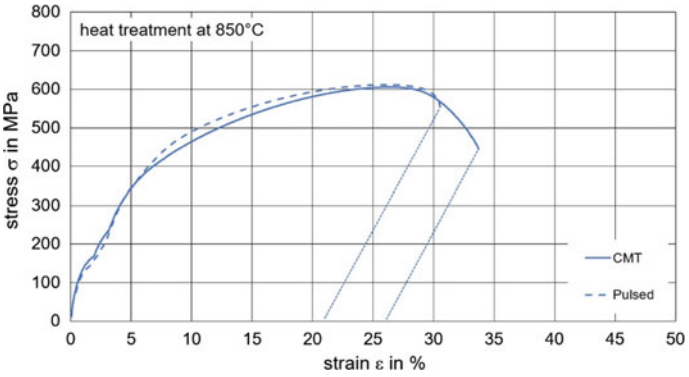

Fig. 10 Stress–strain diagram of the heat-treated (850 °C, 1 h) specimen. (Color figure online)

2.3 Hot Forming at 1150 °C

A further possibility to optimize the mechanical properties of the additive-manufactured components is a subsequent hot forming. For this purpose, the additive-manufactured samples were heated to 1150 °C in a chamber furnace, hot-rolled and then slowly cooled down at room temperature. To ensure comparability with cold forming, the degree of deformation here was also $\varphi = 0,4$.

The microstructural analyses of the hot-formed specimen show a completely different picture from all previous ones (see Fig. 11). Although a grain structure can also be seen here and the precipitates do not collect predominantly at the grain boundaries, as with all previous ones. Both samples show a similar structure independent of the WAAM process. The same applies to the hardness measurement (see Fig. 11). Here both are on a similar level. Compared to the initial state, the hardness could be increased to about 260HV. The increase in the hardness of the material in combination with a coarser grain structure strongly indicates that hot forming is not sufficient to fully complete dynamic recrystallization processes. The remaining hardening of the material, therefore, explains the high measured hardness values.

The stress–strain diagram determined by the tensile tests also shows similar courses for WAAM processes (see Fig. 12).

The strong increase and the low elongation at break of both materials indicate a clear increase in strength of the material achieved by hot forming. The material behaves correspondingly more brittle than in the initial state. The elongation at break was reduced to below $A < 22\%$. This supports the assumption that dynamic recrystallization cannot be completely finished at a plastic strain of $\varphi = 0,4$. A reason for this is the low temperature in the forming zone due to the heat loss when removing from the furnace and the heat transfer into the cold rolls. Similar effects have already been demonstrated in previous investigations on the rolling of weld seams made of G4Si1 (1.5130) [11].

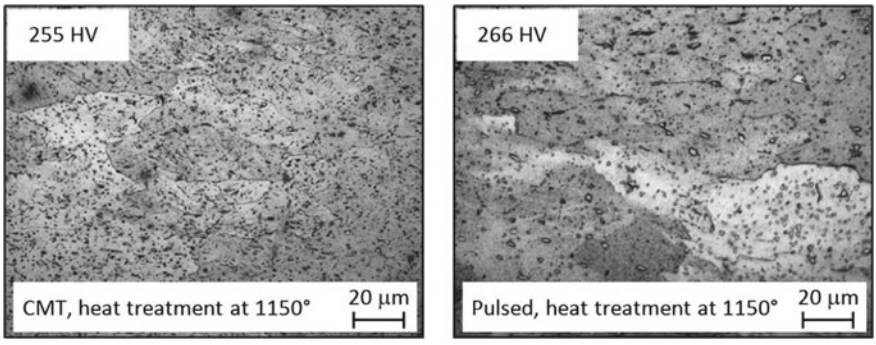

Fig. 11 Microstructure of hot rolled (1150 °C) specimen; $\varphi = 0,4$

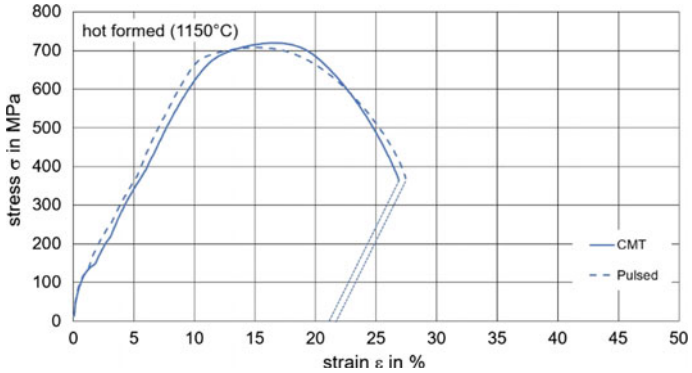

Fig. 12 Stress–strain diagram of the hot rolled $\varphi = 0, 4$ (1150 °C) specimen. (Color figure online)

2.4 Heat Treatment at 1150 °C

Also, for hot forming the influence of forming shall be analyzed by comparison with a simple heat treatment. For this purpose, the additive prepared samples were heated to 1150 °C, the temperature was maintained for 10min (according to the duration of the heat treatment during hot forming) and the samples were then slowly cooled down at room temperature. The components were then machined again, and the micro-tensile samples were taken by wire erosion. The microstructure obtained by heat treatment similar to the hot-formed samples (see Fig. 13). A grain structure with clearly grown grains can also be seen here.

In contrast to the hot-formed samples, however, a significantly lower hardness could be measured for both samples at around 175HV. This is a good approximation of the tensile strength of around $R_m = 560$MPa achieved in the tensile test (see Fig. 14). Regarding the course of the stress–strain curve, the only difference between process variants is the elongation at break. At A = 38% for CMT, the elongation at

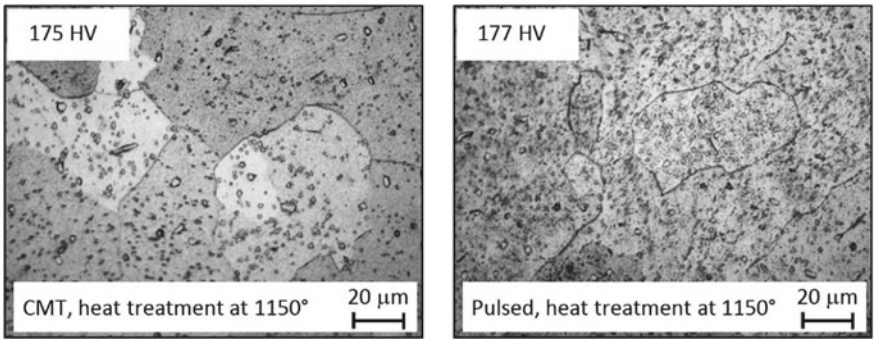

Fig. 13 Microstructure of heat treated (1150 °C, 10 min) specimen

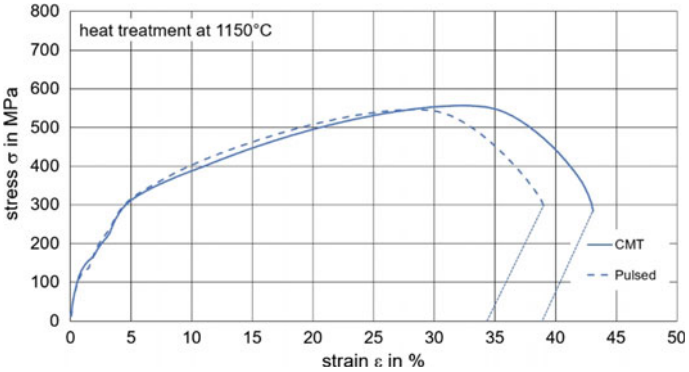

Fig. 14 Stress–strain diagram of the heat treated (1150 °C, 10 min) specimen. (Color figure online)

break is well above A = 34% for pulsed arc welding (see Fig. 14). The analysis of the hardness measurement and the tensile tests clearly shows that it is possible with the help of an appropriate heat treatment to significantly reduce the strength of the additively manufactured components and at the same time significantly increase the forming behavior.

3 Conclusion

With the two process variants CMT and pulsed arc welding process, additive components with slightly different mechanical properties can be produced (without any post-treatment). These differences could be eliminated by subsequent heat treatment and forming. Especially by the forming of the additive-manufactured components a homogenization of the mechanical properties could be achieved.

The degree of deformation of $\varphi = 0,4$ achieved during hot forming was not sufficient to induce complete dynamic recrystallization of the microstructure. This resulted in very high hardness values of around 260HV and a significantly more brittle material behavior with elongations at fracture below A < 22%. A more transformed microstructure with nearly completed recrystallization could be achieved by cold forming ($\varphi = 0,4$) followed by a one-hour heat treatment at 850 °C. As a result, hardness values of around 215HV could be achieved and the tensile strength of both samples was increased to $R_m = 690$MPa.

In order to be able to analyze the influence of the forming process on the microstructural transformations, two heat treatments were also carried out. Firstly, the specimens were heated to 850 °C and tempered for one hour. Due to the absence of a previously introduced forming process, a grain structure was formed and refined, but the mechanical properties could hardly be changed significantly. In contrast, the heat treatment at 1150 °C resulted in significant grain growth. This resulted in a reduction in strength and a significant increase in formability to over A > 34%.

On the basis of the collected data, further interesting investigations could now be set up. For example, cold forming is to be combined with heat treatment at higher temperatures in order to produce components with a completely recrystallized microstructure and significantly improved mechanical properties. Furthermore, the influence of the plastic strain on the course of recrystallization processes taking place during hot forming is to be investigated. Another possible area of investigation could be the influence of pore formation during welding of austenitic steels on their formability.

Validation of Automatically Generated Forging Sequences by Using FE Simulations

Yorck Hedicke-Claus, Mareile Kriwall, Jan Langner, Malte Stonis, and Bernd-Arno Behrens

Abstract To increase the economic efficiency in the production of geometrically complicated forgings, material efficiency is a determining factor. In this study, a method is being validated to automatically design a multi-staged forging sequence initially based on the CAD file of the forging. The method is intended to generate material-efficient forging sequences and reduce development time and dependence on reference processes in the design of forging sequences. Artificial neural networks are used to analyze the geometry of the forging and classify it into a shape class. Result of the analysis is information on component characteristics, such as bending and holes. From this, special operations such as a bending process in the forging sequence can be derived. A slicer algorithm is used to divide the CAD file of the forging into cutting planes and calculate the mass distribution around the center of gravity line of the forging. An algorithm approaches the mass distribution and cross-sectional contour step by step from the forging to the semi-finished product. Each intermediate form is exported as a CAD file. The algorithm takes less than 10 min to design a four-stage forging sequence. The designed forging sequences are checked by FE simulations. Quality criteria that are evaluated and investigated are form filling and folds. First FE simulations show that the automatically generated forging sequences allow the production of different forgings. In an iterative adaptation process, the results of the FE simulations are used to adjust the method to ensure material-efficient and process-reliable forging sequences.

1 Introduction

Due to their excellent mechanical properties, forgings are used in highly stressed areas such as automotive and aircraft engines. Because of their high component complexity, forgings are often produced in several process steps (forging sequence) [1]. The most important step toward increasing efficiency in a forging sequence is the reduction of the used material [2]. The quality of the forging sequence and the material efficiency are primarily depending on the design of the individual preforms. For an efficient forging sequence, the mass distribution of the individual preforms must therefore be sensibly approximated to the mass distribution of the finished forging. The cost of designing a material-efficient forging sequence increases significantly with the increasing complexity of the forged part, especially for components with a significant mass distribution in 3D space. One reason for this is the opposite direction between the backward-oriented design of the forging sequence and the forward-oriented FEM simulations, which is used to check the forging sequence. Conventionally used design methods such as the mass distribution diagram according to Mathieu [3] are not suitable for complex forged parts, since an application in 3D space for determining the mass distribution can only be computed by using several complex diagrams. Therefore, in the research project "Efficient Forging Sequence Planning" a method is being developed, which automatically generates a single multi-stage forging sequence based on a CAD file of the finished forged part geometry. The aim is that the method is applicable for forgings of different shape classes. Based on the mass distribution around the center of gravity of the finished forged part, a multi-stage forging sequence is generated step by step by approximating the cross-sectional contour and mass distribution of the forged part and semi-finished product. Without performing FEM simulations, the method is to generate multi-stage forging sequences within a few minutes, instead of several hours or days that are currently required. By using a computer-aided method for efficient forging sequence planning, both material costs and development time can be reduced, thus increasing the economic efficiency of the forging process [4]. There are several projects dealing with a computer-aided design of material-efficient forging processes with the aim to reduce the use of time-consuming FEM simulations during design process. Behrens et al. present an approach for inverse material flow simulation during drop forging. For a rotationally symmetric component, the material movement is modeled via so-called displacement paths, based on the least constraint. By means of this method a backward simulation for the design of intermediate forms during drop forging is possible [5]. However, this approach only applies to 2D space. Guan presents the development of a model for the preform design of a single 3D preform in a multi-stage drop forging process. The approach is based on potential field method and response surface method. Using this approach, a forging can be achieved without defects and a lower flash ratio [6]. Torabi et al. also deal with preform optimization for a turbine blade. The use of extruded elliptical cross section was considered as a blade preform, and then response surface method and multi-objective genetic algorithm was used to optimize this preform. Maximum filling ratio of the final blade

and minimum flash volume, forging force and strain variance of the final blade were considered as objectives of optimization. Results are achieved by simulations and experimental investigations [7]. For rotationally symmetric components, Knust et al. have developed a method that enables preform optimization within a few minutes without the use of FE simulations [8, 9]. The modular description of the component by single cross section allows the optimization of preforms by evolutionary algorithms. The optimized preforms significantly reduced the flash ratio. Alimirzaloo et al. optimize the preforms of a two-stage forging process for a wing blade by using artificial neuronal networks (ANN) and fuzzy logic. A more even strain distribution and a significant reduction of the flash ratio could be achieved [10]. SHAO presents an approach to predict the influence of preform geometry on the forging process for a turbine blade, using genetic algorithms and particle swarm optimization [11, 12].

The presented work on the computer-aided design of forging processes is mainly concerned with the automated design of individual or the optimization of a single multi-stage forging sequence for a defined component. At present, the authors are not aware of any work that allows to automatically generate multi-stage forging sequences for forgings of different shape classes. This study describes the method to achieve this. In the following, we first describe the structure and functionality of the method. Then the results of automatically generated forging sequences for three test components are presented. Subsequently, FE simulations of the forging sequences are carried out and the results of the simulations are discussed.

2 Development of the Method for Efficient Forging Sequence Planning

The method for efficient forging sequence planning consists of several modules and is programmed and implemented in MATLAB. The interaction of the individual modules is outlined in Fig. 1 and the functionalities of the individual modules are presented below.

In the first step, the STL file of the forging is loaded and the geometric dimensions of the component are recorded. An automated classification of the forging into one of the form classes according to SPIES (stocky component, disk form, long form [13]) by an ANN follows [14]. Important information for the automated design of the forging sequence such as bending, holes, and cutting axes for the calculation of the center of gravity line is determined from the analysis and form class classification. For bent components or existing holes, special algorithms are called within the method, which represent a bending operation or close the holes before generating the forging sequence. Parallel to the shape recognition by means of ANN, the complexity of the forging is evaluated by means of a complexity score model. Within this model, various existing evaluation criteria such as envelope volume and fineness factor (cf. [13]) as well as the mass distribution in the cross section (cf. [8, 9]) are combined with each other and in addition combined with further developed evaluation criteria such as the

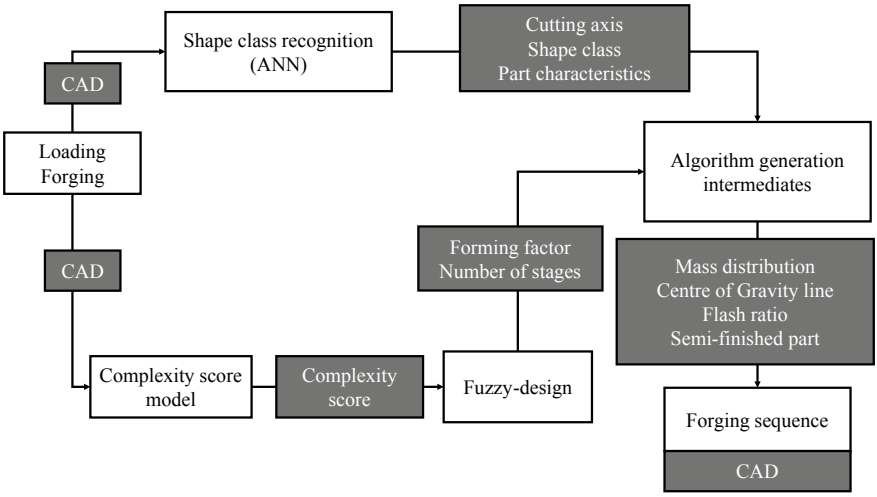

Fig. 1 Flowchart of the method for efficient forging sequence planning

consideration of cross-sectional changes in a forging. The complexity score model can be used to automatically output a statement about the complexity of a forging. The evaluation of the complexity of the forging is done by a numerical value of 0–1 in which all standardized evaluation criteria are added. The value 1 is the maximum complexity and 0 the lowest complexity. The complexity factor of the forging is an important parameter for the automated design of the forging sequence. Depending on the complexity, the flash component in the method is determined according to the approach by Knust [8]. In addition, the number of intermediate forms is initially designed as a function of complexity. A fuzzy control system was developed in order to be able to map the cause–effect relationships of the individual design parameters such as component complexity, number of stages, and forming factors for forging sequences (e.g., "high" component complexity leads to "many" intermediate forms). In addition to the number of stages, the distribution of the deformation per stage is also determined by the fuzzy system. Table 1 shows a possible result for a three-staged forging sequence. However, the user of the method always has the possibility to define input parameters manually. For example, one can specify the number of

Table 1 Exemplary distribution of the forming factors for a three-stage forging sequence from the forging backward to the semi-finished part

Iteration	1	2	3
Forming factor f	0.05	0.8	0.15
Explanation	Small forming, since from the preform to the finished form it is only a matter of the contour shape	Main forming	Small forming, e.g., descaling at the beginning of a forging sequence

stages as a function of one's machine park. As a result, the fuzzy design tool provides the number of stages of the forging sequence as well as the percentage distribution of the forming in the respective stages. The sum of the forming factors f_i over all stages or iterations k must result in one, which is presented in Eq. 1:

$$\sum_{i=1}^{i=k} f_i = 1 \tag{1}$$

The forming factors defined in this method do not correspond to the conventionally defined degree of forming. In the method for efficient forging sequence planning, the forming factors indicate the percentage of the total necessary forming from semi-finished product to finished forged part that is carried out in the respective stage.

The output parameters of the individual modules are then transferred to the algorithm for generating the intermediate forms. The component is divided into n individual cross-sectional planes along the component length L by a slicer algorithm. The distance of the individual section planes is calculated to $d = {}^{L}/_{n}$. The cross-sectional contour of the forged part is represented by a polygon chain P_i. The center of gravity S_i and the area A_i are calculated for each cross section. From this information, the algorithm calculates the mass distribution around the center of gravity line ($\sum_{i=1}^{i=n} S_i$) of the forging [4]. Based on the component complexity and the cross-sectional contour, an adaptive flash ratio is calculated according to KNUST (cf. [8, 9]). However, this calculation approach is only suitable for rotationally symmetric shapes and is extended by a percentage flash addition factor in the method for efficient forging sequence planning. This factor can be set manually by the user of the method. The diameter or length of the semi-finished product can be specified by the user. The cross section of the semi-finished product can be round or square. When automatically calculating the diameter of the semi-finished product, the method is based on the largest cross-sectional area of the forging and the maximum permitted change in length per stage. For each point of the polygon chain in a section plane, target coordinates are assigned on the semi-finished geometry. The corresponding displacement vectors are defined from the start coordinates and the target coordinates of the points as shown in Fig. 2.

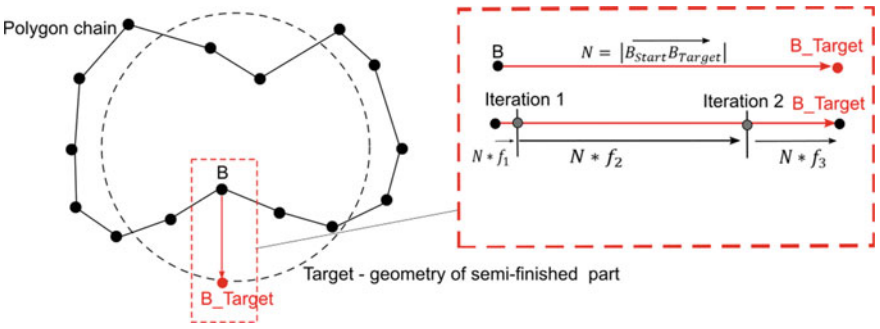

Fig. 2 Iterative procedure for intermediate form generation by point shifting. (Color figure online)

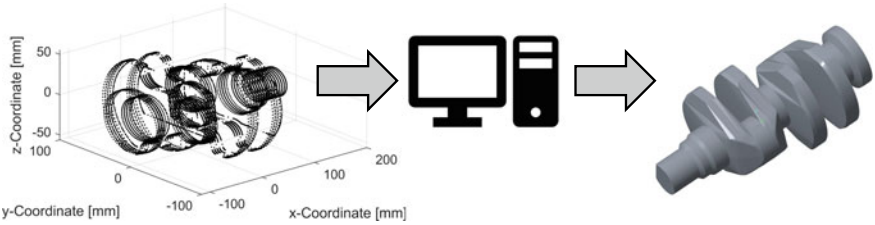

Fig. 3 Creation of the STL file. (Color figure online)

The points are moved step by step along the displacement vectors in order to gradually approximate the mass distribution and center of gravity line of the forging and the semi-finished product. Figure 2 shows the stepwise displacement of a point along the displacement vector for a stage sequence with two intermediate forms between semi-finished product and forging. The point B is moved stepwise to the target point B_{Target} on the semi-finished part geometry. The stepwise displacement along the vector results from the number of stages and the determined percentage deformation (forming factors f_i) per stage. The change in length from intermediate to intermediate within the forging sequence is represented by a change in the distance between the individual cutting planes. Volume constancy must apply to the forging sequence. This means that the volume of the semi-finished product corresponds to the volume of the forging, plus the volume for the calculated adaptive flash ratio, which is presented in Eq. 2:

$$V_{Semi-finishedpart} = V_{Forging} + V_{Flash} \tag{2}$$

After an iteration and thus the change of the cross-sectional areas in all section planes, the volume constancy is checked. If the volume is too high, the distances are reduced; if the volume is too small, the distances between the section planes are increased. After a displacement iteration, the displaced points result in a point cloud of the contour of the respective preform as shown in Fig. 3. A CAD file is then generated from the point cloud using an algorithm and exported thereafter.

3 Results of the Method for Efficient Forging Sequence Planning

In this paper, the validation of the automatically generated forging sequences for different forgings is described. Forged parts of different shape classes (long parts and disk shape) and different complexity will be considered. The following test components are presented in this paper:

- Connecting rod (long part, low complexity; length = 215 mm; volume = 211,638 mm^3);
- Disk (disk shape, low complexity, height = 110 mm; volume = 706,403 mm^3); and
- Crankshaft (long part; high complexity, length = 275 mm; volume = 1,204,704 mm^3).

Table 2 shows the results obtained by the method for each of the components. The class of shape is the result of the ANN. The shape class code in Table 2 corresponds to the classification according to [13]. The form classes according to SPIES consist of the three main shape classes of stocky components (class 1), disk form (class 2), and long form (class 3). Depending on the main axis and the secondary shape elements of the forged part, there are also subclasses in the individual main shape classes. For example, the connecting rod is assigned by the ANN to main class 3 (long forms) with a straight main axis and without secondary form elements (subclass 311). The other meanings of the shape class codes can be found in the literature [13]. The number of steps corresponds to the individual intermediate forms of the forging sequences, i.e., the number of iterations until the forged part has been transferred into the semi-finished product geometry by shifting the cross-sectional points. The deformation factors indicate the percentage deformation for the individual iterations. The specified value for the flash in Table 2 corresponds to the calculated average flash ratio over the entire component. The lengths for the individual intermediate forms are also output by the method.

Figure 4 shows the exported CAD files of the intermediate forms for the forging sequences for the connecting rod (a), the disk (b), and the crankshaft (c). The calculation time for the automated generation of the forging sequence is less than 10 min for each of the three forged parts.

Table 2 Result parameters of the automatically generated forging sequences for the test components

Component	Shape class [13]	Stages	Forming factors	Flash ratio	Length intermediate forms (mm)
Connecting rod	311	3	I1 = 0.1 I2 = 0.6 I3 = 0.3	12%	I1 = 211 I2 = 208 I3 = 183
Disk	211	2	I1 = 0.6 I2 = 0.4	5%	I1 = 64 I2 = 110
Crankshaft	312	4	I1 = 0.1; I2 = 0.4 I3 = 0.35 I4 = 0.15	34%	I1 = 275 I2 = 272 I3 = 246 I4 = 234

4 Validation of the Method by Using FE Simulations

When generating the intermediate forms, no characteristics of special preform processes, such as cross-wedge rolling (cf. [14]), are considered when generating the mass distribution and changing the cross-sectional contours. Therefore, in this paper, all intermediate forms are checked for process reliability and freedom from errors by FE simulations of drop forging processes. The dies are first constructed based on the CAD files for the individual intermediate forms of the forging sequence. The simulation of the forging sequences is then carried out using FORGE® NXT 3.0. In validating the method for efficient forging sequence planning, the quality criteria of form filling and freedom from folds are considered in this paper. Based on these quality criteria, it can be checked whether the method is able to design error-free processes and thus suitable for industrial use or whether changes must be made to the algorithm for creating the intermediate forms. Especially the parameter of the form filling is an important assessment parameter for the validation of the forging sequence and a qualitative statement about the generated forging sequences.

The material modeling in the simulations is done with the HENSEL-SPITTEL equation implemented in FORGE® NXT 3.0 [15]. With this equation, the forming behavior is determined by means of a function dependent on the temperature T, the effective strain ε, the flow stress σf, the strain rate $\dot{\varepsilon}$, and the coefficients A and $m1\text{-}4$. The HENSEL-SPITTEL equation used by FORGE® NXT 3.0 is represented in Eq. 3:

$$\sigma_f = A e^{m_1 T} \varepsilon^{m_2} e^{m_4/\varepsilon} \dot{\varepsilon}^{m_3} \tag{3}$$

The flow curve used for hot bulk metal forming processes is sufficiently precise by means of the coefficients A, m_1, m_2, m_3, m_4.The used material in this study is 1.5120. The individual regression coefficients of the HENSEL-SPITTEL equation of 1.5120 are shown in Table 3.

Material modeling will not be the focus of this study, as only qualitative estimation of the results for efficient forging sequence planning will be carried out. For the FE simulations, nondeformable dies and the simulation parameters shown in Table 4 are used.

Table 3 Regression coefficients of Hansel–Spittel equation (Eq. 1.5120)

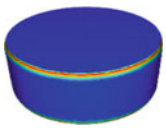
Coefficient	Dependence of temperature	Dependence of strain hardening	Dependence of equivalent strain rate	Dependence of equivalent strain	Solidity
Value	$m_1 = -0.0029$	$m_2 = -0.14227$	$m_3 = 0.14102$	$m_4 = -0.05764$	$\acute{y}A = 1809 N/mm^2$

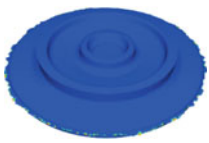
Table 4 Simulation parameters for the FE simulations carried out to validate the forging sequences

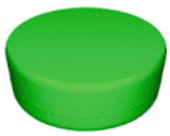
Simulation parameters	Value
Material	1.5120
Billet temperature	1250 °C
Die temperature	250 °C
Mesh size	4 mm
Press kinematics	Hydraulic press
Ambient temperature	50 °C
Friction μ	0.3
Forming velocity	20 mm/s

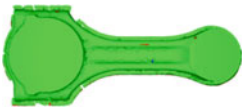
Table 5 shows the results of the FE simulations for the forging sequence of the disk. On the one hand, the form filling and, on the other hand, the freedom of folds are considered. The form filling is checked via the contact between billet and die. The results of the form filling can be seen in the top of Table 5. If there is no direct contact between die and billet, this is indicated by red coloring of the billet in those areas. A form filling can be seen in both stages. Only at second iteration (Stage 1), at edge areas no complete form filling is to recognize. The bottom of Table 5 shows that both iterations, the upsetting process (Stage 1) and the final forming (Stage 2), are free of folds. Both quality criteria are fulfilled. Overall, the simulations show

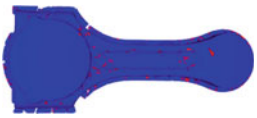
Table 5 FE results for the disk shape (Top: form filling (contact); bottom: Folds)





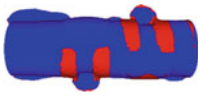


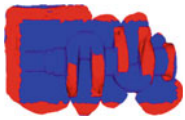


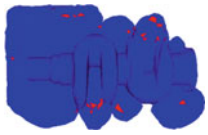


Stage 1	Stage 2
	
Form filling	Form filling
	
No folds	No folds

Table 6 FEM result stage sequence of connecting rod (top form filling; bottom folds)







Stage 1	Stage 2	Stage 3
		
Form filling	Form filling	Form filling
		
No folds	Folds	Folds

that the method for efficient forging sequence stadium planning is able to design a material-efficient stadium sequence.

