Preface

Dear Colleague,

The "lucky" thirteenth International Conference on the Technology of Plasticity (ICTP) was the meeting that just was not destined to happen live. The COVID-19 pandemic forced us to move it from July 2020 to July 2021, and now as I write, the world is starting to recover, vaccinations are coming, but the end of July 2021 is just too early for extensive international travel. This represents the archive of peer-reviewed papers that accompany this meeting.

This is a meeting series with the strongest of international traditions. Meetings have been held in Tokyo, Japan (1984); Stuttgart, Germany (1987); Kyoto, Japan (1990); Beijing, China (1993); Columbus, Ohio, USA (1996); Nuremberg, Germany (1999); Yokohama, Japan (2002); Verona, Italy (2005); Gyeongju, Korea (2008); Aachen, Germany (2011); Nagoya, Japan (2014); and Cambridge, England, and this meeting was to be held in Columbus, Ohio, USA.

This meeting has a strong tradition, and we hope that the papers here and the remote meeting format will maintain the ICTP's traditions of innovation impact and collegiality across the globe.

This meeting is noteworthy also for several special symposia for pioneers of metal forming:

Taylan Altan, The Ohio State University, USA
Niels Bay, Technical University of Denmark, Denmark
Xue-yu Ruan, Shanghai Jiao Tong University, China (memorial symposium)
Yasuhisa Tozawa, Nagoya University, Japan
Rob Wagoner, The Ohio State University, USA
Zhongren Wang, Harbin Institute of Technology, China

I am grateful for the many hours of planning (much for events that are not to be realized) by the planning committee:

Glenn Daehn, The Ohio State University, USA
Jian Cao, Northwestern University, USA
Brad Kinsey, University of New Hampshire, USA
Erman Tekkaya, Technical University of Dortmund, Germany

Anupam Vivek, The Ohio State University, USA
Yoshinori Yoshida, Gifu University, Japan

Despite the unusual circumstances, I think you will agree that this series of full papers (246) shows great quality and innovation in keeping with the spirit of ICTP. The papers are arranged topically and then alphabetically.

The organizers wish to thank the various people and institutions that supported us in organizing the ICTP and in preparing the proceedings. Our sincere thanks go to all authors who submitted excellent papers and who make our (metal) forming community so strong. Secondly, we wish to thank all our reviewers who carefully and constructively evaluated all the submitted papers. The bulk of this reviewing was carried out by the international scientific committee, which is named below and the members of my research group who skillfully filled in several gaps. We are also grateful to the members of the scientific committee and the standing advisory board for their valuable help and advice.

I hope you find these innovative papers useful and enjoy the online conference.

With best wishes,

Glenn Daehn
Mars G. Fontana Professor of Metallurgical Engineering
The Ohio State University
Columbus, OH, USA

ICTP 2021 International Scientific Committee:

Tatsuhiko Aizawa, Shibaura Institute of Technology
Julian Allwood, University of Cambridge
Birgit Awiszus, TU Chemnitz
Tudor Balan, LCFC, Arts et Métiers ParisTech—Metz Campus
Markus Bambach, BTU Cottbus–Senftenberg
Dorel Banabic, Technical University of Cluj-Napoca
Francois Bay, MINES ParisTech
Niels Bay, Technical University of Denmark
B-A Behrens, Leibniz Universitat Hannover
Yan Beygelzimer, Donetsk Institute for Physics and Engineering
Regis Bigot, Ecole Nationale Supérieure d'Arts et Métiers
Pierre-Olivier Bouchard, MINES ParisTech
Jose Divo Bressan, University of Santa Catarina State
Alexander Brosius, Technische Universität Dresden
Stefania Bruschi, University of Padova
Sergio Button, State University of Campinas

Demircan Canadinc, Koç University
Jian Cao, Northwestern University
Jianguo Cao, University of Science and Technology Beijing
Oana Cazacu, University of Florida
Elisabetta Ceretti, University of Brescia
Jose Cesar de Sa, University of Porto
Paulo Roberto Cetlin, Federal University of Minas Gerais
Yvan Chastel, Renault
Francisco Chinesta, Arts et Metiers Institute of Technology
László Cser, Corvinus University of Budapest
Elías Cueto, University of Zaragoza
Zhenshan Cui, Shanghai Jiao Tong University
Glenn Daehn, The Ohio State University
Prashant P. Date, Indian Institute of Technology Bombay
Joost Duflou, KU Leuven
Gang Fang, Tsinghua University
Luigino Filice, University of Calabria
Livan Fratini, Università degli Studi di Palermo
Lander Galdos, Mondragon Unibertsitatea
Andrea Ghiotti, University of Padova
Sergey F. Golovashchenko, Oakland University
Zbigniew Gronostajski, Wroclaw University of Science and Technology
Gerhard Hirt, RWTH Aachen
Werner Homberg, Paderborn University
Sung-Tae Hong, School of Mechanical Engineering, University of Ulsan
Odd Sture Hopperstad, Norwegian University of Science and Technology
Yujie Huang, Korea Advanced Institute of Science and Technology
Hoon Huh, Korea Advanced Institute of Science and Technology
Y-T Im, Korea Advanced Institute of Science and Technology
Shohei Kajikawa, The University of Electro-Communications
Celalettin Karadogan, Institute for Metal Forming Technology—University of Stuttgart
Hyunok Kim, EWI
Brad Kinsey, University of New Hampshire
Antti Korhonen, Helsinki University of Technology
Toshihiko Kuwabara, Tokyo University of Agriculture and Technology
Da Yong Li, Shanghai Jiaotong University
Jian-Jun Li, Huazhong University of Science and Technology
Mathias Liewald, Institute for Metal Forming Technology—University of Stuttgart
Lars-Erik Lindgren, Lulea University of Technology
Gang Liu, Harbin Institute of Technology
Hui Long, The University of Sheffield
Evripides Loukaides, Bath University
Lukasz Madej, AGH University
Ryo Matsumoto, Osaka University

Takashi Matsuno, Tottori University
Marion Merklein, Universität Erlangen-Nürnberg
Wojciech Misiolek, Lehigh University
Pierre Montmitonnet, CEMEF—Centre de Mise en Forme des Matériaux
Y. H. Moon, Pusan National University
Ken-ichiro Mori, Toyohashi University of Technology
Omer Music, TED University
Thomas Neitzert, Auckland University of Technology
Gracious Ngaile, North Carolina State University
Takeshi Nishiwaki, Daido University
Takahiro Ohashi, Kokushikan University
Mats Oldenburg, Luleå University of Technology
Masaaki Otsu, University of Fukui
Hengan Ou, University of Nottingham
Aleksandr Pesin, Magnitogorsk State Technical University
Jean-Philippe Ponthot, University of Liege
Warren Poole, University of British Columbia
Alexandre Rocha da Silva, Federal University of Rio Grande do Sul
Andrzej Rosochowski, University of Strathclyde Glasgow
Jinn-Jong Sheu, National Kaohsiung University of Science and Technology
Kazunari Shinagawa, Kyushu University
Andreas Sterzing, Fraunhofer IWU
Erman Tekkaya, Technische Universität Dortmund
Miklós Tisza, University of Miskolc
Hiroshi Utsunomiya, Osaka University
Ton van den Boogaard, University of Twente
Anupam Vivek, The Ohio State University
Frank Vollertsen, Bremer Institut fur angewandte Strahltechnik
Robert Wagoner, The Ohio State University
Zhigang Wang, Gifu University
Michael Worswick, University of Waterloo
Jian-xin Xie, University of Science and Technology Beijing
Dong-Yol Yang, Gwangju Institute of Science and Technology
Yoshinori Yoshida, Gifu University
Hai Liang Yu, Central South University
Mei Zhan, Northwestern Polytech University
Shihong Zhang, Institute of Metal Research, Chinese Academy of Sciences
Guoqun Zhao, Shandong University
Zhen Zhao, Shanghai Jiaotong University

Contents

Part I Honorary Symposium: Taylan Altan

Self-optimized, Intelligent Open-Loop-Controlled Steel Strip Straightening Machine for Advanced Formability 3
Fabian Bader, Lukas Bathelt, Eugen Djakow, Werner Homberg, Christian Henke, and Ansgar Trächtler

A Vision of Numerically Controlled, Autonomous Manufacturing and Metal Forming 13
Glenn S. Daehn

Investigation of Effects of Part Features in Single Point Incremental Forming of Narrow Channels 25
Suwat Jirathearanat, Dharmesh Kumar, Kai Soon Fong, Atsushi Danno, and A. Senthil Kumar

Enhancing Tool Life by Manipulating the Die Elastic Strain Field During Extrusion 37
Gracious Ngaile and Daniel Santiago

Part II Honorary Symposium: Niels Bay

Oscillation-Free Determination of Material Properties at High Strain Rate 53
Xiangfan Fang

Tribological Conditions in Hot Bending of 22MnB5 Tubes 67
Enrico Simonetto, Andrea Ghiotti, and Stefania Bruschi

In Search of the Perfect Sheet Metal Forming Tribometer 81
L. Schell and P. Groche

A Contact and Friction Model for Forming of Galvanized Steel Sheet Based on Fractal Theory 97
Yao Huang, Leigang Wang, Mingxiao Shi, and Xiang Ma

On the Characterization of Fracture Loci in Thin-Walled Tube Forming 113
J. P. Magrinho, M. B. Silva, and P. A. F. Martins

Deformation Mechanisms in Tool–Workpiece Asperity Contact in Metal Forming 127
Chris Valentin Nielsen, Xiaodan Zhang, Marcel Moghadam, Niels Hansen, and Niels Bay

Welding of Aluminium in Chip Extrusion 139
André Schulze, Oliver Hering, and A. Erman Tekkaya

Part III Honorary Symposium: Xue Yu Ruan

Bulk Microforming from Sheet Metal—A Promising Approach for the Mass Production of Cold-Formed Metallic Micro Parts 151
Martin Kraus and Marion Merklein

Machine Learning (ML)-Based Prediction and Compensation of Springback for Tube Bending 167
J. Ma, H. Li, G. Y. Chen, T. Welo, and G. J. Li

Ductile Fracture Prediction of Hot-Stamped Boron Steel 22MnB5 with Modified Mohr–Coulomb and Hosford–Coulomb Models 179
Fangxing Wu, Bingtao Tang, Ning Guo, Huiping Li, and Qiaoling Wang

Understanding the Microscale Plastic Behavior and Deformation Mechanism of Magnesium Alloy via Ex Situ Experiments and Full-Field Crystal Plasticity Modeling 189
Haiming Zhang, Shuai Xu, Xiaoqing Shang, and Zhenshan Cui

Part IV Honorary Symposium: Yasuhisa Tozawa

A Plasticity Framework for Forming Applications 201
Frédéric Barlat and Toshihiko Kuwabara

Hole Expansion Simulation of Steel Sheet Considering Differential Hardening 209
Shunya Nomura and Toshihiko Kuwabara

Surface Quality of Extruded Sidewall in Cold Backward Cup Extrusion with Low-Frequency Torsional Oscillation 217
Ryo Matsumoto, Seiji Takatsuka, and Hiroshi Utsunomiya

Anisotropic Ductile Fracture Estimation of Diagonal Cracks in Flange-Shaped Parts 227
Atsuo Watanabe, Kunio Hayakawa, Shinichiro Fujikawa, Tatsumi Takeshita, and Mika Furutani

Prediction of Microstructure Behavior During Large-Scale Hot Forging of Ni-Based Superalloy 239
Nobuki Yukawa, Chihiro Osawa, Takayuki Yamada, and Eiji Abe

Part V Honorary Symposium: Rob Wagoner

Simulated Microstructure Effects on Macroscopic Mechanical Properties Based on Multiscale Crystal Plasticity 253
Yoshiteru Aoyagi, Ryota Kobayashi, and David L. McDowell

Experimental Study on Texture Evolution of Mg-Y Magnesium Alloy in Extrusion 263
Dayong Li, Weiqin Tang, Ding Tang, and Yinghong Peng

Advancing the Accuracy of Computational Models for Double-Sided Incremental Forming 271
Newell Moser, Dohyun Leem, Shuheng Liao, Kornel Ehmann, and Jian Cao

Nonlinearity of the Crystal Yield Function in the Rate-Independent Crystal Plasticity and Its Effect on the Evolution of Anisotropy 283
Taejoon Park, Ji Hoon Kim, Hojun Lim, Sobhan Alah Nazari Tiji, Amir Asgharzadeh, and Farhang Pourboghrat

Experimental Study and Analysis on the Effects of Cyclic Bending on the Stress-Strain Curves of Aluminum Plate 291
Yongjun Wang and Pengyan Tong

Part VI Honorary Symposium: Zhongren Wang

Professor Z. R. Wang's Contributions to Metal Forming Theory, Technology, and Education 303
Gang Liu, Shijian Yuan, and Kaifeng Zhang

Adding Value by Advancing Metal Forming Technology 319
Trevor Dean, Bo-Zhou Di, and Li-Liang Wang

A Study of the Forming Quality of Magnesium Alloy Cylindrical Parts with Inner Ribs by Induction-Heating-Assisted Spinning 333
Qinxiang Xia, Jinchuan Long, Gaozhu Huang, Shuai Yuan, and Yi Qin

A Porosity Closure Model for the Integrated Casting and Forging Process of Aluminum Alloy and Its Application 343
Qi Zhang, Liqun Niu, Zhenglong Liang, and Miao Cao

Robust Hydroforming Technologies to Enhance the Formability of Sheet and Tube 353
Shi-Hong Zhang, Da-Yong Chen, Yong Xu, and Yan Ma

Part VII Agile Metal Forming

Recent Investigations on Incremental Sheet Forming: From Fundamentals to Industrial Application Technologies 369
Jun Chen and Zhidong Chang

The Effect of Ultrasonic Vibration on Material Movement in Incremental Sheet Forming 383
Randy Cheng, Ankush Bansal, Jiarui Kang, Xun Liu, and Alan Taub

Investigation of an Integrated Process for Bending and Cross-Section Forming of Tubular Lightweight Parts Based on a Working Media Made of Materials with High Plasticity 395
Matthias Hermes and Viktor Holstein

Instability Analysis in Incremental Rotary Forming of Tube Flanges 403
Bhaskaran Krishnamurthy, Olga Bylya, Kyle Watt, Alastair Conway, Martin Tuffs, and Paul Blackwell

Incremental Collar Forming Process for the Manufacturing of Branched Tubes and Pipes 417
André Leonhardt, Peggy de Witt, Matthias Rehm, Holger Schlegel, and Verena Kräusel

Deformation Analysis in Ultrasonic-Assisted Multi-stage Incremental Sheet Forming 429
Zinan Cheng, Yanle Li, Fangyi Li, and Jianfeng Li

A New Test Method for Sheet Metal Deformation Subject to Tension Under Cyclic Bending and Compression (TCBC) 441
H. Long, S. Ai, F. Tian, B. Lu, J. Chen, and H. Ou

Numerical Modelling and Deformation Mechanics of the English Wheel Process 457
Daniel T. Bowen, Omer Music, A. Alaz Erdinc, Alborz Shokrani, and Evripides G. Loukaides

The Dieless Drawing Process for the Elongation of Ultrafine Copper and Brass Wire 467
Andrij Milenin, Piotr Kustra, Miroslaw Wróbel, Valeriy Pidvysots'kyy, and Marek Packo

Robotic Roller Forming Process and Strategies to Eliminate Geometrical Defect of Edge Waves 479
Yi Liu, Junying Min, and Jianping Lin

Numerical Modelling of the Flow Forming Process: Computation Time Optimization and Accuracy Analysis 493
Ahmed Mehdi Roula, Katia Mocellin, and Pierre-Olivier Bouchard

On the Geometrical Accuracy in Incremental Sheet Forming 507
Gerhard Hirt, Roman Kordtomeikel, Thomas Bremen, Marvin Laugwitz, and David Bailly

Tube Roll Forming Flower Design and Flexible Roll Adjustment with CAE Simulation 523
Jinn-Jong Sheu, Bao-Shan Wang, and Cheng-Hsien Yu

Open Die Forging of Copper Cone 537
A. Shirizly, G. Harpaz, and A. Shmuel

Flexible Manufacturing of Concave–Convex Parts by Incremental Sheet Forming with Active Medium 549
Sebastian Thiery and Noomane Ben Khalifa

Manufacturing of Tailored Blanks with Pre-shaped Involute Gearings by Using a Flexible Rolling Process and Its Application in a Sheet–Bulk Metal Forming Process 563
Manfred Vogel, Robert Schulte, Onur Kaya, and Marion Merklein

Roll Forming of Cup with Curved Rotary Profile 577
Baohong Zhang, Bin Hu, Chunyu Wei, and Xi Zhao

Part VIII Big Data and Metal Forming

Investigation of Machine Learning Models for a Time Series Classification Task in Radial–Axial Ring Rolling 589
Simon Fahle, Thomas Glaser, and Bernd Kuhlenkötter

Toward Neural Network Models to Model Multi-phase Solids 601
Maysam B. Gorji, Julian N. Heidenreich, Mojtaba Mozaffar, and Dirk Mohr

Comparison of Linear Regression and Neural Networks as Surrogates for Sensor Modeling on a Deep Drawn Part 611
Matthias Ryser and Markus Bambach

Development of Mechanical Cards for Finite Element Analysis of Mild Steels by Parameter Optimization 625
M. Emin Tamer, Eda Çapa Kızıltaş, and B. Celal Seyalıoğlu

Part IX Characterization of Plasticity and Ductile Fracture of Metals under Proportional and Non-proportional Loading

Cyclic Loading Tests Based on the In-Plane Torsion Test for Sheet Metal 635
Chong Zhang, Yanshan Lou, Till Clausmeyer, and A. Erman Tekkaya

Plastic and Fracture Characteristics of WE43 Mg Alloy Under Complex Stress States 647
Pengfei Wu, Chong Zhang, Yanshan Lou, Qiang Chen, and Haiqing Ning

Strain Hardening of AA5182-O Considering Strain Rate and Temperature Effect 657
Hongchun Shang, Pengfei Wu, and Yanshan Lou

New Methods for Fracture Detection of Automotive Steels 667
J. Noder, P. Samadian, J. Dykeman, A. Abedini, A. Zhumagulov, M. Worswick, and C. Butcher

Evaluation of Isotropic and Anisotropic Constitutive Models on Plasticity Prediction of AA7075 Extruded Tube Under Tension–Tension and Tension–Compression 681
Sobhan A. Nazari Tiji, Amir Asgharzadeh, Taejoon Park, Madhura Athale, and Farhang Pourboghrat

Estimation and Prevention of Strain Localization in Shear Tests 691
Heinrich Traphöner, Till Clausmeyer, and A. Erman Tekkaya

Experimental and Numerical Studies on Plastic Deformation and Failure Behavior of Carbon Nanotube-Reinforced Al Composite Sheet Under Uniaxial Loading Condition 709
Zhenming Yue, Xinrui Min, Zhanqiu Tan, Junyan Ni, Zhiqiang Li, Jun Gao, and Jie Zhang