Table 6 shows in the top row the FE results for the contact analysis to check the form filling and in the bottom row the FE results for the monitoring of the fold formation for the connecting rod. The evaluation of the FE results for the forging sequence of the connecting rod shows that form filling is achieved for the individual intermediate forms. During the analysis of the fold formation as seen in the bottom of Table 6, it must be determined that folds are likely to occur on the component in the intermediate forms. This is indicated by FORGE® NXT 3.0 by red coloring of the certain areas. Particularly in the middle area of the connecting rod, many folds occur during the forming process from preform to finished form. This means that the stage sequence is not directly suitable for immediate use in practice yet. The surface quality of the STL files of the intermediate forms can be a possible cause for the folds that occur. In some cases, the surfaces of the STL files from which the dies are constructed exhibit irregularities. In the future, a smoothing algorithm is to be implemented in the method, which will further increase the surface quality of the STL files.

Table 7 shows the simulation results for the crankshaft. The quality factor form filling is considered by the contact between billet and dies. Red areas indicate no contact between workpiece and tool. The largest distance can be identified in the first iteration (Stage 4), with 3 mm between die and billet. When validating the forging sequence for the two-cylinder crankshaft, it must be noted that no form filling is achieved in the cross-sectional area of the crankshaft with large surface contents (area of the crank webs). In the areas of smaller cross sections, on the other hand, there is a clear excess of material. The forging sequence of the crankshaft generated by the method still requires significant changes by the designer before a basic production of the crankshaft with this stage sequence is possible. The FE results show that folds occur in the flash during the forging sequence of the crankshaft. No folds appear in the first stage. Afterward only in the flash. No folds can be identified directly on the crankshaft.

Table 7 FE results for crankshaft forging sequence (form filling (top); folds (bottom))

Stage 1	Stage 2	Stage 3	Stage 4
			
No form filling	No form filling	No form filling	No form filling
			
No folds	Folds in the flash	Folds in the flash	Folds in the flash

Several approaches can be pursued to improve the form filling of the automatically generated forging sequences. One possibility is to change the calculation of the flash ratio so that more material is calculated for the flash ratio. However, this does not meet the requirements for the method to generate material-efficient forging sequences. A further possibility to improve the form filling is to make constructive changes to the dies and to use flash barriers. However, this means increased effort in construction and therefore increased time expenditure.

In order to improve form filling for the crankshaft, adjustments were made to the algorithm for point shifting. The maximum permissible length change in the forging sequence was reduced, resulting in a different calculation of the semi-finished product diameter due to volume constancy. Due to the reduced length change (of approx. 7 percent compared to approx. 15 percent (see Table 2)) in the forging sequence, it was hoped to achieve an improved mass distribution and improved form filling. Figure 5 shows the results of the adapted variant of the algorithm in comparison with the previous state of the algorithm for the crankshaft. In Fig. 5, only the final stage is

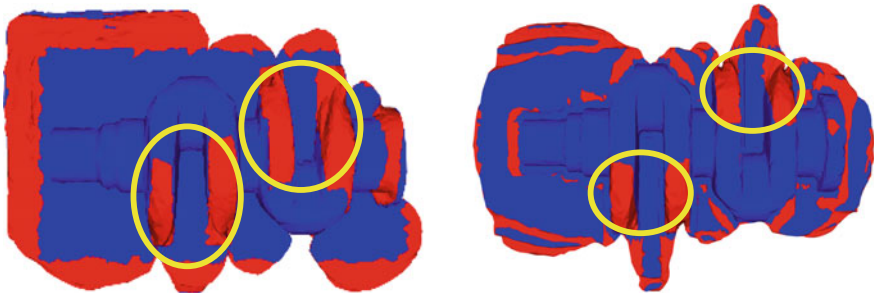


Fig. 5 Results for FE simulations with insufficient form filling in final stage (left) and final stage with adapted algorithm (right). (Color figure online)

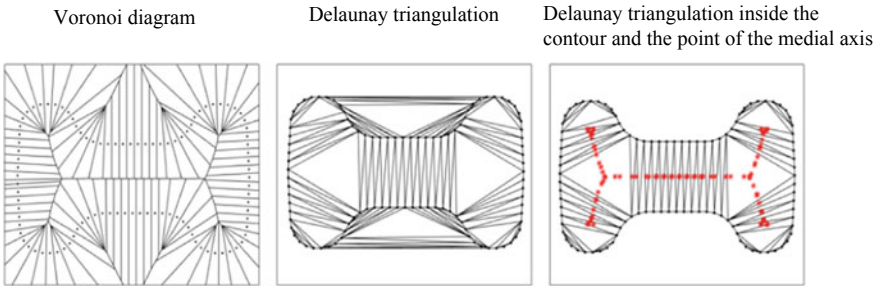

Fig. 6 Schematic representation of the Voronoi diagram, the Delaunay triangulation, and the points of the medial axis from a cross section of a connecting rod. (Color figure online)

presented. The results in terms of form filling for the other stages are comparable and are therefore not shown here. The adjustments have already led to improved form filling in the critical areas. However, there is still no complete form filling. For this reason, the algorithm for the point shift and generation of the individual intermediate form will be fundamentally revised in the future.

The algorithm is to be modified to move the points along the material flow paths in the forging. Determining the material flow paths allows inverse material flow modeling for backward design of the forging sequence. By shifting the points along the material flow paths, the forging sequence can be approximated much closer to the real forging process. Currently, the displacement vectors are defined by the shortest distances of the points on the polygon chains to the semi-finished part geometry. To determine the material flow paths, a Voronoi diagram and a Delaunay triangulation are to be used to determine the medial axis and to derive the material flow paths (see Fig. 6). Subsequently, a new displacement vector is to be determined for the points as a function of the material flow paths. The schematic procedure of this new approach for the point shifting is shown for a cross section from the connecting rod in Fig. 7. Points in the center of the component are shifted perpendicular to the first-order material flow path. Points in the area of the H-contour of the component are displaced along the second-order material flow path. Points in the area of the H-contour of the component are displaced along the second-order material flow path. In the future, a set of rules must be developed that shifts the points depending on the position on the component contour and the calculated material flow paths.

5 Summary and Outlook

The FE simulations of the automatically generated forging sequences show that the developed method partly already delivers very good results and can generate multi-stage forging sequences based on forging geometry for different shape classes. When considering the FE results, it becomes clear that the designer of a forging sequence

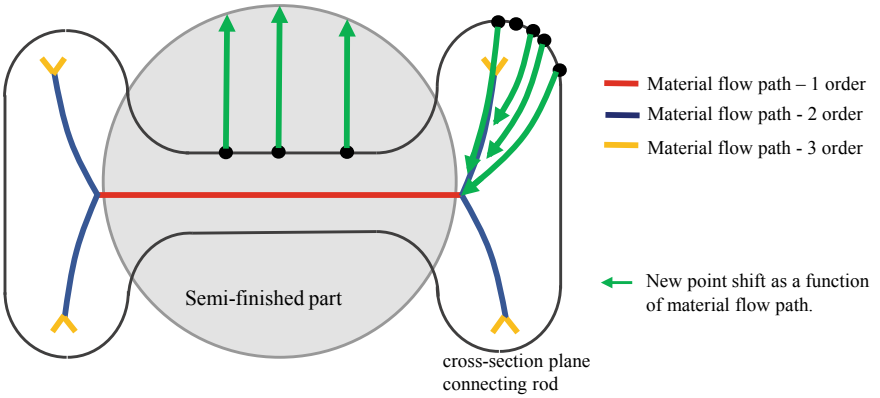

Fig. 7 New approach to shifting the points along the material flow paths. (Color figure online)

using the method already receives an initial very good proposal for a forging sequence in the shortest possible time. The FE results also show that the generated forging sequences do not reliably allow an error-free production of forged parts of different shape classes without corrections yet. The method calculates enough flash to achieve form filling for a connecting rod (24% flash) and a disk (5% flash) and to generate a material-efficient forging sequence. For the crankshaft, no form filling could be achieved in areas with large cross sections, but in small cross-sectional areas there was a large excess of material. In order to improve the form filling for the crankshaft, a smaller change in length within the forging sequence was initially calculated. This resulted in a slight improvement in form filling. However, complete form filling was still not achieved. An approach was presented to calculate the point shifting vectors as a function of the material flow paths in the future. This modification to the algorithm is expected to result in a significantly more process-oriented design of the intermediate forms and the entire forging sequence. In the FE simulations carried out, it was found in some cases that folds occur. In order to avoid the formation of folds in the future, an algorithm is to be implemented in the method, which, after each iteration, checks the generated point cloud based on already existing criteria for the prediction of folds (cf. [9, 16]). The FE simulations are used here for the first validation of the method in order to be able to investigate the first basic quality criteria such as mold filling and freedom from folds without the need for cost-intensive test forging. In the further course of the project, an experimental validation will be performed in addition to the verification of the results by means of FE simulations. Already industrially used forging sequences of different components are to be compared with the forging sequences automatically generated by means of the method. In addition to the quality criteria of form filling and freedom of folds, the forces occurring in the experimental validation, the consumption of material, and the duration of the creation of the design are to be considered. In the future, it will also be possible to combine procedures for preform optimization with evolutionary algorithms (cf. [8, 9]) with the method of

efficient forging sequence planning in order to optimize the individual intermediate forms and further increase the efficiency of the forging sequence.

Tube Forming and Fabricating Technologies for Contributing Society by Tackling Problems of Environment and Aging Population

Takashi Kuboki, Atsushi Shirayori, Masaaki Mizumura, Noah Utsumi, and Yeong-Maw Hwang

Abstract Technologies for forming and fabricating tubes have been contributing to the development of society, and should evolve and have great roles in the future societies, considering the problems on environment and population. Global warming is a critical problem and the average temperature in the world is still increasing. The world population number is stopping rapid increase accompanying with decreasing birthrate, resulting in aging society. Tubes have advantages of high rigidity for a unit weight and could manufacture light-weight components for transport equipment. The technologies are utilized for forming parts in medical devices. The technologies on tubes should contribute for solving these problems and realizing sustainable societies. This paper introduces the author's technologies and reviews others' recent technologies on tubes. The technologies include hydro and air forming, rotary forming, bending, micro forming and so on. These technologies are qualitatively evaluated in terms of conflicting characteristics, such as formability, strength, productivity, flexibility and miniaturization. Some technologies are emerging to improve some of the conflicting characteristics at the same time for realizing excellent performances of the formed products.

Keywords Tube forming · Productivity · Strength · Formability · Flexibility · Light-weight

1 Introduction

Tube forming technologies have been contributing to the development of society, and should evolve and have great roles in the future societies, considering the environmental problems. Global warming is a critical problem and the average temperature in the world is still increasing although many countries are tackling to suppress CO_2 emissions [1]. The CO_2 emissions would be suppressed by the combination of strengthening and lightweight of components of vehicles, and tubes have structural advantages, as the section modulus and second moment of inertia of area are high for a unit cross-sectional area. Realizing these structural advantages requires securement of formability. Some tube forming technologies have been developed for realizing both high formability and strength of material, though they are often conflicting.

The population is another problem, which might be alleviated by the tube forming technologies. The world population number is predicted to stop rapid increase in 2050 accompanying with decreasing birthrate [2], and the proportion of the laboring population would decrease. The tube forming technology should evolve for contributing to the aging society. The tube forming technology would be used for effectively manufacturing the components for medical equipment. The technology would also compensate the lack of the talented engineers and technicians. Many of technologies still depend on the knowledges and skills of the engineers and technicians, many of whom are elderly people in some engineering fields. Therefore, the technical conveyance is urgently needed, and the digitalization of their knowledge with the help of the computational technology would be of great help.

This paper reviews recent technologies and perspectives in tube forming, referring to the recognition of metal forming in the academy. The technologies include hydroforming, air forming, rotary forming, bending, micro forming and so on. These technologies are qualitatively evaluated in terms of conflicting characteristics. Moreover, perspectives and expectation of the tube forming technologies are mentioned, considering environmental problems, ageing societies and development of computational technologies.

2 Trends in Metal Forming

Table 1 shows titles of the keynote papers of STC-F (The Scientific and Technical Committee - Forming) in CIRP (Collége International pour la Recherche en Productique, The International Academy for Production Engineering) for the latest five years. All the papers can be related to tube forming. Prediction and setting product properties (2015) are also important in tube forming. Closed-loop controls (2016)

Table 1 Keynote papers in CIRP annals—manufacturing technology in the latest 5 years

Year	Title	1st author
2019	Models and modelling for process limits in metal forming	W. Volk
2018	Flexibility in Metal Forming	D. Y. Yang
2017	Hot stamping of ultra-high strength steel parts	K. I. Mori
2016	Closed-loop control of product properties in metal forming	J. M. Allwood
2015	Metal forming beyond shaping: predicting and setting product properties	E. Tekkaya

are still difficult, but some technologies are already applied and others are expected to be applied in the industry. One of the examples is TSS bending of tube (Torque Superposed Spatial bending) [3]. Hot stamping (2017) is a superior technology which realizes both formability and strength after forming. Further superior tube forming technology, STAF (Steel Tube Air Forming), is developed in Japan [4]. Flexibility (2018) is also important in tube forming, many tube forming technologies have been developed for realizing flexibility. Prediction of process limits (2019) are also important issue in tube forming, and the prediction method can be expected to evolve with the help of the computational technologies.

Tekkya et al. shows their opinions on innovations and trends in metal forming in "60 Excellent Inventions in Metal Forming" [5]. Technologies and analyses, which would be related or applicable to tube forming technologies, are summarized in Table 2. Some technologies started in advance of the prosperous duration which was recognized in the world. While the duration for hydroforming was 1994–2010

Table 2 Innovations and trends related or applicable to tube forming from "60 Excellent Inventions in Metal Forming [5]"

	Innovations	Prosperous duration
Technology	Hydroforming	1994–2010 (Ogura et al. [6], U.S patent [7])
	Micro forming	1998–2014
	Incremental sheet forming	2002–2020 Matsubara [8, 9]
	Flexible forming	1992–ongoing
	Closed-loop control	2011–ongoing
Analyses	FEM in forming	1977–2005
	Multi scale	2012–ongoing (Matsui et al. [9])
	Damage mechanics	2010–ongoing

in the Table, Ogura et al. showed some results on hydroforming using a purpose-built machine in 1985 [6] after a series of experiments following a U.S. patent in 1940 [7]. While the duration for incremental forming was 2002–2020 in the Table, Matsubara showed some results on incremental forming for tube [8] and sheet metal [9] in 1984. While the duration for Multi-scale analysis started in 2012 in the Table, Matsui et al. showed some results of the analyses on plastic deformation in 2002 [10]. Therefore, some present technologies, which is currently not paid attention to, might be prosperous in the future.

3 Processes in Two Axes of Characteristics

3.1 Hydroforming and Air Forming in Strength and Formability

It might be interesting to analyze processes in terms of different characteristics, which conflict each other. Tube forming processes often enable us to realize some of conflicting characteristics at the same time. Strength and formability conflict each other as shown in Fig. 1, which was qualitatively made depending on the author's impression and interpretation. For example, the flow stress of steels with fine grains is high, but the formability is low, compared to plain carbon steels. Many hydroforming technologies have been developed mainly focusing upon improving formability without concerning strength. The formability was improved by pushing a tool to the point where fracture occurs. Manabe et al. used a counter punch in T-shape hydroforming with the combination of fuzzy theory for improvement of the forming limit [11]. Wada et al. shows the further improvement result of forming limit by applying movable dies [12]. The movable dies utilize the friction affirmatively for

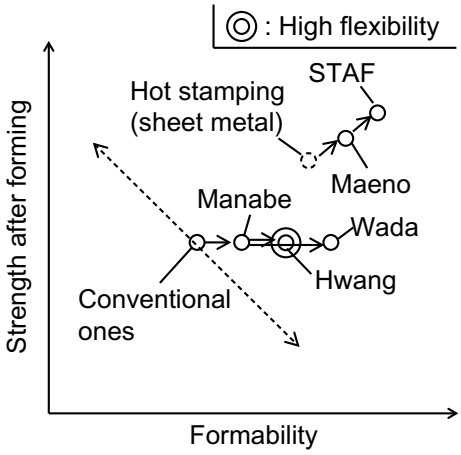

Fig. 1 Hydro and air forming in strength after deformation and formability

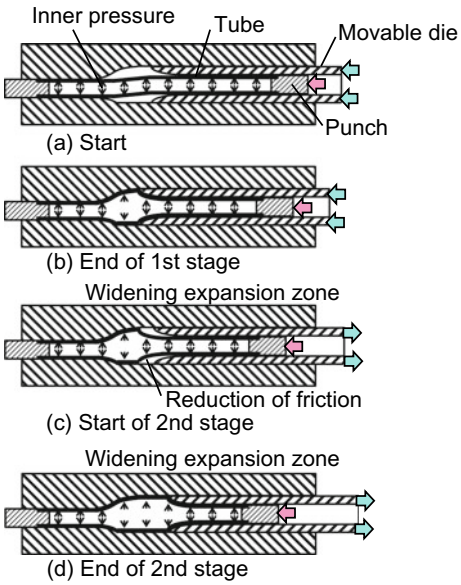

Fig. 2 Enlargement of axial forming area by forward and backward of movable dies [13]. (Color figure online)

supplying the material into where the tube is expanded by the hydro pressure. As the result, the tube periphery-expansion ratio reached 300%. Hwang et al. enhanced the potential ability of the movable dies for high flexibility as shown in Fig. 2 [13]. A movable die pushes the tube end for supplying the material into expansion area as shown in (a)–(b). The movable die moves backward for the enlargement of the axial expansion area. The forward and backward movement of the die improves the flexibility as well as the formability.

Some metal forming processes were developed for improving both strength and formability by controlling the strength during and after deformation as shown in Fig. 1. Hot stamping deforms the sheet metals at high temperature and rapidly cool the metals down for obtain higher strength by utilizing phase transformation [14]. However, hot stamping of sheet metals or tubes still has some disadvantages for manufacturing hollow parts. Hot stamping of sheet metals needs to create flanges and join them together, resulting in low productivity. Hot stamping of tubes is difficult as the inside surfaces of the tubes cannot be supported by tools, resulting in buckling.

Maeno et al. proposed a gas forming process for conquering the problem of hot stamping of tubes [15]. A high-pressured air is enclosed inside the tube, which is heated up by resistance heating. The enclosed air supports the inside surface of the tubes and suppresses buckling. This method improves both formability and strength with realizing lightweight as welding is not needed. Ishizuka et al. (Sumitomo Heavy Industries, Ltd.) developed another gas forming process for commercial use, STAF (Steel Tube Air Forming) as shown in Fig. 3, which utilizes the air pressure more effectively for bulging tubes against the die walls [16]. This method decreases the number of processes from four to two, compared to hot stamping of sheet metals,

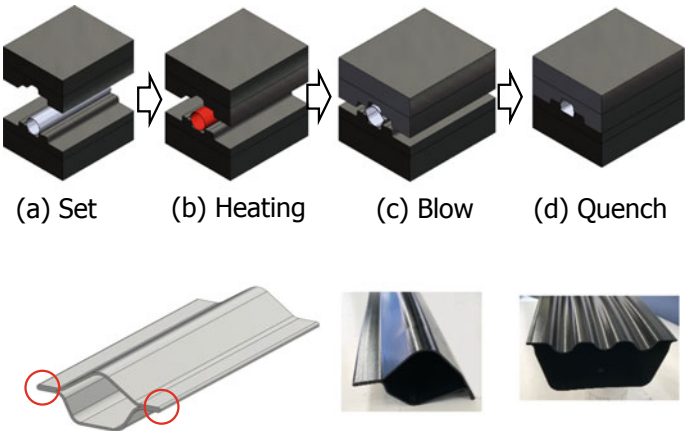

Fig. 3 Steel tube air forming for realizing high forming limit and strength [16]. (Color figure online)

for manufacturing frames of vehicles. Flanges are produced during blow and quench process according to the necessity. The production system is now available in the market.

3.2 Forming for Diameter-Reduction in Productivity and Formability

Figure 4 qualitatively shows forming processes for reducing diameters of tubes in terms of productivity and formability. High flexibility is also denoted by double circle in the figure. Press nosing is commonly used for reducing the diameter of the tube end

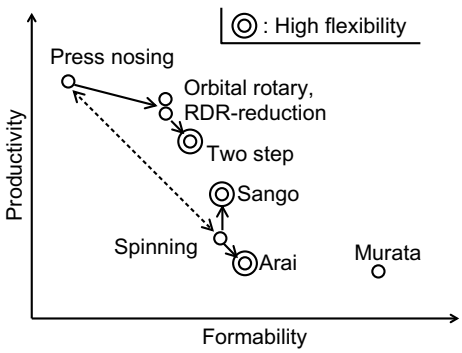

Fig. 4 Forming technologies for diameter-reduction in productivity and formability

when the nosing ratio is not high [17]. While productivity is very high for press nosing, formability is very low. Rotary forming improves the formability, and spinning is an opposite process to nosing in terms of productivity and formability. While formability is very high for spinning, productivity is very low. Murata et al. succeeded to apply spinning to magnesium tube for reducing the tube diameter up to reduction ratio of 95%, using rollers with heaters inside [18]. Sango Co. Ltd. succeeded to develop a spinning machine for mass production for increasing flexibility and improving productivity [19]. The machine evolved on hard and soft wares, and then reduced the diameters of both ends in tilted and eccentric manners within just a few tens of seconds. Arai et al. developed a spinning process, which reduced the tube diameter in an asymmetric manner by synchronizing the rollers position with the rotation angle of the tube [20].

Spinning processes reduces the tube diameter by multi pass formation, where the tools/rollers travel along the tube axis in several times, because the contact area between the tools/rollers and the tube is very small. Other rotary forming processes, which travel tools once, were proposed. They are "orbital rotary forming" by Kitazawa et al. [21, 22] and "RDR-reduction (Relieved Die Rotary reduction, rotary reduction with relieved die)" by Kuboki et al. [23]. These rotary forming have intermediate contact areas between press nosing and spinning.

This paper explains RDR-reduction in a detailed manner. Figure 5 shows a schematic illustration of RDR-reduction. The unique point of this process is to use a relieved die, which is composed of working surfaces and relieves. When the number of working surfaces is three, the highest limit nosing ratio is achieved. The main defects in press nosing is buckling caused by high pushing force and wrinkle caused by high compressive stress in hoop direction. The existence of relieves reduces both pushing force and compressive stresses, leading to higher limit nosing ratio. Adoption of two-step forming is effective for enhancement of limit nosing ratio [24]. The total contact angle γ of 240° gives the highest limit nosing ratio κ_L of 0.49 in the case of one-step forming. Two-step forming elevates κ_L up to 0.75 by adopting the total contact angle for 1st step γ_{1st} of 240° and that of 2nd step γ_{2nd} of 180°. It would be attributed to the difference of defects mechanism between buckling and other

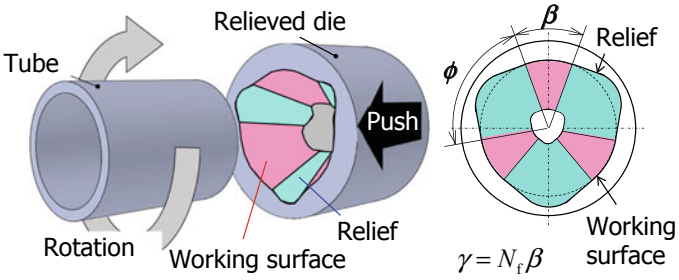

Fig. 5 RDR-reduction (Relieved Die Rotary reduction, rotary reduction with relieved die) [23]. (Color figure online)

defects. Buckling is caused by the temporary value of pushing force, while split and polygonal wrinkle is caused by the accumulation of damage or some unconformity. It is assumed that little damage accumulates during the 1st step of γ_{1st} of 240° and that the damage starts to accumulate during the 2nd step of γ_{2nd} of 180°, leading to higher limit nosing ratio. RDR-reduction should be tried in the industry and its effectiveness should be discussed.

3.3 Tube Bending in Terms of Flexibility

Tube bending processes include many aspects, such as the ratio of bending radius to tube diameter, precision on cross section and radius, flexibility, strength and others. This paper mainly focuses upon the flexibility, sparing other aspects to the next opportunity. Table 3 shows some bending processes in terms of flexibility. Draw bending is one of the most common tube-bending processes, and it can bend tubes in a target radius precisely as bending dies are used considering springback. However, the flexibility is low.

Draw bending is a common process for bending tubes in a precise manner. The process winds the tube around a bending die. The bent radius can easily controlled with evaluation of spring-back in a trial-and-error approach. However, the cross-sectional precision tends to deteriorate due to flattening. Although the mandrel is used for suppression of flattening, there is some limit for its effect. Utsumi et al. proposed a unique mandrel, which is called "laminated elastic mandrel" [25]. The mandrel is a bundle of thin sheets of polyvinyl chloride, stainless steel and acrylic material as shown in Fig. 6. The thin sheets are laminated alternately so that the mandrel might bend flexibly. The laminated elastic mandrel is suitable tube with rectangle cross section and secures the cross-sectional precision while suppressing defects. Further applicability of the laminated elastic mandrel should be discussed and enhanced for circular or smaller tubes.

Dieless U-bend process was developed for bending tubes at various radius from 700 to 2000 mm for atomic power plants [26]. The bending radii can flexibly be set by positioning feeding rolls and a clamp on the bending arms. The bending radii

Table 3 Bending processes on flexibility and unique points

Process	Flexibility			Unique points
	2D	3D	Twist	
Draw bending [25]	–	–	–	Precise bending according to die shape
Dieless U-bend [26]	[✓]	–	–	Precise bending, by open-loop control
MOS bending [27, 28]	[✓]	[✓]	–	Open-loop control
TSS bending [3]	[✓]	[✓]	[✓]	Closed-loop control
3DQ [29]	[✓]	[✓]	[✓]	Strengthen by quenching

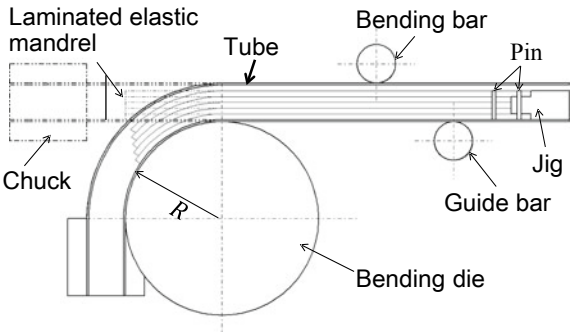

Fig. 6 Draw bending with laminated elastic mandrel [25]

can properly be controlled in an open-loop manner by changing the bending-roller position and the ratio of tube-feeding velocity to travelling velocity of the clamp.

One of the most famous 3-dimensional bending method is MOS bending, which is named after the inventors, Murata, Ohashi and Suzuki [27, 28]. The bending machine is composed of a guide cylinder, a bending die, a spherical-surfaced supporter of the die and a tube-feeding system. Positioning of the bending die according to the tube feeding enables the tube to bend in an arbitrary direction and radius.

Institut für Umformtechnik und Leichtbau (IUL) developed TSS bending, which can bend a tube in a 3-dimensional manner while twisting the tube [3]. The concept is that twisting torque can be superimposed on the bending moment, and then the tube can be twisted as well as bent. One of the unique points of the process is that it uses closed-loop control for controlling bending radius. The target moment is set instead of the target-bending radius. If the target value is set for bending radius, it would inevitably take time for measuring the shape and the bending radius of some portion must be out of the tolerance. On the other hand, the moment can be measured immediately, and the moment is used for the immediate closed-loop control.

Nippon Steel Co. developed 3DQ (3 Dimensional Hot Bending and Quench) as shown in Fig. 7 [29]. The bending system is composed of a robotic manipulator, supporting rollers, a feeding equipment, an induction heater, a cooling system and so on. The bending point of the tube is locally heated by the induction heater while the end of tube is supported by the robotic manipulator. The positioning of the robot hand flexibly determines the bending direction and bending radius. The heated portion was

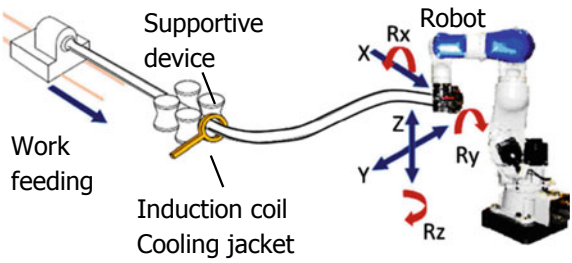

Fig. 7 3-Dimensional Hot Bending and Quench [29]. (Color figure online)

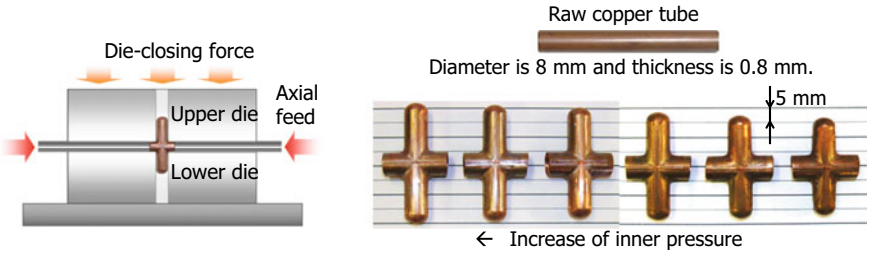

rapidly cooled down after bending, and the strength of the tube is drastically enhanced by the phase transformation.