Experimental Study on Uniaxial Strain Cyclic Behavior of GS-20Mn5 719
Zongyuan Zou, Shuting Han, Hongzhong Wang, Qun Li, Baofeng Guo, and Shiyan Zhao

Part X Constitutive Behavior

Influence of Deformation on Texture Development During Cold Drawing of Tubes 729
P. Bella, P. Burik, P. Bucek, and M. Ridzon

Dynamic Recrystallization Behaviors of 5083 Aluminum Alloys with Different Initial Microstructures Under Hot Compression 739
Sheng Ding and Jun Yanagimoto

Application of Barlat's Yld 2000-2d Yield Criterion to Predict the Anisotropic Response of Stainless Steel 749
Mauricio Vicente Donadon and José Divo Bressan

Evaluation of Press Forming Technique for Bent Automotive Body Parts Using In-Plane Shear Deformation 763
Yusuke Fujii, Masaki Urabe, Yuji Yamasaki, and Yoshikiyo Tamai

Simulation of Cold Forging Processes Using a Mixed Isotropic-Kinematik Hardening Model 773
Lander Galdos, Julen Agirre, Nagore Otegi, Joseba Mendiguren, and Eneko Saenz de Argandoña

Analysis of the Thermomechanical Flow Behavior of Carburized Sheet Metal in Hot Stamping 789
Alexander Horn and Marion Merklein

Effect of Short Pulsed-Current on Stress Relaxation in Uniaxial Tensile Test 801
Ichsan Indhiarto, Qiu Zheng, Tetsuhide Shimizu, Tsuyoshi Furushima, and Ming Yang

Experimental Study on Mechanical Response of Q235 Steel Under Cyclic Stress Loading 811
Qingling Zhang, Miao Jin, Baofeng Guo, and Qun Li

The Effect of Trace Nitrogen on Microstructure and Property of Cr-Mo-V Hot-Working Die Steel 829
Jinbo Gu, Jingyuan Li, and Lihao Li

Rate-Dependent Hardening Behavior of Autobody Sheet Metals in Tension and Compression 839
H. Huh, G. Joo, and M. K. Kim

Analysis of Creep Behavior of Magnesium Alloy Sheet (AZ31B) in Warm Forming 847
JaeHyeong Yu and Chang-Whan Lee

The Effect of Electroplasticity on the Flow Behavior of AA7075 in T6 Temper 857
Dong Hongrui, Li Xiaoqiang, Wang Haibo, Li Dongsheng, and Yang Yanfeng

Effect of Pulse Current on Mechanical Properties and Microstructure of Ultrahigh-Strength Steel 867
Xin Chen, Dongkai Xu, Lei Shi, Hua Xiao, Xifeng Li, and Jun Chen

Experimental Study and Modelling of Stress Relaxation Ageing Behaviour and Post-form Mechanical Properties in Creep Age Forming of Al-Zn-Mg Alloy 877
Yong Li, Fenggong Lyu, Zhusheng Shi, Yuansong Zeng, Xia Huang, and Jianguo Lin

Flow Behavior and Processing Map of a Nickel-Based Superalloy During Hot Plastic Deformation Process 891
Baoyun Zhang, Shuo Huang, Wenyun Zhang, Beijiang Zhang, and Yongquan Ning

Hot Deformation Behavior and Constitutive Modeling of a Novel Ni-Based Superalloy 901
Hao Yu, Hao Yang, Qi Liu, Baoyun Zhang, Bingchao Xie, and Yongquan Ning

Accurate Modelling of Flow Stress of AISI1025 at Room Temperature and Its Application to Precision Forging Simulation 911
M. S. Joun, M. K. Razali, J. B. Byun, and K. H. Lee

Stress-Relaxation Age Forming of a Component with Complex and Large Curvatures: Simulation and Manufacturing 921
Qi Rong, Zhusheng Shi, Yong Li, and Jianguo Lin

Toward an Efficient Industrial Implementation of W-temper Forming for 7xxx Series Al Alloys 935
Ricardo Trân, Lukas Kertsch, Sebastian Marx, Shreyas Hebbar, Verena Psyk, and Alexander Butz

Calibration and Validation of Stress–Strain Curve in High-Strain Region of Mild Steel Sheet 949
Hideo Tsutamori, Takeshi Nishiwaki, and Hiroaki Onishi

Influence of the Quenching Rate and Natural Ageing Duration on the Formability and Mechanical Properties of EN AW-7075 959
B.-A. Behrens, S. Hübner, H. Vogt, O. Golovko, S. Behrens, and F. Nürnberger

Constitutive Model and Plate Forging Ability of 5052 Aluminum Alloy Under Different Temperatures 973
Yantao Li, Wenzheng Dong, Qiquan Lin, and Zhigang Wang

Research on Rolling Process and Superplasticity for 5A90 Al–Li Alloy 983
Li Xiaoxing, Chen Yangkai, Lang Lihui, and Xiao Rui

Part XI Extrusion and Drawing

Co-Extrusion of Compound-Cast AA7075/6060 Bilayer Billets at Various Temperatures 993
Hui Chen, Danai Giannopoulou, Thomas Greß, Tim Mittler, Jonas Isakovic, Wolfram Volk, and Noomane Ben Khalifa

Reducing Aluminum Extrusion Transverse Weld Process Scrap 1003
Gregory J. Oberhausen, Anselm A. A. Christopher, and Daniel R. Cooper

Introduction of a New Method for Continuous Aluminum Hot Extrusion 1021
Johannes Gebhard, Patrick Kotzyba, Oliver Hering, and A. Erman Tekkaya

Study on Complex Extrusion of Multi Billets: Evaluation of Mechanical Properties of Butt-Joined Products and Analysis of Joining State 1033
Michihiko Hoshino and Izuru Otake

Effect of Expansion Ratio on Formability in Tube Drawing with Diameter Expansion 1043
H. Kawaguchi, T. Kuboki, I. Akasaka, Y. Terashita, M. Akiyama, and S. Kajikawa

Investigation of Forward–Backward–Radial Extrusion Process of Aluminum Alloy Wheel Hub 1055
Qiang Wang, Mu Meng, Xubin Li, and Zhimin Zhang

Part XII Forging

Galling-Free Micro-Forging of Titanium Wire with High Reduction in Thickness by β-SiC Dies 1065
Tatsuhiko Aizawa, Koh-Ichi Ito, and Tatsuya Fukuda

Deformation Mechanism of the Tooth Material Filling for Precision Forging of Spur Gears 1077
Wei Feng, Zengjie Feng, Mengjuan Zhou, Ling Mao, and Xiangyang Jia

Compression of Printed CFRT Composite: Shaping Parameters and Material Health 1087
Eric Becker, Victor Haguenauer, Ludovic Freund, Damien Félix, and Régis Bigot

Influences of Key Forging Parameters on Cold Orbital Forging of Thin Parts with High Circular Ribs 1099
Wuhao Zhuang, Xinghui Han, Lin Hua, and Wei Feng

FE-Based Investigation on the Influence of Inhomogeneously Heated Billets on Subsequent Forging Processes 1107
Arne Jagodzinski, Hendrik Gerland, Mareile Kriwall, Jan Langner, Malte Stonis, and Bernd-Arno Behrens

Development of Automatic Design System for Closed Die Forging Process of Disk-Shaped Products 1121
Yoshihiko Kobayashi, Eiji Sakamoto, and Tetsuya Yagami

A FE Billet Model and A Spring-Mass-Damper Model for the Simulation of Dynamic Forging Process: Application to a Screw Press 1131
Jean-François Mull, Camille Durand, Cyrille Baudouin, and Régis Bigot

Optimization of Open-Die Forging Using Fast Models for Strain, Temperature, and Grain Size in the Context of an Assistance System 1145
Fridtjof Rudolph, Martin Wolfgarten, Viktor Keray, and Gerhard Hirt

General Step Reduction and Enlargement Method for Knowledge-Based Process Planning of Totally Non-axisymmetric Forged Products with Blanking and Punching 1161
Masanobu Umeda, Yuji Mure, Keiichi Katamine, and Kazuya Matsunaga

Investigation of Failure Mechanisms of Cemented Carbide Fine Blanking Punches by Means of Process Forces and Acoustic Emission 1173
Herman Voigts, Rafael Hild, Andreas Feuerhack, and Thomas Bergs

Microstructural Evolution of Ti-55511 Titanium Alloy During Quasi-Beta Forging 1189
Yu-Qiang Jiang, Y. C. Lin, and Guo-Dong Pang

Part XIII High Speed and Impulse Forming

High-Speed Material Characterization Using an Instrumented Forging Hammer 1201
Julen Agirre, David Abedul, Angel Oruna, Nagore Otegi, and Lander Galdos

Advancements in the Simulation of Magnetic Pulse Forming Processes with FORGE® 1217
José Alves, François Bay, Ugo Ripert, Julien Barlier, and Nicolas Poulain

The High-Speed Deformation Behavior of High-Strength Lightweight Al-Li Alloy Sheets 1231
Ali Abd El-Aty, Shi-Hong Zhang, Xunzhong Guo, Yong Xu, Ma Yan, Dayoung Chen, and Jie Tao

The Effects of the High-Velocity Shearing Speed on the Sheared Edge Quality and Edge Cracking 1245
J. Gu, F. Alamos, D. Schoch, J. Bornhorst, and H. Kim

Local Microscopic and Integral Macroscopic Analysis of Magnetic Pulse Welds and Deformations for Dissimilar Metal Joints 1255
Frank Huberth, Balaji Ragupathi, Christian Scheffler, Verena Psyk, and Johannes Preußner

Computational Modeling of Magnetic Pulse Dissimilar Alloys Welding: Aluminum Alloy 6082-T6 and HC420LA Steel 1269
N. Rodriguez-Barrio, E. Iriondo, D. Jouaffre, and F. A. Girot

Influence of Ultrasonic Assistance on the Forming Limits of Steel 1281
Manuel Jäckisch and Marion Merklein

Design and Fabrication of a High-Performance Magnetic Actuator for Magnetic Pulse Welding of Metal Tubes with Large Diameters 1291
Xiaoxiang Li, Quanliang Cao, Zhipeng Lai, Yiliang Lv, Siyuan Chen, Yi zhang, Xiaotao Han, and Liang Li

Deformation Behavior in Magnetic Pressure Parallel Seam Welding 1305
Takashi Ichimura, Yusuke Ito, Makoto Miyazaki, and Akira Hatta

Shaping of Sharp-Edged Design Elements by Electromagnetic Forming 1315
Verena Psyk, Christian Scheffler, Albrecht Stalmann, and Martin Goede

Augmentation of Plasma-Based Impulse Generation with Rapid Chemical Reactions 1329
Brian Thurston, Yu Mao, Troy Lewis, Anupam Vivek, and Glenn Daehn

Recent Developments of Vaporizing Foil Actuator Technique for Manufacturing Applications 1341
K. Sajun Prasad, Jianxiong Li, Blake Barnett, Yu Mao, Glenn S. Daehn, and Anupam Vivek

Grain Size Effect on Formability in Electromagnetically Assisted Micro-Bulging of Pure Titanium Sheet 1351
Chengxi Zhu, Jie Xu, Haiping Yu, Debin Shan, and Bin Guo

Mathematical Model and Quantitative Analysis of Residual Stress Hole During Laser Shock Peening 1361
Xiuquan Cheng, Junhao Zhang, Sizhu Cheng, Chang Yan, and Qinxiang Xia

Part XIV Joining by Forming and Deformation

Simulation and Experimental Analysis of Electromagnetic Pulse Spot Welding of Sheet Metal with a Field Shaper 1373
Hang Zhang, Ning Liu, Qingjian Wang, and Hongfa Ding

Mechanical Properties of Aluminium/Stainless Steel Bimetal Composite Fabricated by Extrusion Process 1383
Kai Soon Fong, Danno Atsushi, Dharmesh Kumar, Wee Kiat Ong, and Suwat Jirathearanat

From Bridge to Bumper: Utilization of Pre-stressing During Manufacturing of Hybrid Sheet Metal Structures 1395
Henning Husmann and Peter Groche

Computer-Aided Modeling of the Hot Forming Staking Process Based on Experimental Data 1411
Sebastian Härtel, Eric Brückner, Birgit Awiszus, and Michael Gehde

Fatigue Characteristics and Failure Mechanism of Self-piercing Riveted Joints of DP590 and AA6061 Plates 1423
Zhichao Huang, Yinglian Jia, and Jiamei Lai

Fretting Damage and Fatigue Property Analysis of Self-piercing Riveted Joints of AA5052 Aluminium Alloy 1437
Zhichao Huang, Yongchao Zhang, and Jiamei Lai

Elastoplastic Finite-Element Analysis of Multi-Body Processes for Joining Mechanical Parts 1451
SukHwan Chung, Jaedong Yoo, and ManSoo Joun

A New Non-destructive Testing Method Applied to Clinching 1461
Rémi Lafarge, Alexander Wolf, Christina Guilleaume, and Alexander Brosius

Investigation on the Strain Induced Oxide Layer Fracture and Bonding During Cold Rolling of Aluminum Alloys 1469
Mahsa Navidirad, Wojciech J. Stepniowski, Elijah Cartier, Tyler Christ, Masashi Watanabe, and Wojciech Z. Misiolek

Ultrasonic Forming—Alternative to Orbital Riveting for Small Bimetallic Components 1479
Wojciech Presz

Self-Piercing Riveting Using Rivets Made of Stainless Steel with High Strain Hardening 1495
Benedikt Uhe, Clara-Maria Kuball, Marion Merklein, and Gerson Meschut

Numerical and Experimental Investigations on Riveting Assembly Processing Parameters of Hub Bearing Unit 1507
You Wang, Wei Xiong, Jia-hua Zhou, and Peng Ren

Part XV Lubrication and Surface Effects

Evaluation of Lubricant Performance for Thick Sheet Ironing Process by Ball Ironing Test 1519
Nuttakorn Sae-eaw and Yingyot Aue-u-lan

Development of Oil-Type Lubricants for Cold Forging Using Phase Transition Behavior Under High-Pressure Conditions 1529
Tomoaki Okano, Nobuhide Tanino, and Kazuhiko Kitamura

Self-optimized, Intelligent Open-Loop-Controlled Steel Strip Straightening Machine for Advanced Formability

Fabian Bader, Lukas Bathelt, Eugen Djakow, Werner Homberg, Christian Henke, and Ansgar Trächtler

Abstract Innovative self-correcting process control techniques which adapt to the initial geometric characteristics of the strip are a promising approach to fix the local varying distortion of coiled strips by optimizing the leveling process. This paper presents an innovative strategy to improve straightening of AHSS materials (1.4310). This implies optimized leveling, adding minimal plastic deformation, and, thus, strain hardening. Therefore, an "intelligent straightening machine" is being developed which will be presented. To operate an intelligent straightening machine a reliable online measurement of the surface defects is fundamentally essential. This paper describes an approach towards the measurement of a bent steel strip for an automatic straightening process. Therefore, various ways of measuring the bending curvature are investigated. Optical, tactile, and the electromagnetic induction testing MagnaTest are compared with each other. The bending measurement is linked to open-loop control, providing an optimal straightening result in regards of formability, leveling, and reduced strain hardening.

Keywords Intelligent straightening machine · Innovative measurement system · Residual stress · Degeneration of elastic modulus

1 Introduction

As a result of increasing globalization and rising quality requirements, the steel and metal processing industry is facing growing cost and innovation pressure to meet market demands. Not least because of their high lightweight construction potential, high-strength steel materials meet the growing material requirements of steel and metal processing, such as geometrical and dimensional accuracy in various fields of the industry, including aerospace, medical, and electrical connectivity technology.

The especially narrow tolerances and dimensional accuracy required in processing high-strength steel strip materials present economic and ecological challenges. These are best addressed by improving the processability of high-strength steel materials using straightening devices with setup assistance systems to significantly increase their potential to compete with other materials in the market. These system configurations achieve a higher amount of acceptable formed parts, reducing the quantity of rejects, thus requiring less material and financial resources. The setup assistance systems require additional information regarding material behavior during straightening as well as the straightening process in general.

Numerous publications regarding various topics of investigation of the straightening process have been conducted. To achieve a straightened steel strip, it is first necessary to correctly set up and adjust the straightening machine while its input parameters are changing, which naturally takes place while the material is uncoiled and the curvature of the steel strip changes. Therefore, it is necessary to analyze the material and its forming history as the subsequent forming behavior of the steel strip is directly linked to the state of residual stresses. Hence, [4, 6, 11, 13] analyzed the residual stresses of the steel strip to increase the accuracy of a following FEM calculation. These numerical investigations are used to identify a suitable setup of the straightening roll infeed and the state of stress within the material [3, 5, 10, 12]. But not only numerical calculations are expedient, analytical models can help as well to provide information concerning the infeed of the straightening rolls, as shown in [1, 2, 7, 8]. Morris et al. [9] show the impact that the different adjustable machine rolls have, and demonstrate that the second adjustable roll of the often used seven roll straightening machine has the most impact on curvature, and, consequently, the straightening process. In order to use the calculation results and to straighten a steel strip, an electro-mechanical automated straightening machine is required.

2 Intelligent Straightening Process

In order to meet the requirements of the economical and ecological challenges, the process chain must be modified. Rather than adjusting the rolls of the straightening machine by hand, it needs to be automated. Consequently, there are several different matters that need to be developed/investigated. The test rig setup is shown in Fig. 1.

Live measurement of the steel strip curvature is essential for an automated straightening machine. Continuously gathering the curvature and other surface defects of the steel strip facilitates an automated response to eliminate the curvature. Process steps (straightening roll setup) to react on the changing curvature are indispensable for the automated straightening machine. Therefore, a finite element model is required. The results from the numerical calculation at the first step are fed to a database, which provides the control of the straightening machine with data regarding the roll setup. There is a possibility of using a (semi-) analytical model live, as it may be fast enough to calculate the roll setup after receiving the measured curvature of the sensors, but until that is developed, and its accuracy is meeting the numerical model,

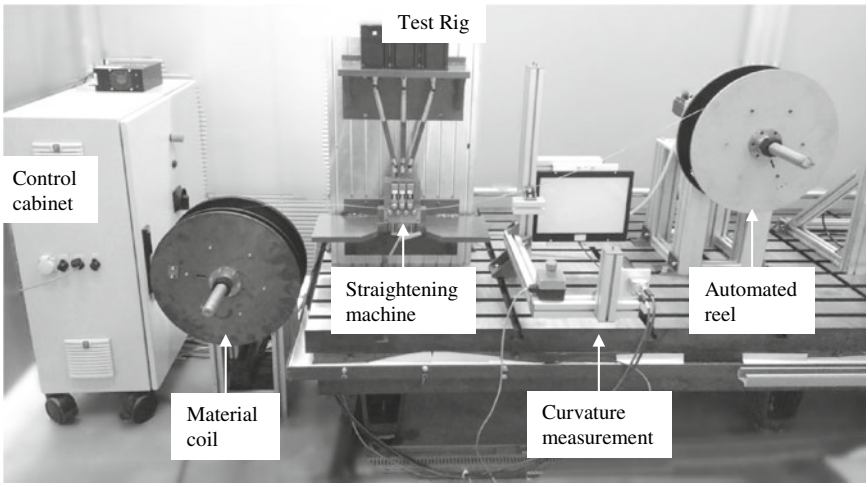

Fig. 1 Test rig setup

the finite element model will be used. The straightening rolls of the straightening machine are connected to guide rails, which are powered by stepper motors. This holistic approach of straightening a steel strip leads to an increased formability and a reduced degeneration of the yield limit, which is preferable for subsequent forming operation.

3 Sensors

The sensor technology includes an upstream detection for the fluctuations in material properties. For this purpose, a magnetic inductive eddy current measurement of the steel strip is carried out using the MagnaTest D system of the Foerster company. The physical principle of this measurement is based on the combination of two coil windings around a die into which the component to be tested is inserted. A switched alternating current in the transmitter winding results in a magnetic field, which induces eddy currents in the material under test. These eddy currents induce another magnetic field, the secondary field, and its influence on the second coil, the receiving sensor, is measured. This influence is evaluated by determining the phase and amplitude shift of the received signal compared to the transmitted signal, and is displayed by the evaluation unit in the impedance plane (Fig. 2a). The evaluation unit enables the measuring points of different components to be categorized, making it possible to detect components that are made of different materials.

For the measurement of the steel strip, the dependency of the residual stresses of the steel strip on the secondary field and thus the measurement results at the receiving sensor are used. As shown in Fig. 2b, the steel strip curvature is indirectly dependent

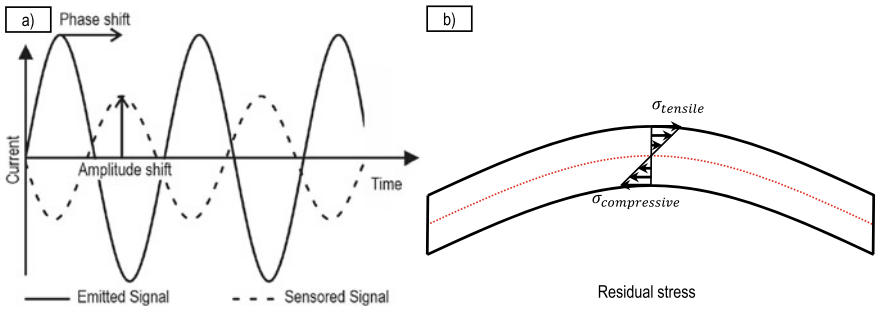

Fig. 2 **a** Phase and amplitude shift **b** residual stresses within the steel strip while bending. (Color figure online)

on the residual stresses in this way, so that the MagnaTest can be used to determine a change in curvature.

The measurement results of a test run are shown in Fig. 3. The test procedure is simple. Up until 25 s the steel strip, as it is, was pulled through the magnetic induction sensor. Then the straightening device was adjusted that one roll was changing the curvature of the steel strip. As indicated, the imaginary part as well as the real part decreases, which can directly be linked to the change of curvature. Since it is not yet possible to assign the magneto-inductive measurement to absolute radii of curvature, a setup procedure for the straightening apparatus is necessary. Hence, the current steel strip curvature is determined at the beginning with the help of a camera-based

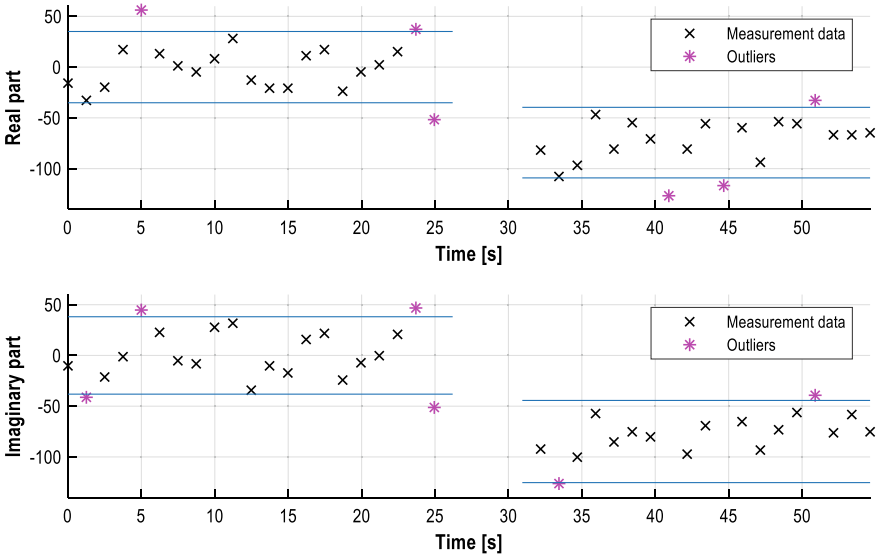

Fig. 3 Measurement results of a curvature change. (Color figure online)

recognition. A camera system from Balluff is used for this purpose, which enables a semi-automated evaluation and curvature determination at the free end of the wire. With this information, the straightener is initially set using the model-based values. The property changes in the material over the entire length of the coil are recorded by MagnaTest D. Thus, the straightening machine is adjusted accordingly. In addition, three load cells determine the forces transmitted by the straightening rolls into the material at each point in time, thus monitoring the process.

When a new coil is inserted, the straightening process begins by optically detecting the current curvature in the wire via the camera. For this purpose, the gravity force is calculated, its influence is subtracted from the optical image, and thus the current steel strip curvature is determined. This curvature value is then fed to the model together with the material parameters and the geometry data. Consequently, the target positions of the straightening rolls, which are then adjusted, are calculated, and the unwinding of the coil can begin. The magnetic induction measurement records the changes in the material properties with the continuous decoiling of the steel strip. Based on this change, the position of the straightening rolls is constantly readjusted so that the straightening result is as uniform as possible.

4 Finite Element Calculation of the Straightening Process

Finite element simulations of the straightening process were conducted to build a database where the significance and the influence of various parameters can be determined. The yield limit from a tensile test of the virgin 1.4310 material is 1719 MPa, while the ultimate tensile strength reaches1939 MPa and Young's modulus is 176 GPa.

The steel strip is subject to a non-linear strain path by alternating bending, and, consequently, it is crucial to describe the material behavior precisely. Hence, it is important to take the Bauschinger effect into account, which describes the early re-yielding of the material in case of pressure loading, which is the case at alternating bending. The Yoshida-Uemori (Y-U) material model [14] accounts for the Bauschinger effect. This model has two yield surfaces. One yield surface represents the kinematic hardening, which upon reaching a certain threshold, affects the isotropic hardening. In this model the isotropic hardening is regarded by the bounding surface, which surrounds the kinematic yield surface [14]. In LS-Dyna, there are different types of material cards that are either the standalone Y-U-model (Mat125) or a combination of the Y-U and Barlat model (Mat226 and Mat 242). For this work, the material type 125 will be used. Additionally, the elastic modulus, which is degenerating under plastic loading, will be taken into account in this material model.

The parametrization of this complex material model requires the testing of three different types of load for the material. A tensile test, a tensile-pressure test (Fig. 4a) to identify the early re-yielding phenomenon, and a cyclic loading-unloading test in the tensile domain, to identify the degeneration of the elastic modulus (results

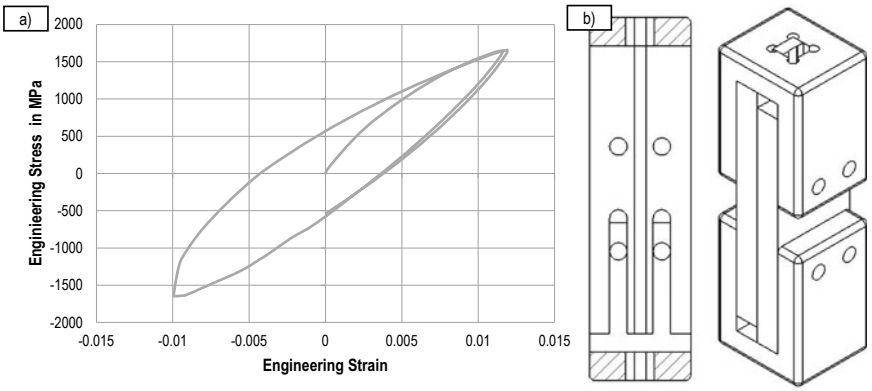

Fig. 4 **a** Tensile-pressure curve. **b** Anti-buckling device for pressure tests

in 176 GPa). Tests were carried out in the department of forming and machining technology lab of Paderborn University. In order to identify the material parameters for the Yoshida-Uemori material card, these exact tests need to be modeled in LS-Dyna for the parameter identification using the LS-Opt tool from Dynamore.

To run a tensile-pressure test, it is necessary to prevent the steel strip from buckling under pressure. For this purpose, an anti-buckling device was manufactured, as shown in Fig. 4b, whereby the steel strip is held in position by the device through the recess. The results of the tensile-pressure test are depicted in Fig. 4a. Since the 1.4310 is advanced high-strength steel, with a yield limit to ultimate tensile strength ratio of 0.886, the elasto-plastic deformation is limited to a small margin. This is reflected by the tensile-pressure curve, where no distinctive shift from the elastic domain to the elasto-plastic domain is visible.

The determination of the material parameters for advanced high-strength steel is not yet completed, however it will be conducted in the near future.

The model is described by the following formula:

$$E = E_0 - (E_0 - E_A)\left[1 - \exp\left(-\xi * \varepsilon^p\right)\right]$$

where E represents the depending elastic modulus, E_0 is the virgin elastic modulus, E_A stands for the asymptotic elastic modulus at a large strain, ξ is a constant, and ε^p is the current plastic strain. This underlines the complex behavior of the advanced high-strength steel material that is used in alternating bending processes, which requires a sound model description to capture the increasing elastic domain with plastic pre-strain.

5 Database

A database is built with the results of the finite element model. Its primary parameters are the current curvature of the steel strip and the setup position for the straightening rolls for a desired final shape, which most of the time will be a straightened steel strip. Additionally, parameters necessary for the calculation of the final curvature are needed, such as the shape of the steel strip, since a round steel strip requires a different straightening approach than a square cross-sectional area. Height, width, diameter, and the orientation of the steel strip in regards to the straightening machine, like a concave or convex inlet into the straightening machine, are all important to take into account.

A database like this can be fed by different sources, such as the mentioned finite element calculation, an analytical model, or recorded experimental data. An interpolation function is planned for missing data between given data. Thus, the control of the straightening machine is able to transfer the data from the database towards the actuators, dependent on the measured values of the curvature.

6 Actuators

The intelligent straightening machine essentially has three actuators. These are the three stepper motors (Beckhoff AM8031 0F20) with a maximum torque of 1.4 Nm that control the straightening rolls. Each straightening roll is controlled individually and independently of the others. Their position is determined at any time by means of the encoders on the stepper motors. In this way, they can be moved independently of each other under position control, and constantly react to the necessities in the process.

7 Conclusion

The subject of this paper is to introduce the work on the intelligent straightening machine and its various facets. The measurement of the curvature with MagnaTest D while superposing tensile stress by the decoiling process is shown. This online measurement system, which links the state of residual stress and its change to the curvature, enables the possibility to set up corrective strategies while running the process. This presents opportunity for a major transition from the manual adjusted straightening machine towards the intelligent automated straightening machines.

Additionally, it is shown that the finite element calculation requires three different types of testing in order to parametrize the material card 125 of LS-Dyna, which is promised to be the most accurate material model for this kind of alternating bending process. The tensile-pressure curve underlines the complex behavior of the advanced

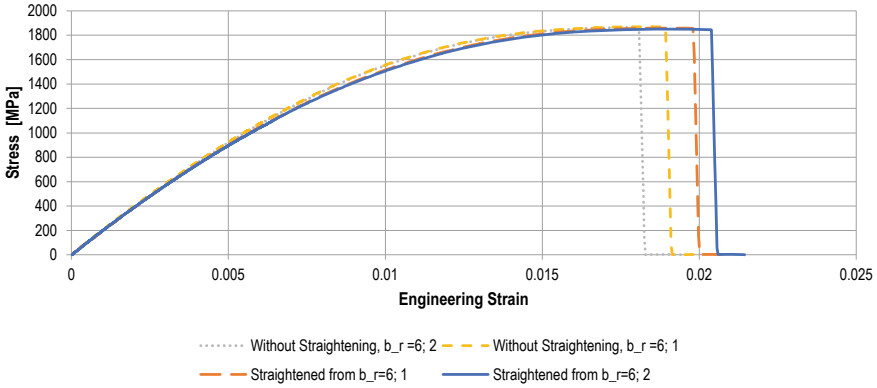

Fig. 5 Results of a tensile test, with and without straightened steel strip. (Color figure online)

high-strength steel and the need for the combined isotropic and kinematic hardening material description.

The results of the numerical calculation and the experimental work will be combined in a database that provides the correct straightening roll setup dependent on the current curvature, the material type, and its geometry, as long as a live calculation is not yet feasible.

This approach of an online measurement leading to an online setup of the straightening machine results in a fully automatic straightening machine. This method promises improved results compared to conventional straightening machines, with first results showing an increased formability of the straightened steel strip of up to 12% compared to the unstraightened steel strip as shown in Fig. 5. There are four different tensile test results shown, where two steel strips have a slight curvature of $0.00053 \frac{1}{\text{mm}}$ and two steel strips are straightened, with the same curvature prior to straightening. The results show that although there is no visible increase to the ultimate tensile strength the deformability increases after a steel strip is straightened.

A Vision of Numerically Controlled, Autonomous Manufacturing and Metal Forming

Glenn S. Daehn

Abstract Here I lay out a vision for hybrid autonomous manufacturing. Imagine you have a robot-automaton machinist who really likes and knows deformation. What would this enable? What's needed to get there? Use cases and brief research agenda are presented.

Keywords Agile · Metamorphic manufacturing · Open-die forging · Forging · Microstructure

1 Introduction

I hope you will give me some leeway for violating some conventions here. I will organize and write this paper differently than the typical, and I will be the sole author, despite foundational contributions from many in the acknowledgements list. This hopefully provides a single voice and lays responsibilities with shortcomings to me. I do also want to use this as an opportunity to acknowledge and thank those who have really opened my eyes to the magic in metal forming and manufacturing with simultaneous room for creativity and rigor. When I came to the Ohio State University over 30 years ago, the Engineering Research Center on Net Shape Forming, run by Prof. Taylan Altan, was one of the biggest and most influential centers for thought and innovation in the university. This taught me the value in solving real industry problems and mentorship by Prof. Rob Wagoner (who, with Altan is honored at this ICTP) taught me a rigorous approach to describing plasticity. Beyond this, I have also been influenced by the European research I've seen, particularly the work in Dortmund under Prof. Erman Tekkaya, where there is much more activity in re-thinking processes and equipment than we typically have in the US. From these roots and being able to take part in the formation of a Manufacturing USA Institute (LIFT, in Detroit), and interactions with many great colleagues here, we have developed a slightly different approach to the role metal forming may play in the future, as a

dual process for shaping components and refining materials and microstructures to optimize their properties.

The key question I hope to address with this short note is what would manufacturing look like if we started from first principles and did not have our imaginations corrupted by all the analysis and reverence we have for the existing processes. Are there other ways of doing things? And can we get away without all these complex and expensive, product-specific tools and dies?

2 A Bit of History

We material scientists are well aware that our "ages" are named for materials, copper (~5000 BC), bronze (~3000 BC), iron (1500 BC), steel (~0 AD), and sometimes silicon ages. Extraordinary components and shapes were produced in these time periods. We also know that swords with remarkable properties were produced in Damascus, Syria, and Japan from around 1000 AD, without detailed understanding of metallurgy. The artisan skill of blacksmithing grew from this and provided components that were supremely functional and beautiful. Examples of items about 500 years old are shown in Fig. 1.

In the early 1900s, there was a distinct shift to high productivity metalworking processes, including rolling, extrusion, and stamping. These technologically important processes became the focus of academic and practical study. Further, with the growth of the steel, aluminum, and other specialty metal industries in the early 1900s, there was a great emphasis on the development of thermomechanical processes to achieve desirable performance and processing objectives. High-strength steels, magnetic alloys for transformers, and alloys with the right texture and ductility to create aluminum cans were notable achievements in this period.

The next major wave of "manufacturing science" was centered on computer numerical control (CNC) machining. In the 1920 and 30s, systems of cams and templates were used to move cutting heads to develop complex shapes. It was the confluence of the development of servomechanisms that were first used in artillery gun control and early computer technology that led to CNC machining. The need to economically produce complex airfoil shapes for helicopter and aircraft applications led to the formal birth of CNC machining systems in the late 1940s from collaborations between Parsons Corporation, MIT, and Sikorsky Helicopter. Since then, there have been remarkable advances in tool path planning, tool changes, lubrication, closed-loop control, and fast precision locating mechanisms. Over time, a number of industry standards have emerged in this field including the widespread use of G-code and standard practices have evolved for efficiently converting designed shapes to practical tool paths. CNC is now a strong foundational element in the creation of low-volume and custom components as well as in tool and die and machine manufacturing. CNC machining represented the first wave in digitally controlled manufacturing.

Fig. 1 Examples of artisan blacksmiths' products large and small, all about 500 years old. Top shows a Japanese national treasure: thirteenth-century katana produced by Masamune. Left center shows an Italian embossed steel Burgonet (helmet sculpture, weighing about 3.75 lb) from about 1540. Bottom left shows an Italian steel shield (overview and detail) from about 1560. Right shows "Armors for Man and Horse," German etched steel and leather from about 1548. (Color figure online)

One could argue that additive manufacturing has been with us since civilization or before. Bees and paper wasps create their hives using basically an additive process. Mud huts, adobe, and brick structures were created by the progressive addition of material to meet a desired shape. The modern age of additive manufacturing is described well by a 2014 Wohlers Associates report [1] that both describes the early technical underpinnings that preceded commercial additive manufacturing by decades, as well as chronicles the many commercial starts (and failures) in this field. Like CNC machining, most of the fundamental precursor work was carried out well before the base technologies were assembled into "additive manufacturing" equipment in the US and the first commercial companies were based in the US. The central idea of the additive manufacturing is the ability to add or solidify material to create a physical object that is first defined in the virtual space, often again using G-code as a guide. A number of technologies ranging from light-curing of polymers to robotic hot glue guns and molten metal addition by welding-like processes have all been developed that led to the creation of the ASTM committee (F-42) for developing

common standards in the area, in 2009. Additive manufacturing is the second wave of digital manufacture.