3.4 *Tube Forming for Medical and Electronic Devices in Terms of Miniaturization*

The tube forming technologies are expected to manufacture small or micro parts in medical and electronic devices. The benefit of the parts would generally increase with decrease of the size when they are used for medical or electronic use. One of the examples for medical use is a joint for a surgical manipulator. Kawashima et al. develop a surgical manipulator which uses a spring joint instead of mechanical joint with gears inside [30]. The concise joint with spring would decrease the diameter of the manipulator, and then reduce the size of holes which are made on the patient's body. The less the hole diameter, the less the burden on the patients would be. The cross section of the spring fiber has a shape of high rectangle ratio, which enables the spring to bend easily and convey heavy twisting torque. The fabricating cost was huge as the spring was made by machining.

Kuboki et al. developed a method for fabricating the spring with a cross section of high rectangle ratio [31]. It is a combination process of coiling and upset using a tube as a raw material. The tube is bent into a spring shape by a conventional coiling process. The positioning of the coiling pin arbitrarily determines the bending radius and the diameter of the spring. The spring is upset and deformed into the spring with a cross section of high rectangle ratio. The usage of a tube instead of a wire as raw material realizes a stable deformation in the upsetting process. However, the process still leaves further improvement to be considered on the dimensional accuracies.

Other tube forming technologies have been developed. Hydroforming technologies for fabrication of cross-shaped tube were developed by Shirayori for tube diameter $D_0 = 8$ mm and thickness $t_0 = 0.5$–0.8 mm as shown in Fig. 8 [32]. A pair of upper and lower half dies are used and the effect of lubrication was clarified. Tubes with a rather thick wall of 0.8 mm were easily deformed into cross shapes with

(a) Experimental set-up (b) Cross-shaped tubes

Fig. 8 Hydroforming for cross-shaped tube with small diameter [32]. (Color figure online)

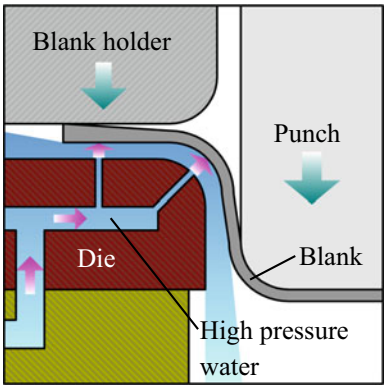

Fig. 9 Deep drawing using high-pressured water [38]. (Color figure online)

very long protrusions by optimization of forming conditions. Furthermore, S. Mori applied the hydroforming technology for micro tubes with diameter $D_0 = 0.5$ mm and thickness $t_0 = 0.1$ mm [33]. The fabricated cross-shaped tubes are expected used for medical, communication and electronic devices in the trend of miniaturization.

Dieless drawing is another prospective technology, and Furushima et al. have been improving the technology [34]. This method reduces the cross section of a hollow tube in a homothetic manner. The portion of tube to be deformed is locally heated by an induction heater or laser, and cooled down immediately after deformation. The tube is stretched at a certain speed and the heating point moves at another speed, and the ratio of the two speeds determines the reduction in area. One of the advantages of this method is that it can reduce the cross section with high area reduction while keeping the similarity. Therefore, once a complicated cross section is fabricated in a macro scale, the same complicated structural cross section can be realized in a micro scale by this method. The method is also applied for magnesium alloy [35] with an expectation that the fabricated magnesium tubes can be used as medical devices in human bodies, such as stents in the near future.

3.5 Supporting Technologies

Computer technologies and information science are rapidly developing. IoT or AI would be used for tube forming technology. Material and products can be tagged and tracked inside works or the preference of customers can be surveyed.

The usage of these science and technologies for conveying technical knowledge to the next generation would be another important aspect in the aging societies. Kuriyama et al. applied design-mapping technology for structuring engineers' knowledge for accumulating technical knowledge for conveying it to the next generation [36]. A few experts have huge amount of implicit knowledge and determine the

processes in many small to medium-sized enterprises. Once they leave the enterprises, it might be difficult to convey their knowledge to other engineers or technicians perfectly. Kuriyama et al. interviewed an expert on tube forming, extract words and classified them. The classified words were put and linked by arrows in a "design mapping". The mapping would tell successors and others the essence of the important knowledge even after an interval of years.

The development of computer technology would help higher analysis methods to become more realistic to be applied in the industry. Multi-scale analyses seem to start to be applied for metal forming around 2000 [10]. Multi-scale analyses should idealistically be conducted in a two-way manner, i.e. from micro to macro scale, and from macro to micro scale. However, the analyses are often conducted in a one-way manner from macro to micro scale due to the limitation of the computer ability. Watanabe et al. succeeded to predict stress-strain diagrams of ferrite-pearlite carbon steels based on the microstructure using the one-way multi-scale method [37]. The developing computer technology will help engineers to conduct two-way multi-scale methods easily and that enhance the benefit of the methods in the industry.

Multi-physics simulations are another possibility in the near future. Some of them started to be used for metal forming. Multi-physics simulation would be useful for evaluation of lubrication, which plays an important role in deformation of metals. Kuboki et al. shows some results on deep drawing using high-pressured water [38]. The deep drawing process is carried out as shown in Fig. 9. The water is supplied between the blank and the die instead of oil for alleviating the damage of oil to the environment. The multi-physic simulation was conducted as shown in Fig. 10. FEM is conducted for blank deformation, and CFD is conducted for lubrication behavior. The geometries after deformation and lubricant pressures are conveyed between the two analyses. The developing computer technologies will make multi-physics simulations easily available for tube forming in the near future.

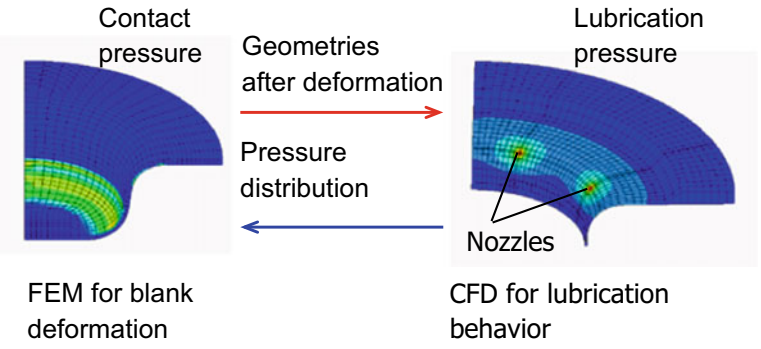

Fig. 10 Multi-physics simulation for deep drawing using high-pressured water [38]. (Color figure online)

3.6 Other Aspects

Thickness control would be another aspect though many research works have been focusing upon precision on bending radius and circularity. Thickness variations are inevitably given by tube forming, leading local weakness when the tubes are mounted into some machines or structures. Some controlling technologies would alleviate the weakness. Studies on thickness of formed tubes started to be reported by a research group under Institute of Steel and Iron Japan (ISIJ). For example, Utsumi et al. tried a unique method for controlling the thickness in tube bending [39]. Tube bending ordinarily causes thinning in extrados and thickening in intrados. Utsumi et al. intentionally gave thickness deviation to the raw tube for cancelling the deviation, which was caused by bending. The research has now started and its effectiveness should be verified by their further study.

Microstructural approaches would be required for tube forming in the future. The tube would be strengthened with decrease of grain size by sever plastic deformation or twin deformation. Anisotropy by texture might be utilized for improvement of the quality of the final products. However, many of present studies for tube forming seem to focus upon the microstructure just for evaluation of the formed products. For example, Wu et al. observed the microstructure of tubes after gas forming for validity of the uniformity [40].

4 Summary

This paper reviews recent technologies and perspectives in tube forming. The technologies include hydroforming, air forming, rotary forming, bending, micro forming and so on. These technologies are qualitatively evaluated in terms of conflicting characteristics, such as formability, strength, productivity, flexibility and miniaturization.

Some technologies are emerging to improve some of the conflicting characteristics. These technologies are expected to contribute for solving problems in environment and aging society. Attainment of both strength and formability will manufacture lightweight parts in vehicles, which will reduce CO_2 emissions. Attainment of both productivity and flexibility will respond the demanding requirements from the diversified societies. Miniaturization will sophisticate the medical devices for helping the society to tackle the problems in aging population.

The developing computer technology and informatics science will boost the tube forming technology. Digitalization of experts' knowledge will help the next generation to realize the sustainable societies. The availability of multi-scale analyses and multi-physics simulations will be improved, and the simulations would help the tube forming technologies to develop rapidly.

Multi-objective Sizing Optimization of Elbow-Bar Driving Mechanism of Cold Forging Press

Xinyu Dong and Yu Sun

Abstract The kinematics and dynamics characteristics of driving mechanism will directly affect the processing quality and efficiency of multi-link die mechanical press. Based on the structural parameters of a certain type of cold forging press, the dynamic optimal model of elbow-bar driving mechanism is established. Several performance indexes both in the respect of kinematics and dynamics were put forward which were took as the objective functions and constraint functions. Based on virtual prototyping, this paper proposed an improved algorithm method for an elbow-bar driving mechanism, which can also be applied to optimal synthesis of multi-link mechanism. And with this, we find an optimized dimension of elbow-bar driving mechanism. Theoretical and simulation results examine the performance of the optimized mechanism, and demonstrate that its performance parameters are improved obviously.

Keywords Sizing optimization · Elbow-bar mechanism · Multi-objective · Forging press

1 Introduction

Under the background of near-net shape forming, the requirements of press working products have become higher and higher, so it is urgent to improve the working performance [1]. The fluidity of metal under cold forging condition is much lower than that under hot forging condition, and the forming force per unit area is much higher. The forming force of cold forging is sensitive to the forming speed, which requires "forming in accordance with the trend," that is, the forming speed should be as low as possible. The traditional crank press has been unable to meet the needs of the current industrial production. Multi-link presses are widely used in the precision forging of parts, owing to its more reasonable main driving mechanism. The dimension synthesis of the connecting rod is an important part of the design of the

press. The dimension parameters of the elbow-bar mechanism determine the main performance of the press [2–4].

The relationship between the rod dimension parameters and the motion lows of the elbow bar press is intricate and nonlinear, so there are still many difficulties in designing a superior mechanism which can satisfy all the requirements and constraints. In the last two decades, several papers on synthesis driving mechanism of mechanical multi-linkage press have been published. In Refs. [5], the kinematic simulation analysis of six link mechanism is carried out by using the simulation software SIMULINK. This method does not need to write tedious programs, reduces the workload, and can easily get the displacement, velocity, and acceleration curves of the pressure mechanism, but this method cannot be used for optimal design. The author makes kinematic analysis on the mechanical characteristics of the linkage mechanism of mechanical press, and studies and compares the mechanical characteristics of traditional driving and new design driving from the aspects of sliding speed, productivity, bearing capacity, and possible workpiece size [6]. In Refs. [7], the optimization model of the six link mechanism was established by using the self-developed universal optimization design software SIPESC. OPT. The optimization software first uses genetic algorithm to get an optimization result, then uses SLP and SQP algorithm to optimize the solution, respectively, compares the optimization results of the three algorithms, and finally gets a satisfactory optimization result. In Refs. [8], the formulas for calculating displacement, velocity, and acceleration of a given motion track are derived by using the theory of Fourier series, and the optimization mathematical model of the mechanism is established. In reference [9], the optimal design of the driving mechanism of the six bar mechanical press is carried out by using the optimization algorithm combining the penalty function and the complex shape, taking the minimum speed fluctuation of the slider and the minimum speed of the contact plate as the optimization objective. Li [10] takes minimum of crack length and maximum of stamping angle as the evaluation index. In the meantime, the optimal model was established with MATLAB.

There are a few studies on multi-objective optimization of the multi-link press both in kinematics and dynamics at once. Researchers always optimize the mechanism for kinematic first, and then check its dynamic performance. In order to improve the working performance of cold forging press both in the kinematics and dynamics, this paper defines the minimum eccentric gear input torque and minimum velocity when the slider first contacts with the workpiece as the objective function. The optimal design model of the press is established by using ADAMS to optimize the size of elbow-bar driving mechanism.

2 Modeling of Elbow-Bar Driving Mechanism

2.1 Introduction of Elbow-Bar Mechanism

Multi-link mechanism presses have become widely used. Compared with the crank press, the elbow-bar press has the other two components: the toggle rod and the upper rod, which can be seen from Fig. 1. The crank is in uniform circular motion during the runtime, the eccentric gear and multi-linkage transfer the circular motion to sliding vertically. Finally, the sliding motion of main slider is achieved along guide rail in vertical direction.

The elbow-bar cold forging press has a more reasonable driving mechanism, which can achieve large slider stroke with small eccentric gear torque; in the plastic deformation area of workpiece, the slider has low working speed to prevent the workpiece from cracking, reduce impact vibration and noise, and improve the service life of die.

2.2 Modeling of Elbow-Bar Mechanism

Adams/view is a commercial software for kinematic and dynamic simulation of mechanical system. A parametric virtual prototyping model was build up using the modeling and analysis function of ADAMS to model. According to the parameterized length of the rod, each component of the model is created. And the corresponding

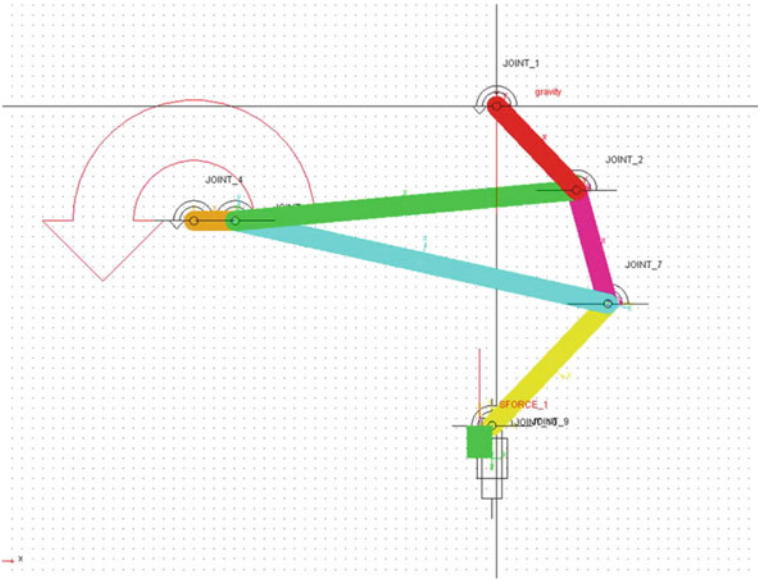

Fig. 2 Parametric virtual prototype model. (Color figure online)

rotating pair and sliding pair are added to the parts according to the actual motion. The established virtual prototype model is shown in Fig. 2.

Based on the parametric virtual prototype model, several parameters can be input or measured. In order to analyze the kinematics and dynamics of the elbow-bar driving mechanism and get the constraint and objective function, it is necessary to input the rotation speed of the crank according to the actual working condition. Nominal pressure is applied to the slider when it is in the nominal stroke. Then, measurement for the speed, acceleration, and displacement of the slider is established. Because the cross-sectional shape and area of the bar system cannot be determined, the friction coefficient and self-weight of the rods and the slider are ignored here. In addition, it can also measure the input torque of the drive shaft, that is, the eccentric gear. Finally, the output performance of the press is calculated when the input torque is obtained. All the physical parameters and notations are listed in Table 1.

3 Optimization Design of Elbow-Bar Driving Mechanism

3.1 Design Variable

The driving mechanism and coordinate system are shown in Fig. 1b, which is used for representing the mechanism easily.

Table 1 Physical parameters (i = 1,…,6)

Parameters	Notation
Length of link	Li
X-coordinate of eccentric gear center	C_x
X-coordinate of eccentric gear center	C_y
Angle between link to horizontal axis	α_i
Angle between L_2 and L_5	θ
Nominal pressure	F
Nominal pressure stroke	S_t
Stroke	H
Slider acceleration	a
Slider velocity	v
Slider displacement	s
Stroke rate	n
Eccentric gear input torque	T

As can be seen from Fig. 1b, we can know that the geometric parameters in the bar system include length of the rods:$L_1, L_2, L_3, L_4, L_5, L_6$, the lateral distance between center of slider and point O, x- and y-coordinates of the center of eccentric gear C_x, C_y. The angle θ between L2 and L5 is a redundant parameter, so the number of parameters which expect to be optimized are 9. The corresponding design variables are defined as follows:

$$X = [x_1, x_2, x_3, x_4, x_5, x_6, x_7, x_8, x_9]^{\mathrm{T}} = [L_1, L_2, L_3, L_5, L_6, \mathrm{e}, C_x, C_y]^{\mathrm{T}} \quad (1)$$

3.2 Objective Function

How to determine the evaluation index of transmission mechanism reasonably is of great significance to improve the overall performance of transmission mechanism. The evaluation index must be relevant with the working performance and process requirement.

Firstly, in the case of a certain nominal force and nominal stroke, the input torque of the press should be as small as possible. This is favorable for the selection of motor, the price of high-power motor is very high, and reducing the power of motor can prove economical. This also ensures that the same power of the motor can produce greater output force, and can produce and form larger products. Besides, the quick-return characteristics can reconcile quality of products and production efficiency. The working speed of the slider of the mechanical press in the forging stage should be less than the maximum speed allowed by the workpiece deformation.

So, this paper sets the optimization goal as minimum eccentric gear input torque and minimum velocity when the slider first contacts with the workpiece.

$$f_1(X) = \min V_{st} \tag{2}$$

V_{st} means the velocity of slider on the nominal stroke.

$$f_2(X) = \min T \tag{3}$$

In order to get the accurate stroke of the slider and improve the quality of the running curve of the slider, the stroke constraint is treated by the outer point penalty function method, and the penalty term is added to the objective function. According to the trade standards, the minimum value of slider travel is set as H_{min}, the maximum value of slider travel is set as H_{max}, generally H_{min}, $H_{max} = H \pm 1\%$.

Therefore, the unified objective function is established as follows:

$$\min f(X) = \min \left\{ \sum_{j=1}^{2} \omega_j f_j(X) + \gamma_k \varphi(X) \right\} \tag{4}$$

where ω_j is the weighting factors of the branch objective function, while γ_k is penalty factor in penalty function method.

Among them, the penalty is

$$\varphi(X) = \left| H(X) - \frac{H\max + H\min}{2} \right| - \frac{H\max - H\min}{2} \tag{5}$$

3.3 Constraint Function

As can be seen from Fig. 1b, there is a crank rock mechanism in the driving mechanism. The constraint conditions for establishing the crank rock mechanism are

$$\begin{cases} g_1(X) = x_3 - x_2 \le 0 \\ g_2(X) = x_3 - x_1 \le 0 \\ g_3(X) = x_3 - L_0 \le 0 \\ g_4(X) = x_3 - x_2 + L_0 - x_1 \le 0 \\ g_5(X) = x_3 - L_0 + x_2 - x_1 \le 0 \\ g_6(X) = x_1 - L_0 - x_2 + x_3 \le 0 \end{cases} \tag{6}$$

L_0 represent the distance between origin of coordinates—point O and the center of eccentric wheel—point C.

In order to ensure the good force transmission effect and prevent the slider from being subjected to excessive lateral force, the constraint conditions of sliding block transmission angle are established as follows.

In order to prevent the sliding block from being subjected to excessive lateral force and ensure that the lateral force does not change direction in the forging process, the constraint condition of sliding block transmission angle is established as follows:

$$\begin{cases} g_7(X) = \arccos\left(\dfrac{L_0^2 + x_1^2 - (x_3 + x_2)^2}{2L_0x_5}\right) - \arctan(-x_8/x_9) - \beta_{\max} \le 0 \\ g_8(X) = -\arccos\left(\dfrac{L_0^2 + x_1^2 - (x_3 + x_2)^2}{2L_0x_5}\right) + \arctan(-x_8/x_9) + \beta_{\min} \le 0 \end{cases} \tag{7}$$

$\beta_{\max}$, $\beta_{\min}$ express the maximum and minimum allowable upper link deflection angles, respectively.

4 Optimization Result

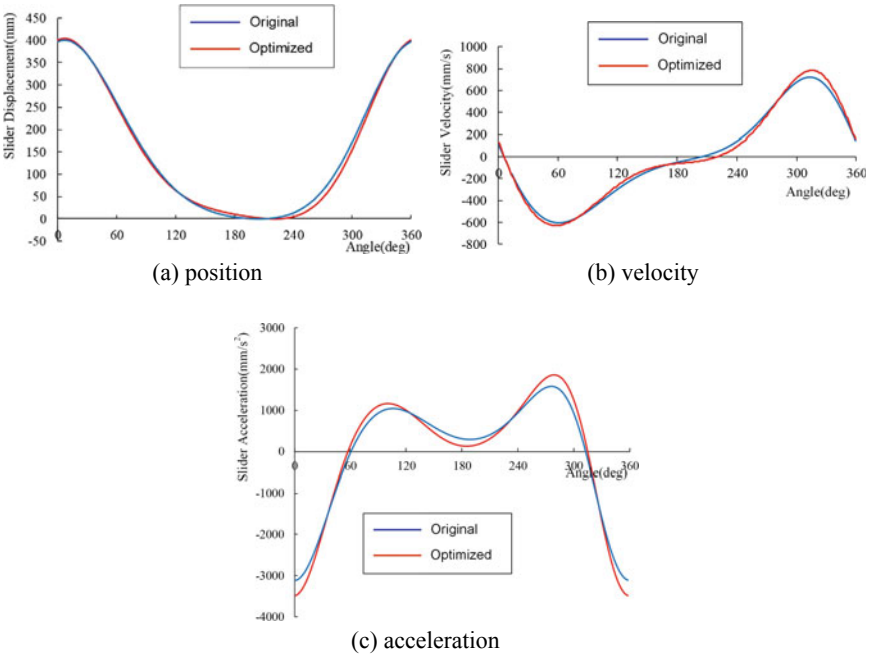
Taking a cold forging press that is used for net-near shape forming, for example. The technical parameters of the press are as follows: nominal pressure, 10000 kN; nominal pressure stroke, 25 mm; main slider stroke, 400 mm; and maximum stroke rate of main slider, 30SPM.

Weighting factors $\gamma_k = 10$, $\gamma_k = 10$, considering the limitation of the structure size of the press frame, the feasible region of design variables is taken as

$$\begin{aligned} X = [x_1, x_2, x_3, x_4, x_5, x_6, x_7, x_8, x_9]^T \in \\ [550, 670, 1650, 1800; 190, 250; 1850, 2000; 600, 800; \\ 750, 950; -25, 5; -1600, -1400; -650, -550]^{\mathrm{T}} \end{aligned}$$

According to the mathematical model of the above optimal design, the optimization program is written by MATLAB. In order to facilitate the manufacturing and accuracy detection of each pole in engineering practice, the optimized results are rounded. The optimal and initial design values are given in Table 2.

Through kinematic analysis, we can get the different curves of the slider. According to the comparison of the curves of the slider before and after optimization, it is obvious that the optimization result is superior to the original parameter, as shown in Fig. 3.



The position of the bottom dead center moves to the right, and the displacement is much more gentle in the forming stage, which shows that the speed of the workpiece forming process is slow and the return speed is fast, with good quick-return characteristics.

Table 2 Initial value and optimal value of design variables

Design variables	Initial variables	Optimal value
L1/mm	610	574
L2/mm	1720	1670
L3/mm	205	220
L4/mm	1930	1882
L5/mm	720	602
L6/mm	845	803
e/mm	−15	−20
Cx	− 1500	−1500
Cy	−615	570

Table 3 Comparison of optimization of the objective function

Objective function	Initial	Optimal
Stroke/mm	400.34	402.4
Crank angle in the down stage/°	198	215
Crank angle in 25 mm Nominal stroke/°	58	68
Velocity on the height of 25 mm/mm/s	−150	106
Total high/mm	2208.8	1972.6
Eccentric gear input torque/N·m	590000	405000

(a) position (b) velocity

(c) acceleration

Fig. 3 Kinematic curve comparison **a** position, **b** velocity, **c** acceleration. (Color figure online)

Then, the dynamic analysis was done by the virtual prototyping mode. The eccentric gear input torque is about 31.3% smaller than initial. The crank angle in 25 mm nominal stroke increases from 58° to 68°, and the crank angle in the down stage increases from 198° to 215°. This means that the time for the slider to return from the top dead point to the bottom dead point is delayed, and the corresponding coefficient of change of the stroke speed of the slider is increased. The quick-return characteristic of the mechanism is significantly enhanced.

5 Conclusion

Based on the parametric modeling in ADAMS, a virtual prototype model of elbow-bar mechanism was established. According to the process performance requirements of near-net forming and the characteristics of the mechanism, the constraint conditions and optimization objectives were set. The correctness and effectiveness of the proposed method are verified by an example. The computer simulation results indicated that the mechanical press with optimized kinematic dimensions can produce better output motion for near-net forming, and the driving torque is also reduced a lot. This paper provides theoretical basis and reference for the optimization design of similar mechanisms. The parameterized optimization results depend on the initial value to a great extent. The selection of the initial value has a great influence on the optimization results. The optimization can be continued on the basis of the given scheme.

Pre-forging Shape Design Using Conformal Mapping Method

Chengshang Liu, Wujiao Xu, and Minyao Liu

Abstract For a forging with complex shape, it is necessary to design one or more pre-forging shapes before the final forging to avoid forging defects and improve forging performance. In this paper, a novel method of using conformal mapping to design the pre-forging shape is proposed to achieve a reasonable three-dimensional (3D) shape of the pre-forging. Firstly, the 3D final forging was two-dimensionally (2D) sliced to simplify the design problem. The new profile of each slice was calculated based on the conformal mapping method. Then, the discrete points on all new profiles were combined into a 3D point cloud for surface reconstruction to obtain 3D model of the pre-forging. Next, four parameters (conformal factor and triaxle scaling factors) were applied to describe the pre-forging shape. Finite element analysis was used to simulate the forging process of the designed pre-forging. Finally, this method was applied to design the pre-forging shapes of different forgings. Through reasonable parameter values, a satisfactory pre-forging shape can be obtained. This method is effective, easy to implement, and has universal adaptation.

Keywords Pre-forging shape design · Conformal mapping · Finite element analysis

1 Introduction

For a forging with complex shape, it is necessary to design one or more pre-forging shapes before the final forging to avoid forging defects and improve forging performance. The design method of the pre-forging shape is mainly to verify the design results by using numerical simulation technology. The basic ideas are usually as follows. First, the design parameters of the pre-forging are selected, such as geometric parameters (length, width, fillet radius, etc. [1–3]), or curve parameters (polynomial curve parameters, Bessel curve parameters, etc. [4, 5]). Next, specific values for each parameter within a reasonable range was set to form a pre-forged shape. Then, the

G. Daehn et al. (eds.), *Forming the Future*, The Minerals, Metals & Materials Series,
https://doi.org/10.1007/978-3-030-75381-8_241

numerical simulation technology is used to analyze the advantages and disadvantages of this pre-forging shape. And the performance of this pre-forging shape is parameterized to obtain the fitness value. The change of each parameter value will lead to a different pre-forging shape, thus obtaining a different fitness value. Furthermore, the mathematical relationship between design parameters and the fitness can be constructed by using a response surface or a neural network [6, 7]. Finally, the optimization method can be applied to optimize the fitness value to obtain an optimized combination of design parameters [3, 8].

The design parameters of the pre-forging shape are mainly determined by the experience of designers, so the design parameters of different forgings may be completely different. Moreover, the pre-forging shape is complicated for a complex final forging shape, so it is impossible to describe the pre-forging shape with a few simple design parameters. Therefore, poor universality and excessive design parameters are the important reasons that limit the application of the traditional method. In order to improve the above problems in the pre-forging design process, a novel method of conformal mapping for designing the shape of pre-forging was first proposed in this paper.

2 Conformal Mapping Method

2.1 Slice of Final Forging

The 3D design problem can be transformed into a 2D design problem by slicing, which simplifies the design process. Therefore, the slice of a 3D model is an important part of the pre-forging shape design. And a series of 2D closed profiles are the basis for subsequent analysis.

An automobile connecting rod forging is taken as an example. Figure 1a shows the 3D solid model of the final forging. In order to illustrate the slice results clearly, the final forging was cut into slices with thicknesses 20 and 10 mm, respectively, as shown in Fig. 1b, c. In the actual slicing process, the number of slice layers reached 1,000, which minimized the error of the step effect [9]. The conformal mapping method was used to process the 2D slice in the following section.

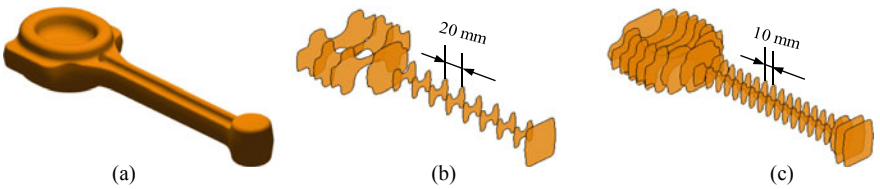

Fig. 1 Slicing results for **a** connecting rod final forging **b** with a thickness of 20 mm and **c** with a thickness of 10 mm. (Color figure online)

2.2 Conformal Mapping Theory

The motion of the continuum can be represented by the initial and instantaneous coordinates of a particle. Set the initial coordinate of the particle at the time t as $\boldsymbol{p}(x, y, z)$, and the instantaneous displacement of the particle is $\Delta \boldsymbol{u}$ after the time Δt. So, the instantaneous coordinate of the particle at the time $t + \Delta t$ is $\boldsymbol{p} + \Delta \boldsymbol{u}$. Set $\Delta t \to 0$, then the velocity vector field of the deformation region can be expressed as

$$\boldsymbol{v}(\boldsymbol{p}, t) = \lim_{\Delta t \to 0} \frac{\Delta \boldsymbol{u}}{\Delta t} \tag{1}$$

Equation (1) represents the instantaneous velocity vector field of all particles in the deformation region. According to the principle of volume invariance of materials during plastic deformation, $\mathrm{div}\boldsymbol{v} = 0$ can be obtained, which can be expressed by the potential function φ as

$$\mathrm{divgrad}\varphi = \nabla \cdot \nabla \varphi = 0 \tag{2}$$

so

$$\nabla^2 \varphi = \frac{\partial^2 \varphi}{\partial x^2} + \frac{\partial^2 \varphi}{\partial y^2} + \frac{\partial^2 \varphi}{\partial z^2} = 0 \tag{3}$$

Besides, the velocity vector field satisfies the irrotational condition, i.e., $\mathrm{rot}\boldsymbol{v} = 0$, which can be expressed as the stream function ψ:

$$\nabla^2 \psi = \frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} + \frac{\partial^2 \psi}{\partial z^2} = 0 \tag{4}$$

It can be seen from Eqs. (3) and (4) that the potential function and the stream function of the velocity vector field satisfy Laplace's equation.