While these methods that were very amenable to academic analysis were being created and refined, the tradition of the blacksmiths in creating small numbers of custom components was continuing and being extended, and variants of G-code have been used for incremental sheet metal forming [2]. For bulk deformation, the blacksmith's tradition ran strong and human force has been augmented with hydraulic presses and power hammers. Very large components have been formed using massive presses and robotic manipulators in open-die forging. Sheet metal forming for most custom parts is carried out with hydroforming and more artistic parts, or lower volume components, are often created by artisans using hand tools such as English wheels, stretcher and shrinker elements in presses, hammers, sandbags, and ingenuity. There are hours and hours of fascinating YouTube videos of very clever artisans making motorcycles, cars, art, and aircraft parts using these methods. A key enabling differentiator between this artisan approach and high productivity methods is that the artisan can check the workpiece in progress against a form and correct the shape by further bending, stretching, or shrinking, and then checking against the form again. This kind of correction is central to the fabrication metallic aircraft sheet metal components after forming close to shape in hydroforming. It also enables dieless forming. Whereas predicting a precise sheet metal shape in bending is difficult, requiring correct assumptions and stable material properties, achieving a precise bend angle, for example, is a trivial matter if one can bend, measure, correct in a re-bend, and repeat until the part has the correct shape.

In the following paragraphs, I will discuss a vision for taking the kinds of processes used by an artisan and executing them using automated systems.

3 A Vision of Metamorphic Manufacturing

A previous paper with Alan Taub, from our LIFT collaboration [3], and an international expert study (http://tms.org/metamorphicmanufacturing) have developed a vision of what is sometimes called the easily understood term Robotic Blacksmithing or my preferred term of metamorphic manufacturing which emphasizes that both the component shape and microstructure are transformed by the process. The key idea is to transfer the essential tasks of a blacksmith and his tools to an automated system that can shape components and optimize microstructure, much the way a blacksmith might, but using greater forces, power, sensing ability, dimensional precision, and most importantly potential reproducibility. The ability to sense, record, and reproduce actions gives a powerful gateway to the possible production of standardized components that can be used in safety-critical applications (Fig. 2).

Most important are the variety of fundamental tools that can be assembled to create a metamorphic manufacturing system. The key difference between the metamorphic approaches and those based on dies is that the final punch and die usually dictates the full shape of the final component. Metamorphic methods use incremental forming and

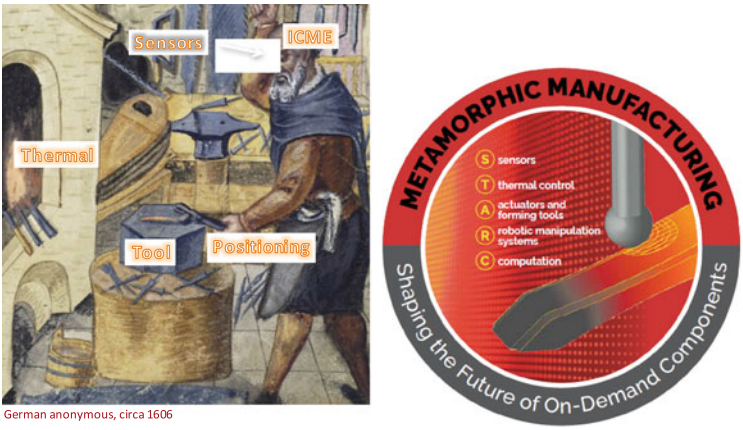

Fig. 2 Key concepts in blacksmithing that can be automated and a "mission badge" resulting from the TMS report that calls out the key aspects that must be considered (Sensors, Thermal control, Actuators and forming, Robotic manipulation, and Computation), giving the STARC moniker. (Color figure online)

numerically positioned or controlled tools (for example, a robot locating a workpiece between the punches of a hydraulic press and repeatedly deforming a programmed amount, moving the workpiece and repeating). There are a large number of processes that can be adapted to this fundamental framework. These are indicated in Fig. 3. In all cases, the incremental deformation of the forming tool introduces displacement that can also be seen as plastic strain. These plastic strains simultaneously provide the ultimate shape of the component, but we also know that they introduce important changes in material microstructure that change (usually improve) properties. These changes can include closing porosity, providing work hardening, introducing texture, or refining large phases that may be the result of a solidification process. Such processes may be very effective at taking a pre-form that may be produced by casting (as is commonly done with billets in open-die forging) or a numerical weld deposit or 3-D printed material and refining the microstructure and setting details of component shape. In short, there are numerous methods that can be used in an incremental fashion, with lightweight tools to at once control shape and microstructure, and the main constraint is our imagination. The blacksmith has demonstrated this for us and the next obvious task is to automate this process with modern deformation tools, robotic control, and optical sensing for dimensions and strains.

4 A Bigger Vision

Imagine taking this concept of an autonomous artisan and take it to its logical conclusion. Artisans are not bound by their processes, but the tools at their disposal. A

Fig. 3 Examples of motivations and possible tools for metamorphic manufacturing, as classed by sheet, bar, bulk, axisymmetric, and profile shapes. There is, of course, much room for interplay among these limiting shapes, and this figure may give some inspiration for new processes. Sheet row shows from left to right: incremental forming example from mechmining.uq.edu, English wheel used for thinning from Desert Precision, a press and robot concept from [4], and a sheet shrinker from Heliotech. Similar sheet stretchers are also available. Bar row shows from left to right: a CNC shaping concept [5], an open-die forging example from Scott Forge, the concept of thread rolling, which can be generalized, from madehow.com, and CNC bending of bar from tradeindia.com, Bulk row shows: shape required for a Joint Strike Fighter bulkhead, general process of use of a hammer with humanoid control, concept for use of a punch in forging to develop recessed shapes, and implementation of turret punches to give agility, from SAMIN Turret Punch Press. Axisymmetric row shows: typical manual example of spinning against a form, ring rolling, and concept for agile CNC-controlled two-sided spinning [6]. Profile row shows: left two images show concept for flexible roll forming of metallic strip, schematic of a CNC 3-D profile bending system from the IUL in Dortmund, Germany, and right shows profile stretch-bending from Fairmount Technology [7, 8]. (Color figure online)

skilled artisan with a relatively small set of simple hand tools can do amazing things, as blacksmiths have shown. These can rival the size, complexity, and utility of components from large presses. If we examine the detailed work of one of these artisans, we notice that they cheat. They are not simply metal forming but will use whatever tricks they can to get the job done, including bending or hammering out to straighten a component out or welding in filler metal and hammering it smooth to take care of a divot.

Just as one small example of how rapidly maturing technologies can be merged to create something new, consider that wire-arc additive can create components with rough geometry and easily locally modify composition by changing wires. This component can then be forged to final shape while improving properties. This deposition and forming can both be incremental.

If we think about the tools that an artisan has at their disposal, they really fall into a very limited number of classes:

- *Deposition and solidification.* Methods such as casting, welding, extrusion-deposition, and so forth are used to physically deposit materials into place. This is largely the heart of additive manufacturing.
- *Material Removal*. This can take place by cutting, grinding, ablation, etc. This is at the heart of CNC machining.
- *Deformation.* Forging, bending, stretching, peening, and so forth are high productivity and highly effective methods to create components.
- *Material Transformation.* Thermodynamic properties such as temperature, pressure, and controlled chemical potentials are used for sintering, curing, carburizing, heat treatment, and so forth. This is often done in concert with deformation in thermomechanical processing.
- *Inspection and sensing*. Are usually currently used post-process to assess quality. New processes for automated bending, incremental forming, and welding, for example, can use dimensional sensing during the process for optimal control.

These kinds of processes all are amenable to agile and incremental fabrication. We can imagine a suite of tools that can be used to carry out the kinds of processes described above, and in situ sensing can provide input for quality assurance and control. We can imagine automated workstations with extreme levels of sensing and tool kits that include general-purpose tools such as hammers, cutting tools, torches and induction coils, deposition nozzles or arc welding equipment, robotic control for positioning and a suite of sensors to monitor shape, temperature, and possibly other properties of the structure or material(s). The most important next element is an intelligent computational system to oversee, manipulate the tools, and make decisions. This tool would take on a role analogous to a blacksmith's brain and execute the myriad of decisions required to create a component that is sufficient for service. This can include aspects such as controlling torch angle, motion, and gap in a welding operation, deciding when given operations are needed—for example, might we need to deform a part to make it fit. And this system can also record all the steps, settings, and data. These data can be used in assessing reproducibility and are essential in qualifying a component for service. These tools quickly move into the

realm of artificial intelligence, where disparate data from position, force, temperature, and part configuration must be brought together to make decisions. This problem of sensor fusion leads to forward predictions, and from there we can monitor and correct for issues. One key issue will be how to transfer the part from one operation to another while maintaining dimensional fidelity and locating datums. Furthermore, the base algorithms should be able to be transferred from one physical automated workshop to another, where the tool set may be somewhat different but perform the same essential functions. Operations may be done on a single "workbench" or the component could be transferred from one piece of equipment to another while maintaining dimensional information.

Again, if we take this idea to its logical conclusion, we can imagine a fully autonomous system for manufacturing that can manufacture a wide range of products with a limited, but versatile set of tools. The production rate of such systems would not rival those of mass production stamping, forging, die casting, and so forth, but because robots can work 24/7, lights out, they could be far more productive than a human-run machine shop and the data produced, provide a digital thread that can be used to assure quality. Formal quality systems would need to be developed around this approach. A pathway to autonomy is shown in Fig. 4 that is inspired by SAE Standard J3016. One could imagine that most of this exists inside a controlled automated factory environment, but it would also have interfaces to supply chains to source optimal raw materials, preforms, and possibly specialized cutting or deformation tools. All of this is a strong analogy to what a human artisan might do.

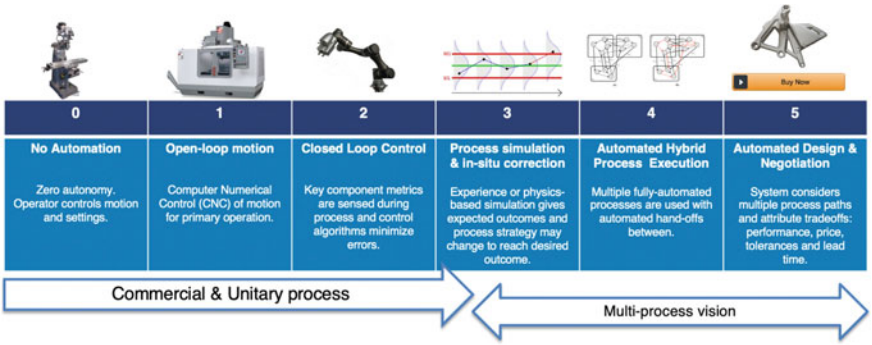

Fig. 4 Analogous to the levels defined for autonomous driving, autonomous manufacturing may move through a progression, gradually becoming more autonomous. This is modeled after SAE Standard J3016. Levels 0–2 are already commercially available. (Color figure online)

5 What Can This Enable? Some Use Cases

Imagine we could build something like this. What would the uses and benefits be? Brief comments on a few use cases that show that there would be substantial value in building automated manufacturing systems that feature plastic deformation.

a. Rapid forgings; near-optimal properties

One of the most obvious uses of closely controlled digital open-die forging is in rapidly producing components similar to those that may have been created by closed-die forging. Forgings are the gold standard for high-quality components and this "robotic blacksmithing" approach should be able to develop essentially the same shapes and strain distributions as closed-die forging. One outstanding challenge will be developing thermal control that approximates that of closed-die forging.

b. Point of Care Medical Manufacturing

Often when patients undergo trauma surgery with bone damage metallic plates are required to hold bones together for healing. Facial impact, for example, can produce multiple fractures requiring many plates of varied forms (see, for example, Arce et al. [9]). These are often created in the operating room by bending plates to the form of the patient. This is slow and imprecise and misfitting can increase stresses, leading to failure. Additive manufacturing is recently being considered to replace the manual bending of standard parts. The numerical bending, with error correction, could be a far faster solution to providing components than additive manufacturing and more precise with less time with the patient in surgery than the manual bend, test, and re-bend procedure now used. The process would be optimal if the fitting could be to a numerical file (as developed in CAT scanning, for example) rather than to a patient or physical form.

c. Novel structures and materials (additive plus deformation)

There are a number of processes to create shapes from metals: casting, wire-arc additive, net-shape powder consolidation, welding of plates, etc. These processes generally produce components with properties that are inferior to those from forging, but these all are candidate processes for developing preforms that can then be forged. This can close voids, develop texture, refine microstructure, and control shape among other benefits.

d. Ultralarge forgings

Because incremental forming uses many small bites to form a part, the press that is used could be dramatically smaller than those in common use. One of the most interesting potential uses of metamorphic manufacturing may be to use preforms and systems with large robots and modestly sized presses to develop very large forgings. The basic work of the blacksmith, again, shows that this is basically possible. This kind of application can have great utility in aircraft and other large structures. This

movie about the US Air Force Heavy Press Program from the early 1960s shows the great utility that this can have [10] and we are largely limited to our ingenuity as to how this might be done. Note that the basic tools used then are essentially unchanged to those used now, except that dies are designed computationally and cut with CNC machining.

6 What Do We Need? A Brief Research Agenda

I hope I have been able to convince you gentle reader that it is worthwhile to develop a coordinated program to develop what a group of us here at Ohio State refer to as hybrid autonomous manufacturing. It's a big area, with potentially a big payoff and would require coordinated work of many people to get there. The metamorphic manufacturing study had some near-term recommendations to jump-start the technology. This echoes some of this and adds some others.

The first thing we probably need are some simple tools and ways to disseminate them. Brian Thurston has been developing a system (during the pandemic) in his living room that is suited for forming plasticine, as an early model material. This system is capable of making complex shapes with interchangeable general-purpose forming tools and by upgrading the press, it can be easily adapted for metal forming. This system can be replicated for under $7000 and it is our intent to share this design so that schools can develop this approach (Fig. 5).

As deformation is at the core, we need a new language (physical and computational) to plan and execute singular deformation steps to create targeted shapes. All of our work as children with modeling clay and more formal work with Plasticine

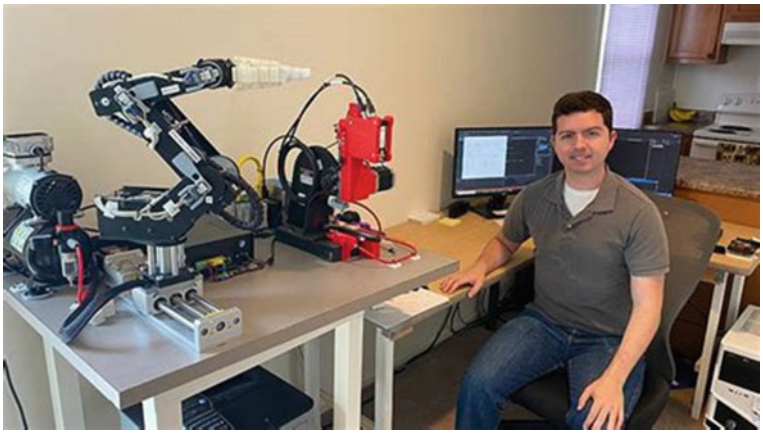

Fig. 5 Physical Exploration and Training Factory Automaton Box system (PET-FAB) being developed by Brian Thurston, including positioning an automated arbor press, optical scanning, and numerical control scheme. (Color figure online)

and the LIFT Prize program showed this is basically possible. This should become akin to computer-aided manufacturing and path planning now done for machining but has very different physics at its core.

Next, we need to add modules for heating, inspection, planning, surface quality, and so on. This requires sensor fusion and artificial intelligence. These tools need to be integrated, abstracted, and essential properties tracked so that common approaches can be used in varied locations and learning shared from one autonomous location to another.

Acknowledgments These ideas have been in development with many colleagues, including those from the TMS study group and local colleagues at Ohio State including Michael Groeber, Steve Niezgoda, David Dean, and Nate Ames. From my group, particularly Brian Thurston has been very active and Anupam Vivek and Sajun Prasad have helped with ideas and putting this in final form.

Investigation of Effects of Part Features in Single Point Incremental Forming of Narrow Channels

Suwat Jirathearanat, Dharmesh Kumar, Kai Soon Fong, Atsushi Danno, and A. Senthil Kumar

Abstract Narrow channels or ribs can be commonly found in sheet metal products. These narrow with high length-to-width aspect ratio channels are often integrated into sheet metal panels for functional features such as stiffeners or guide rails of various topographies, i.e. straight line or composite of curves. This work focused on the development of Single Point Incremental Forming (SPIF) as a cost-efficient forming alternative to stamping or embossing of these features in short-series production. These channels present unique forming challenges, i.e. effects of channel spline geometry, varying cross section, end geometries on part formability, and geometrical accuracy. SPIF of SS316L 0.5-mm-thick narrow channels of three different geometries with a maximum width of 20 mm and its length-to-width aspect ratio larger than 5, i.e. (1) straight channel, (2) taper channel, and (3) curvature channel, was investigated. Based on the experimental results, 5 mm dia. carbide tool and 0.1 mm step-down size were recommended to optimize SPIF of these narrow channels. The effects of the different part features and their interactions with SPIF forming parameters on part formability and deviations are presented and analyzed for further development of die-less narrow channel forming for sheet metal industry.

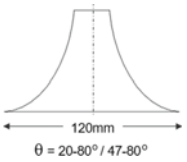
topographies. Embossing using dedicated geometry-dependent stamping tools is traditionally employed to form these channels. Most embossing operates far from the sheet metal drawing limit ratios, thus a fully stretching process. The resultant channels are typical of small depth and small wall angle. Recently, CNC turret punching machine with roller tools can form shallow ribs of straight or gentle curvatures on flat sheet metal. Similar to embossing, these roller tools can only form ribs with limited depth. In this work, the focus was on application of SPIF as a forming alternative of these channels with deeper depth and larger wall angel in short-series production. Incremental Sheet Forming (ISF) is a die-less and cost-efficient sheet metal forming owning to its use of a generic small hemispherical-tipped tool and CNC-controlled movements [1]. Single Point Incremental Forming (SPIF) is the most basic variation of ISF processes as it requires minimum tooling, i.e. a generic forming tool, fixture table with a dedicated backing plate, and with or without a blank holder. Due to its localized deformation mode, ISF can form sheet metal products far exceeding its material drawing limit ratios [2]. SPIF of sheet metals has been studied by many researchers. Formability of SPIF is largely represented in terms of maximum achievable wall angles (i.e. θ_{max}) determined experimentally either by SPIF of truncated cones with fixed wall angles or varying wall angle cones, which tends to give θ_{max} slightly larger than those obtained from fixed wall angle truncated cones [3]. It was also revealed that SPFI of truncated square pyramids would fracture around the corner of the part due to larger deformation as compared to that happens on flat areas [3]. This information is typically used in process planning for SPIF forming process of various part geometries. In terms of effects of step-down size and tool size on max. wall angle, generally speaking, it was shown that decreasing both step-down size and tool size would increase $\theta_{max,}$ [4]. However, there is an optimum tool size, below which forming instability (i.e. surface cutting) would take place, following a critical tool radius to blank thickness ratio of about 2.2, regardless of sheet metal materials [5]. Pillow effect, metal squeezing, or corner fold are another type of defect normally happen in unformed bottom area of the part. These directly contribute to low part dimensional accuracy and may adversely affect the part formability. Al-Ghamdi et al. studied this pillow effect and pointed out that smaller tool size, smaller step-down size, and strong strain hardening materials would worsen this pillow effect [6]. Based on this knowledge, one must understand interactions between defect characteristics, part features, and material in order to design and optimize process parameters for successful SPIF of any specific part geometry. There is a limited study done on SPIF of any narrow channels in the literature. Afonso et al. studied SPIF of channels and developed special tool path strategies for the forming [7]. However, these channels investigated have large channel widths and open ends, thus not quite applicable to typical narrow channels or ribs with closed ends of this study. Therefore, this investigation focused on SPIF of SS316L 0.5 mm-thick long and narrow channels (20 mm wide) of various features to reveal forming behaviors and optimize SPIF process parameters for this class of geometry.

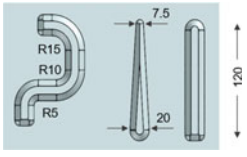
2 Experimental Procedure

In this investigation, two sets of experiments were conducted, as shown in Tables 1 and 2. Stainless steel sheet SS316L 0.5 mm-thick was incrementally formed into cones (Table 1) and narrow channels of three different shapes (Table 2) using both SKD11 and carbide hemispherical forming tools with diameter of 3, 5, and 15 mm. In Table 1, SPIF of varying wall angle cones was conducted to determine material formability or material maximum achievable wall angles with respect to tool size and tool material. Forming feed rate and spindle speed of 70 mm/min and 2000 rpm were used, respectively. Step-down size of 0.2 mm was applied in forming with tool 5 and 15 mm dia., while for 3 mm dia. tool was used with 0.1 mm step-down size as 0.2 mm step-down size would cause unacceptable surface finish. The varying wall angle cone geometry has the base diameter of 120 mm and the wall angle from 20 to 80°.

In the second set of experiments, three different narrow channels were investigated—(a) straight channel with round and flat ends, (b) taper channel with round ends, and (c) curvature channel with three reducing turning inner radii (i.e. R15, R10, and R5). These channels were formed with various wall angles from 45° to 70°

Table 1 Experimental matrix—SPIF of varying wall angle cones of SS316L 0.5 mm





Geometry	Tool dia. (mm)/Tool material	Step-down size (mm/rev)	Feed rate (mm/min)	Spindle speed (RPM)
 Varying wall angle cone	3 mm carbide	0.1	2000	70
	5 mm carbide	0.2		
	5 mm SKD11	0.2		
	15 mm SKD11	0.2		

Table 2 Experimental matrix—SPIF of narrow channels of SS316L 0.5 mm. (Color figure online)

Geometry	Tool dia. (mm)/Material	Wall angle (°)	Step-down size (mm/rev)	Feed rate (mm/min)	AVG spindle speed (RPM)
 3 narrow channels	3 mm carbide	45–70	0.1	1000	170
	5 mm carbide	45–70	0.1	1000	100
			0.2		

as summarized in Table 2. The forming feed rates and spindle speeds used in this set of studies were adjusted to provide rolling condition to the tool-sheet contact. In the experiments, only 3 mm dia. carbide tool was used with 0.1 mm step-down size, while 5 mm dia. carbide tool was used with both 0.1 and 0.2 mm step-down sizes. All parts were formed using SPIF tooling set up in a heavy-duty CNC milling center. UX software was used to generate forming tool paths with a z-level strategy. Parts thicknesses were measured by a handheld ultrasonic device with 0.001 mm accuracy. Part dimensions were laser scanned and measured using GOM inspect software.

3 Results and Discussion

3.1 Effects of Tool Size and Tool Material on SPIF of Varying Wall Angle Cone

Based on the results from first set of experiments, Table 1, the maximum achievable wall angles of SS316L 0.5 mm cones formed with various conditions are plotted in Fig. 1. The avg. max. wall angle of each sample was calculated based on the measured heights (i.e. lowest and highest fracture points), and the cone geometry employed. Photos of the formed parts are shown and compared in Fig. 2. Max. wall angle of 62° was obtained from using SKD11 tool of size 15 mm dia. There was a slight improvement in formability gained when reducing the SKD11 tool size from 15 to 5 mm—max. wall angle of 65° was obtained. It was observed that SKD11 tool of 5 mm dia. caused significant galling on the tool-sheet contact surface. This galling defect, which was caused by higher contact pressure on the surface of 5 mm dia. tool as compared to 15 mm dia. tool, seems to have caused premature fracture earlier than expected. A significant formability improvement was observed when switching the forming tool material from SKD11 to carbide in the case of 5 mm

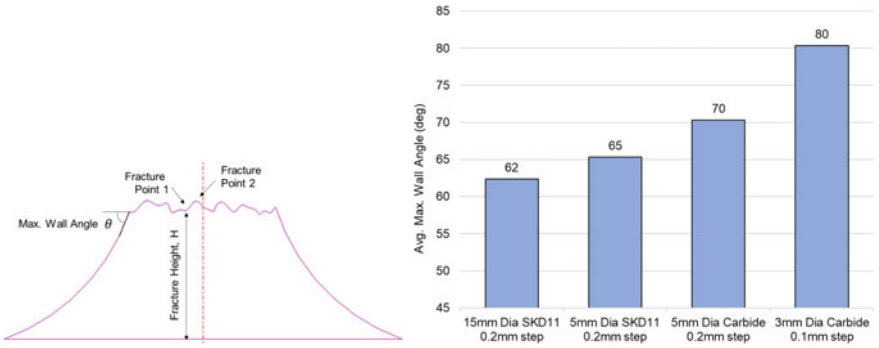


Fig. 1 Effect of tool size and material on maximum wall angle of SS316L 0.5 mm varying wall angle cone. (Color figure online)

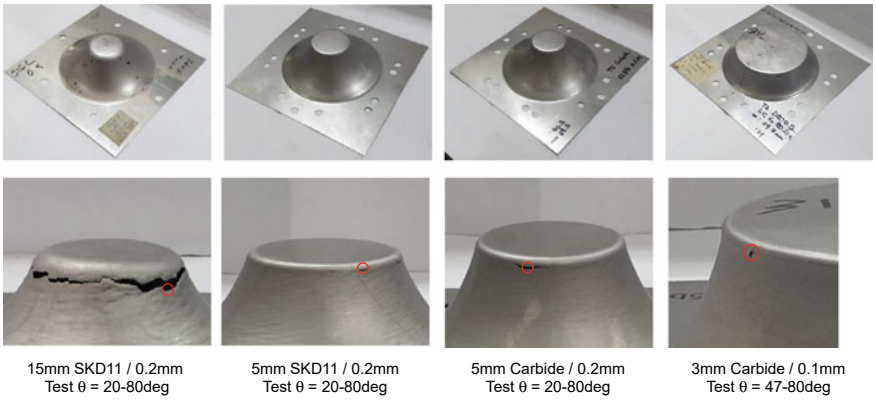

Fig. 2 Varying wall angle cones at maximum wall angle formed by different tool size and material. (Color figure online)

dia. tool, the maximum wall angle increased from 65° to 70°, and there was not any galling defect observed. In order to further investigate the effect of tool size on the stainless steel formability, an even smaller carbide tool of 3 mm dia. was considered. It should be noted that the starting wall angle of the cone geometry used for 3 mm dia. tool was 47° instead of 20°, which was used in the earlier cases (see Fig. 2), to avoid severe pillow formation in the unformed area, which was observed in other experiments conducted. The step-down size had to be reduced from 0.2 to 0.1 mm as to avoid bad surface finish. As a result, the maximum wall angle was markedly increased to 80° as compared to 70° seen in 5 mm dia. carbide tool. Based on the results of varying wall angle cone forming experiments, it can be concluded for SPIF of SS316L 0.5 mm-thick that smaller tools (i.e. 3 and 5 mm dia. Tool) can improve the formability given that surface galling defect can be minimized by using harder tool material such as carbide. It should also be pointed out that these results were obtained by using specific cone geometry that does not lead to any pillow formation during the forming, see Fig. 2. Interestingly, this condition may be difficult to design for SPIF of other part geometries, such as narrow channels.

3.2 Formability of Narrow Channels

Based on the results from second set of experiments, Table 2, max. wall angles of the channels (i.e. straight, taper, and curvature) are plotted and compared in Fig. 3. It can be observed that 3 mm tool with 0.1 mm step-down performed the worst as compared to those of 5 mm tool with 0.1 and 0.2 mm step-down. This finding does not agree with the results from the cone tests presented. With the 3 mm carbide tool, even the straight channel of 45° wall angle could not be formed successfully, and the curvature channel could only be formed up to 55° wall angle, which is much <80° the

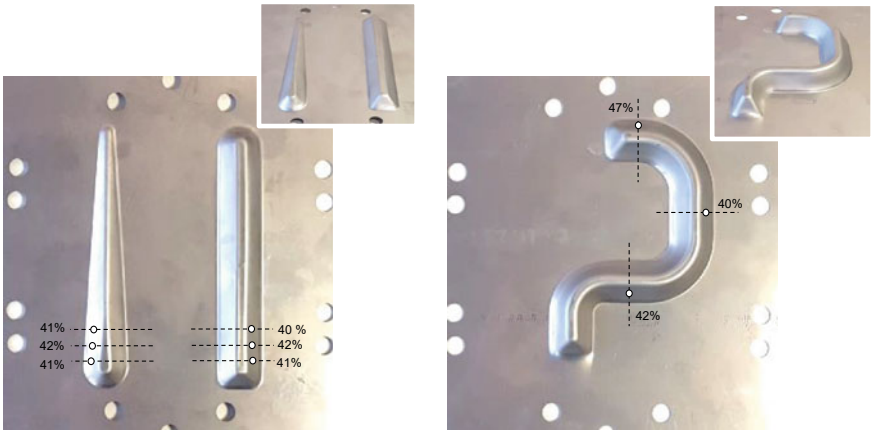

Fig. 3 Maximum wall angles of 3 channels formed by 3 and 5 mm carbide tools 0.1 mm step-down. (Color figure online)

max. wall angle observed in the corresponding cone test. From Fig. 3, there appears to be some interaction between channel geometry and achievable max. wall angle at least in the case of 3 and 5 mm tools with 0.1 mm step-down size, where the straight channels have the smallest max. wall angle and the curvature channels have the largest max. wall angle. Interestingly, by increasing the step-down to 0.2 with 5 mm tool, this interaction disappeared and all the three channels formed equally well at 55° max. wall angle. Generally, increasing step-down size will decrease formability. This is true for the curvature channel as its max. wall angle dropped from 60° to 55° for 0.2 mm step-down. However, increasing step-down to 0.2 mm had caused max. wall angle to increase from 50° to 55° for the straight channel.

Figure 4 compares in detail formability and part height of the channels formed by 5 mm tool and 0.1 mm step-down in order to gain some insights into the interaction of channel geometry and formability. From Fig. 4, it can be seen that fracture site is different for each channel geometry. It is well known for SPIF that part will typically fracture at tighter corner areas, where large deformation is more likely to occur as compared to that at more "open" areas. While the taper and curvature channel fractured at their tight corner as expected (see Fig. 4b and c), the straight channel fractured along the straight "open" side rather than at any of its tight corners, see Fig. 4a. This will be further investigated in the next section.

Max. wall thinning measurements of channels formed successfully using 5 mm tool and 0.1 mm step-down are shown in Fig. 5. Taper and straight channel (Fig. 5a and b) at 50° wall angle have roughly the same max. wall thinning of 41%, while curvature channel at 60° wall angle shows a larger wall thinning of 47% around its top corner. These thinning values agree with most findings in literature.

3.3 *Effect of Part Features on Formability*

Upon a closer examination of the parts, it was noticed that pillow effect was quite pronounced on top area in some of the straight channels. This particular pillow defect may have caused premature fracture along the straight sidewall of straight channel. Figure 6 displays pillow depths measured and calculated along profile section cuts on scanned surfaces of the channels formed by 5 mm tool and 0.1 mm step-down. It can be seen that the straight channel has the largest pillow depth (i.e. 0.17 mm). Though quite small, these pillow depths may play a significant role in part formability considering they occur over a tight narrow land of the straight channel top (i.e. 5 mm in this case). This pillow, or inverse bulge of the unformed flat top area, folds and in fact wraps around forming tool tip causing a "tight" corner condition, which may lead to premature sidewall fracture. When compared with forming tool radius, this max. pillow depth of the straight channels is approximately 6% of 5 mm tool and as much as 11% of 3 mm tool. It is believed that this pillow effect had caused 3 mm carbide tool to prematurely fracture the straight channel ($\theta_{max} < 45°$), see Fig. 3, and 5 mm carbide tool to premature fracture the part along the straight open sidewall ($\theta_{max} = 50°$), see Fig. 4a. From further pillow depth measurements, it was revealed that this max. pillow depth was reduced to 0.10 for 0.2 mm step-down. This reduced pillow depth may explain the increase in max. wall angle from 50° to 55° for SPIF forming of the straight channel using 5 mm tool with 0.2 mm step-down, see Fig. 3.

As for the taper channel, there appears to be very small pillow (max. 0.05 mm). Therefore, the fracture occurred at the highest tight corner, see Fig. 4b. The pillow formation in the curvature channel is rather complex, Fig. 6. It can be seen that the pillow is quite shallow in the bend sections, but becomes deeper in the straight sections. Though the max. pillow depth (i.e. 0.16 mm) in the lower straight section is just as deep as that of the straight channel, it only happens over a small length bounded by the bends where the pillow seems to shallow up. It is postulated that curvature channels can sustain a larger wall angle as they tend to alleviate the pillow effect

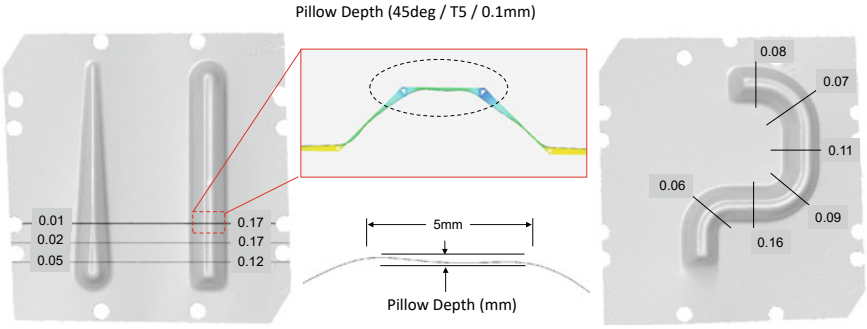

Fig. 6 Pillow depth measurements of channels at 45° wall angle formed by 5 mm carbide tool and 0.1 mm step-down. (Color figure online)

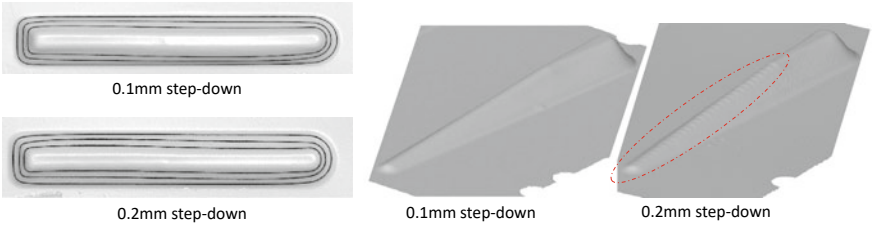

Fig. 7 Part deviation characteristics of **a** straight, and **b** taper channel with 50° wall angle formed by 5 mm carbide tool and different step-down sizes of 0.1 and 0.2 mm. (Color figure online)

around each bend. Therefore, they only fail around the tight corner, see Fig. 4c. Nevertheless, it is possible that premature fracture along a straight section may happen if that straight section is long enough. In another word, a narrow channel of a complete circle may never fail prematurely by the pillow effect.

3.4 Effect of Part Features on Part Dimensional Accuracy

Some interesting characteristics of part geometry deviations are shown in Fig. 7. There appears to be some waviness in the sidewalls of straight channel, Fig. 7a, as can be observed by wavy level contour lines on the channels. This waviness seems to be more pronounced when the step-down size is increased from 0.1 to 0.2 mm. It seems to have been caused by residual stress induced by pressing of the forming tool over a large flat area of the walls. Figure 7b shows a well-known stairs-stepped surface defect on the ridge of taper channel formed with 0.2 mm step-down. This defect can be corrected by decreasing the step-down size to 0.1 mm for this case. In terms of the geometry deviations, its sidewalls are quite flat and symmetrical. This might be due to its rigid triangle-shaped wall.

Part deviation measurements from the curvature channel are shown in Fig. 8. It was observed that cross-sectional profiles of this channel geometry are quite unsymmetrical, especially around the bend sections. Figure 8 plots normal max. deviations of inner and outer wall around each bend section of curvature channels with different wall angles from 45° to 60°. It can be seen that this curvature channel is mostly under formed. For low channel wall angles ($\theta = 45$–$55°$) the part deviations seem to be stable, but become quite sensitive at high wall angle ($\theta_{max} = 60°$). As the channel wall angle increases to maximum at 60°, part deviations seem to be larger for the sidewall on the top side (R35, R30, and R5), and smaller for the sidewall on the bottom side (R15, R10, and R25), Fig. 8. Initially, it was postulated that part deviations around each bend might be correlated to its bend radius, outer bend, and inner bend just, as how stress state of the wall can be related to tensile state and compressive state in curved profile flanging process, respectively, then it would be easier and

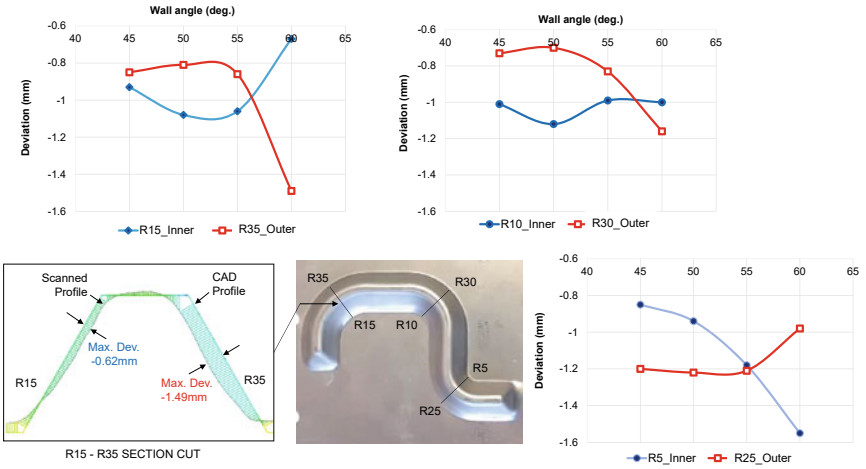

Fig. 8 Maximum part deviation measurements at different turning radii of curvature channels with wall angles from 45 to 60° formed by 5 mm carbide tool and 0.1 mm step-down size. (Color figure online)

systematic to correct such deviations by tool path compensation approach. Unfortunately, there does not appear to be any obvious patterns of part deviations based on the deviation measurements, thus difficult to minimize the deviations by tool path compensation. Heat treatment approach such as pre-annealing of SS316L blank to reduce forming stress levels might be more effective than tool path compensation approach in minimizing part deviations for this class of geometry.