In mathematics, conformal mapping has been classically applied to harmonic functions, i.e., solution of Laplace's equation [10]. In physics, it is noted that some physical equations are conformal invariant and thus are equally well suited for conformal mapping, including the advection–diffusion equation for potential flows, the Nernst–Planck equation for bulk electrochemical transport, and Laplace's equation for electrostatic potential.

The equipotential method [11] uses the similarity principle to design the pre-forging shape. However, this method often requires the coupling of multiple software, for example, Ansys software used for solving Laplace's equation to obtain the contours distribution, and Catia software used for surface reconstruction. Repeated data import and export operations reduced the practicality of such a design method. The conformal mapping method uses the numerical method of MATLAB software to solve the contour of the same conformal value, which is called potential value in

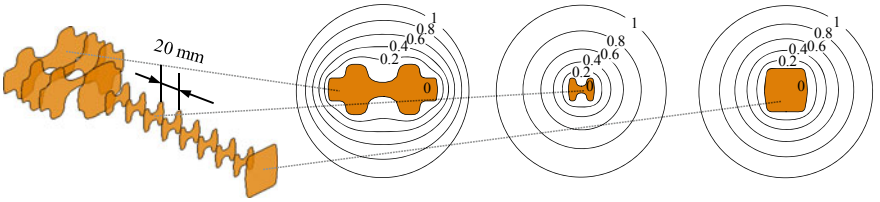

Fig. 2 The conformal mapping results of three representative slices extracted from all slices. (Color figure online)

the equipotential method. There is no need to use other platforms when designing the shape of pre-forging by using the conformal mapping method, which is more convenient and simpler.

The conformal value of the final forging is set as 0 and the conformal value of the initial billet is set as 1. Then the conformal value of the pre-forging is in the range of 0–1. Figure 2 is the conformal mapping results of three representative slices extracted from all slices, where different conformal values correspond to different profiles that do not intersect each other. As shown in Fig. 2, the lower the conformal value, the closer the similarity between the profile and the final forging. The higher the conformal value, the closer the similarity between the profile and the initial billet. Therefore, the conformal value can be adjusted to control the shape of pre-forging.

2.3 Surface Reconstruction

After selecting an appropriate conformal value, the conformal mapping was performed for all slices. Figure 3a shows the mapping result of the conformal value of 0.2 for all slices of Fig. 1c. Next, discrete points were extracted from the mapping profile on the slice. Then the discrete points on all 2D slices were constituted into a 3D point cloud, as shown in Fig. 3b. Finally, surface reconstruction of the point cloud was performed to obtain the 3D model of pre-forging, as shown in Fig. 3c.

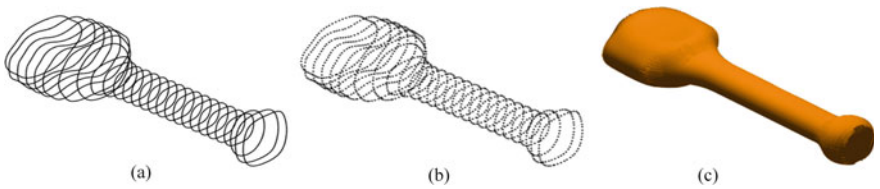

Fig. 3 Construction flow of the pre-forging shape: **a** conformal mapping result; **b** point cloud; **c** surface reconstruction. (Color figure online)

3 Results and Discussion

In the Chap. 2, the conformal mapping method was used to design the pre-forging shape. As a result, the 3D model of the pre-forging shape was successfully obtained. Following this, the influence of some parameters on the shape of the pre-forging was studied, mainly the conformal factor α and scaling factor β.

Firstly, the influence of the conformal factor α on the pre-forging shape was discussed. According to the conformal mapping method, the 3D models of pre-forging with different conformal factors were obtained, as shown in Fig. 4. It can be found that for the 3D shape of pre-forging, the lower the conformal value, the closer the similarity between the pre-forging and the final forging. From the perspective of plastic forming, the physical significance of the conformal factor is to characterize the amount of deformation. The lower the conformal value, the smaller the total deformation. Specifically, the shape of pre-forging is the same as the shape of final forging if the total deformation is 0.

The actual forging process is usually not net-shape forming or near-net-shape forming, so the volume of the pre-forging V_{pre} is not equal to final forging V_{final}, i.e., the flash volume V_{flash} should also be considered. Therefore, the triaxle scaling factors, β_x, β_y , and β_z, were introduced, and satisfying

$$V_{\text{pre}} = V_{\text{final}} + V_{\text{flash}} = \beta_V \cdot V_{\text{final}} = \beta_x \beta_y \beta_z \cdot V_{\text{final}} \tag{5}$$

where β_V is the volume scaling factor, $\beta_V = \beta_x \beta_y \beta_z$, and $\beta_V \geq 1$. For a net-shape forming, $\beta_V = 1$, i.e., $\beta_x \beta_y \beta_z = 1$. For an oblong-shape forming, the metal flow along the axial direction (the axis z) is usually less, i.e., $\beta_z = 1$. The forging of connecting rod can be regarded as an oblong-shape forging, so $\beta_z = 1$. And fixed $\beta_x = 1$ to ensure that the pre-forging can be placed in the mold. In order to ensure that the final forging has a suitable amount of deformation, set $\alpha = 0.2$. Next, the

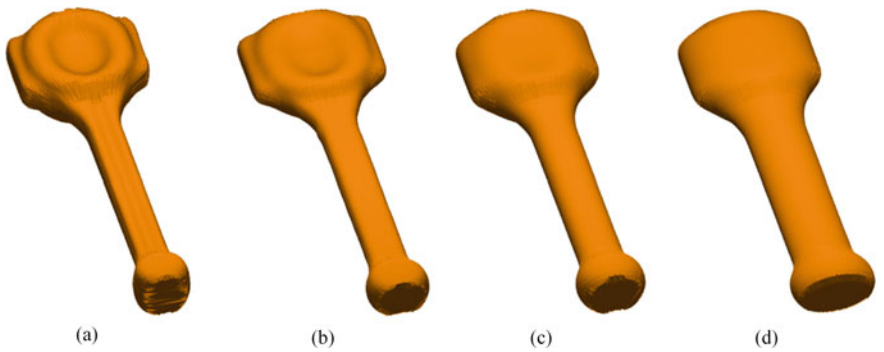

Fig. 4 Effect of conformal factor α on the shape of pre-forging: **a** $\alpha = 0.05$, **b** $\alpha = 0.1$, **c** $\alpha = 0.2$, **d** $\alpha = 0.4$. (Color figure online)

influence of the scaling factor β_y along the axis y on forming quality was discussed, as shown in Fig. 5.

When the scaling factor was small, there were significant unfilled areas on the forging due to insufficient materials, as shown in Fig. 5a, b. When the scaling factor was large, the flash area was also large, which caused material wasting, as shown in Fig. 5c, d. The above two phenomena were consistent with the conclusion of Eq. 5. Thus, it is important to choose an appropriate scaling factor. Finally, the design parameters of the connecting rod in this paper were selected as $\alpha = 0.3$, $\beta_x = 0.9$, $\beta_y = 1.20$, and $\beta_z = 1$. The shape of pre-forging and the forming results are shown in Fig. 6a.

In order to test the universality of designing pre-forging by the conformal mapping method, the pre-forgings design was carried out for different forgings, such as landing gear and transmission bar. As shown in Fig. 6b, c, the desirable forming result can be obtained through the well-designed parameters of pre-forgings.

As shown in Fig. 6, for various forgings with different shapes, four design parameters were reasonably taken to obtain a satisfactory pre-forging shape. The finite

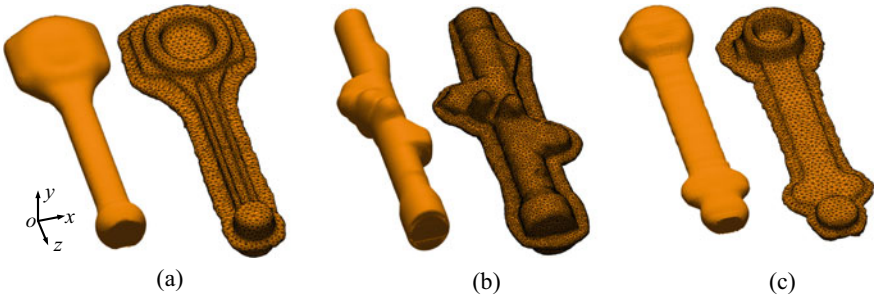

Fig. 6 The shape of pre-forging and forming results for different forgings: **a** connecting rod ($\alpha = 0.3$, $\beta_x = 0.95$, $\beta_y = 1.20$, $\beta_z = 1$); **b** landing gear ($\alpha = 0.2$, $\beta_x = 0.9$, $\beta_y = 1.25$, $\beta_z = 1$); **c** transmission bar ($\alpha = 0.2$, $\beta_x = 0.95$, $\beta_y = 1.20$, $\beta_z = 1$). (Color figure online)

element analysis indicates that the designed pre-forging was well filled and the flash distribution was uniform. Therefore, the conformal mapping method proposed in this paper can be used to design the pre-forging shape of complex forging.

4 Conclusions

In this paper, the main conclusions are as follows:

(1) Physically, the potential function and the stream function of the velocity vector field satisfy Laplace's equation. The conformal mapping has been classically applied to solve Laplace's equation.
(2) The 3D solid model of the pre-forging is reconstructed by the conformal mapping method. This method has the characteristics of high calculation speed and easy implementation.
(3) For various forgings with different shapes, four design parameters were reasonably taken to obtain a satisfactory pre-forging shape. The conformal mapping method has universal adaptability to different forgings.

Value of, and Limits to, Simulation

Constitutive Law Parameter Identification for Hot Forging Using Compression Experiments on Forging Presses

Gabriel Venet, Cyrille Baudouin, and Tudor Balan

Abstract Constitutive laws for hot forming typically consider the effects of strain, strain rate, and temperature. Their parameter identification requires experiments performed on wide ranges of these three factors. Usually, specialized equipment is utilized to ensure uniform strain, strain rate, and temperature. Alternatively, parameter databases provide parameter sets for various materials and constitutive laws at a low cost. This work explores the potential of using compression experiments on industrial presses for parameter identification of such constitutive models, in order to balance the cost and accuracy of these two existing alternatives. The results are compared with the reference results produced on specialized large temperature/strain rate compression equipment. Two materials are used to prove the usefulness of the proposed methodology.

Keywords Forging · Identification · Constitutive law

1 Introduction

Numerical simulations of the forging process are widely used to prepare the production. In order to have a simulation in line with the reality, a correct modeling of the material rheology is needed. The chosen rheological model must therefore have parameters well identified. Usually, the parametric identification is done by taking as a reference experiments done with specialized equipment (see, for example, [1–4]). However, these specialized equipment aren't cheap and often force the industrial to outsource the testing to a laboratory. This paper's goal is to perform a parametric identification by using industrial presses and therefore present a possible alternative to the specialized devices. The rheological test done here is a compression test. This test was chosen because it is one of the most common tests to identify rheological parameters for the forging process [5–7]. Two presses were used to do the compression: a 600 Ton Loire hydraulic press and a 31.5 kJ Lasco screw press. The hydraulic

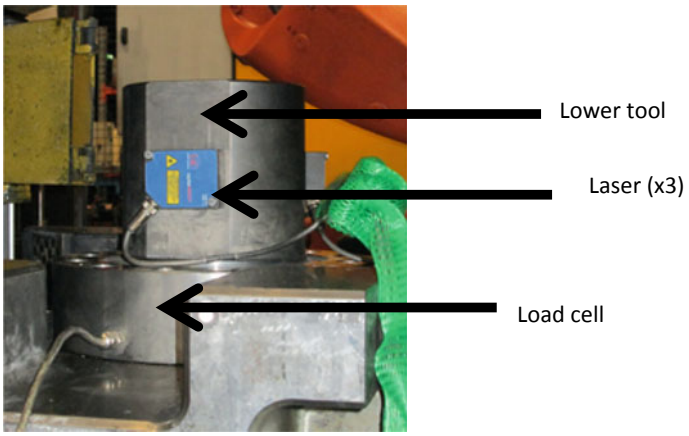

Fig. 1 Tools used for the compression tests on industrial presses. (Color figure online)

press is slow and the screw press is fast. This will help to assess the effect of speed on the rheology of the material. The studied material is a 42CrMo4 steel.

2 Tools

Although the rheological models usually link the stress to the effect of strain, strain rate, and temperature, it is not possible to measure directly the stress and the strain. Instead, the force and the displacement were measured. A specific set of tools was used to do this measurement on any press. It uses three Micro-epsilon optoNCDT 1401 laser sensors to measure the distance between the lower and upper tool at any time of the test. The force is measured with a SCAIME load cell screwed below the lower tool. Fig. 1 is a picture of the lower tool with the sensors attached to it.

3 Thermal Parameters Identification

Since we aim to identify the rheological parameters in the hot forging conditions, the billet must be heated before compression. The billets are heated in a furnace in a controlled atmosphere to prevent oxidation. But as soon the billet is moved out of the furnace, it will cool down. When the compression effectively begun the temperature inside the billet it will be very heterogeneous. To take into account this heterogeneity, a cooling test is made.

Three thermocouples are welded on the billet surface (see Fig. 2). The temperature is recorded as soon as the billet is out of the furnace. The billet is moved to the press

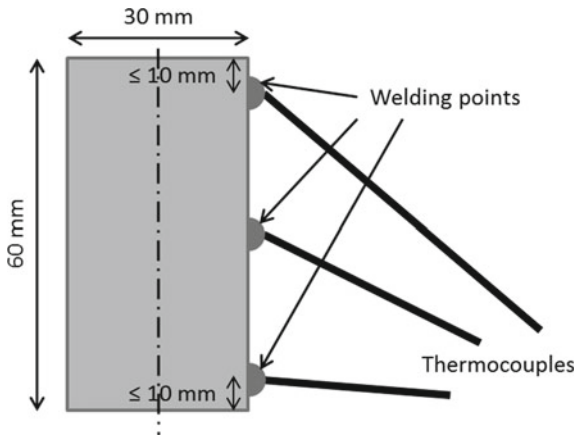

Fig. 2 Thermocouples placement

Table 1 Thermal exchange coefficients

Emissivity	Thermal exchange with air (Wm^{-2} K^{-1})	Thermal exchange with the lower tool (Wm^{-2} K^{-1})	Thermal exchange with the tools under pressure (Wm^{-2} K^{-1})
0.95	10	680	1715

and the upper tool goes down until contact (but not compression) and the temperature recording stops 40 s later.

This experiment is then reproduced with the finite element software FORGE®. Four thermal parameters are changed to simulate the temperature recorded: the billet emissivity, the thermal exchange with air, the thermal exchange with the lower tool when the billet is not under pressure, and the exchange with the two tools when the billet is under pressure. The final parameters are given in Table 1.

4 Friction Coefficient Identification

The ring test [8, 9] was used to evaluate the friction between the billet and the tools. The rings in 42CrMo4 used are 20 mm high. Their inner diameter is 35 mm and their outer diameter is 70 mm. The compressions of the rings are done with the tools presented earlier, and they are made on the screw press and the hydraulic press with two heating temperatures: 950 °C and 1100 °C. These experiments are then reproduced using the finite element software FORGE®. The friction model used is a combined Coulomb-Tresca model with two parameters. These parameters are identified by varying their values in the simulation until the inner diameter of the ring after compression in the simulation is as close as possible to the real ones. The

Table 2 Friction coefficient determined by the ring test

	Hydraulic press (1 s^{-1})	Screw press (10 s^{-1})

1857 MPa	−0.0025	−0.24	0.157	−0.06	0.00059	−0.037	0.00002	−0.069	0.033

hydraulic press and the screw press use different values of friction coefficient due to their different speed. These coefficients are presented in Table 2.

5 Compression on Industrial Presses and Parametric Identification

The compression tests are done on cylindrical billet of 60 mm high and 30 mm wide. Six different testing configurations are done with the hydraulic press (1 s^{-1}) and the screw press (20 s^{-1}) at 950 °C, 1100 °C, and 1250 °C. The force/displacement curves recorded during these tests have served as reference data in the identification. For each configuration, the thermal gradient at the beginning of the compression is simulated, thanks to the thermal exchange coefficients found earlier. Then, the simulation of the compression is made. The rheological model used is the Hensel-Spittel equation [10] (see Eq. 1).

$$\sigma = A e^{m_1 T} (\varepsilon + \varepsilon_0)^{m_2} \dot{\varepsilon}^{m_3} e^{\frac{m_4}{(\varepsilon+\varepsilon_0)}} (1 + (\varepsilon + \varepsilon_0))^{m_5 T + m_6} e^{m_7 (\varepsilon+\varepsilon_0)} \dot{\varepsilon}^{m_8 T} T^{m_9} \quad (1)$$

σ is the stress, ε the equivalent strain, $\dot{\varepsilon}$ the strain rate, and T the temperature. A, ε_0, and the coefficients m_1 to m_9 are the parameters. By using the built-in optimization algorithm of FORGE®, a genetic algorithm helped by a kriging metamodel [11, 12], the rheological parameters of the material are changed until the solution presented in Table 3 and Fig. 3 is found.

6 Discussion and Conclusion

The average difference on all the curves between the simulation and the measure is equal to 13.6%. Although this difference is not negligible, it is in the same order of magnitude as the difference if the simulation is made with the Hensel-Spittel parameters from the FORGE® database (16.9%). Consequently, the identification

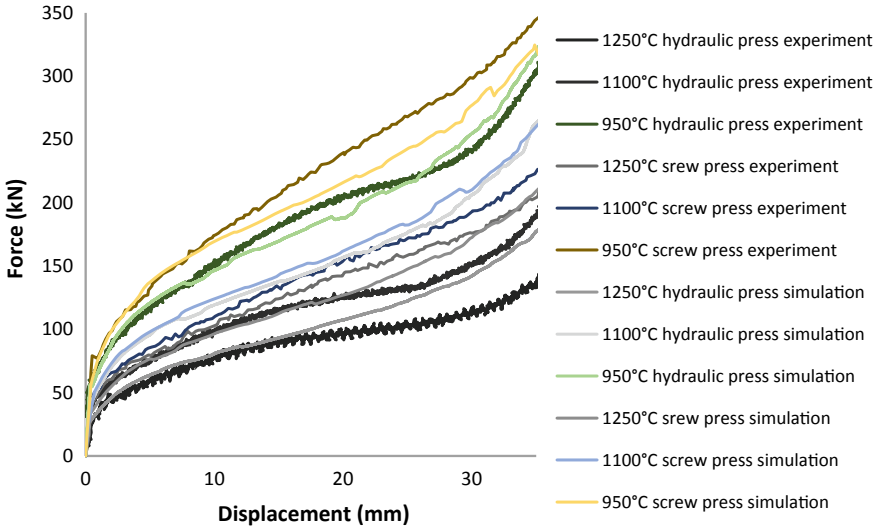

Fig. 3 Force/displacement curves from the experiment and the simulation after optimization. (Color figure online)

on industrial press could serve as an alternative to the specialized devices, in particular if there is no database available. This situation is more and more frequent in industry as new materials are adopted for manufacturing. The advantage is not only the cost but also the availability of the identification procedure onsite and its adaptability to the actual forming conditions (temperature, press speed, etc.).

FE Simulations of Piercing and Trimming of AL and AHSS Alloys

David Diaz-Infante, Advaith Narayanan, Adam Groseclose, and Taylan Altan

Abstract For a given sheet material and thickness, the cutting conditions (punch/die clearance, punch shape, tool corner radii, lubrication, cutting speed, tool wear, and elastic deflection of tool and press) affect the cut edge and the quality of the subsequent forming or flanging operations. Factors such as friction and tool wear are becoming more important as the use of stronger alloys is increasing. This study uses the finite element method to evaluate the effect of these parameters on the edge characteristics and the cutting forces involved (vertical and horizontal). Aluminum 5182-O and CP-W 800 with different sheet thicknesses (1.2 mm and 4.0 mm) were considered. The results indicated that both tool wear and coefficient of friction play a role on the analysis of piercing and trimming and should be accounted for. The effect of each of these variables changes with sheet thickness, material, and process type. This study also illustrates the difficulties and limitations of FE analysis in predicting piercing/trimming variables.

Keywords Critical damage value · FE simulations · Piercing · Trimming · Edge quality · AHSS · Aluminum

1 Introduction

Piercing and trimming are required operations in nearly all sheet metal processes and the characteristics of the edge produced by these operations are influenced by the cutting method. It is well known that mechanical piercing and trimming produce significant damage to the edge, which limits the edge stretchability in subsequent operations. On the other hand, waterjet cutting [1] or laser cutting [2] generate lesser

work hardening and minimal burrs at the cut edge, thus enhancing edge stretchability. However, waterjet cutting and laser cutting may not be practical for mass production due to the tight time constraints involved. Hence, this study will only deal with mechanical cutting processes as it is the most prevalent during production of sheet metal parts.

Some of the variables involved in mechanical trimming and piercing are (a) blank material properties, microstructure and thickness, (b) punch/die alignment, (c) punch/die clearance, (d) elastic deflection and vibrations in the press and tooling, (e) press speed, (f) tool wear and tool edge radii, (g) hardness near the cut edge before and after the cut, (h) coefficient of friction, and (i) possible use of a counter punch. The current trend in the metal forming industry is to move to higher strength and/or lighter alloys. Thus, parameters such as coefficient of friction, tool wear, and tool radii are becoming more important as the operating conditions are getting more severe.

The schematics of piercing and trimming are shown in Fig. 1. The parameters involved in piercing and trimming include sheet material and thickness (t), punch-die clearance (s), punch and die corner radius (r_p and r_d), punch shape, cutting speed (r_p), and blank holder pressure (p_b). Additionally, cutting length (l_c), punch length (l_p) for trimming, and diameter of the punch (d_p) for piercing. Studies conducted on the effect of punch-die clearance (s) on edge stretchability showed that clearances of 15% of sheet thickness or below yielded a good edge in piercing and trimming for aluminum alloys [2, 3] while a clearance in the range of 10–20% of sheet thickness is ideal when cutting advanced high strength steels (AHSS) [4–6].

While the vertical forces involved in trimming and piercing are typically considered, the horizontal forces are often neglected. The literature including horizontal forces in such cutting processes is limited even when these forces may be significant

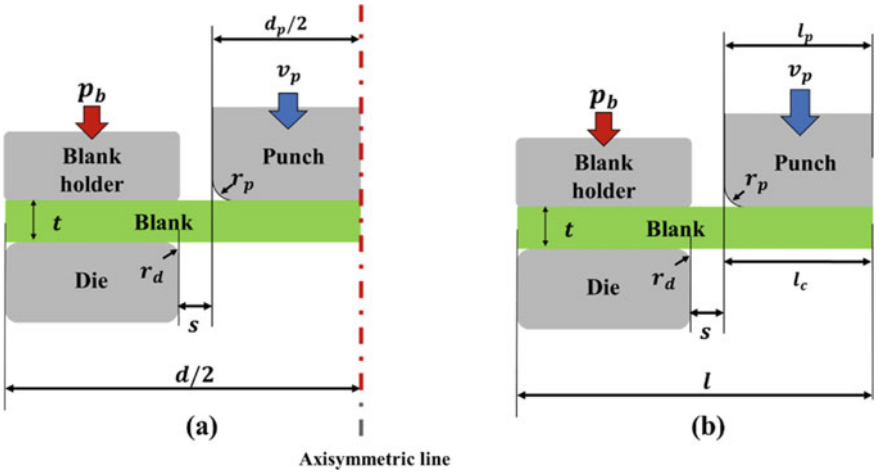

Fig. 1 Schematic of **a** piercing (closed-line cutting) and **b** trimming (open-line cutting). (Color figure online)

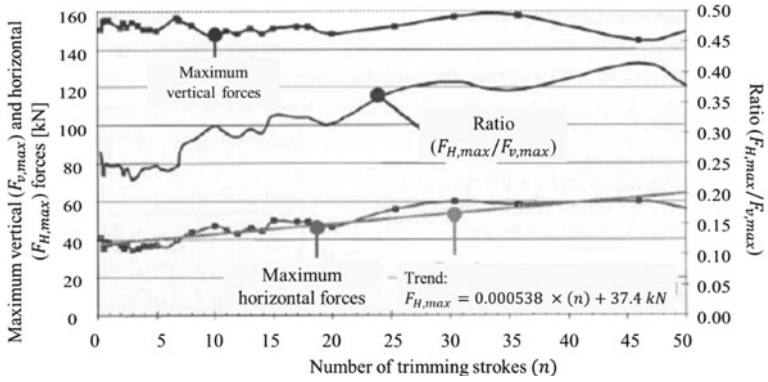

Fig. 2 Variation of the ratio ($F_{H,max}/F_{v,max}$) on tool wear (or number of trimming strokes) for DP600 [7]. (Color figure online)

[7]. This is especially interesting in the presence of worn tools (increased tool radii), which also lead to a significant decrease of the edge stretchability [8, 9]. The findings [7] indicated that the horizontal forces on the punch increase with tool wear (Fig. 2). This study was conducted for a 1.15 mm thick dual-phase (DP) steel with ultimate tensile strength of 600 MPa, and the high cutting forces made the process more prone to elastic deflections and subsequently a non-uniform cutting clearance.

In addition to the horizontal forces, the effect of coefficient of friction (CoF) on the characteristics of the cut edge is also often overlooked. Some FE simulations indicated that the blanking load increased by up to 8% when increasing the coefficient of friction (CoF) from 0.0 to 0.3 for a 1 mm thick mild steel [10]. However, to the best of the authors' knowledge, the effect of CoF on edge quality and forces has not been investigated for AHSS and aluminum. Furthermore, whether a given trend of edge quality and forces hold for sheets of various thicknesses was not investigated previously.

By comparing "thin" 1.2 mm (used in A and B-pillars) and "thick" 4.0 mm (used to make chassis components) sheet metal and using FE simulation, this work aims to approximate the effect of the coefficient of friction and the tool wear (change in tool radii) on the edge quality and cutting forces (vertical and horizontal). Materials included are one aluminum alloy (Al5182-O) and one AHSS (CP-W800). The illustration of the advantages and limitations of FE simulations in predicting the edge quality is also part of the objective.

2 Definition of Edge Quality

There are mixed opinions regarding how to define edge quality or edge stretchability. One of the most common methods is to characterize the cut edge by its geometry (Fig. 3). Previously, the burr height has been related to edge cracking for DP500 and

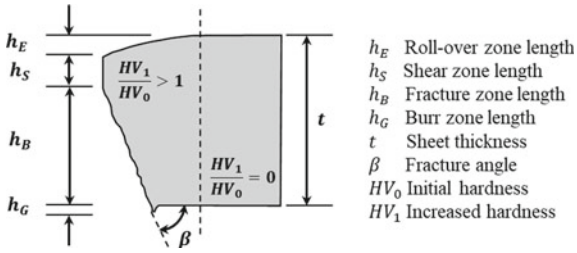

Fig. 3 Cut edge geometry and its characteristics [15]

AA6111-T4 [11]. However, it has been reported that the burr length is practically non-existent for 980 MPa dual-phase (DP) steel for clearances from 5% to 30% [12]. Therefore, the interpretation of edge geometry in terms of what constitutes a good edge quality is wide. Furthermore, it was proposed that the ratio of shear zone length (h_S) and the fracture zone length (h_B) is a good indicator of edge quality for AHSS [12]. Measuring or calculating the stresses at the edge is another method used to estimate edge quality. A study [13] indicated that tensile residual stresses at the edge leads to earlier edge fracture. Certain studies [8, 14, 15] indicated that strain hardening or hardness near the cut edge is the primary factor dictating edge fracture in a material.

Based on the various approaches in the literature, this study will attempt to differentiate the edge quality among cut edges in terms of burr zone length (h_G) and strains, which bear a direct relation to strain hardening or hardness. These strains are calculated near the cut edge and averaged (Fig. 4).