4 Conclusions

This work investigated Single Point Incremental Forming (SPIF) as a forming alternative to stamping of narrow channels or ribs in short-series production. SPIF forming experiments on SS316L 0.5 mm-thick sheet metal were conducted using two sets of part geometries (i) varying wall angle cone and (ii) three different narrow channels—straight, taper, and curvature. The main findings are as the followings:

1. Smaller hemispherical carbide tool will increase formability of SS316L varying wall angle cone—3 mm dia. carbide tool can form the cone up to $\theta_{max} = 80°$, while 5 mm dia. carbide tool can form the cone up to $\theta_{max} = 70°$.
2. Unlike the varying wall angle cone, the smallest tool does not increase but rather decreases the formability of narrow channels. SPIF of narrow channels inherently induces pillow formation, which seems to adversely affect the formability—3 mm dia. carbide tool fails to form even a straight channel of $\theta = 45°$.

3. Formability of narrow channels can be improved by using a bigger tool of 5 mm dia. with 0.2 mm step-down—all the 3 narrow channels can be formed at $\theta_{max} = 55°$. Nevertheless, SPIF of narrow channels seems to yield max. wall angles which are still much smaller than those observed in larger parts such as the cones.
4. Some part deviations in the straight and taper channel are more pronounced when using a large step-down of 0.2 mm. Therefore, 5 mm dia. carbide tool and 0.1 mm step-down size is recommended for SPIF of these particular channel geometries.

Enhancing Tool Life by Manipulating the Die Elastic Strain Field During Extrusion

Gracious Ngaile and Daniel Santiago

Abstract A die design architecture for axisymmetric forgings which minimizes the residual contact pressure at the die–workpiece interface during the ejection stroke is proposed. The underlying principle of this die design is that during the forging stroke a tapered die can move in the direction of the forging load thus inducing negative radial elastic strain on the die. When the forging load is removed, the elastic strain energy stored in the die is released thus reposition the die to its initial state. With this design architecture the workpiece can be ejected at no load. Finite element (FE) warm forging simulations for constant velocity joint and pinion gear blank were successfully carried out to evaluate the viability of the process. In addition to reducing residual contact pressure which enhances tribological conditions, the FE simulations conducted have shown that a total energy saving of up to 15% can be achieved with the proposed die designs.

1 Introduction

Tool life is a major factor in the cost of forgings, productivity, and part integrity. Forging tools are usually subjected to mechanical, thermal, chemical, and tribological loads. Subjecting dies and punches to severe loading will bring about their eventual failure. The three common modes of failure are tool wear, fatigue fracture, and plastic deformation. In hot forging, tool wear accounts for approximately 70%, whereas the primary mode of failure in cold forging is fatigue fracture [1–4]. A multitude of parameters influence die failure in cold, warm, and hot forging. The interaction of these parameters is complex, as a result, enhancement of tool life has always been a challenge, and strategies to increase tool life can vary greatly from one forging operation to another. Strategies to reduce tool failure which have been

adopted over the years include improved lubrication and cooling systems; selection of the tool materials and adequate thermal treatments; surface treatment of the tools via thermochemical reactions such as nitriding which involve diffusion of atomic nitrogen in the steel surface; utilization of hard materials like ceramics; tool shape optimization which at present is carried out with the aid of numerical simulations; and modern tool work supervision where certain parameters can be monitored on the forging machine [5–8].

Lubricants play a critical role in the success of the forging operation. It reduces the friction stress at the tool–workpiece interface, the forming loads, and energy expended in the process. Good lubricant is also critical for the longevity of the tool and surface integrity of the forgings. A wide range of lubricants based on mineral oils and grease are available for simple forging. However, for severe cold forging operations, which exhibit high interface pressures and larger surface expansion, the choices of effective lubricants are limited. For example, the most common lubrication systems for steel and aluminum used in industry today are based on conversion coatings. The conversion coatings adhere to the billet by chemical reactions that create a pre-coat which has proven to bond well with various lubricants such as metal soaps [9]. The conversion coating process, however, involves heavy metal sludge that is difficult to dispose and thus poses health risk to workers [10–13]. The demand for environmentally benign lubrication systems for cold forging prompted the development of less toxic lubricants as an alternative to conversion coatings. Detail review of environmentally friendly lubrication systems can be found in Ref. [13].

On the other hand, lubrication for hot forging operation presents a different set of challenges to those observed in cold forging. For example, high thermal loading at the die–workpiece interface in hot forging precludes the use of many lubricants. One of the attributes of a good lubricant for hot forging is that it should lubricate and cool the die as well. This is crucial because the temperature of the dies needs to be kept below certain levels to prevent die thermal softening. To that effect, the most widely used lubricant in hot forging is water-based graphite. Graphite provides good anti-galling performance due to lower friction and heat resistance. However, graphite oxidizes at 370 °C, thus, it starts losing its performance. It should be noted that graphite lubricants pollute the atmosphere, so it is considered a non-environmentally benign lubricant. Environmental and safety concerns prompted the growth of research on white lubricants. There are three classes of white lubricants that are used in industry today; water-soluble polymer base, carboxylic acid base, and liquid glass base. These lubricants, however, exhibit low lubricity compared to graphite and pose difficulties in releasing the dies [13]. A detailed review of white lubricants used in hot forging can be found in [14]. Another way of enhancing die life is through thermochemical surface treatment. Efforts for developing die coatings for both cold and hot forging operations have been going on for the past 20 years. Physical Vapor Deposition (PVD) and Chemical Vapor Deposition (CVD) are the major methods that are used to diffuse chemical elements into the lattice of the tool material. With recent advances in additive manufacturing, a variety of materials can be sintered together without the need for additional processes. Using powder metallurgy technology,

the matrix phase of a pure metal or alloy can be sintered together with a solid lubricating material, making an antifriction compound. These compounds are called self-lubricating materials. Researchers have studied the effect of adding CaF_2 to a matrix of H13 steel, a steel widely used for tooling in hot forging, and they observed friction reduction when CaF_2 is added up to 10% [15].

As discussed above, there are different ways that could be used to enhance the life of the forging tool. Each of these methods, however, has its limitations. This paper discusses a different approach for improving tool life by manipulating the elastic strain field during the forging cycle. The forging cycle can be divided into two steps: (1) the forging stroke, where forging takes place and (2) the tool–workpiece disengagement stroke, where the workpiece is disengaged from the tooling. The tool–workpiece disengagement part of the cycle can exhibit a substantial tool–billet "residual contact pressure" with potential for galling and tool wear. The goal of this study is to explore innovative tooling designs, which are capable of reducing or eliminating the residual contact pressure via manipulation of the elastic strain field of the dies during the forging cycle.

2 Concept Development

Prior to discussing the concept pertaining to manipulation of elastic strain field in extrusion die design, the mechanics of a typical extrusion tool setup for backward cup extrusion were examined as shown in Fig. 1. The tooling has a compounded die arrangement, with one stress ring and a die press-fitted together. A forging cycle will be regarded as consisting of a "forging stroke" and a "workpiece disengagement stroke." The tool–contact pressure evolution along the boundary of the deforming body *a-b-c-d-e-f-g-h-a* plays a major role in wearing of die and punch (Fig. 1). Due to the elastic deformation characteristics of the tool and the billet, it can be shown that

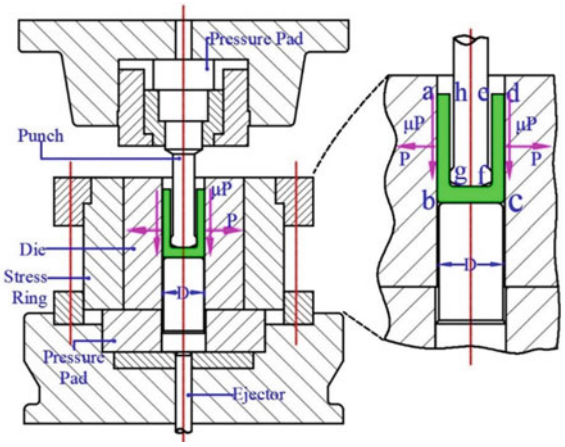

Fig. 1 A typical extrusion tooling setup. (Color figure online)

the contact pressure is exhibited during both the forging stroke and the workpiece disengagement stroke. During the forging stroke, the diameter of the die D will expand to D + Δd. As soon as the load is removed, the expanded die will spring back to D causing a secondary deformation to the forged part. This is the reason for the occurrence of residual die-workpiece contact pressure.

Similarly, as the punch load is removed at the punch–workpiece, the forged cup will attempt to spring back, thus compressing the punch, causing residual contact pressure at the punch land. In addition to causing this mechanical loading, the tool contact pressure has a cascading effect in intensifying thermal and tribological loads.

This paper proposes an extrusion tool architecture that will minimize or eliminate die–billet contact pressure during the disengagement stroke. This can be achieved by modulating the elastic strain field during the forging cycle. The die-workpiece contact pressure domain can be reduced, thereby enhancing tribological conditions, reducing/eliminating ejection load, and ultimately increasing tool life. The tooling architecture shown in Fig. 2 for forward–backward extrusion is design in a way that during the forging stroke, the die will shrink as the tapered die slides along the taper. After releasing the extrusion load, the compressive strain field in the die will be relaxed causing the die to expand (spring back) creating a gap in the order of few microns between the die and the workpiece. If the gap is created along with the whole tool–workpiece interface, residual contact pressure will be zero. Else, very little contact pressure will be exhibited at the interface. With optimization, there is potential to eliminate residual contact pressure during the ejection stroke.

The positive attributes of the tooling architecture given above include the potential to drastically reduce wear, reduce thermal loading to the dies, increase the quality of parts' surfaces, and reduce the possibility of lubricant breakdown as total sliding distance under high pressure is reduced. Manipulation of elastic strain field can be done on the punch by segmenting the punch into two parts thus the contact stress at the punch–workpiece interface is eliminated during the ejection stroke. Details on this technique can be found in an earlier publication by one of the authors [16].

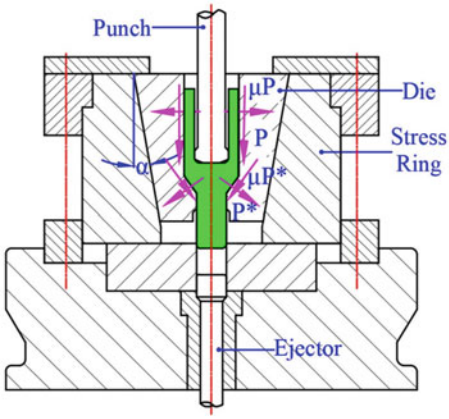

Fig. 2 Taper die design for manipulating die elastic strain field. (Color figure online)

3 Analysis of Tool Loading in Typical Forging Process: Constant Velocity (CV) Joint

This section will present finite element analysis of a constant velocity joint aimed at establishing loading characteristics during forging cycle. Assessment is then made on how the tool load evolution path predetermines the tool life. The forging sequence for manufacturing of a CV joint (outer race) consists of a forward extrusion stage, an upsetting stage, a backward–forward extrusion stage, and sizing stage. Details on forging sequences can be found elsewhere [17]. It is common that the first three stages are performed in a warm or hot workpiece condition, while the sizing stage is performed as cold forming. For this analysis, the geometry will be considered axisymmetric and therefore a preform without the grooves is considered as a final workpiece (Fig. 3). The simulations were carried out with 2D DEFORM Software package. AISI 1045 was used as workpiece material and warm forging conditions were investigated. The flow stress of this material was obtained from DEFORM Software database. Other common parameters entered in DEFORM are given in Table 1. Only the forward extrusion stage will be presented.

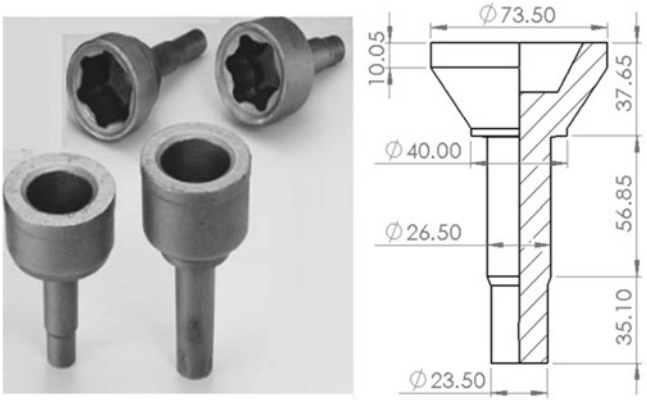

Fig. 3 CV joint preforms and dimensions used in the FE model

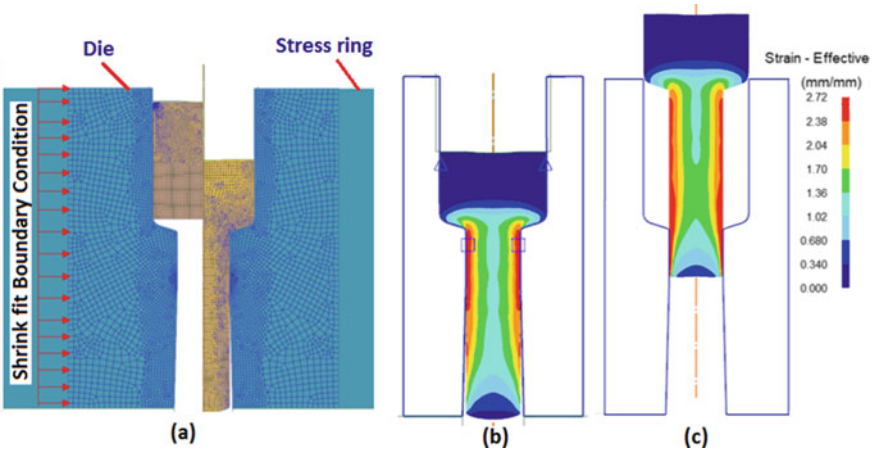

Fig. 4 **a** FE model. **b** Effective strain before ejection. **c** Effective strain after ejection. (Color figure online)

Forward Extrusion Stage

The FE model with representative meshes for the die and the workpiece are shown in Fig. 4a. The stress ring is present in the simulation and by definition; it must be elastic and meshed. The mesh of the ring is similar to the one of the dies, and it is not shown to facilitate the visualization. The shrink-fit boundary condition is applied as a uniform 0.1 mm interference.

Effective strain: Fig. 4b shows the effective strain at the end of the extrusion process. The maximum strain in the material is 2.7. A gradient in the strain distribution occurs on the surface of the extruded part along the axis of the workpiece and it varies from 1.0 to 2.7. During the ejection process, a secondary deformation takes place as clearly seen in Fig. 4c. The effective strain on the surface of the extruded shaft is now about 2.7 along the whole length. It should be noted that the secondary deformation is not an intended operation, but rather it occurs because the dies spring back after removing the extrusion load. This deformation is thus the consequence of residual pressure at the die–workpiece interface.

Forging load and ejection load: Fig. 5a shows the forming and ejection load. The sharp reduction in the cross section causes the load to increase rapidly to its maximum value, close to 250 t. After reaching its maximum, the load stabilizes and slightly decreases with stroke since the die–workpiece contact surface is also decreasing. The interface pressure during the extrusion stage is shown in Fig. 5b. Then, the extrusion load is removed, and the workpiece must be ejected. At this moment the die springs back and thus compresses the workpiece causing a residual pressure. This pressure state is defined as the pressure the die exerts on the part when no load is being applied. The initial residual pressure (just before the ejection starts) can be seen in Fig. 5b. This pressure mainly causes the required load during ejection, Fig. 5a. During FE simulation, the same shear friction parameters were used during forward extrusion

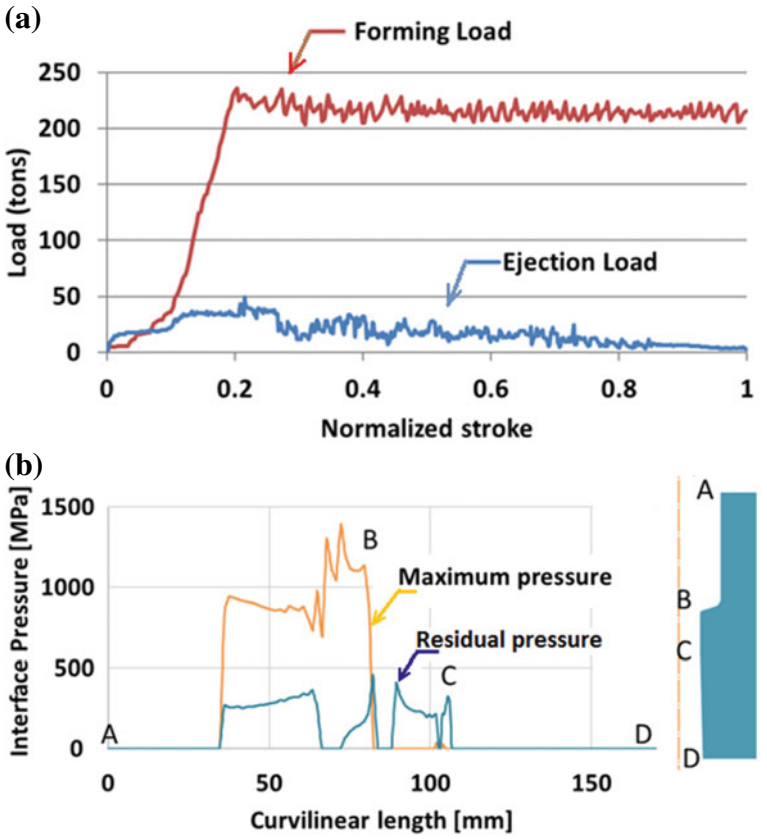

Fig. 5 **a** Load curves for forward extrusion stage of CV joint. **b** Tool–workpiece interface pressure profiles for forward extrusion stage. (Color figure online)

and ejection stroke. In practice, however, the lubricant may have thinned/depleted implying that the friction during ejection may be higher.

Residual pressure: As stated above the residual pressure is the pressure the die exerts on the workpiece when there is no load being applied. As seen in Fig. 5b this pressure is substantial, it is about 30% of the maximum pressure. During ejection, the contact surface area decreases. This may cause contact pressure in certain locations to increase dictated by the overall elastic strain energy stored in the die. This behavior can also be reflected on the ejection load profile. Note that as the ejection progresses; the land of the die (B–C) will exhibit a significant larger residual pressure up to the end of the ejection stroke. This region is thus bound to endure significant die wear. In short, this residual pressure hinders the ejection of the workpiece and plays an important role in the overall wearing of the die. The goal of this study is therefore to devise a methodology to reduce or eliminate residual pressure.

4 Reduction of Residual Contact Pressure in Extrusion by Manipulating Die Elastic Strain Field

As discussed in section two a tooling setup is designed which stores elastic strain energy during the forging stroke. As soon as the extrusion load is removed, the stored elastic energy is released thus repositioning the die such that the residual contact pressure is at its minimum or eliminated. The storage of elastic strain energy is facilitated by compressing the die during the forging stroke. Upon release of the extrusion load the die springs back in accordance with Hooke's law ($\sigma = E\varepsilon$), where E is Young's modulus and ε is the elastic strain. Note that the workpiece which was also under compression will spring back as well, but because the yield stress of the deforming material is smaller compared to that of the tooling, the magnitude of spring back, δ, for the workpiece will be smaller than that of the die. The optimal tooling design regarding the part ejection should generate $\delta_{die} - \delta_{billet} > 0$ along the contact surface. For this condition, the residual contact pressure is zero and the forged part can be ejected by only overcoming the weight of the part.