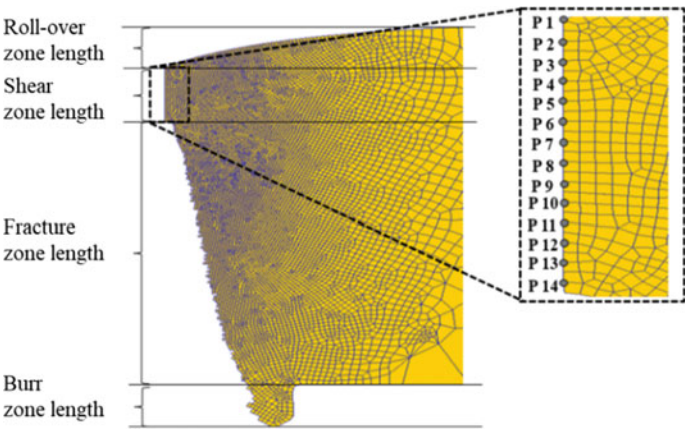

Fig. 4 Calculation of average effective strains at the shear zone of a cut edge by using the points P1-P14 [16]. (Color figure online)

3 Approach

3.1 Finite Element (FE) Model Setup

The piercing conditions used in [14] were replicated by using an axisymmetric model in DEFORM 2D software, similar to the FE model used in [16]. The mesh was generated using brick elements and refined to a size of 1% of sheet thickness near the cutting region. The punch corner radius used in [14] was chosen as 0.05 mm. However, r_p and r_d were modified to a value of 0.1 mm in this study, as previous literature indicates that the use of smaller punch and die corner radii leads to generation of slivers in aluminum. Likewise, sharpening of tools to very small radii (e.g. corner radii = 0.02 mm) may lead to very high contact pressures when piercing AHSS which may lead to chipping of tool. A punch-die clearance of 15% of sheet thickness was chosen for CP-W800 in accordance with the industry consensus that recommends clearance (s) for AHSS to be between 10 and 20% of sheet thickness. A clearance of 12.5% of sheet thickness was chosen for Al5182-O, also as per industry recommendation.

The trimming conditions used were modeled as a plane strain behavior in DEFORM 2D. The mesh size, punch-die clearance (s), and the corner radii (r_p and r_d) were kept the same as piercing. A summary of the conditions used in FE simulations is listed in Table 1.

The flow stress curve for CP-W800 was calculated from its yield strength, ultimate tensile strength, and Young's modulus (values obtained from [14]) by using the procedure described in [17, 18]. The Young's modulus (E) was assumed to be 210 GPa. The flow stress curve was extrapolated using the Holloman's power law to approximately model the behavior of the material at high strains (up to 3). The flow stress curve for Al5182-O was obtained from bulge tests previously conducted at the Center for Precision Forming (CPF)/The Ohio State University and was similarly extrapolated using the power law equation. The dependency of the flow stress curves on the strain rate and temperature was ignored for simplicity. The flow stress curves used in simulation are shown in Fig. 5.

The determination of critical damage value (CDV), which is the parameter that defines the onset of fracture during the FE simulations, was done by comparing the

Table 1 Simulation matrix for both piercing and trimming FE simulations. The clearance (s) for CP-W800 and Al5182-O were 15% and 12.5% of sheet thickness, respectively

	Sheet thickness [mm]	Coefficient of friction (CoF)	Punch/die corner radius [mm]
1		0	0.1
2	4.0	0.1	0.1
3		0.1	0.3
5		0	0.1
6	1.2	0.1	0.1
7		0.1	0.3

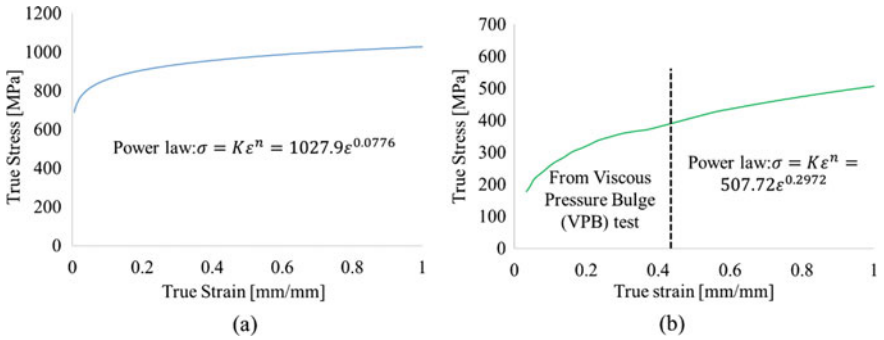

Fig. 5 Flow stress curves for **a** CP-W800 [16] and **b** Al5182-O. (Color figure online)

measured shear zone length in experiments conducted in [14, 19] and the corresponding value calculated in simulations replicating the experimental conditions, through an iterative procedure [20]. 'Adapted Rice & Tracey' fracture criterion was used to define the CDV (Eq. 1) based on observations which compared several fracture criteria in terms of correlation of simulation with experimental cut edge geometry [20].

$$\int_0^{\overline{\varepsilon}_f} e^{\frac{\alpha\sigma_m}{\overline{\sigma}}} d\overline{\varepsilon} = CDV \tag{1}$$

where σ_m = Hydrostatic stress, $\overline{\sigma}$ = effective stress, $\overline{\varepsilon}$ = effective strain and α = 2.9 for Adapted Rice & Tracey criterion. The CDV for CP-W800 and Al5182-O was found to be 1.25 and 1, respectively.

3.2 Simulation Matrix

The FE simulations conducted for piercing and trimming are listed in Table 1. The effect of coefficient of friction (CoF) and tool wear (r_p *and* r_d) on edge quality and cutting forces were investigated. Furthermore, the influence of sheet thickness (1.2 mm and 4.0 mm) on these variables was also considered for both materials. The simulation with CoF = 0.1 and corner radii (r_p, r_d) = 0.1 mm was considered as the base case. The changes in various variables were evaluated with respect to the results obtained in this simulation.

4 Results

4.1 Piercing

4.1.1 Horizontal and Vertical Cutting Forces

The maximum vertical and horizontal cutting forces corresponding to various values of coefficient of friction (CoF) and corner radii (r_p, r_d) in piercing of thick sheets (thickness = 4.0 mm) are shown in Table 2. None of the variables seem to affect the vertical cutting force (< 10% difference). The CoF seems to affect the horizontal cutting forces by up to 20% and 25% for CP-W800/4 mm and Al5182-O/4 mm, respectively, while the effect of tool wear is negligible.

Similarly, the maximum cutting forces in piercing of thin (thickness = 1.2 mm) sheets are shown in Table 3. As expected, none of the variables seem to affect the vertical cutting forces. However, tool wear seems to play a significant role on the horizontal cutting forces, about 80% and 70% increase for CP-W800/1.2 mm and

Table 2 Max. vertical and horizontal forces during piercing of thick (4.0 mm) sheets

	Case	Max. vertical cutting force [kN]	Max. horizontal cutting force [kN]
CP-W800	CoF = 0.0	308.1	116.3
	CoF = 0.1	317.9	136.0
	Worn tools (CoF = 0.1) ($^{r}pi\ ^{r}d$ = 0–3 mm)	331.2	138.0
A15182-O	CoF = 0.0	116.4	46.2
	CoF = 0.1	123.6	58.2
	Worn tools (CoF = 0.1) (r_p, r_d = 0.3 mm)	134.0	64.1

Table 3 Max. vertical and horizontal forces during piercing of thin (1.2 mm) sheets

	Case	Max. vertical cutting force [kN]	Max. horizontal cutting force [kN]
CP-W800	CoF = 0.0	100.3	*25.2*
	CoF = 0.1	101.8	24.4
	Worn tools (CoF = 0.1) (r_v,r_d = 0.3 mm)	108.4	43.4
	CoF = 0.0	39.6	16.1
A15182-O	CoF = 0.1	41.3	17.0
	Worn tools (CoF = 0.1) (r_p,r_d = 0.3 mm)	46.6	24.4

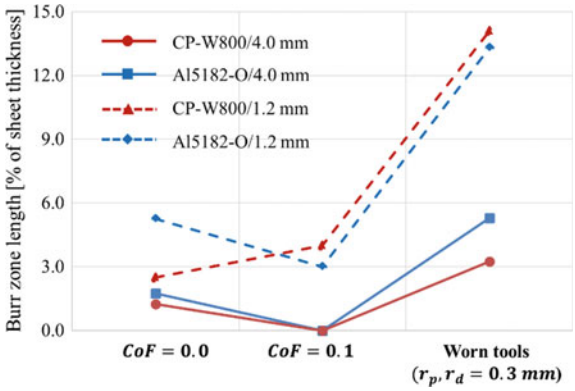

Fig. 6 The burr zone lengths (h_G) after piercing of thick and thin CP-W800 and Al5182-O sheets. (Color figure online)

Al5182-O/1.2 mm, respectively. It is hypothesized that the ratio between the punch corner radius and the sheet thickness influences the effect of the tool wear on the horizontal cutting force. Thus, this effect is more noticeable for thin sheets for similar tool wear assumption (represented by larger punch corner radius).

4.1.2 Cut Edge Geometry

The burr zone length h_g from FE simulations of piercing of thick, as well as thin sheets, is shown in Fig. 6. The burr zone length (h_G) was considered to be the parameter affecting edge quality. Regardless of the sheet material and thickness, tool wear was found to be the most significant parameter affecting the edge quality (based on cut edge geometry), among all the parameters considered in this study. Moreover, the burr length did not change significantly with the sheet thickness, and therefore, this length represents a larger percentage of the thickness for the thin sheets. This idea suggests that an absolute value for the burr length should be used as a limiting factor rather than the ratio to the total sheet thickness. The variation in burr zone lengths with changes in CoF was in the order one to two element sizes (difference of 2–3% of sheet thickness) and was considered negligible.

4.1.3 Strain Hardening Near the Cut Edge

The effective strains in FE simulations were assumed to bear a direct correlation to experimental hardness measurements. As calculations during FE simulations are subject to errors, it is assumed that a given parameter has an influence on strain hardening only if there is a difference of 10% or more in the average effective strains, at both the shear and fracture zones.

The average effective strains after piercing of thick CP-W800 and Al5182-O sheets are shown in Table 4. For thick sheets (4.0 mm thick), the CoF did not affect the edge quality for CP-W800/4 mm. However, the average strains for Al5182-O/4 mm

Table 4 Average effective strains after piercing of thick (4.0 mm) CP-W800 and Al5182-O sheets

Material	Piercing condition	Avg. effective strain at shear zone [mm/mm]	Avg. effective strain at fracture zone [mm/mm]
CP-W800	CoF = 0.0	1.68	0.81
	CoF = 0.1	1.61	0.83
	Worn tools (CoF = 0.1) (r_p, r_d = 0.3 mm)	1.89	1.04
	CoF = 0.0	1.48	0.71
A15182-O	CoF = 0.1	1.65	0.85
	Worn tools (CoF = 0.1) (r_p, r_d = 0.3 mm)	1.78	1.02

Table 5 Average effective strains after piercing of thin (1.2 mm) CP-W800 and Al5182-O sheets

Material	Piercing condition	Avg. effective strain at share zone [mm/mm]	Avg. effective strain at fracture zone [mm/mm]
	CoF = 0.0	1.50	1.00
CP-W800	CoF = 0.1	1.60	1.10
	Worn tools (CoF = 0.1) (r_p,r_d = 0.3 mm)	1.79	1.23
	CoF—0.0	1.45	0.81
A15182-0	CoF = 0.1	1.44	0.91
	Worn tools (CoF = 0.1) (r_p,r_d = 0.3 mm)	1.76	1.30

increased by about 15% with increase in CoF. It is hypothesized that the effect of CoF on edge quality as defined by strain hardening near the cut edge may be a material, as well as thickness dependent. Tool wear increased the effective strains at the edge for CP-W800/4 mm and Al5182-O/4 mm by about 25% and 20%, respectively, during piercing.

For thin (1.2 mm thick) sheets, only the tool wear seemed to increase the strains (by about 20% and 22% for CP-W800/1.2 mm and Al5182-O/1.2 mm, respectively) in piercing, as seen in Table 5.

4.2 Trimming

4.2.1 Horizontal and Vertical Cutting Forces

The maximum vertical and horizontal cutting forces per unit width of the blank for various conditions in trimming of thick sheets (thickness = 4.0 mm) are shown in Table 6. Like what was observed for piercing, none of the variables seem to affect the

Table 6 Max. vertical and horizontal forces during trimming of thick (4.0 mm) sheets

	Case	Max. vertical cutting force [kN/mm]	Max. horizontal cutting force [kN/mm]
CP-W800	CoF = 0.0	1.74	0.52
	CoF = 0.1	1.81	0.74
	Worn tools (CoF = 0.1) (r_p.r_d = 0.3 mm)	1.86	0.83
A15182-O	CoF = 0.0	0.67	0.23
	CoF = 0.1	0.71	0.30

Table 7 Max. vertical and horizontal forces during trimming of thin (1.2 mm) sheets

	Case	Max. vertical cutting force [kN/mm]	Max. horizontal cutting force [kN/mm]
CP-W800	CoF = 0.0	0.55	0.16
	CoF = 0.1	0.57	0.17
	Worn tools (CoF = 0.1) (r_v,r_d = 0.3 mm)	0.60	0.25
A15182-O	CoF = 0.0	0.22	0.09
	CoF = 0.1	0.23	0.10
	Worn tools (CoF = 0.1) (^{r}p > ^{r}d = 0.3 mm)	0.27	0.17

vertical cutting forces. However, the CoF as well as tool wear affected the horizontal cutting forces by up to 30% and 12%, respectively, for CP-W800 and by up to 25% and 25%, respectively for Al5182-O.

For thin (1.2 mm thickness) sheets, the CoF did not affect the horizontal and vertical cutting forces during trimming (Table 7). The tool wear again seems to play a significant role on the horizontal cutting forces, by about 45% and 70% for CP-W800/1.2 mm and Al5182-O/1.2 mm, respectively.

4.2.2 Cut Edge Geometry

Similar to what was observed for piercing, tool wear seemed to generate the worst edge quality for trimming of thick as well as thin Al5182-O and CP-W800 sheets, as seen in Fig. 7.

4.2.3 Strain Hardening Near the Cut Edge

The effective strains corresponding to various conditions during trimming of thick sheets (4.0 mm thick) are shown in Table 8. Contrary to what was observed for

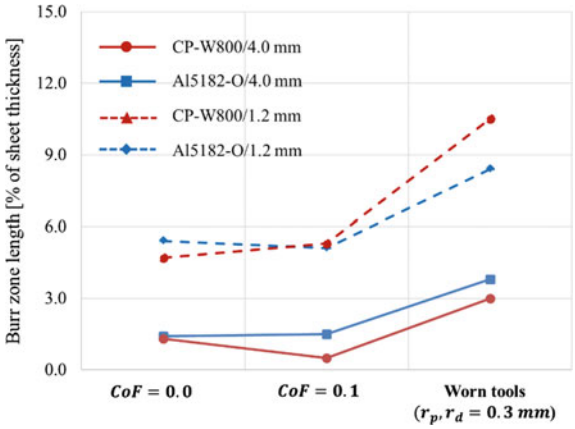

Fig. 7 The burr zone lengths (h_G) after trimming of thick and thin CP-W800 and Al5182-O sheets. (Color figure online)

Table 8 Average effective strains after trimming of thick (4.0 mm) CP-W800 and Al5182-O sheets

	Case	Max. vertical cutting force [kN/mm]	Max. horizontal cutting force [kN/mm]
	CoF = 0.0	1.37	0.50
CP-W800	CoF = 0.1	1.83	0.73
	Worn tools (CoF = 0.1) (^{r}p. ^{r}d = 0.3 mm)	2.04	0.91
	CoF = 0.0	1.72	0.50
A15182-O	CoF = 0.1	1.64	0.58
	Worn tools (CoF = 0.1) (r_p, r_d = 0.3 mm)	2.10	0.77

piercing, the CoF affected the edge quality for CP-W800/4.0 mm by about 25% during trimming, but did not affect the edge quality during trimming of Al5182-O/4 mm. The tool wear affected the edge quality for CP-W800/4 mm and Al5182-O/4 mm by about 20% and 25%, respectively, during trimming.

Similar to what was observed for piercing of thin (1.2 mm thick) sheets, only the tool wear seemed to affect the edge quality (by about 50% and 40% for CP-W800/1.2 mm and Al5182-O/1.2 mm, respectively, at the fracture zone) in trimming, as seen in Table 9.

Table 9 Average effective strains after trimming of thin (1.2 mm) CP-W800 and Al5182-O sheets

Materials	Trimming condition	Avg. effective strain at shear zone [mm/mm]	Avg. effective strain at fracture zone [mm/mm]
CP-W800	CoF = 0.0	1.54	0.60
	CoF = 0.1	1.66	0.66
	Worn tools (CoF = 0.1) (r_p,r_d = 0.3 mm)	1.81	1.04
	CoF = 0.0	1.58	0.52
A15182-O	CoF = 0.1	1.70	0.62
	Worn tools (CoF = 0.1) (r_p,r_d = 0.3 mm)	1.90	1.10

5 Conclusions and Limitations

5.1 Conclusions

In this study, the effects of the coefficient of friction (CoF) and the tool wear (represented by larger punch corner radii) were analyzed for CP-W800 and Al5182-O materials with 1.2 mm and 4.0 mm thicknesses. Based on the results from the FE simulations for piercing and trimming, the following conclusions are drawn:

5.1.1 Vertical Cutting Forces

- The vertical cutting forces increased by less than 10% by any of the process variables or the cutting process (i.e. trimming or piercing).

5.1.2 Horizontal Cutting Forces

- Horizontal forces were influenced the most by CoF on thick sheets and by tool wear on thin sheets.
- The ratio between punch corner radius and sheet thickness seems to influence the effect of tool wear on horizontal cutting forces. The larger the ratio, the larger is the effect.
- The effect of CoF on horizontal cutting forces seems to decrease with decreasing sheet thickness.
- Horizontal forces should be considered when designing tools for piercing and trimming to prevent elastic deflections which can lead to non-uniform cutting clearances. The calculated horizontal forces represented up to 50% of the vertical cutting force. This can be particularly important when dealing with high strength materials.

5.1.3 Edge Quality

- The tool wear worsens the edge quality during cutting (if either burr length or strains at the edge are considered as parameters affecting edge quality), irrespective of the material, the definition of edge quality, the cutting process (i.e. piercing or trimming), and thickness of the material.
- The CoF alone does not affect the edge quality during cutting of thin sheets. However, the effect of CoF on edge quality (defined by strain hardening near the cut edge) in thick sheets depends on the material, thickness, and the cutting process.

5.2 Limitations

- The effect of punch speed (v_p) on the edge quality and the cutting forces was not considered. It is possible that the punch speed influences the edge quality through the combined effect of increase in strain rate and temperature. However, this analysis is outside the scope of this study as the flow stress curves for the above considered materials, in function of strain rate and temperature were not available. This is compounded by the difficulty in quantifying the exact relation between these variables. Furthermore, it is difficult to obtain the heat transfer coefficients between the tools and the workpiece due to variability in the tool materials and workpiece thermal properties.
- The determination of critical damage value (CDV) is dependent on the cutting conditions and the flow stress curve. In this study, the CDV for a given material is assumed to be the same irrespective of the cutting conditions; in reality, this may not be the case. Additionally, batch-to-batch variations in a coil of a given material ensure non-uniformity in its mechanical properties. The value of CDV may affect the results obtained from FE simulations.
- Due to loss of elements and remeshing during FE calculations, it is difficult to quantify the relative effect of each process parameter. Hence, it is not recommended to rely solely on FE simulation results, especially for cutting operations such as trimming or piercing.
- The effect of each of the process parameters mentioned before was considered in isolation. The interaction between these variables and other process parameters (e.g. cutting speed (v_p), if any, cannot be accounted for in these FE simulations.

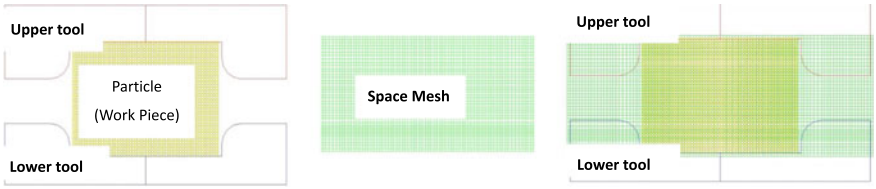
Finite Element Method Based on Space Mesh

Gang Yang and Atsushi Kinoshita

Abstract The finite element method has been widely used because of its powerful calculation since it was proposed. The method has been well developed in many different fields such as civil engineering and the aerospace industry. FEM was also used to simulate the deformation performance of materials in the metal forming process. But one of the critical problems of the conventional FEM is the termination of simulation caused by large deformation of mesh. Many studies are focused on the geographic technical method to solve the problem such as re-mesh. But the method is limited and time consumed. An element called **space mesh** is proposed for the large deformation simulation in this paper. The shape of the space mesh used in the simulation is not changed when the calculation is progressed. And the large deformation can be simulated without termination caused by the shape irregularity of the mesh.

Keywords Space mesh · Finite element method · Large deformation simulation · Boundary condition

1 Algorithm of Finite Element Method Based on Space Mesh



The **space mesh** is a square-shaped element covering the space in which the deformation happens. The nodal values of the space mesh, such as velocities, are calculated by FEM. The deformation of the workpiece is simulated by interpolation from the nodal values of the space mesh in which the workpiece is involved. For the next simulation step, the physical values of the deformed workpiece, such as strain and

Fig. 1 Definition of space mesh and workpiece. (Color figure online)

stress, are transferred from the particles to the space mesh which the particles enter. So the space mesh is not changed from the beginning to the end of the deformation simulation.

1.1 Definition of Space Mesh and Workpiece

The simulation space is divided into a square-shaped **space mesh(green)** as shown in Fig. 1. The workpiece is dispersed into dots called **particles (yellow)** and linked with lines. The space mesh is used for the formulation of FEM and particles are used to simulate the deformation of the workpiece.

1.2 Formulation

The nodal velocities of space mesh are gathered by minimizing the following functional [1]:

$$\Phi = \int_V \overline{\sigma}\dot{\overline{\varepsilon}} dV + \int_S |\tau_f \Delta v| dS + \lambda \int_V \varepsilon dV \tag{1}$$

where $\overline{\sigma}$ is the equivalent stress, $\dot{\overline{\varepsilon}}$ is the equivalent strain-rate, $|\tau_f|$ is the friction shear stress, Δv is the relative velocity, λ is Lagrange coefficient, and $\dot{\varepsilon}$ is the hydrostatic strain rate in the element defined as

$$\dot{\varepsilon} = \dot{\varepsilon}_x + \dot{\varepsilon}_y + \dot{\varepsilon}_z \tag{2}$$

Partial differentiation of formulation (1) with respect to the nodal velocity of the space mesh is expressed as

$$\frac{\partial \Phi}{\partial u_i} = 0 \quad (i = 1 \sim n)$$

$$\frac{\partial \Phi}{\partial \lambda_j} = 0 \quad (j = 1 \sim m) \tag{3}$$

where $\boldsymbol{n}$ is the number of nodes and $\boldsymbol{m}$ is the number of the space mesh which are involved in the calculation.

1.3 Boundary Condition Assignment

As shown in Fig. 2, the particle P(x,y) (yellow circle) is in contact with the tool (red line) within a space mesh (green square). To keep the particle P(x,y) moving along the surface of the tool, the boundary condition is given as follows:

$$ul_2 + vl_1 = a \tag{4}$$

where *l1* and *l2* are the cosine values of the normal vector of the tool at point P(x,y), $\boldsymbol{a}$ is a velocity of the tool in the normal direction, $\boldsymbol{u}$, $\boldsymbol{v}$ are velocities of the particle in the X,Y directions and they can be expressed as follows:

$$\begin{aligned} u &= N_1u_1 + N_2u_2 + N_3u_3 + N_4u_4 \\ v &= N_1v_1 + N_2v_2 + N_3v_3 + N_4v_4 \end{aligned} \tag{5}$$

where $\boldsymbol{N}$*1-4* are the values of interpolation function of the space mesh at point P1, $\boldsymbol{u}_{1\text{-}4}$, $\mathbf{v}$1-*4* are nodal velocities of the space mesh. By substituting formula (5) into formula (4), the boundary condition can be expressed as follows:

$$(N_1u_1 + N_2u_2 + N_3u_3 + N_4u_4)l_2 + (N_1v_1 + N_2v_2 + N_3v_3 + N_4v_4)l_l = a \tag{6}$$

The nodal velocities are calculated by minimizing the formula (1) under the boundary condition expressed in formula (6) with the nodal velocities of the space mesh.

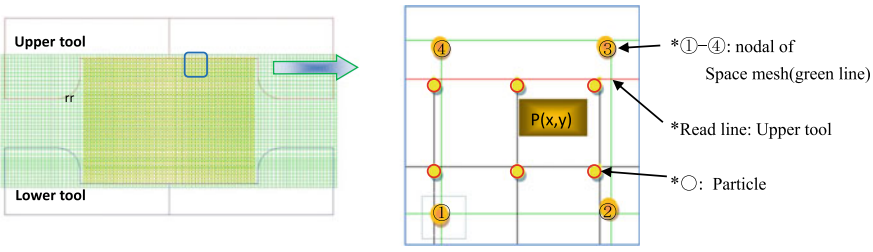

Fig. 2 Boundary condition assignment. (Color figure online)

1.4 Calculation of Workpiece

The velocity of the particle of a workpiece is calculated by interpolation from the 4-node of the space mesh in which the particle is involved.

$$\begin{aligned} u &= a_0 + a_1 x + a_2 y + a_3 xy \\ v &= b_0 + b_1 x + b_2 y + b_3 xy \end{aligned} \tag{7}$$

where ***u,v*** are velocities of particle P(x,y). Parameters ***a0-3, b0-3*** are values related to coordinate values of the particle P(x,y) and decided as follows:

$$\begin{cases} a_0 + a_1 x_1 + a_2 y_1 + a_3 x_1 y_1 = u_1 \\ a_0 + a_1 x_2 + a_2 y_2 + a_3 x_2 y_2 = u_2 \\ a_0 + a_1 x_3 + a_2 y_3 + a_3 x_3 y_3 = u_3 \\ a_0 + a_1 x_4 + a_2 y_4 + a_3 x_4 y_4 = u_4 \end{cases} \tag{8}$$

where ***u1-4,v1-4*** are nodal velocities of the space mesh.

$$[\mathrm{A}]\{\mathrm{a}\} = \{\mathrm{u}\} \tag{9}$$

where $[A] = \begin{bmatrix} 1 & x_1 & y_1 & x_1 y_1 \\ 1 & x_2 & y_2 & x_2 y_2 \\ 1 & x_3 & y_2 & x_3 y_3 \\ 1 & x_4 & y_4 & x_4 y_4 \end{bmatrix}$, $\{a\} = \begin{Bmatrix} a_0 \\ a_l \\ a_2 \\ a_3 \end{Bmatrix}$ $\{u\} = \begin{Bmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{Bmatrix}$

where the parameters ***a0-3*** are computed as

$$\{a\} = [A]^{-1}\{u\} \tag{10}$$

where $[\mathrm{A}]^{-1}$ is the inverse matrix of [A], which is a function of coordinate values of 4-node. So the velocity u of the particle P in the X-direction can be expressed as

$$u = a_0 + a_1 x + a_2 y + a_3 xy = \left\{ 1 \; x \; y \; xy \right\}\{a\} = \left\{ 1 \; x \; y \; xy \right\}[A]^{-1}\{u\} \tag{11}$$

The velocity v of the particle P in the Y-direction can also be expressed in the same way as

$$v = \left\{ 1 \; x \; y \; xy \right\}[A]^{-1}\{v\} \tag{12}$$

Therefore, the strain rate of particle P(x,y) can be calculated from both formulas (11) and (12).

For example, the plane-strain deformation

$$\begin{aligned}\varepsilon_x &= \frac{\partial u}{\partial x} = \{0\ 1\ 0\ y\}[A]^{-1}\{u\} \\ \varepsilon_y &= \frac{\partial v}{\partial y} = \{0\ 0\ 1\ x\}[A]^{-1}\{v\} \\ \varepsilon_x &= \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} = \{0\ 0\ 1\ x\}[A]^{-1}\{u\} + \{0\ 1\ 0\ y\}[A]^{-1}\{v\}\end{aligned} \tag{13}$$

Stress is calculated as

$$\{\sigma\} = [D]\{\dot{\varepsilon}\} \tag{14}$$

2 Calculation Result

2.1 Calculation Condition

A ring compress process calculation under different friction is carried out to verify the effectiveness of the method [2]. The results in Fig. 3 show that the method is effective even if the compress ratio is bigger than 80%. The calculated data is also used to verify the correctness of the method by comparing it with the experiment data in Fig. 3. They are bigger than the experiment ones (μ is the coefficient of friction between compress tools and ring in Fig. 3).

The property of the material used in the calculation, work condition, and simulation condition are shown in Table 1. A rotational symmetry deformation is assumed

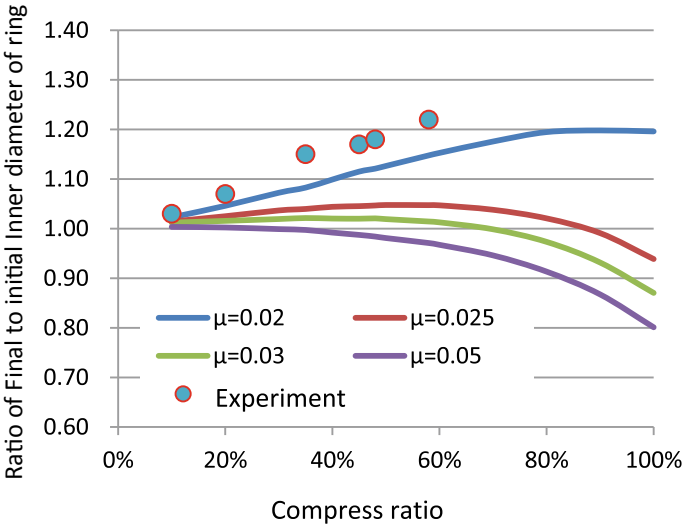

Fig. 3 Ratio of the final and initial inner diameter of a ring with different coefficient of friction (experimental data is used as the data from Reference 2). (Color figure online)

Table 1 Property of material, work condition, and simulation condition

Flow stress / Kgf/mm^2	$\bar{\sigma}23.75\bar{\varepsilon}^{0.127}$
Coefficient of friction	0.05

Number of particle	699

in the calculation.