This tool design is applied to the CV joint forging simulations discussed in Sect. 3. Due to the new tool setup, the workpiece should be formed in a similar manner as in conventional dies, i.e. using same press, devices, and developing the same levels of plastic strain on the workpiece as well as the extrusion load. The new tooling setup would ease the ejection of the workpiece from the die thus reducing the forging energy to be expended, wear on the tool, and potentially reducing overall stresses on the forging tooling setup.

4.1 Constant Velocity (CV) Joint—Forward Extrusion: Proposed Tooling Design

As shown in Sect. 3, a substantial residual pressure was received at the die–workpiece interface. This pressure caused a high ejection load. Moreover, this pressure was present during the entire ejection stroke, and therefore a higher force was required to remove the workpiece throughout the ejection stroke. The retained contact stress has detrimental effects on tool life, as it intensifies tool wear, increases temperature dissipation from the workpiece to the tools, and worsens the tribological conditions.

The proposed tooling concept is aimed at improving the technical challenges during the ejection process. To manipulate the elastic strain, a set of die and sleeve with a taper angle of 7° is designed as shown in Fig. 6. The FE simulation conditions remained the same as that discussed in Sect. 3 for conventional tooling setup. The only exception was imposition of a friction coefficient of 0.1 at the interface between the die and the sleeve. During the extrusion process, the insert slid about 0.7 mm downward as shown in Fig. 6. This movement causes the insert to undergo radial compression storing elastic energy, while at the same time compressing the workpiece radially. When the load is removed, the stored elastic energy is used to return the die

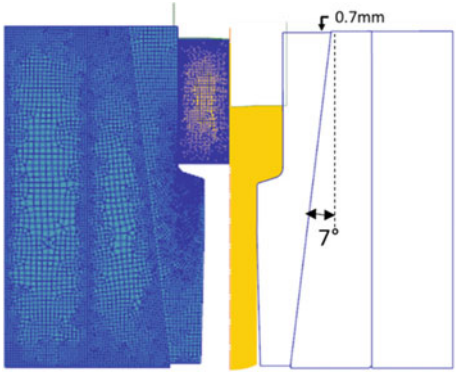

Fig. 6 FE model CV Joint forward extrusion—New die design. (Color figure online)

back to its initial position, creating a gap between die and workpiece in the order of few microns (Fig. 7). This gap allows the workpiece to be removed with minimum load.

The effective stress induced in the new die setup is shown in Fig. 8. The maximum stress attained is at the same level as what was observed in the conventional tooling setup. The new tooling setup, however, provides better stress distribution. The plastic strain distribution of the workpiece at maximum stroke can be seen in Fig. 9a, which is similar to the strain, obtained from the conventional tooling shown in Fig. 4b. Contrary to the conventional tooling, the strain distribution after ejection remains the same for the new tooling (Fig. 9b). This implied that in the new tooling setup no secondary deformation took place during ejection.

Figure 10 shows the extrusion load and ejection load. As expected, the ejection load with this new tooling setup is lower. This implies that during ejection the workpiece is barely in contact with the die. This is also evident for the residual pressure plotted in Fig. 11.

4.2 Comparison Between Conventional and New Tooling Designs

The residual pressure profiles for the conventional and new design at beginning of the ejection process is shown in Fig. 12. The average pressure along the area A–B–C is about 300 MPa for conventional die design. In the new setup, the pressure is almost zero everywhere except a small region. From a tribological point of view, an interface pressure of 300 MPa is substantial. In the absence of appropriate lubrication, friction can increase drastically leading to die wear. Therefore, the new tooling setup has the potential to increase tool life substantially. Due to reduction in the residual stress, the ejection load decreased significantly as seen in Fig. 13. Through integration on

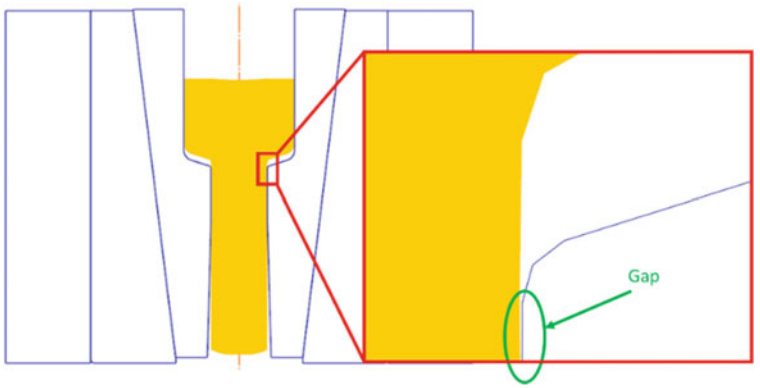

Fig. 7 Illustration of gap created at the land of the die ($\delta_{die} - \delta_{billet} > 0$). (Color figure online)

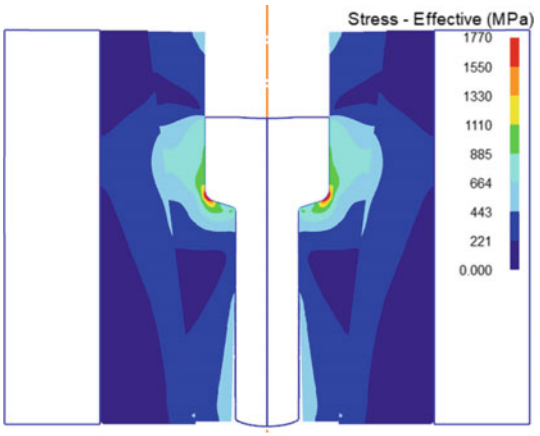

Fig. 8 Effective stress distribution for proposed die/sleeve for forward extrusion. (Color figure online)

the load curves, the total energy saving can be quantified. This case study shows an energy saving of 15% if a new die setup is used.

Another benefit of reducing/eliminating residual pressure is the reduction in heat transfer from the workpiece to the die. In hot forging, die–workpiece contact time is kept at a minimum to prevent thermal softening of the die, which is bound to reduce the hardness of the dies. If the hardness of the dies is reduced below acceptable levels, the tool life will be compromised. Thus, by reducing the residual contact pressure, the amount of heat that can be transferred to the die will be reduced. In turn, the potential for die softening can substantially be reduced.

5 Conclusions

This paper presented a new methodology for designing extrusion dies which result in minimal contact pressure at the interface between the die and the extruded part during the ejection stroke. The proposed die setup is bound to enhance tool life since the tribological loads are substantially reduced. The methodology is based on manipulating elastic strain energy of the dies during extrusion. To demonstrate the viability of the proposed tool design, finite element extrusion simulations for a CV joint were carried out. The major conclusions drawn from this study are:

- Manipulation of the die elastic strain energy is achieved by segmenting a die into a tapered insert and a sleeve. During the extrusion stroke, the tapered die insert can move downward, whereas the sleeve is constrained. Since it is moving on a tapered wall, compressive strains are induced on the die insert, storing elastic energy. During ejection, the die insert sprang back allowing the forged part to be released with minimal load. For the simulation cases studied, a die taper angle of 7° was enough to reduce the contact pressure to insignificant levels.

- The FE simulations conducted have shown that the residual pressure in the range of 400–500 MPa received in conventional dies can be eliminated when the new die setup is used. From the tribological point of view, this level of interface pressure is substantial. In the absence of appropriate lubrication, friction can increase drastically leading to die wear. Therefore, the new tooling setup has the potential to increase tool life substantially.
- Reducing the residual contact pressure results in the reduction of heat transfer from the workpiece to the die, a condition that is critical in hot forging where die–workpiece contact time needs to be kept at a minimum to prevent die thermal softening, which is bound to reduce the hardness of the dies. If the hardness of the dies is reduced below acceptable levels, the die life will be compromised.
- The simulated case studies have shown that a total energy saving of up to 15% can be achieved with the proposed die setup designs.

Oscillation-Free Determination of Material Properties at High Strain Rate

Xiangfan Fang

Abstract The determination of the plastic deformation properties of materials under high-speed loading is a challenge. The system ringing in a conventional servo-hydraulic tensile machine deteriorates the quality of force measurement. A precise determination of the plasticity and damage is thus difficult. In this work, the system ringing effect of the entire test system, including machine, sample, etc., was analyzed. We found that the system ringing is location- and geometry-dependent. Inspired by the principle of the split-Hopkinson bar, a new type of tensile sample has been developed. In a certain restricted area of this new sample, the tensile forces can be measured without any oscillation effect. The plastic deformation and damage behavior can be determined by using this type of specimen for a wide strain rate range of $10^{-4}-10^{3}$/s. To explain the functionality of the sample and sample design, a one-dimensional stress wave model has been developed.

Keywords Specimen geometry · High-speed tensile test · Servo-hydraulic testing machine · Stress wave · Stress-strain curve · Strain hardening rate

1 Introduction and State of the Art

During a vehicle crash event, large multi-axial plastic deformation occurs. The strain rate of this deformation ranges from 10^{-4} to 10^{3}/s [1, 2]. The material behavior must be correctly described for the FE simulation, which is commonly used in the vehicle development process.

In order to determine flow curves in the strain rate ranging from 10^{-4}/s to 10^{3}/s, three different measuring techniques are generally used: a quasi-static testing machine with 80 mm tensile specimen for 10^{-4}/s to 10^{-2}/s; a servo-hydraulic high-speed testing machine with 20–25 mm smaller tensile specimens according to SEP

1230 or ISO 26203-2 standards [3, 4] for a range of up to 1000/s; and the Split-Hopkinson Bar (SHB) for the range >1000 1/s with very small 5–10 mm specimens [5]. The experimental techniques and conditions (i.e., the measurement of force, deformation, specimen geometry and size, as well as the specimen fixation) are different for the various strain rate ranges and produce an apparent discontinuity in material behavior [6].

The use of the different experimental techniques is the result of force signal oscillations at high strain rates, the so-called system ringing effect [7, 8]. It is well known that a sudden force application on a solid body induces a stress impulse σ that is directly proportional to the loading speed V, the material density ρ and its sound speed C according to the Eq. (1) [7].

$$\sigma = V \cdot \rho \cdot C \tag{1}$$

Xiao et al. [8] stated that the insertion of a rubber damper in the force introduction increases the force rise time in such an experiment so that the stress wave has time to move back and forth at least three times within the specimen. This allows a quasi-equilibrium of the force within the specimen to be approximated and the oscillation of the force signals to be reduced. Zhu et al. [9] used the mode analysis of the entire system to filter out the force signal oscillations by using the eigen-frequencies and amplitudes of the system. While the method in [8] also reduces the maximum achievable strain rate and counteracts the goal of the high-speed test, signal filtering is an important intervention in the measurement data. In [3, 4, 10], suitable specimen geometries, measuring techniques and filtering were developed and recommended by extensive investigations. With the SEP 1230/ISO 26203-2 [3, 4], a specimen with a measuring length of 20 mm is given the highest possible natural frequency in order to reduce the vibration amplitude. In addition, the force measurement should be carried out as closely as possible to the gauge length of the specimen at the specimen shoulder area by the use of strain gauges instead of a load cell [10]. With this method, flow curves with reduced oscillations can be obtained up to approximately 200/s.

Using a split-Hopkinson bar (SHB), the force signals can be measured without any oscillation for the range $>10^3$/s. However, the results of such experiments by different research groups for one and the same material are considerably different. Verleysen stated [11] that in an SHB experiment, many of the fundamental assumptions for the evaluation of the test results are not valid in reality. The stress and strain in the very small specimens are not homogeneous as assumed, and the achievement of a quasi-static equilibrium is not always given. This is a contributing factor to the overestimation of the deformations and deviation of the determined stresses. Therefore, many efforts have been made to extend the application range of the servo-hydraulic high-speed tensile machine.

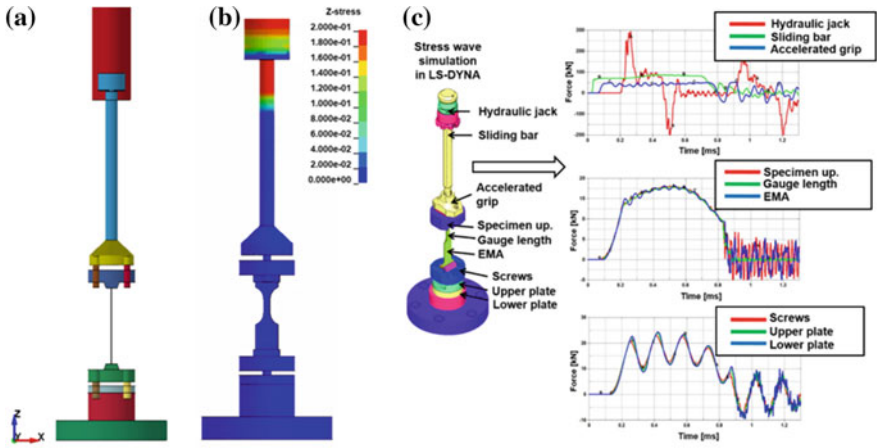

Fig. 1 Loading condition between hydraulic jack and sliding bar (**a**) and the stress wave there at 20 m/s speed (**b**); **c** Force fluctuations at different positions of the test system (EMA: Elastic Measurement Area). (Color figure online)

2 Stress Wave Propagation and System Ringing Analysis

In a high-speed tensile test using the servo-hydraulic tensile machine by the Zwick Roell Group (here a HTM5050 machine), a stress wave with $\sigma \approx 4-500$ MPa occurs on the contact area between the hydraulic jack and the sliding bar when the hydraulic jack hit the sliding bar at 20 m/s (Fig. 1a). Based on the CAD data provided by Zwick, an FEM model was developed in [1, 12] and validated.

There, as can be seen in Fig. 1c, a phenomenon was discovered—the oscillations in the area of the sliding bar are extremely large, they are very large in the area of the load cell and they are very small in the gauge length of the specimen.

3 Development of the New Specimen for Ringing Free Force Measurement

The above conclusion is used as a starting point for the development of a new specimen geometry. Since the force oscillations in the area of the specimen with large plastic deformation are almost zero, it is assumed that the stress waves may be absorbed by the plastic deformation.

Böme reported in [10] that the force vibration is smaller in the sample clamping area of the SEP 1230/ISO 26203-2 sample in comparison to the measurement in the load cell of the tensile machine. The SEP sample is modified in [1, 12] to a so-called Generation I (Gen. I) sample (see Fig. 2). In the test results in [1, 12], the force

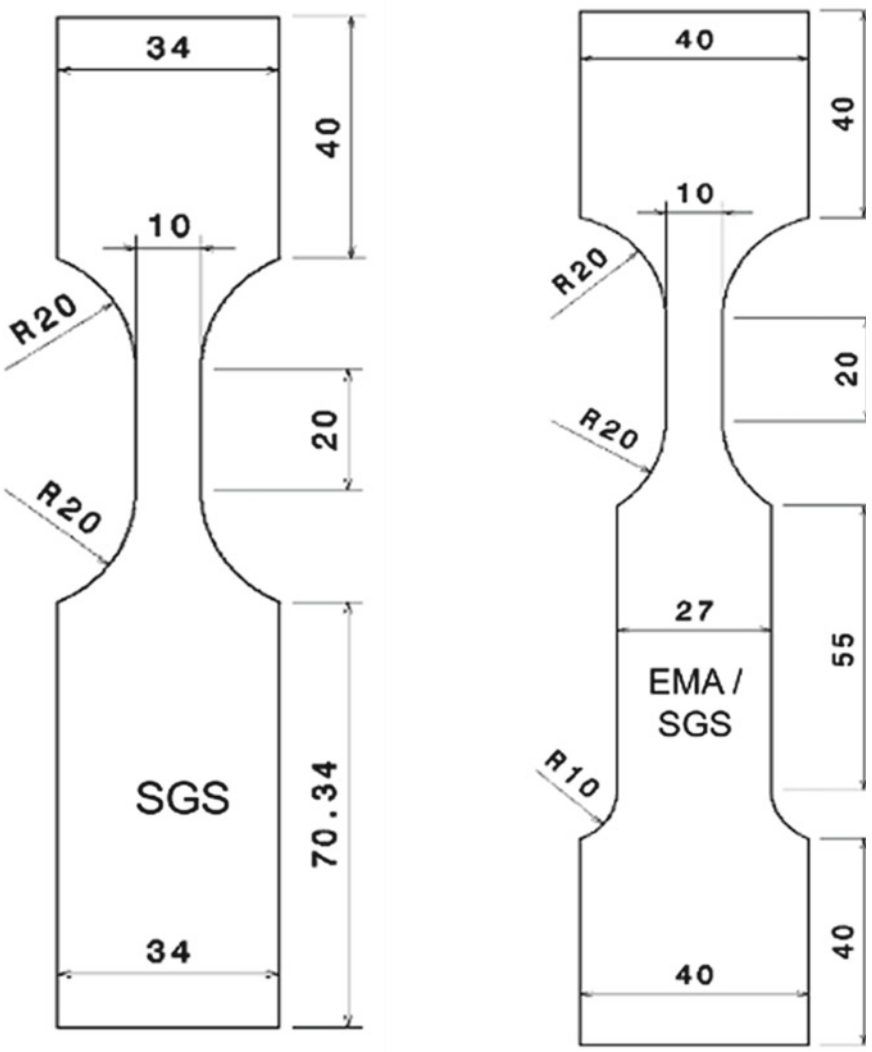

Fig. 2 Comparison of different specimens. Left: SEP 1230; right: Generation I specimen (Gen. I); SGS: strain gauge sensor measurement; EMA: elastic force measurement area

vibration in the area of strain gauge sensor (SGS) in the Gen. I sample is smaller than that of the SEP/ISO sample.

If the force oscillations in the strain gauge sensor (SGS) measurement or elastic measurement area (EMA) of the specimen could be significantly reduced further, a solution for force vibration may be found. Therefore, the geometry of the Gen. I sample has been further modified in different ways, and it ends up at the discovery

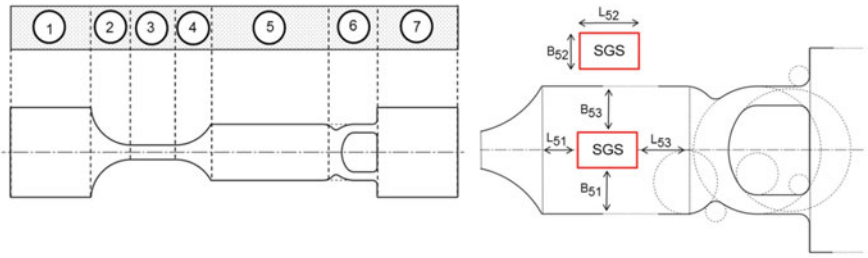

Fig. 3 Gen. III specimen geometry and its characteristics. (Color figure online)

of the Gen. III sample (Fig. 3). In the Gen. III sample, a cut-off (area 6 in Fig. 3) has been introduced in the EMA area of the Gen. I specimen. We hoped to create a kind of geometric filter which may prevent the stress waves from reflecting back to the strain gauge measurement (SGS or EMA) of area 5 when the rightward stress waves coming from area 1 pass areas 5 and 6 and are reflected at the end of area 7.