2.2 Calculation Result

Figure 4 shows the velocity (black arrow) of the particle calculated by interpolation from the 4-node of the space mesh (green square). The shape of the workpiece is deformed with the velocity but the space mesh is not changed.

As shown in Fig. 5, the positions of four particles of the workpiece in each different calculation step are changed greatly. In a conventional FEM, the calculation cannot

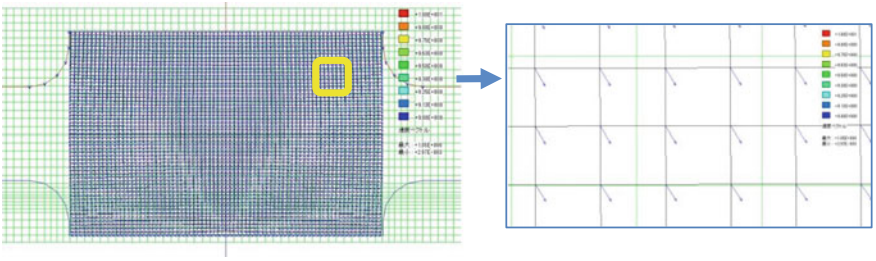

Fig. 4 The velocity of the particle calculated by the space mesh. (Color figure online)

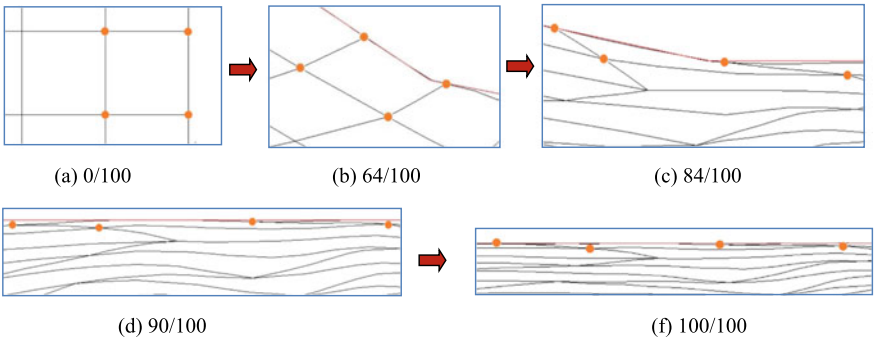

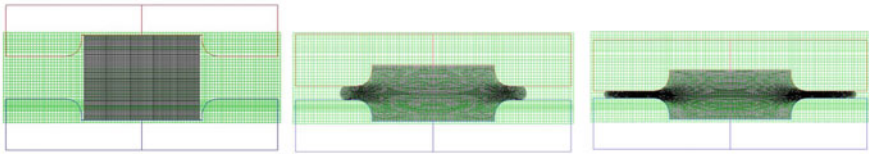

Fig. 5 Large change of positions of a particle in each step. (Color figure online)

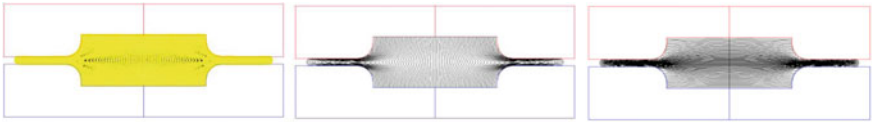
be continued when the mesh is changed as shown in Fig. 5c, but the simulation is not terminated because of usage of space mesh.

The simulated deformed shape of the workpiece in each step is shown in Fig. 6, and the same space mesh (green square) is used in each calculation step both in shape and position.



The final shapes are shown in Fig. 7 with particles linked with both vertical and horizontal lines together, respectively. The deformation performance of the material is closer to reality.

The large value of equivalent strain rate appears at cornea as shown in Fig. 8 and the deform force is changed greatly when deformation is close to the final step, as shown in Fig. 9.

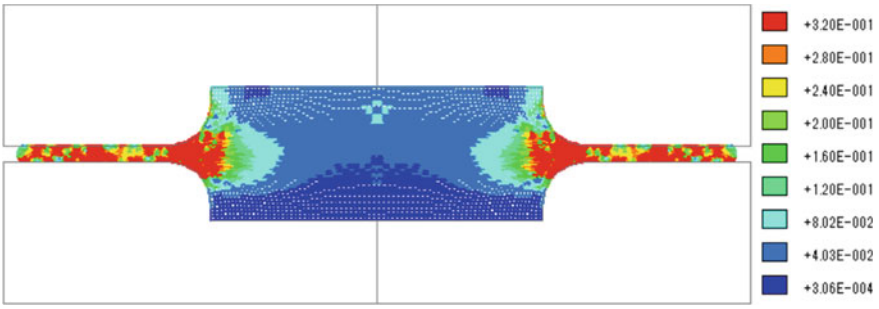

Fig. 8 Equivalent strain rate distribution at the final step. (Color figure online)

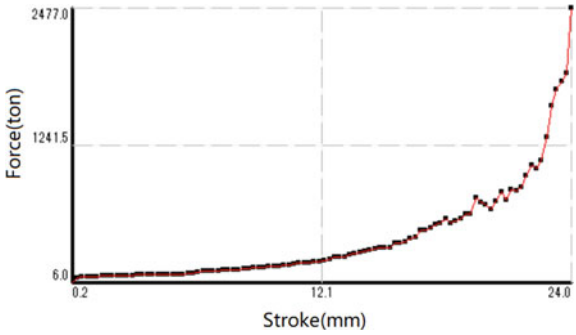

Fig. 9 Calculated deform force. (Color figure online)

3 Conclusion

The space mesh is proposed to be utilized in the FEM. The boundary condition is assigned in a new way. A large deformation simulation is carried out to verify its advantage. The method makes the finite element method more effective and powerful for the large deformation. The large deformation of the metal forming process can be calculated without termination. The performance of the material can be expressed more visibly and more clearly because the same mesh is used in the entire simulation process. By use of space mesh, the FEM becomes easier to be formulated and programmed in many fields, such as hydromechanics, heat transfer, elastic, and plastic deformation simulation.

Comparison on the Processing of Height Deviations of Disks from FEM and Real Rollings in Radial-Axial Ring Rolling

Thomas Glaser, Patrick Schwarz, Simon Fahle, Kai Uwe Paffrath, and Bernd Kuhlenkötter

Abstract Transferring insights from simulations to an industrial application is a state-of-the-art procedure. The knowledge of how to design a manufacturing process, e.g. for Radial-Axial Ring Rolling, is mainly taken from two sources: the machine operator's experience and experiments, which are time- and cost-intensive. Therefore, creating results by using finite element method is a valuable alternative. This paper focusses on the shape deviations in the domain of Radial-Axial Ring Rolling. It is a hot forming process to produce, e.g. steel rings, used as blanks for the manufacturing of huge bearings or gear rims. Real Radial-Axial rolled disk-shaped rings will be compared to data of a FEM Simulation Software (QForm 3D) with a focus on the height deviation of the ring. Regarding disk-shaped rings, the production of a constant height is of high importance to save effort and costs of rework.

Keywords Radial-axial ring rolling · Simulation · Quality control

1 Introduction

Simulating a hot forming process like Radial-Axial Ring rolling (RARR) is used to save time and energy, which results in lower expenses [1]. Forecasting an optimized hot forming process design will reduce experimental costs and increase the efficiency [2]. In the domain of Radial-Axial Ring Rolling, the process chain consists of several steps from cutting a piece from an ingot, piercing to forming it into the desired ring-rolling pre-form. After the rolling process itself, the ring in most cases needs to be machined and heat-treated to assure the geometrical and microstructural properties.

Each of these steps can be simulated. The requirements regarding the accuracy and computational time are high, since the generated data needs to be transferred or processed in further simulations [3]. Assuming that the optimization of an existing production process takes several real world experiments, it needs many resources (staff, material, and energy) and creates lots of scrap material. The same can be said about the feasibility analysis of a new ring geometry. Finite-Element (FE) simulations are an efficient way to get insights on how to reduce the rolling time, avoid form errors or whether to consider a temperature control for specific materials like titanium. Temperature controlled simulations are state of scientific knowledge, since the need to include them into the rolling process goes back to 1997 [4, 5]. The validation of Finite Element Method (FEM) is often based on the behaviour of process parameters such as the growth of the outer diameter, the reduction in height or the axial and radial forces [6–8]. WANG et al. simulated the rolling of a titanium ring with good agreement to the experimental data by comparing the height and thickness plots and the resulting roundness of the ring. Besides that, WANG et al. optimized the initial rolling phase by adjusting the mandrel feeding rate. Thus, by increasing the mandrel feed, the velocity of the ring and the main roll could be adjusted to avoid slip in the radial gap [9].

The further step is the validation of FEM models, which will be presented in this paper. It investigates the comparison of the resulting form deviations like height deflection. The aim is the development of a versatile tool for the geometrical characterization of rings. This paper presents the steps that have been implemented in the geometric characterization tool and shows further developments. Regarding the ring geometry, the focus is set to disk-shaped rings, which due to their extreme shape have a particularly strong tendency to geometrical deviations. Disks are defined by a high wall-thickness-to-height-ratio. This extreme geometry is due to a lower stiffness in axial direction more sensitive for height deviation, which can be caused by an unfavourable distribution of the moments in the axial gap [10]. The disk-shaped rings used here have a ratio of 3:1 in the initial shape and 4:1 in the final dimension. Form deviations can be compensated by adding material. This is not wanted in the high number of industrially produced rings, since it results in higher material costs and reworking costs. The material additions are particularly critical with extreme geometries, for example, disk-shaped rings. Even if no process and thus shape defects occur in the rolling process, the added material must be machined afterwards [11]. In these issues, it can be seen that the geometric characterization of rolled rings with extreme geometries is of great importance. This paper contributes to the measurement, calculation, analysis, and visualization of form deviations. In particular, the topic of the height deviation in the domain of Radial-Axial Ring Rolling is addressed.

1.1 Radial-Axial Ring Rolling

Radial-Axial Ring Rolling has established itself as the most important production process for axial-symmetric parts due to the possibility of manufacturing near-net-shape seamless rings in a wide range of materials and geometries without tool changes and up to a diameter of 16 m [12, 13]. Those rings are used in applications like aerospace, gear manufacturing, and offshore use cases as bearing races and flanges [3, 12, 14, 15]. Other common production processes for rings are forging, casting, and welding. These have negative properties with regard to the possible dimensions, caused casting defects or unfavourable mechanical properties in the welding zone, which can have a negative effect on the fatigue [15]. The principle of the RARR process is based on a diameter growth by synchronous and continuous forming in two oppositely arranged rolling gaps, leading to a reduction of the rings' cross-section because of the variable position of the specific rolls. These two rolling gaps are the radial and axial rolling gap and describe the relevant forming direction. The height of the ring in the rolling process is defined by the position of the upper axial roll in the axial rolling gap towards the lower roll, which is fixed in horizontal position. Both axial rolls are driven. The mandrel roll in the radial gap moves towards the main roll to define the wall thickness. The main roll is driven and by the nearing movement of the mandrel towards the main roll, leading to a compression, the ring rotates. The course of the radial and axial feed rate describes the rolling process. Due to the instability of RARR, deviations from the target process design can occur during forming. This leads to process and form errors, which disturb the forming process and in most cases have a negative effect on quality. The form errors are to be measured and evaluated afterwards using suitable measuring and analysis methods. Another approach is the use of data driven technologies to control or increase quality in the Ring Rolling domain. Appropriate research is done by FAHLE et al. where machine learning in form of time series classification is used to predict the quality of rolled rings [16]. In addition to that innovative method, FAHLE et al. compared different pre-processing methods, resulting in a domain specific approach to use an individual scaling of the log data [17].

1.2 Process and Form Errors in Radial-Axial Ring Rolling

Material additions are used to compensate for example the height deviation, as described in the previous chapter. This stands in contrast to the idea of a near-net-shape process, with which the material is already close to the final geometry. These material surcharges cost companies a lot of effort and money, because in addition to the additional material input during Ring Rolling, there is also additional work in the subtractive post-treatment. This becomes necessary if errors occur during the process. The ring can, for example, move in its height direction or sideways during the process. This instability combined with heavy material weight, high process

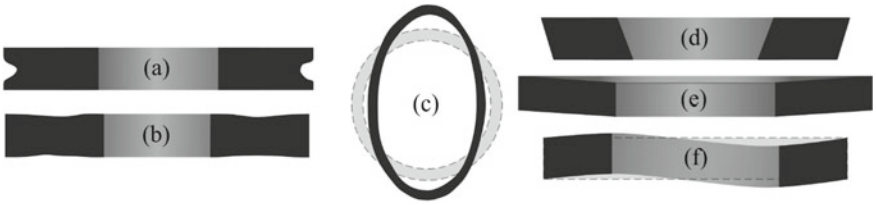

Fig. 1 Form errors in Radial-Axial Ring Rolling. **a** Radial-, **b** axial-cavity, **c** non-circularity, **d** conicity, **e** dishing, and **f** height deviation

forces, and forming speeds leads to inconsistencies in the process sequence, which can result in process and form errors. These errors must be compensated or reduced to ensure a high quality ring and an increased repeatability of the process. By adjusting the rolling process, the system can react immediately when an error occurs. With a suitable adapted rolling strategy, for example, slowing down the roll speeds for a defined period, the process and thus shape errors can be counteracted. Another strategy is to change the axial trim as a reaction or as a standard value from the beginning of the process. The axial trim describes the ratio of the angular speeds of the two axial rolls to each other and can be used to provide a force into the ring that is directed to the rolling table, which leads to a stabilized process. The alternative is a ring that has to be machined afterwards—or is unusable for further processing due to too high deviations. Either way, not counteracting process errors increase the costs of ring production drastically. Six different resulting form errors are described in Ring Rolling related literature. The degree of defects depend, for example, on the geometry of the blank, force and torque ratios and the rolling process itself [10–12]. The focus of the analysis in this paper is on the height deviation of a ring, which is defined as the periodic curvature of the upper and lower face side of a ring. The six form errors are shown in Fig. 1a–f.

1.3 Simulation

FEM software is based on the solution of continuous functions (physical and thermal problems) by the approximation using simpler functions. In the three-dimensional FEM application of Radial-Axial Ring Rolling presented here, the volumes of the tools and the workpiece are divided into smaller elements, which are contacted in the so-called finite element nodes. In forming processes, the rate of deformation of these individual smaller volumes is of high interest. For this purpose, systems of equations are set up based on the FEM model, which are then solved. The solution and thus the forming properties depend strongly on the selected material, the temperature, as well as the boundary conditions. There are several advantages of using simulation methods to design a production process or the process chain from a blank to the final ring. The number of time-consuming and material-intensive test rollings can be reduced

significantly or an optimized rolling strategy can be tested in simulation. Besides simulation, the field of data analysis is growing—also in the domain of hot forming. One advantage of data analysis is the improvement of the Ring Rolling process and to specifically reduce form errors by simulating the rolling. Allegri et al. [18] set up an FEM environment using Deform 3D FEM and initially simulated a standard configuration ring with a constant main roll angular velocity, which leads to a decrease in the ring's angular velocity over time. The approach is to optimize the height and width dispersion, as well as the fishtail defect, by achieving a constant angular velocity of the ring through adapting the main roll's angular velocity over time. The evaluation of the resulting geometry shows the positive influence in comparison to the standard configuration [18]. Another simulation approach to enhance the quality by Giorleo et al. [19] leads to two regression models regarding the rolling ratio (relation between the idle roll feed and the main roll angular velocity) and the idle roll feed.

2 Experimental Setup

The presentation of the experimental part consists of two components. Firstly, real rings are rolled on a Radial-Axial Ring Rolling mill and secondly, the rolling of these rings is simulated in the QForm (QForm Cloud 9.0.9.0) software. The rings of real and simulated rollings are afterwards characterized with respect to their geometry with focus on the height deviation. For this purpose, a coordinate measurement machine (CMM) is used for the real rings, whereas the required measurement data for the simulated rings is drawn directly from the software. The focus of the paper is to present the capabilities of a novel software solution that calculates and clearly visualizes the geometric deviations.

For this study, the Radial-Axial Ring Rolling mill type RAW 20/16-1000/160 from Thyssen Maschinenbau GmbH Wagner Dortmund at the Chair of Production Systems of the Ruhr-University Bochum is used. The mill is capable of rolling rings with dimensions of 200–1000 mm in outer diameter, height between 30 and 160 mm, and wall thickness from 10 to 250 mm. The maximum weight of a ring is 50 kg. Radial forces of 200 kN and axial forces of 160 kN are possible. The used main roll has a diameter of 450 mm and the mandrel roll has a diameter of 130 mm. The rolling force cylinders are modernized to electrohydraulic systems that provide a high precision for the position of the mandrel roll, axial, and centering rolls.

The blanks used for the experiments are made of S355 structural steel with an outer diameter of 380 mm, an inner diameter of 140 mm, a resulting wall thickness of 120 mm, and an initial height of 40 mm. The target height after rolling is 30 mm, while the wall thickness is held constant during the rolling. The final geometry has a wall-thickness-to-height-ratio of 4:1 and is, therefore, declared as a disk-shaped ring. The identification of the real rollings is composed of the prefix Ring_ (for example Ring_2). The rollings differ only in the axial trim, which is varied between 96% (Ring_1, Ring_2, and Ring_3), 100% (Ring_4, Ring_5), and 90% (Ring_6). This is intended to produce a variance in the measurement results to prove the detection

of different height deviations. In each case, the experiments were not repeated, as the focus of this paper is to investigate the capability of the presented tool. Thus, the absolute values and their possible influences are not discussed in the results. A further paper on such an influence analysis is being planned.

With regard to simulation, the FEM Software QForm is used. It offers a high-resolution and fast simulation environment and works with the dual mesh method. The equations of plastic flow are calculated using the computational mesh. In the geometric mesh, the thermo-mechanical fields and the geometry are stored. In the used QForm ring-rolling module, a defined two-dimensional square-shaped equidistant grid is applied to the top and bottom of the ring before simulation. The number of points per side length is user-defined and the grid is placed over the ring. Those points which do not hit the ring surface are ignored for further evaluation. This grid is attached to the nodes of the ring mesh and is carried along accordingly in the simulation/rolling process. The identification of the simulations contains of the prefix Sim_. The plots shown in the result chapters show the pairs of real and simulated rollings. The radial and axial feeds from the real rollings were used for the simulation, so that, for example, simulation Sim_2 uses the input data of the real rolling Ring_2.

To obtain the geometrical data of real rolled rings, a ZEISS Coordinate Measuring Machine in portal design was used. The CALYPSO software of the ZEISS CMM is used to enable the measurement of circular paths on predefined surfaces. In order to prevent the measurements from being influenced by a change in the position of the test specimen, the component is fixed to the test field of the CMM by means of an angle construction so that both end faces of the ring are freely accessible. However, the exact position and orientation of the measurement object is not defined beforehand. To define a circular path, one side of the ring is initially scanned with three points in the first step. The detection of the end faces is done with a T-shaped probe, so that a measurement of both end faces is possible without changing the probe or the position of the ring. This makes it possible to not only measure one face of the ring and calculate the height deviation, but calculate the height of the ring with the same data. The resolution of the measured surface depends on the number and distribution of the measuring points. For this purpose, the theoretical center of the ring is determined by probing the inner diameter with three points. Furthermore, the surface to be measured is defined by probing three points. From the combination of these characteristic values the plane coordinates are determined, on which the circular paths are automatically traced. In the shown case, diameters of 240, 290, 340, 390, and 440 mm as well as 12, 20, 33, 45, and 60 points are used for the measurement. To maintain a constant resolution of the measuring points and a suitable reproduction of the real rings' geometry, the number of measuring points increases the further they are located on the outer diameter.

3 Geometry Characterization Tool

Before the results of the rolling and simulation are presented, the geometry characterization tool is introduced in this chapter. The tool is written in python and uses freely available libraries for calculation and visualization of the data. It is used after a rolling or after a simulation. The point clouds of the geometry resulting from (a) the measurement of the ring or (b) the exported simulation data are processed by the tool. After the processing of the data, a comparison with other rings is then possible, since random influences such as the position of the ring on the measuring table no longer affect the measurement result. The following schematic drawing (Fig. 2) illustrates the point of application of the geometry characterization tool. The input raw data is transformed into the so-called processed data by using the method of least squares or calculations within the covariance matrix.

In the case shown here, the measurement data is available in two varieties: (a) Measuring at the CMM: tangential arranged point clouds for each side of the ring and (b) data from QForm: one measurement file per ring, which is separated into the two surfaces by an additional script. In both cases, the data points are available as x, y, and z coordinates line by line. The measured coordinates of the ring faces are available as point clouds, which are positioned and oriented in space depending on the global CMM or simulation coordinates. Regarding the CMM, in addition to the coordinates of the ring, the measurement data also includes the normalized directions of the force acting on the probe. The measured coordinates correspond to the center of the probe element or the displayed touch point of the probe. For the calculation of the adjusted touch point, an adjustment vector is necessary, which is formed with the help of the normalized force direction and the radius of the used probe elements. The analysis of the unprocessed data would lead to a distorted, wrong result. In this case, processing the data does not lead to an intentional improvement of the measurement result, but only to an evaluable positioning of the ring. To achieve this, the point clouds needs to be rotated and moved. Therefore, a regression plane is needed as a reference for the calculation of the form errors in order to determine the axial positions of the measuring points. The method of calculating the regression plane is crucial for the quality of the results, since the calculation of the key parameter is based on it. The regression plane is a flat plane that is positioned between the two faces of the ring.

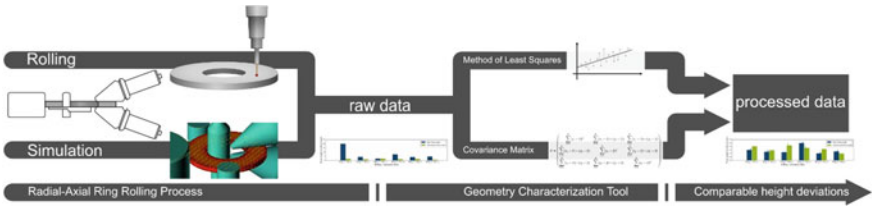

Fig. 2 Sequence of the origin of the raw data via the preparation by the geometry characterization tool to processed data. The graphs illustrate the adjustment of different rollings and simulations. (Color figure online)

For the qualitative evaluation of the axial profile of the rings, a regression plane is calculated where the distances of the measured data to the regression plane are minimal. The covariance matrix and the method of least squares are used in this case so evaluate the regression plane. The methods of vector and matrix calculation enable to move or rotate the measuring points and determine positional relationships. The regression plane can be calculated in the tool by two approaches. First, with the help of the eigenvectors and eigenvalues of the covariance matrix of the point clouds. For this purpose, the covariance matrix is set up and the eigenvalues and eigenvectors are extracted by calculating the roots of the characteristic polynomial. The normalized eigenvector of the smallest eigenvalue corresponds to the surface normal. The second approach is the least squares method. The resulting system of equations is solved using the Gaussian elimination method. After calculating the regression plane, the height deviation is calculated. The method first determines the distance to the regression plane for each data point of both data sets (both sides) using the implemented vector functions. In the following, the minimum and maximum values of the distances of the two data sets are identified. The minimum and maximum values are used to calculate the height deviation of the two sides of the ring. The result of the visualized geometry of the top and bottom side of a ring (simulation Sim_2) is given in Fig. 3.

The following plot in Fig. 4 shows the distance to the regression plane over the angle around the z-axis. An ideal ring would be constant over the whole angle range. From the colour code, the distance of each point to the calculated centre can be read. In this example, the top side of the simulated ring of Sim_2 shows a periodic height deviation, which increases in the direction of the outer diameter. In the first angular range up to about 180°, an increasing height deviation close to the outer diameter of the ring is noticed. This top side of the ring shown here has a calculated height deviation of 1.424 mm, which can be directly read from the plot.

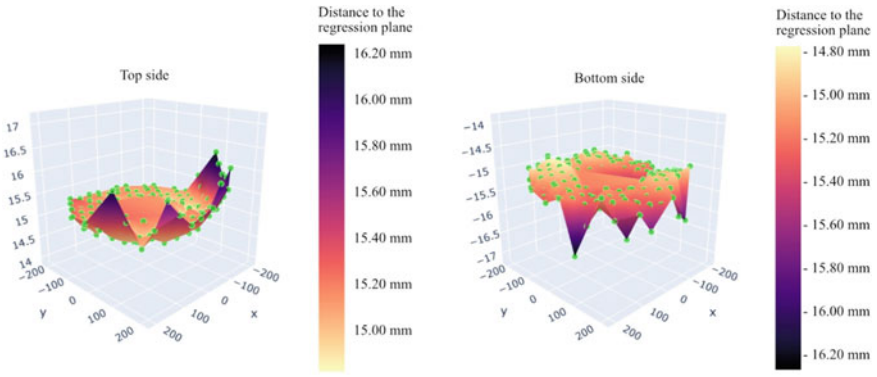

Fig. 3 3D-visualization of the processed upper and lower side of a simulated ring after the rolling (Sim_2). The raw data has been rotated and shifted be the tool. The center of the ring lays on the coordinate origin in the x-y-area. (Color figure online)

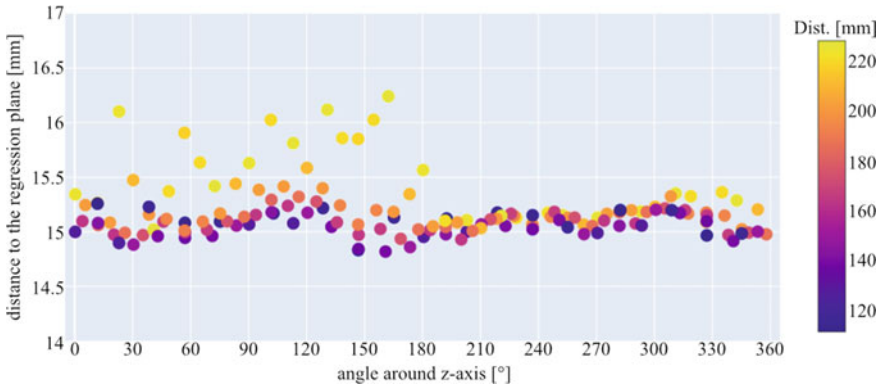

Fig. 4 Example plot of the distance to the regression plane over the angle around the z-axis. (Color figure online)

With the output of these plots, it is quickly possible to classify the ring with respect to the height deviation. Furthermore the calculated values are output. This allows an efficient classification by automated reading and processing of the data.

4 Results

The tool for geometric characterization is the basic component for the evaluation of form deviations, and therefore, important for further research within this subject area. In order to demonstrate the usability of the tool, rolling, and simulations are carried out. The results are shown in pairs, for example, Ring_1 and Sim_1. This is due to the fact that Sim_1 is the simulative reproduction of the rolling Ring_1 and is, therefore, used for direct comparison. Each bar in the following plots represents the mean height deviation of both sides of the referred ring. Within each bar there are two more bars that represent the individual values of the top (left bar) and bottom (right bar) side, giving insights to the deviation between the sides. For further comparison, the mean height deviation will be used in this paper. Raw data in this context means the three-dimensional measurement values from the CMM or simulation that have not been rotated or shifted. Processed as a key word shows the data that went through the calculation of the tool that has been developed and presented in Chap. 3. In the specific coordinate direction, which is orthogonal to the surfaces of the ring, the height deviation can be described as the difference of the minimum and maximum value within this coordinate direction. The comparison of both raw data sets shows the inequality of the data, depending on whether the measurements are from real rings or simulation.

Figure 5 shows that the mean height deviation of the simulation data is rather constant with a mean value of 1.80 mm and a standard deviation of 0.384 mm. The

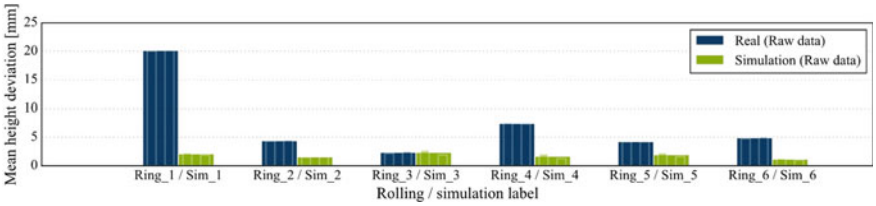

Fig. 5 Mean height deviation of the raw data of real and simulated rollings. Each bar shows the individual values of the top (left bar) and bottom (right bar) side. (Color figure online)

analysis of the time-dependent height deviation is currently researched by the author. Regarding the CMM, an average value of 7.250 mm with a high standard deviation of 5.953 mm is obtained. This is due to the fact, that the rings are positioned and aligned manually on the measuring table which is not possible in any repeatable state. The raw data shows this clearly. The raw data of Ring_1 in particular is about 20 mm and shows, that the ring was tilted strongly on the measuring table. That deviates strongly from the other measurements and, after a first macroscopic examination, does not agree with reality. To avoid this case and to obtain correct, generally valid values, the tool developed here is necessary. Note that the values shown in Fig. 5 do not indicate whether the height deviation is actually high or low. This is only possible after processing by the tool (see Fig. 7).

It can be clearly seen in Fig. 6 that due to the uneven positioning of the rings on the CMM, the height deviation calculated from the raw data varies significantly. This figure shows only the measurements (raw and processed) of the real rollings. Mean values between 2.347 and 20.133 mm are obtained in this way. After processing the data with the presented tool, the height deviation of the processed data differs considerably from the raw data with a factor up to 10. This shows the strongly varying raw measurement results and the capability of the tool.

In the following Fig. 7, the comparison of the processed height deviation of the real and simulated data is shown. For absolute height deviations in the range of 1 to 2.5 mm, the deviations between reality and simulation must be considered strongly. The average deviation is about 0.5 mm. In four of the six data sets the height deviations of the simulation are higher than in the measured reality. This is to be considered positively, as it gives a pessimistic representation of the experiments carried

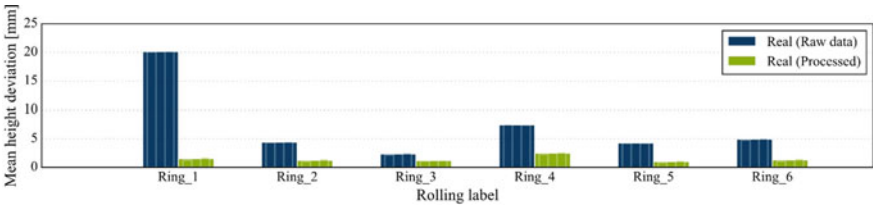

Fig. 6 Raw and processed by the tool data from real ring-rolled rings. Each bar shows the individual values of the top (left bar) and bottom (right bar) side. (Color figure online)

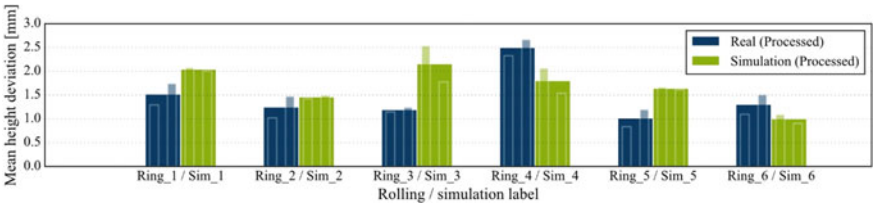

Fig. 7 Mean height deviation of the processed real and simulated rings data. Each bar shows the individual values of the top (left bar) and bottom (right bar) side. (Color figure online)

out. It should be noted here that the height deviations shown in Fig. 7 correspond to the values optimally aligned to the respective regression plane and thus allow comparability.

5 Conclusion

The geometrical characterization of real rolled disk-shaped rings, as well as rings simulated by QForm 3D FEM, are successfully performed with the tool presented in this paper. It is shown that the developed tool is useful for the evaluation of geometric data regarding height deviations. After the pre-processing of the point clouds, vector calculations and mathematical methods (least squares, least variance) are applied to calculate the necessary rotation and displacement of the point clouds. The evaluation of the height deviation considered here is carried out afterwards and aims at the output of the characteristic values as well as visualizations. It is shown that the calculated height deviation scatters strongly without post-processing through the tool. By using the tool and the resulting reorientation of the data points, they are adapted to reality and made comparable. Thus, a clear and constant statement about the quality regarding the height deviation is possible. For further work in the research project, the rolling and simulation of disk-shaped rings will be of high interest. Since the extremely disk-shaped geometries that will be investigated have a strong tendency to height deviation, the tool will be used extensively, also regarding the validation of the simulations.

Further investigations will deal with the robustness of the simulation software itself as well as the stability of the Ring Rolling process in relation to the resulting height deviation. Research specifically related to simulation is currently being carried out. It is of interest here to what extent the results vary when the identical input data is run through several times. The results of the software differ with identical input parameters due to the parallelization and resulting different processing time of the computing operations. A further point is the calculation of the height deviations and other geometric criteria such as roundness over the entire process. For this purpose, the corresponding data can be exported and analyzed at each time step of the simulation (usually about 10–50 ms). The information obtained from this allows

critical points to be defined, which can then be further investigated with regard to possible influencing factors for the occurring form deviation. The corresponding implementation is currently part of the research and is developed by the author.

PID Controller Integrated with FEM Model to Generate Boundary Conditions for Free Tube Bulging for Tubular Material Characterization

Sobhan Alah Nazari Tiji, Taejoon Park, Hyunki Kim, Amir Asgharzadeh, Madhura Athale, Ji Hoon Kim, and Farhang Pourboghrat

Abstract A PID controller was implemented in FEM platform as a user subroutine instead of a sophisticated and expensive control system implemented in a tube hydroforming machine to numerically generate the required boundary conditions, axial feed, and pressure profiles, based on proportional strain path at the pole of the bulging tube in the FEM simulations. The generated boundary conditions can directly be used in free tube bulging experiments to generate different deformation modes for tubular material characterization based on accumulated plastic work equivalency. It was also shown that the numerical algorithm developed works accurately for isotropic and anisotropic yield functions. In this study von-Mises and Hill's 1948 were used as the material models.

Keywords PID control · FEM · Tubular materials · Characterization

1 Introduction

A few studies have been performed on tubular material characterization [1, 2, 3, 4, 5]. In all these studies, free tube bulging as a process by which biaxial deformation modes can be generated to characterize tubular structures were employed. In most of these studies, a tube hydroforming machine equipped with a sophisticated feedback control system, which is expensive to implement, was used to generate the axial feed and pressure profiles based on stress proportionality at the pole of the tube to characterize the yield surface of the material. For instance, in the study performed by Kuwabara

et al. [2], different deformation modes were experimentally generated by controlling the ratio of the true principal stresses by employing a closed-loop, electrical feedback circuit in order to generate the yield surface for extruded 5000 series aluminum alloy tubes. They then used these experimental data to calibrate different yield functions to capture the tubular material's anisotropy. Korkolis and Kyriakides [3, 6] also studied the inflation and burst of anisotropic aluminum tubes during the hydroforming process. They pressurized the tubes under volume control and the axial actuator was run under load control. The generated engineering principal stresses were then controlled through a feedback control system to create linear stress paths. However, stress or strain proportionality is not a necessity when it comes to characterization of the yield surface of the material based on accumulated plastic work equivalency [7].

At the same time, the boundary conditions, axial feed, and pressure profiles, in free tube bulging cannot be randomly generated for the sake of tubular material characterization. But, as long as we can generate a range of biaxial deformation modes with appropriate axial feed and pressure profiles, we will still be able to characterize tubular materials no matter if the generated stress/strain paths will be linear or not.

This study presents the development of a PID controller integrated with a FEM model to numerically generate the required axial feed and pressure profiles for free tube bulging process based on proportional strain path control at the pole of the bulging tube. In order to show that this developed algorithm works accurately for different assumed yield functions in the FEM, two very simple yield functions such as; von-Mises and Hill's 1948 were used in this study. The generated boundary conditions can be later used for free tube bulging experiments for tubular material characterization.

2 Experiments

In order to calibrate the yield functions to be used in the FEM model, uniaxial tensile test and electron backscatter diffraction (EBSD) tests were performed on the AA6061-O tubular material. The uniaxial test data will be enough for the calibration of von-Mises yield function. However, to calibrate the anisotropy coefficients of Hill's 1948, other biaxial and uniaxial tests data are required. Because of the geometrical constrains of the tubular materials it is difficult to acquire these data. Therefore, these results are obtained through crystal plasticity simulations in this study.

2.1 AA6061-O Tubular Material Characterization

2.1.1 Microstructure Characterization

To characterize the microstructure of the tube, EBSD imaging was performed on two different cross-sections, i.e., axial and hoop of the tube. Figure 1 shows the pole figure and inverse pole figure of the AA6061-O tube microstructure.

2.1.2 Mechanical Characterization

For the mechanical characterization of the tube, uniaxial tensile tests were performed on the specimens cut out of AA6061-O tubular samples along the axial (extrusion) direction based on ASTM E8 standard for uniaxial tensile tests.

The evolution of strain during the uniaxial tensile tests was measured using a Digital Image Correlation (DIC) system.

3 Material Model

3.1 Material Model

A rate-independent [8], dislocation density based hardening crystal plasticity model [9] was used to predict the anisotropy values for Hill's 1948 anisotropy calibration. To calibrate the rate-independent crystal plasticity model, the measured uniaxial stress–strain curve (Fig. 2) along the axial direction, and the measured texture of the tube from the EBSD images (Fig. 1) were used. Detailed explanation of the crystal plasticity model can be found in [8, 9].

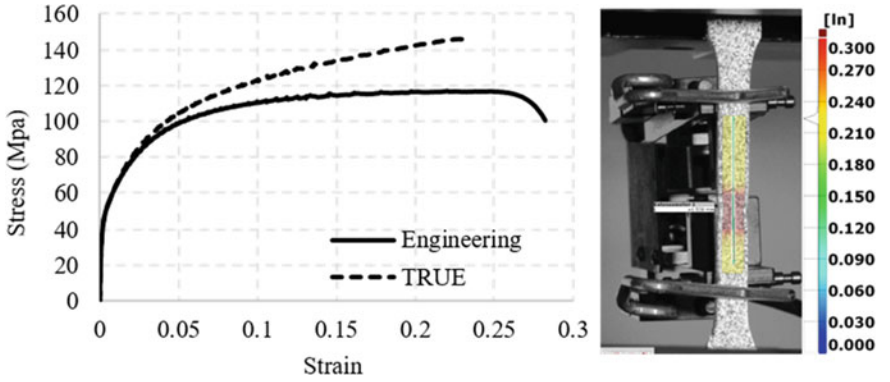

Fig. 2 The stress–strain curve along the axial direction (ED) measured from the uniaxial tensile test utilizing DIC. (Color figure online)

Uniaxial tensile tests for various tensile directions were simulated based on the calibrated crystal plasticity model. Also, the shape of the initial yield surface was predicted as shown in Fig. 3.

Among the crystal plasticity simulation results, the initial yield stress values ofσ_{45},σ_{90}, and σ_{bb}, were utilized to calibrate the Hill's 1948 yield function for AA6061-O tube.

Under the plane stress condition, Hill's 1948 quadratic yield function [10] becomes

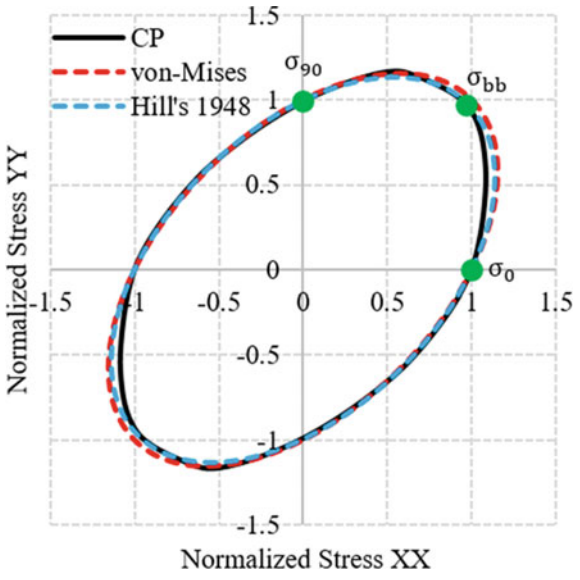

Fig. 3 Calibrated von-Mises and Hill's 1948 yield surfaces based on the uniaxial tensile yield strength and crystal plasticity simulations results, respectively. (Color figure online)

$$f^2 = (G+H)\sigma_{xx}^2 + (H+F)\sigma_{yy}^2 - 2H\sigma_{xx}\sigma_{yy} + 2N\sigma_{xy}^2 = \bar{\sigma}^2 \quad (1)$$

where $\tilde{\sigma}$ is the effective stress, F, G, H, and N are anisotropic coefficients that can be calculated using Eq. (2) [11].

$$\begin{aligned} 2F &= \left(\frac{\sigma_0}{\sigma_{90}}\right)^2 - 1 + \left(\frac{\sigma_0}{\sigma_{bb}}\right)^2;\ 2G = 1 - \left(\frac{\sigma_0}{\sigma_{90}}\right)^2 + \left(\frac{\sigma_0}{\sigma_{bb}}\right)^2 \\ 2H &= 1 + \left(\frac{\sigma_0}{\sigma_{90}}\right)^2 - \left(\frac{\sigma_0}{\sigma_{bb}}\right)^2;\ 2N = \left(\frac{2\sigma_0}{\sigma_{45}}\right)^2 - \left(\frac{\sigma_0}{\sigma_{bb}}\right)^2 \end{aligned} \quad (2)$$

Figure 3 compares the initial yield surface of the tube for the crystal plasticity (CP) model, von-Mises yield function, and Hill's 1948 yield function. It should be noted that all stresses are normalized using the σ_0 value.

4 Finite Element Modeling of Tube Bulging Process

The ABAQUS implicit code was used for the FEM simulations of tube bulging. The FEA simulations of tube bulging were performed with the calibrated von-Mises and Hill's 1948 yield functions and the PID controller to maintain a proportional strain path at the mid-section (pole) of the tube. The outputs from the FEA simulations with these two yield functions were two different sets of axial feed and pressure profiles necessary to maintain the desired proportional strain path. In FEA simulations, the AA6061-O tube was considered to be 75 mm long, 1.651 mm thick, and with an outer diameter of 38.1 mm. Figure 4 shows the boundary conditions applied on the

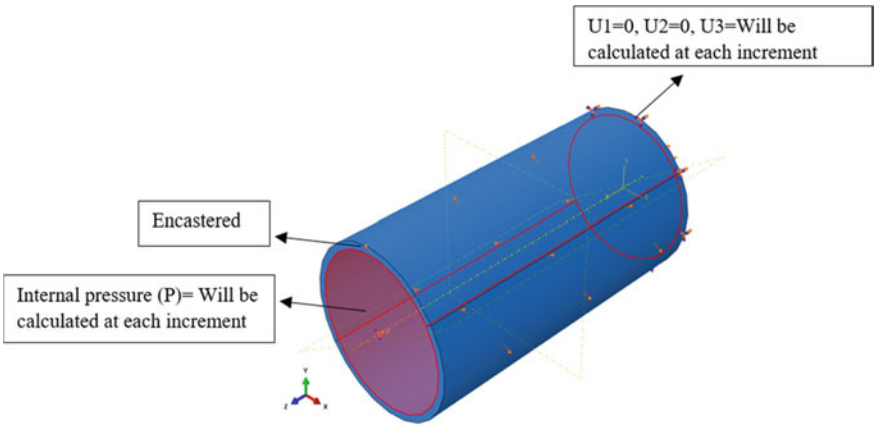

Fig. 4 Applied boundary conditions in FEM. (Color figure online)

tube. The 8-node linear brick element with reduced integration (C3D8R) was used for the tube with a size of 0.7 mm, and three elements were considered through the thickness.

5 PID Algorithm for Boundary Condition Generation for Free Tube Bulging Process Based on Proportional Strain Path Control

Figure 5 shows the flow chart for the PID controller algorithm to generate the axial feed and pressure profiles for free tube bulging based on maintaining a desired strain path during the finite element analysis of tube bulging.

The inputs to the PID algorithm are the desired strain path, β^*, plastic hoop strain rate, $\dot{\varepsilon}^{p^*}_{hoop}$, and the initial internal pressure rate, $\dot{P}_{initial}$. The program starts with the initial internal pressure rate applied as boundary condition in the UAMP user subroutine. Then the first increment of the tube bulging increment will be simulated by ABAQUS implicit code. After that, the principal total and plastic strains along axial (ε_{axial}, ε^p_{axial}) and hoop (ε_{hoop}, ε^p_{hoop}) directions, on the pole element of the tube will be read in UVARM user subroutine and the strain path will be calculated, and afterward, the internal pressure and axial feed are calculated based on the desired strain path, β^*, in the UAMP user subroutine and applied as boundary conditions for the next deformation increment in FEM model in ABAQUS. Tables 1 and 2 show the pressure and axial feed adjustment algorithms.

It is important to mention that the approach taken to calculate the axial feed in the elastic region helps with having a smooth transition from elastic to plastic region in the numerical simulations. This also helps with the PID algorithm to quickly adjust and stabilize the axial feed to obtain the desired strain path during the plastic deformation. In contrast, when elastic strains are ignored and the axial feed is only calculated from when the material goes into the plastic deformation, numerical instability occurs when the PID controller starts to adjust the axial feed.

6 Results and Discussion

FEA simulations were performed for five different strain paths, $\beta = -0.5$ (uniaxial tension), $\beta = -0.2$, $\beta = 0.0$ (plane strain tension), $\beta = 0.5$, and $\beta = 1.0$ (balanced biaxial strain tension), covering a full range of in-plane tensile deformation modes. It must be mentioned that all stresses and strains were recorded for the element at the pole of the tube. The initial internal pressure rate and the plastic hoop strain rate were 0.1 MPa/s, and 0.005/s, respectively. The simulations were performed using both calibrated von-Mises and Hill's 1948 yield functions for all the cases.

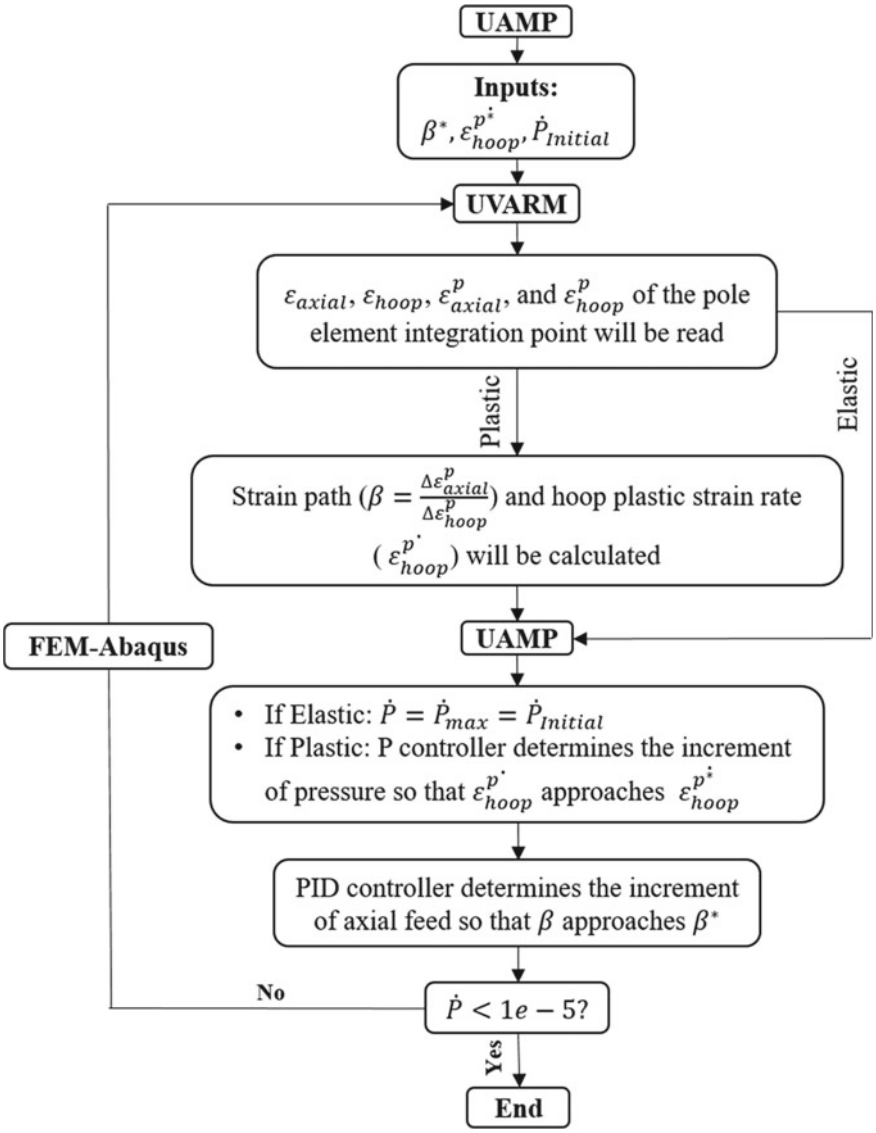

Fig. 5 PID controller algorithm for strain path control in free tube bulging process

Figure 6 shows the five strain paths produced by the PID controller program for von-Mises and Hill's 1948 yield functions. All the strain paths for both yield functions are very well controlled throughout the free tube bulging process.

Figures 7 and 8 also show the boundary conditions generated for three different strain paths generated by von-Mises and Hill's 1948 yield functions.

Table 1 Pressure adjustment algorithm

if $\left(\varepsilon_{hoop}^{p} = 0\right)$ *then*

$\dot{P} = \dot{P}_{Initial}$

elseif $(\dot{P}_{Initial} > \dot{P} * (\frac{\dot{\varepsilon}_{hoop}^{p^*}}{\dot{\varepsilon}_{hoop}^{p}}))$ *then*

$\dot{P} = \dot{P} * \frac{\dot{\varepsilon}_{hoop}^{p^*}}{\dot{\varepsilon}_{hoop}^{p}}$

end if

$P_i = P_{i-1} + \dot{P}dt$

Table 2 Axial feed adjustment algorithm

if $(\varepsilon_{hoop}^{p} = 0)$ *then* (Elastic)

$Axial\ feed = L_0(\beta^* \varepsilon_{hoop} - 1)$ (12)

else (Plastic)

$Error = \beta^* - \beta$ (13)

$Error_{sum} = \sum_i^n Error_i$

$Error_{rate} = Error_i - Error_{i-1}$

if $(-0.2 < \beta^* < 0.2)$ *then*

$\Delta x_i = \Delta x_{i-1} + \left(K_p Error + K_i Error_{sum} + K_d Error_{rate}\right)dt$ (14)

$Axial\ feed_i = Axial\ feed_{i-1} + \Delta x$ (15)

else

$\Delta x = K_p Error + K_i Error_{sum} + K_d Error_{rate}$ (16)

$Axial\ feed_i = Axial\ feed_{i-1}(1 + |\Delta x|)$ (17)

end if

end if

The boundary conditions that were generated can directly be used for free tube bulging tests for tubular material characterization with a tube hydroforming machine that is not equipped with a sophisticated control system. The thing that should be pointed out is that the boundary conditions that were generated were based on very simple yield functions. One can pick the boundary conditions generated using von-Mises yield function or Hill's 1948, but it should be kept in mind that the yield function used for the generation of the boundary conditions may not be an accurate

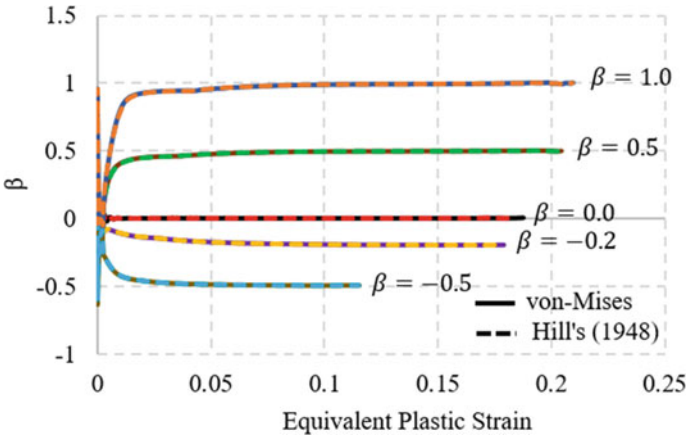

Fig. 6 Controlled strain paths. (Color figure online)

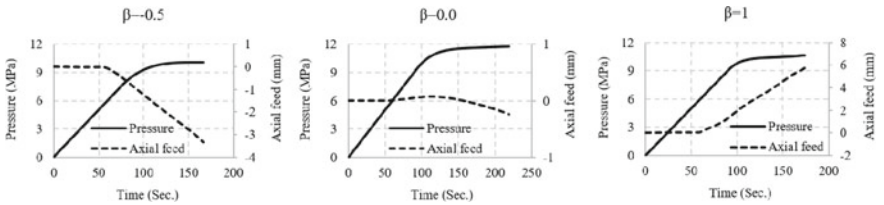

Fig. 7 The axial feed and pressure profiles generated using von-Mises yield function for three different strain paths

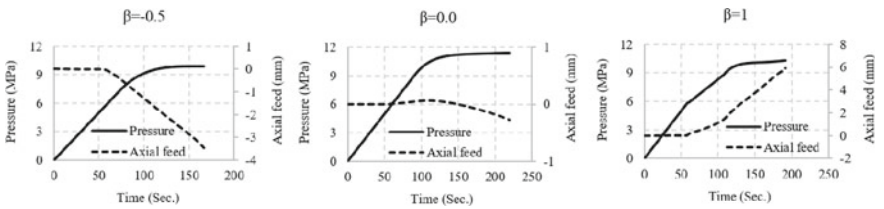

Fig. 8 The axial feed and pressure profiles generated using Hill's 1948 yield function for three different strain paths

representative of the actual material's behavior, therefore, the strain paths that will be obtained in the experiments might not necessarily be similar to the proportional ones generated with the FEM with PID controller. However, the generated boundary conditions will create a range of deformation modes with linear or nonlinear strain/stress paths that can still be used for the characterization of the tubular materials based on accumulated plastic work equivalency.

7 Summary

A PID controller was successfully implemented in FEM platform as a user subroutine to numerically generate appropriate boundary conditions, based on proportional strain path control at the pole of the bulging tube, that can be used for free tube bulging experiments for tubular material characterization based on accumulated plastic work equivalency. It was also shown that the PID controller can generate the boundary conditions based on accurate proportional strain path control using different isotropic or anisotropic yield functions. In this study, von-Mises and Hill's 1948 were employed.

Acknowledgments The authors wish to thank the U.S. Department of Energy for the support of this project through the DOE award DE-FG02-13ER41974 and DOE DE-EE000597, with United States Automotive Materials Partnership LLC (USAMP).

FEM 3d modelling, 1484
Femtosecond laser machining system, 2809
Femtosecond laser trimming, 2811
Ferrite rolling, 1841, 1843
FESEM and TEM analysis, 1834
FE simulation for the determination of the forging load as a function of the billet height, 1137
FE simulations, 611, 921–923, 925, 927, 931, 932, 1131–1133, 1137, 1140, 1142, 1411, 1995, 2927, 2929, 2930, 2932, 2936, 2937
Fiber metal laminate (FML), 2649–2658
Fiber texture, 1767, 1768, 1770–1773
Field shaper, 1373–1375, 1377, 1378
Field transport optimization, 1226
Finding stress relaxation limit, 804
Fineblanking, 1173–1183, 1185, 1186, 2333, 2334, 2336, 2340
Fine-tuning of Process models, 411
Finite Element Analysis (FEA), 209–211, 213–215, 228–231, 235, 2289, 2290, 2307, 2339, 2631, 2635, 2909, 2915
Finite Element Calculation of the straightening process, 7
Finite Element (FE) Model Setup, 2929

Finite element (FE) solution, 542
Finite-element model, 2335
Finite Element Method (FEM), 850, 2056, 2065, 2235, 2939, 2946
Finite element model, 431, 459, 1677
Finite element modeling, 431, 2672
Finite element modeling of the process, 1271
Finite element modeling of tube bulging process, 2963
Finite elements, 271–274, 276, 279, 280, 459, 537, 542, 1220, 1226
Finite elements analysis, 253
Finite element simulation, 482, 2003, 2019, 2021, 2027, 2820–2822
Finite element simulation model, 2821
Finite element type, 274
Fitting scheme for the Swift law's parameters, 2004
Flexible roll forming, 18, 523
5A90, 983, 984, 986–988
5052 aluminum alloy, 973, 974, 976, 977, 981
590R, 667, 669–672, 675, 677, 678
Flange forming, 403, 412, 414
Flatness, 2468, 2483, 2484, 2489, 2494–2496
Flatness of sheet, 2552
Flexibility, 2883, 2885, 2887–2890, 2895
Flexible multi-point forming, 314
Flexible rolling, 563–565, 567, 568, 570, 572, 575
Flexible rolling of tailored blanks and target geometry, 565
Flexible skew rolling, 2521, 2523, 2524, 2531
Flexible skew rolling process (FSR), 2523
Flow behavior, 892–894, 901, 903, 904, 909, 1927
Flow behavior at elevated temperatures, 2686
Flow behavior of 7A85 aluminum alloy, 1816
Flow curve, 692, 693, 697, 700, 704, 1794
Flow forming, 493–501, 503, 505, 1915, 2115–2117, 2120, 2123
Flow rule, 201
Flow stress, 911–915, 917, 919
Flow stresses and microstructures during multi-pass hot compression of Mn18Cr18N, 2372
Folding, 1643, 1644, 1647, 1648, 1651, 1652
Folding over, 668
Force vs displacement results, 1986
Forging, 18–21, 217, 218, 1107–1114, 1117, 1118, 1201–1204, 1208, 1209, 1211, 1213, 1214, 1161, 1162, 1165–1167, 1169, 1170, 2867–2869, 2919, 2920
Forging bimetallic gears, 323
Forging cast preforms, 324
Forging high performance pistons from powder, 323
Forging load and ejection load, 42
Forging net-shape gears, 321
Forging press, 2899–2901, 2905
Forging process by CNC stamper, 1068
Formability, 353–355, 358–364, 441–444, 454, 959–962, 966–970, 1351, 1352, 1805–1807, 1810, 1811, 2819–2821, 2825, 2826, 2883–2889, 2895
Formability in W temper state, 966
Formability limit by fracture, 2605
Formability limit by necking, 2602
Formability limits, 113, 114, 116–121, 124, 2767, 2771
Formability limits in the principal strain space, 2606
Formability of narrow channels, 29
Forming, 1281–1283, 1285, 1286, 1289, 1395–1397, 1743–1755, 1853, 1854, 1981, 1982
Forming apparatus and test platform, 1508
Forming simulation, 1464
Forming behavior, 1411, 1413–1415, 1419, 2864
Forming conditions, 2674
Forming curved complex-shaped profiles, 326
Forming defects, 333, 334, 338, 341
Forming experiments, 1748
Forming for diameter-reduction in productivity and formability, 2888
Forming Limit Curves (FLC), 2631, 2633–2635, 2637, 2638
Forming Limit Diagrams (FLD), 1617, 2631, 2829, 2832
Forming method, 407
Forming pressure, 2167, 2171
Forming process, 1916, 2289–2291, 2293–2296, 2298, 2300
Forming process properties, 2281
Forming quality, 333, 334, 336, 338–341, 2547–2549, 2554
Forward-Backward-Radial Extrusion, 1055–1057, 1061
Forward extrusion, 2277, 2279, 2280, 2285, 2286

Forward extrusion stage, 42
Fractal change of galvanized sheets after friction, 103
Fractal characterization of galvanized sheets, 100
Fractal contact models of galvanized sheets, 104
Fractal theory, 97, 99, 111
Fractography, 113, 121, 122, 124
Fracture, 1947, 1948, 1952–1956
Fracture characterization, 647, 648
Fracture limit, 120, 2601
Fracture limit test and calibration, 1953
Fracture locus, 1563
Fracture mode of the tubes, 1910
Fracture strain, 2777–2779, 2783–2786
Fracture strain measurements, 2783
Fracture strains, 117
Fracture surface, 1563, 1567, 1569, 1571
Fracture toughness, 113–116, 119, 120, 123, 124
Fretting damage, 1437
Friction, 127–131, 133, 136, 218, 223, 1538, 1544–1546
Friction coefficient, 81–93, 2405–2407, 2410–2416
Friction coefficient identification, 2921
Friction coefficient of 45-degree groove roll, 2412
Friction evaluation, 1522, 1525, 1526
Friction model of the hot-dip galvanized (GI) sheet, 109
Friction model of the hot-dip galvannealed (GA) sheet, 109
Friction models of galvanized sheets, 108
Friction of TD groove roll, 2411
Friction-spinning, 2249, 2252
Friction stir forming, 2089
Friction stir processing (FSP), 2221–2223, 2226, 2229
FSR rolling test on DRM-80, 2528
Full explicit scheme model [F-Model], 2058
Full-field, 2041, 2051, 2052
Full-field motion estimation, 1608
Fully connected neural network, 602
Functional design of the actuator, 2612
Further development of an electrodynamic MHP system, 1865

G

Galling free forging, 1074
Galvanized steel, 97, 98, 100, 103
Gears, 2331, 2332
Geometric accuracy, 549, 553, 560
Geometrical accuracy, 507–509, 512
Geometrical features of helicoid auger flighting, 2420
Geometrical modelling based on Voronoi, 712
Geometric comparison, 2106
Geometric deviation, 379, 380
Geometry, 405
Geometry and mesh, 2021
Geometry characterization tool, 2953
Geometry of the elbow, 2024
Geometry reduction, 498
GISSMO damage model calibration and validation, 1955
Global magnetic material behavior, 2313
Grain growth, 1630, 1631, 1903, 1904, 1908, 1909, 1912
Grain orientation, 2507, 2510, 2515–2518
Grain size, 1827–1834, 1837, 1838
Grain size and sheet thickness effects on the Bauschinger effect, 2723
Grain size and thickness effect on springback in U-bending test, 2724
Granular media, 2661–2663, 2669
GS-20Mn5, 719–721, 723, 725

H

Half Specimen Dome Test (HSDT), 1248
Half specimen dome test result, 1251
Hammer, 1201–1205, 1208, 1209, 1211, 1213, 1214
Hardening, 691–693, 695–697, 702, 703, 705, 706, 1947–1952, 1956
Hardening behavior, 839–845
Hardening behavior under large strain, 1949
Hardness, 829, 830, 832, 836, 837, 1727, 1728, 1730, 1732–1735, 1739
Hardness distribution of formed cups, 2738
Hardness measurement of formed cups, 2733
Hardness measurements after drawbead preloading, 1543
Heat transfer, 67, 68, 72, 73, 76
Heat treatment, 1793, 1805–1808, 1810, 1811
Height difference between inner rib and outer rib, 1103
Height of transcribed profile, 2409
Hemispherical shape, 2127, 2131
High carbon steel wire, 1767–1769, 1773

High nitrogen steel, 1498, 1500, 1502, 1504, 1505
High-pressure conditions, 1529, 1530, 1532, 1534, 1535
High-Speed deformation, 1232
High-speed tensile test, 55
High strain rate, 354, 361
High strength steel, 67, 398, 2585–2587, 2589, 2594, 2117
High temperature, 1666, 1671–1673, 1675
High-velocity shearing, 1245, 1253, 1254
Hole-drilling method, 2249, 2250, 2253, 2254
Hole edge formability, 2699
Hole-expansion, 1634, 1991, 1992, 1994–1997
Hole-expansion experiment with prestraining, 1994
Hole expansion forming experiment and FEA simulation, 213
Hole-expansion-test, 2695, 2698, 2791, 2795, 2803, 2805
Homogeneous anisotropic hardening (HAH) model, 639
Homogeneous plane-strain upsetting method, 2430
Horizontal forces, 2611
Hosford–Coulomb fracture criterion, 181
Hot compression, 739–741, 746
Hot cutting, 1655, 1656, 1658, 1661, 1663, 1664
Hot die forging aerofoil blades, 325
Hot extrusion, 1021, 1022, 1025, 1026, 1030, 1031
Hot forming and quenching sheet aluminium alloy, 321
Hot plastic deformation, 891, 892, 894, 897, 899
Hot ring rolling, 2371, 2372, 2372, 2379, 2507, 2508, 2510
Hot ring rolling process of hollow ingots, The, 2372
Hot-roll bonding, 2189, 2190
Hot rolling, 1895, 1897, 1899–1901
Hot stamping, 179, 789–792, 797, 2683–2686, 2688–2690, 2692
Hot stamping tool, 2759, 2760, 2762, 2763, 2766
Hot strip mill, 2559
HSDT and hardness tests, 1588
HTC determination, 75
HTC equipment, 72
Hub bearing unit, 1507
Hybrid concept, 1332
Hybrid experimental-numerical method, 647, 652, 653
Hybrid forming, 2651
Hydraulic-expanding strengthening process of Mn18Cr18N hollow forgings, The, 2377
Hydraulic pressure, 2019–2023, 2027, 2028
Hydroforming, 395–397, 399, 2661
Hydroforming and air forming in strength and formability, 2886
Hydro-mechanical deep drawing, 2729, 2730, 2732, 2733, 2735, 2737–2739
Hydro-mechanical deep drawing condition, 2732
Hydro-mechanical deep drawing process, 2732
Hydro-piercing, 2671, 2672, 2674–2676, 2679, 2682
Hydro-piercing experiments, 2679
Hydrostatic stress, 1595, 1596, 1602
Hypotheses and methodology, 1678
Hysteresis loop, 1694, 1695
Hysteresis loops under cyclic loading, 1694

I

Identification, 2919–2922
Identification of yield function parameters, 953
Identifying of the process limits for burr-free cutting, 2796
Image processing, 2453, 2455, 2456, 2458, 2461
Impact hydroforming, 353, 354, 359–364, 1231, 1242
Implementation of automatic design flow, 1126
Implementation of material model, 925
Implementation of the stabilising control system, 2458
Imprint, 2317
Impulse forming, 1329
Impulse manufacturing, 1341
Incremental bulk forming, 403, 406
Incremental forming, 417, 418, 427, 493, 550, 551, 2067, 2116, 2117, 2237
Incremental grooving, 2180, 2183
Incremental press forming, 2751, 2753–2755
Incremental Sheet Forming (ISF), 375, 441, 507–510, 512, 519
Incremental sheet metal forming, 393

Incremental step cyclic loading test, 723
Indirect extrusion, 1383–1385, 1387, 1393
Induction-heating-assisted spinning, 333, 334, 333
Industrial impact welding tools, 1330
Industrial set-ups of hot and cold strip rolling, 2397
Industrial trials and finite element simulation of the extrusion process, 1717
Influence mechanism, 834
Influence of the die clearance, 2342
Influence of the feed displacement, The, 1512
Influence of air flow and vibrations, 2254
Influence of axial feed, 2665
Influence of ^{Dc} on fatigue property, 1441
Influence of load level on fatigue property, 1442
Influence of lode stress parameter and stress triaxiality ratios, 344
Influence of media friction, 2668
Influence of pre-hole, 427
Influence of process parameters on the weld quality factor, 143
Influence of riveting direction on fatigue property, 1443
Influence of roller feed rate on forming quality, 340
Influence of strain gauge length on strain measurements using DIC, 694
Influence of stress ratio on fatigue property, 1442
Influence of temperature on forming quality, 339
Influence of the feed rate, The, 1513
Influence of the process parameters on the material properties, 1917
Influence of the speckle pattern coating, 2254
Influence of the upper plate on fatigue failure mode, The, 1429
Influence of thinning ratio on forming quality, 340
Inhomogeneous Heating, 1107–1110, 1112, 1114–1118
Initial microstructure, 1626
Initial situation, 1173
Initial situation and motivation, 1863
Injection molding, 2031, 2032, 2034, 2036–2039
Innovative measurement system, 9
In-plane shear deformation, 763–771
In-plane torsion test, 635, 636, 640, 691–693, 695, 696, 698, 699, 701–705
Integral macroscopic analysis, 1260
Integral testing for different process parameters, 1262
Integrated casting and forging process, 343, 348, 349
Intelligent straightening machine, 3, 9
Intelligent straightening process, 4
Interface between CNTs and AZ91D, The, 2228
Interface healing, 2497–2500, 2502, 2504
Interfacial structure of titanium/carbon steel clad plates, 2192
Intermediate layer, 2759, 2760, 2763
Intra-granular ferrite, 1827, 1828, 1833–1836, 1838
Invariant J_2, 1969
Invariant J_3, 1969
Inverse analysis, 949, 950, 1999
Investigated material, 791
Investigated tube material, 421
Investigation methods, 551
Investigation of diagonal cracks in compression tests, 231
Irregular part, 2621
Isothermal compressive tests, 1791
Isothermal forging, 1813–1816, 1820, 1822, 1823
Isotropic hardening (IH) model, 637
Isotropic yield function, 1970–1972, 1974, 1979

J

Joining, 1395, 1397–1400, 1408, 2381, 2383, 2384
Joining and pre-stressing by widening of a FRP-wrapped metal collar, 1398
Joining stress, 1037, 1038, 1040–1042

K

Kinematic hardening, 635–638, 644
Kinematic loading, 2135, 2149
Kinematics, 406, 2419, 2420, 2450
Kinematics of auger flighting rolling, 2435
Knowledge base, 1161, 1162, 1169, 1170

L

Large and complex curvature, 922, 926, 928
Large deformation simulation, 2939, 2946
Large diameter tube, 1292

Laser, 2067, 2068, 2070–2075
Laser heating, 479, 480, 488–490
Laser heat treatment, 2768, 2769
Laser impulse, 1329, 1332, 1333, 1336, 1338
Laser metal deposited material, 1899
Laser shock peening, 1361, 1362
Laser trimming program, 2809
Light-weight, 2883, 2099
Lightweight construction, 1255, 1256
Lightweight design, 1496
Linear strain path, 202
Liquid-solid extrusion, 2221, 2222, 2225, 2226, 2228, 2229
Liquid-solid extrusion process, 2225
Local heat treatment, 1806, 2068, 2070–2073
Local magnetic material behavior, 2311
Local microscopic analysis, 1260
Local solution treatment, 2731
Local strength distribution and process correlation, 1264
Lode parameter, 1077, 1078, 1084, 1085, 1596, 1600
Lode stress parameter, 344–346, 349
Longitudinal buckle, 2468, 2469, 2471–2476, 2479, 2480
Longitudinal peak strain, 479, 484–487, 490
Long-term X-ray analysis and FE-model validation, 2296
Loosening test, 2162–2164
Lower bound, 544
Low load precision bending, 313
Lubricants, 1529, 1530, 1532, 1534, 1535
Lubricated model for the revolute joint, 1553
Lubrication, 1550, 1551, 1555

M

Machine, 406
Machine behavior, 1132
Machine hammer peening, 1863, 1864
Machine learning, 167, 170, 171, 173, 175, 176, 589–592, 595
Machine learning modeling, 171
Macroscopic failure, 1444
Magnesium, 263, 264
Magnesium alloy of AZ31B, 844
Magnesium alloys, 189, 333, 334, 336, 341, 1563–1565, 1568, 1571
Magnesium alloy sheet (AZ31B), 847–851, 855
Magnesium composite, 2221–2223
Magnetic flux barrier, 2305, 2308, 2313
Magnetic pressure seam welding, 1309
Magnetic pulse forming, 1217, 1218, 1229
Magnetic pulse spot welding, 1373
Magnetic pulse welding, 1269, 1270, 1272, 1274, 1278, 1279, 1291, 1292, 1302
Main roll driving power, 2447
Manufacturing aircraft frame part by IHF technology, 1240
Manufacturing of functional components, 573
Manufacturing of Tailored Blanks, 568
Manufacturing process and target geometry, 566
Mapping algorithm, 2046
Martensite content, 1922
Martensite transformation, 1691, 1692, 1697, 1698, 1854, 1857, 1859
Martensitic transformation measurements, 1857
Mass scaling, 272, 273, 276–278
Material, 1905
Material parameters and numerical implementation, 2349
Material and experimental embossing method, 2359
Material and specimen preparation, 802, 1855, 1982
Material Cards, 625, 627–631
Material characterisation of hot forming steels, 2291
Material characterization, 115
Material characterization and parameter identification of constitutive models, 1992
Material Condition, 2278, 2280, 2282, 2286
Material cyclic characterization, 775
Material description, 615
Material efficiency, 1003, 1018
Material flow, 153, 154, 157–160, 162

Sheet forming, 97, 564, 1939, 2620
Sheet metal, 151–155, 157–160, 162–164, 2048, 2357–2360, 2362, 2363, 2365, 2650, 2651, 2653
Sheet metal forming, 81–85, 87, 90, 92, 93, 2574, 2583
SiC coated dies, 1065–1069
Similarity of plasticine and aluminum, 1025
Simulation, 271–280, 1057, 1715–1719, 1723, 1724, 2831, 2832, 2834, 2835, 2947, 2948, 2950–2957
Simulation/numerical simulation, 2149
Simulation matrix, 2930
Simulation results, 928, 2715
Simulation setup, 614, 2664
Simulation setup and modelling, 2792
$\sin^{2}2\ \Psi$, 2261, 2263–2265
Single point incremental forming, 25–30, 32, 34, 35
Single sheet tests, 2309
Single step cyclic loading test, 722
Six-roll straighteners, 2138
6063 aluminium alloy, 1727–1729, 1739
Size effect, 151–155, 158–164, 190, 194, 1351, 1352, 1355–1358, 2719, 2720
Skew-roll straightening machine, 2140
Skin pass, 2470
Slab analysis, 539
Slice of final forging, 2910
Slow cooled microstructure investigation, 1833
Soft material, 2211, 2212, 2214–2216, 2219
Solid boss forming by plate forging process, 975
Solid state bonding, 140, 141
Solution approach, 2070
Space mesh, 2939–2942, 2944–2946
Spatial discretization, 1220
Specimen and equipment, 720
Specimen design, 1961, 1966
Specimen geometry, 54, 55, 57, 59, 65
Specimen geometry and preparation, 1399
Specimen manufacturing process, 2305
Specimen preparation, 1439, 1574
Spectrum analysis, 2089–2091, 2094, 2098
SPHE, 1841–1843, 1847, 1849–1851
Spinner, 2055–2060, 2062–2065
Spinner straighteners, 2139
Spinning process, 1913, 1915
Springback, 167–172, 174–177, 2179, 2180, 2183, 2184, 2186
Springback simulation, 1464
Springback prediction, 2706, 2720, 2726
Spur gears, 1077–1082, 1085
Square plate diagonal stretching, 1939, 1942, 1943
SRAF test verification, 930
Stainless steel, 27, 29, 749, 750, 755, 756, 759, 1383–1386, 1389, 1392–1394, 1495, 1498, 1500, 1502, 1504, 1505, 1853, 1854, 1864–1867, 1868, 1870, 1874–1876, 1981, 1982, 2277–2280, 2285, 2286
Stainless steel pipe, 2019, 2020, 2022, 2027
Staking, 1411–1417, 1421
Stamping, 2619–2621, 2623, 2624, 2627
Stamping by elastic Blankholder with supporting elements, 2624
State of the art, 53, 417, 1109, 1462, 1174, 1863, 2279, 2455

Static recrystallization, 1715, 1716, 1718–1720, 1723, 1724, 1879, 1883, 1884, 1890
Static recrystallization model of 6XXX aluminum alloy based on industrial experiments, 1719
Static transformation during heat treatment, 1795
Steel, 1281–1283, 1288, 2189–2197, 2199
Steel sheet, 209, 210, 215
Steering control, 2557, 2559–2563, 2568
Step shafts forming, 2526
Stone formula, 2533, 2534
Straightener, 2055–2057, 2059, 2065
Straightness, 2055, 2061, 2135, 2136, 2139–2141, 2147–2149, 2151, 2152
Strain, 1605–1607, 1609, 1611–1613, 2009–2016
Strain distribution in conventional shear tests, 694
Strain distribution in in-plane torsion tests, 695
Strain gauge, 1701, 1702, 1704, 1705, 1707, 1710
Strain hardening, 911–913, 915, 1915
Strain hardening near the cut edge, 2932, 2934
Strain hardening rate, 60, 62, 63
Strain localization, 692, 696, 702–704, 706
Strain measurements, 2772
Strain penetration, 2371, 2374, 2375, 2379
Strain penetration during ring rolling forming, 2374
Strain rate, 657–660, 662, 663, 1605, 1606, 1609, 1613
Strain-rate potential, 284, 286–289
Strain results, 1988
Strain state of different forming stages, The, 1084
Strength, 2883–2888, 2890, 2892, 2895
Strengthening mechanism, 1850
Stress, 2009–2011, 2014
Stress deviator, 1970, 1972
Stress exponent, 807
Stress exponent of creep strain, 851
Stress filed comparison of traditional and new tool, 2763
Stress loss ratio, 1361, 1363–1369
Stress metric, 668, 674–678
Stress ratio, 1437, 1438, 1440–1443, 1449
Stress relaxation, 801–809, 847, 848, 850, 853–855, 877–882, 885, 886, 888
Stress-relaxation age forming, 921, 925, 932
Stress relaxation ageing sub-model, 882
Stress relaxation behaviour, 885
Stress state of different forming stages, The, 1083
Stress-strain analysis, 437
Stress-strain behavior, 1236
Stress-strain curve, 60–62, 949, 950, 953
Stress-strain curve of AA 6016-T6, The, 1597
Stress–strain curves, 1858
Stress-strain relationship of auger flighting rolling, 2425
Stress-train curve, 292
Stress triaxiality, 1596, 1600
Stress triaxiality ratio, 343–346, 349
Stress wave, 53–55, 57, 62–65
Stress wave propagation and system ringing analysis, 55
Stress wave simulation, 1464
Stretch straightening machines, 2137
Strip deviation angles, 2445
Strip drawing test, 81, 84, 89, 90, 93
Strip drawing tests and retention forces, 1541
Strip drawing with flat dies (FD test), 90
Strip feeding (bite) condition, 2439
Stripping off, 1173–1185
Strip rolling, 2483, 2487, 2489
Strip steel, 2421, 2425, 2430
Strip velocity in forming zone, 2435
Structured Sheet Metals (SSM), 1701–1703, 1710
Structure of bimetallic microcontact, 1491
Sucrose, 2031–2033, 2035, 2037, 2039
Superalloy sheet, 2719, 2720, 2726–2728
Superimposed vibrations, 2610
Superplastic forming (SPF), 1573, 1574, 1578, 1582
Superplasticity, 983, 984, 986, 988, 1623, 1624, 1628
Supporting technologies, 2893
Surface, 217–224
Surface asperity, 2211
Surface integrity, 1863–1865, 1867, 1868, 1874
Surface layer, 2759, 2760, 2763
Surface morphology, 1576
Surface profiles and textures, 2092
Surface profiles and 3D topographies of galvanized sheets, 100
Surface quality, 377–379, 2120, 2553
Surface reconstruction, 2912
Surface roughness, 1573, 1575, 1576, 1581–1583, 2405, 2406

Surface roughness and hardness, 1870
Surface strengthening, 1362
Surface texture, 2547–2551, 2554
Surfacing technology, 2759, 2760, 2764, 2766
Surface topographies and fractal features of galvanized sheets, 99
Surrogate modeling, 617, 619, 622
Surrogate modeling of drawing aid forces, 619
Surrogate modeling of draw-ins, 617
Surrogate modeling of sensor signals, 617

T

Tailored blank, 563–575
Tailored sheet, 1677, 1678, 1684, 1686–1689
Tailored tempering, 964, 968, 970
Tailored tempering of EN AW 7075, 968
Tailor heat treated blank, 2729
Taylor-Quinney coefficient, 1775, 1776
TCBC experiment and results discussion, 448
TCBC test concept development, 444
TCBC test rig design and manufacturing, 447
Temperature, 1857, 2041, 2042, 2046, 2051, 2052
Temperature filed comparison of traditional and new tool, 2763
Tempering stability, 829, 830, 832–834, 837
Temper rolling, 2467–2470, 2477, 2480
Tensile strength, 2155–2158, 2162–2164
Tensile strength tests, 2162
Tensile experiment and results, 986
Tensile properties, 1665, 1666
Tensile test, 1426, 1574–1576, 1579–1583, 1701–1703, 1705–1707, 1709, 1710, 1898
Tensile testing results, 2578
Tensile test of extruded products, 1035
Tensile tests, 1672, 2771
Tension and compression, 839, 840, 844, 845
Test and calibration of QP1180-EL, 1950
Test cases, 1221
Testing methods and instruments, 1916
Texture, 263, 264, 266–269, 729, 730, 733–736
Texture evolution, 2508, 2509, 2513, 2515, 2517, 2518
Texture rolling, 2406
Theoretical analysis, 2707
Theoretical aspects, 2141
Theoretical model, 2535
Theory of the producible rolling thickness, 2535
Thermal cycle, 70
Thermal flow, 1617
Thermal loading of work rolls during a strip rolling campaign, 2487
Thermal model, 1884
Thermal parameters identification, 2920
Thermal profile, 74
Thermal softening, 657, 660, 662
Thermal strain, 2255, 2256
Thermal treatment, 1656, 1658
Thermographic performance, 2050
Thermomechanical analysis, 1775–1777, 1779–1781, 1783, 1786
Thermomechanical model, 1219
Thickness distribution, 436
Thickness evolution, 429, 431, 436, 438
Thickness profile, 2484, 2493–2496
Thickness reduction, 1043, 1044, 1046, 1048, 1049, 1052
Thin part with high circular ribs, 1099
Thin-walled tubes, 113–115, 120, 123, 124, 2179, 2180, 2767
Thread rolling, 2155–2160
Thread rolling FEM simulation and experiments, 2159
3D-DIC optical residual stress measuring system, 2250
3D digital-image-correlation, 2249
Three-layer sheet hot stamping, 2819, 2820, 2822, 2824–2827
3MA, 2573–2577, 2580–2583
316L, 1743–1745, 1747–1749, 1749–1753
316LN austenitic stainless steel, 1757
Three-point bending test, 2588
Thrust force, 2557–2562, 2567, 2568
Ti-55511 alloy, 1189, 1190, 1192–1194, 1196
Ti–5Al–5Mo–5V–3Cr–1Zr alloy, 1925
Ti-6Al-2Zr-1Mo-1V alloy, 1791–1794, 1802
Ti-6Al-4V alloy, 2751–2753
Time series classification, 591
Titanium, 1065–1074, 2189–2193, 2195–2197, 2199
Titanium alloys, 2695, 2696, 2703, 2819–2826
Titanium wire work, 1068
TNW700 titanium alloy, 1623–1631
Tool design, 1319

Tool force, 465
Tool geometry, 551, 559, 560
Tooling setup, 1522
Tool kinematics, 403, 404
Tool life, 37, 40, 41, 44–46, 48, 49
Tool materials, 2000, 2214
Tool path, 369, 370, 381
Tool path algorithm, 370
Tool path design, 553
Torsion, 217, 220, 224
Toughness, 829, 830, 832, 836, 837
TP340 titanium sheets, 2741, 2742
Transfer printing, 2212
Transverse weld, 1003–1006, 1008, 1013, 1016, 1018
Tribological test methods, 82
Tribology, 81–84, 90, 93
Tribometer, 81–85, 87, 90–93
Tribo-test, 1519–1521
Trimming, 2925–2927, 2929, 2930, 2933–2937
TRIP effect, 1691, 1694, 1698
True stress-strain curve, 741, 903, 976
Tselikov's method, 2428
Tube bending, 167–171, 175, 177
Tube bending in terms of flexibility, 2890
Tube bulging, 682, 683
Tube draw bending, 67–69
Tube expansion tests, 2771
Tube formability tests, 116
Tube forming, 113, 114, 124, 397, 402, 524, 2020, 2768, 2884–2886, 2892–2895
Tube hydroforming, 1880, 1881
Tube material, 2672
Tube spinning, 2077–2080, 2082–2084, 2086, 2087, 2127–2130, 2133
Tube welding, 1291, 1292
Tubular materials, 2959–2961, 2966–2968
Two-roll bar straighteners or reeling machines, 2138
Two-stage counter punching and shaving, 2790
Types of straighteners, 2136

U

U-bending test, 2722
Ultimate strain limit, 291
Ultrahigh strength steel, 867, 875
Ultra-large forgings, 21
Ultrasonic, 1281–1285, 1287–1289
Ultrasonic assisted, 384, 385
Ultrasonic processing, 2224
Ultrasonic riveting, 1479
Ultrasonic vibration, 429, 430
Ultra-thin strip rolling, 2533–2535, 2539, 2540, 2542
Uncoupled model, 1635
Uniaxial tensile creep, 849, 850, 855
Uniaxial tensile creep test, 849
Uniaxial tensile simulation for determination of material parameters, 257
Uniaxial tensile test, 949, 950, 952, 953
Uniaxial tensile testing, 974
Uniaxial tensile tests at elevated temperatures, 791, 793
Uniaxial tension, 1853–1855, 1861
Uniaxial tension test, 721
Universal tensile, 983, 986
Unregularized and regularized linear regression, 613
Upper bound, 537, 538, 540–542, 544, 545, 547
Upper bound solution, 540

V

Validation and evaluation of the results after the collar widening process, 1404
Validation of s-s curve in high strain region obtained by proposed method, 956
Validation of the calibration function, 2577, 2580
Validation of the method by using FE simulations, 2874
Validation of the porosity closure model, 346
Validation of the predictive capacity of the model for copper cylinder upsetting, 1136
Validation of the 6XXX aluminum alloy static recrystallization model, 1722
Validation of the temperature compensation method, 2256
Validation via design of experiments, 2461
Vaporizing Foil Actuator (VFA), 1341, 1342, 1345, 1346, 1348
Vaporizing foil method, 1329, 1330, 1332, 1339
Various loading states, 647
V-bending process, 854
V-Bend mechanics, 671
VDA 238-100 tight radius bend test, 671, 673
Verification, 271, 273–276, 278, 279
Verification target, 1125
Verification of finite element model, 336

Verification of the new approach, 2716
Vibration loosening tests, 2162
Vibration assisted, 385
Visco-plastic constitutive model, 1617
Visual appearance of drawn clad cup, 2642
Visualization of model quality dependent on model complexity, 621
VUMAT, 1617, 1618, 1621

W

Wall thickness measurement, 2107
Warm forming, 847, 848, 2751, 2752, 2755
Wear, 1727, 1729, 1730, 1734–1740
Wear analysis, 1447
Weight reduction versus cost effectiveness, 319
Welding device design, 1378
Welding platform, 1373
Welding principle, 1306
Weld quality prediction and experimental validation, 144
Whole forming process of ring, The, 2201, 2202
Wire, 467–473, 475–477
Wire-Arc Additive Manufacturing (WAAM), 2853–2855, 2857–2860, 2862
Wire drawing, 1768, 1769, 1771, 1773
Wood, 2031–2033, 2036, 2037, 2039
Workability, 467–469, 473, 475, 477
Work hardening, 1537, 1538, 1543, 1544, 1546, 1623, 1624, 1626, 1628, 1629, 1631, 2116, 2117, 2277, 2278, 2777, 2285, 2286, 2780–2783, 2786, 2789, 2799, 2801, 2802
Work-hardening and strain rate sensitivity exponent, 1628
Work hardening behaviour, 886
Work hardening of shear cut edges, 2799
Work roll contour, 2395–2397, 2400–2402
Work roll flattening, 2487
Wrinkle instability, 1939, 1940
Wrinkling, 2067, 2069–2072, 2075, 2777, 2782, 2786
W-temper, 935–939, 942, 943, 945

X

X-ray diffraction, 2233–2235, 2238, 2241, 2242, 2245, 2246, 2261, 2264, 2265, 2289, 2295, 2300

Y

Yield condition, 201–205
Yield function, 209, 210, 212–215
Yield functions calibration, 685
Yield strength, 1842, 1847–1851
Yield strength behaviour, 886
Yield stress surface, 284, 286–289
Yield surface, 201–206
Yoshida-Uemori (YU) model, 638