With a decreasing cross section in the weakening area of 6, a decreasing system ringing could be observed in area 5 which is between the weakened area 6 and the specimen's major plastic deformation, area 3. In the end, the best results could be achieved when a slight plastic deformation occurs in the weakening area 6 in the EMA. The effect of the slight plastic deformation is much larger than the pure geometric changes, i.e., the cross-section reduction between areas 5 and 6.

It seems that in the lower specimen area, the plastic deformation in the weakening area 6 results in the absorption of the elastic waves. This assumption was confirmed by Tasdemirci and Hall [13] and Maurel et al. [14], who analyzed the interaction between stress waves and dislocations in metals and came to the conclusion that dislocation movement may result in wave scattering and attenuate the stress wave [14].

The conditions for an almost vibration-free force measurement in the EMA area of the specimen are now described in detail with the help of Fig. 3. At the same time, it is ensured that the actual major plastic deformation of the specimen in the gauge length remains undisturbed.

The specimen geometry with the best results, the so-called Gen. III specimen (Fig. 3), has five sections (Sect. 2, 3, 4, 5 and 6) with different widths in addition to the two specimen clamping areas (Sects. 1 and 7). The force in the tensile test is applied in Sect. 1, while the specimen is firmly clamped and is immovable in Sect. 7. In Sect. 3, the actual major plastic deformation up to fracture takes place. Section 5 is larger in dimensions than Sect. 3. Next to Sect. 5, another Sect. 6 with geometric weaknesses is introduced. The geometrical dimensions of the specimen must fulfill different conditions:

$$\text{Section 3:} \quad \frac{R_{mB3} \cdot A_{B3}}{R_{mB6} \cdot A_{B6}} < 1 \tag{2}$$

$A_{B(n)}$: Cross section in section (n) with $(n) = 1$–7 (Fig. 3); $R_{mB(n)}$: Tensile strength of the material in section (n)

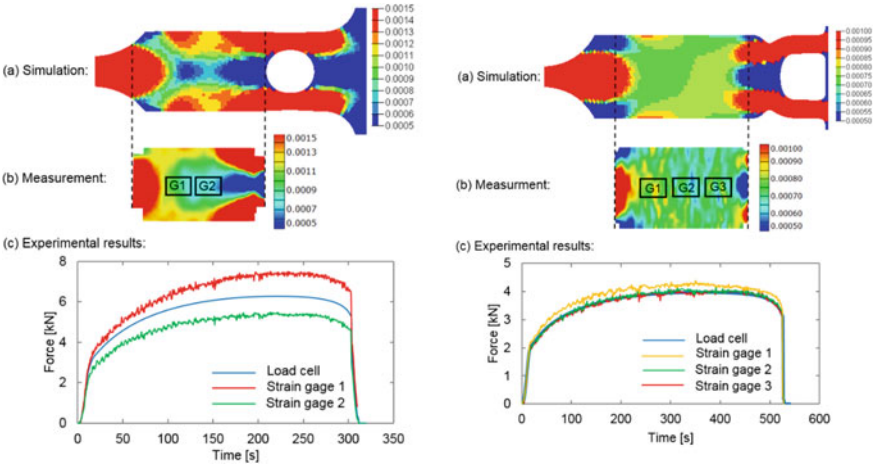

Fig. 4 Influence of the geometry of weakening area 6 on stress homogeneity in area 5 (G1–3: Strain gauge sensor area). FEM and experiment results are both quasi-static tests. Left: sample with a simple hole with in-homogeneous stress in area 5; right: Gen III sample with properly designed cut-outs for homogeneous stress in area 5. (Color figure online)

This ensures that mainly Sect. 3 is deformed. In this section, the specimen deformations are measured to calculate the strains. For a homogeneous quasi-isotropic material, $R_{p0.2}$ and R_m are the same in all sections. The following condition must apply in the force measurement area:

$$\text{Section 5:} \quad \frac{R_{mB3} \cdot A_{B3}}{R_{p0.2B5} \cdot A_{B5}} \leq 1 \tag{3}$$

$R_{p0.2B(n)}$: Yield strength of the material in section (n)

This ensures that only purely elastic deformations occur in Sect. 5. The force is measured locally via strain gauges or via digital image correlation (DIC).

The following conditions must be met in Sect. 6 of the specimen:

$$\text{Section 6:} \quad \frac{R_{p0,2B6}}{R_{mB3}} \leq \frac{A_{B3}}{A_{B6}} < \frac{R_{mB6}}{R_{mB3}} = 1 \quad \text{for homogeneous materials} \tag{4}$$

This is to ensure that Sect. 6 is slightly plastically deformed during the test while Sect. 3 undergoes the major deformations.

Extensive investigation shows that the shape and position of the local weakening in Sect. 6 must be designed appropriately in accordance with Sect. 5. Figure 4 *left* shows that a simple hole may reduce the system ringing, but the stresses in area 5 are inhomogeneous and thus the strain field is also inhomogeneous. The forces measured in G1 are different from G2 and the load cell of the test machine.

Using FEM, this inhomogeneity could be removed, as shown in Fig. 4 *right*. If the strain gauge is placed in G2 or G3, repeatable results can be obtained. The results

are the same as the load cell measurements. Since only the quasi-static material data is required for this sample geometry optimization, this work can be done without any difficulties. Fang and Grams [15] show that the homogeneity of the strain field remains during the whole deformation and that it is valid for both steel and aluminum.

The results of the high-speed tests on two steels in the following section prove that oscillation-free force measurement up to nominal strain rates of $\dot{\varepsilon} = 1000/s$ has now become possible.

4 Experimental Results

With the above-mentioned method, the strain rate dependencies of the flow curves of steel DC 04 and DP 600 are measured and systematically investigated. A Zwick Z100 testing machine was used for the quasi-static tests. The deformations were measured with a GOM 5 M CCD camera (max. frame rate: 29 Hz; max. resolution: 2448 × 2050). The high-speed tests were carried out using a Zwick HTM 5020 testing machine. A PHOTRON SA 5 camera (max. frame rate: 1 MHz; max. resolution 1024 × 1024) was used for the deformation measurement. However, the resolution of the camera had to be limited to 128 × 240 pixels in order to achieve the required high frequency of 150 kHz in the high-speed test up to 1000/s. The measurement data was all post-processed with the GOM ARAMIS software and then evaluated using our own corresponding software. More details can be found in [15].

The nominal strain rates of 4.4×10^{-4}/s, 25/s, 100/s, 200/s, 300/s, 500/s and 1000/s were realized. The same Gen. III specimen was used for all strain rates so that any specimen geometry effects were excluded. The entire strain rate range from 4.4×10^{-4} to 10^3/s could be measured with a single specimen geometry and measurement technique.

The force-time curves for two steels (DC04 and DP600) are plotted in Fig. 5. Force values measured by the load cell of the machine show increased vibrations when strain rate increases. However, the force values measured by strain gauge in

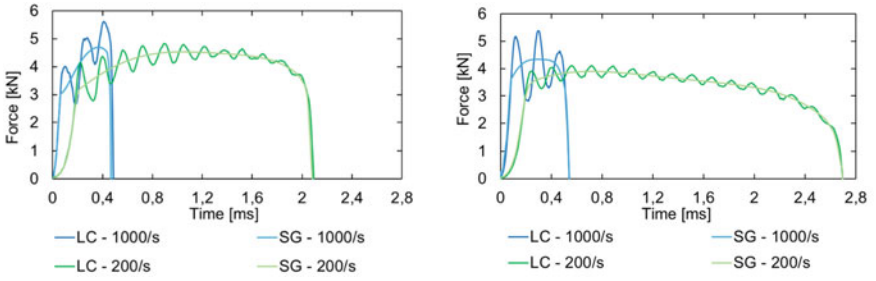

Fig. 5 Force-time signal for **a** DC04 and **b** DP600 steel. LC = force measured directly by the load cell of the machine; SG = force measured by the strain gauge sensor. (Color figure online)

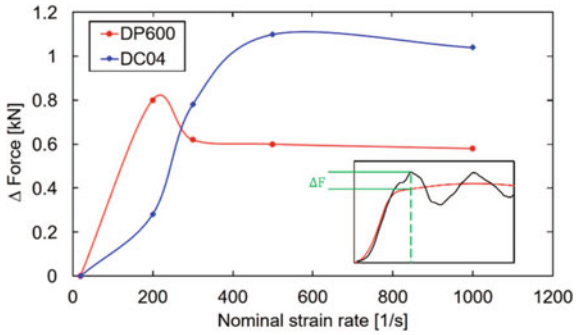

Fig. 6 Force difference between the first peak of the force measured by load cell and the force determined by strain gauge in area 5 of the Gen. III sample. (Color figure online)

area 5 of the sample (Fig. 3) show a very slight oscillation at the beginning that disappears after a certain very short time. This time is dependent on steel grade.

To quantify the effects that system ringing has on force measurements (Fig. 5) by the load cell of the test machine, the difference between the first force peak (as measured by the load cell from the force determined by SG in the EMA) was determined for both DC 04 and DP 600 steel (Fig. 6). The maximum force difference caused by system ringing in DC04 was 1107 N at a nominal strain rate of 500/s. By considering the cross-section area of the sample (6.5 mm width × 1.5 mm thickness), this difference corresponded to a stress difference of 113.5 MPa. In DP600, the maximum force difference was 820 N. Because the thickness of the DP 600 steel was 1.0 mm, the corresponding stress difference was 124 MPa, which is similar to that of DC04. However, using the Gen. III sample, the force value vibration reduces to about 10 N, which corresponds to a stress vibration of only 1 MPa [15], which is nearly negligible.

The stress-strain curves of DC04 are calculated from the Gen. III force data in Fig. 5 and are shown in Fig. 7. Three tests were performed for each strain rate. The fluctuations of the flow curves are small. It should be emphasized that all flow curves are pure measurement data without any filtering.

After these three flow curves are approximated using a cubic spline function, averaging and differentiation take place, which results in a clear hardening behavior (hardening rate $d\sigma/d\varepsilon$). The hardening rate increases with increasing strain rate. This is particularly pronounced in the area of higher stresses. However, there is an anomaly at 500/s that cannot yet be explained. On the other hand, the unusual flow and hardening curves at 100/s can be explained by the conditions of the Zwick testing machine (insufficient energy input at lower speed and readjustment of the hydraulic cylinders).

Figure 8 summarizes the strain rate dependence of the yield strength and the tensile strength of the two steels on a half-logarithmic scale. It should be noted that the strain rates can increase by up to more than 7 times due to the uncontrolled test machine and the increasing localization of the plastic deformation zone at the specimen due to necking (Fig. 9).

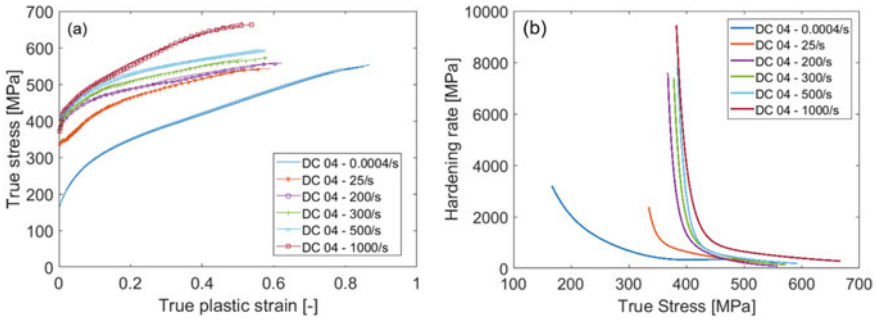

Fig. 7 True stress-strain curves of steel DC 04 (**a**) and the corresponding strain hardening curves (**b**). (Color figure online)

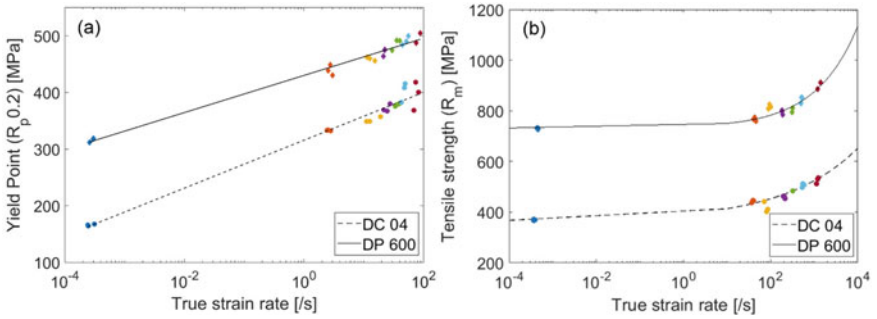

Fig. 8 Strain rate dependence of the yield strength (**a**) and the tensile strength (**b**) of DC 04 and DP 600. (Color figure online)

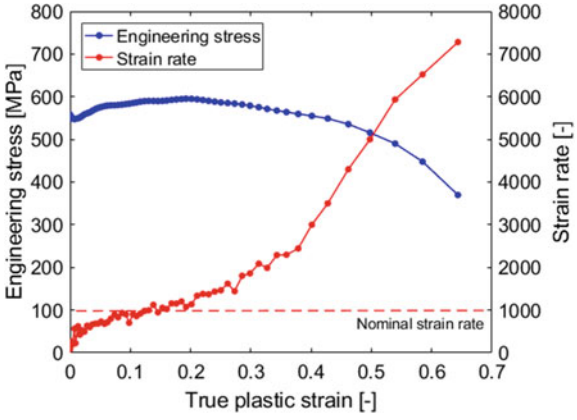

Fig. 9 Strain rate changes of HX 340 steel at 1000 1/s nominal strain rate due to the increasing localization of the plastic deformation (necking). (Color figure online)

At the beginning when yield strength is reached, the pre-set nominal strain rates have not yet been reached, whereas these are already exceeded when measuring

the tensile strength. Therefore, the yield strengths and tensile strengths in Fig. 8 are plotted against the real strain rates, which can be measured by using DIC and calculated using Eq. (5):

$$\dot{\varepsilon}_{\mathrm{yy-real}} = \frac{\in_{\mathrm{yy}}\ (t = t_{n+1}) - \in_{\mathrm{yy}}\ (t = t_n)}{t_{n+1} - t_n} \tag{5}$$

For the yield strength, the slope for DC 04 was slightly larger than the average for DP 600. The tensile strength of the steels also first increased almost linearly in the half-logarithmic scale. However, the increase was much greater at strain rates larger than 100/s. According to [10], these behaviors may be described by using a bi-potential function, and the behavioral change of the strength increase from linear to non-linear may be explained by the change of the thermal activation of the deformation processes from lower to higher strain rates. The strain rate dependence of tensile strength in DP 600 was larger than in DC 04. However, in [10], the dependence of strength on strain rate was only discussed in regard to the nominal strain rate. Based on the results of the present work, data of the dependence on the real strain rate is available.

5 A Physical Model for Gen. III Sample

The Gen. III sample was developed by FEM through trial and error. Meanwhile, a physical model was developed based on theory and equations for a one-dimensional stress wave. As stated in Sect. 1, if a bar is impact loaded, a stress wave with the stress amplitude σ_I will occur according to Eq. (1). This incident stress amplitude is dependent on the material properties $\rho \cdot c$, which is called impedance. The impedance can also be rewritten as $\sqrt{\rho \cdot d\sigma/d\varepsilon}$, where $d\sigma/d\varepsilon$ is the hardening rate of the material. In the case of elastic deformation, it is equal to Young's modulus. In plastic deformation, it is the slope of the stress-strain curve.

When the elastic stress wave created by an impact loading propagates on the bar with different cross sections and impedance, the stress wave may be reflected and transmitted on the cross-section or impedance change areas. The transmitted (σ_T) and reflected (σ_R) stress wave amplitudes are according to Eqs. (6) and (7) [7]:

$$\sigma_T = T \cdot \sigma_I \cdot \frac{A_1}{A_2} \tag{6}$$

$$\sigma_R = F \cdot \sigma_I \tag{7}$$

with n, F and T being defined by Eq. (8a) and (8b):

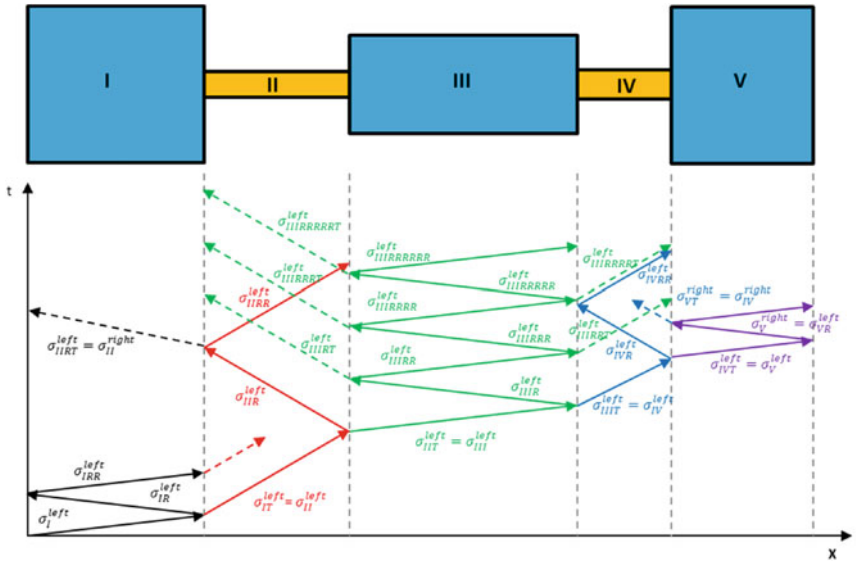

Fig. 10 A simplified one-dimensional beam model of Gen. III sample. (Color figure online)

$$n = \frac{(\rho_0 C_0 A)_1}{(\rho_0 C_0 A)_2} = \frac{\left(\sqrt{\frac{d\sigma}{d\varepsilon} \cdot \rho} \cdot A\right)_1}{\left(\sqrt{\frac{d\sigma}{d\varepsilon} \cdot \rho} \cdot A\right)_2} = \frac{A_1}{A_2} \cdot \alpha \tag{8a}$$

$$F = \frac{1-n}{1+n} \tag{8b}$$

$$T = \frac{2}{1+n} \tag{8c}$$

where α is the ratio between impedance in area 1 to area 2 or between elastic Young's modulus and plastic work hardening rate according to Eq. (9), if the waves are transmitting from a material section in elastic state into a material section in plastic deformation state. If both sections are in elastic state, $\alpha = 1$.

$$\alpha = \frac{(\rho C)_{el}}{(\rho C)_{pl}} \tag{9}$$

It is thus obvious that the transmitted (σ_T) and reflected (σ_R) stress wave amplitudes are different for the incident stress σ_1.

Based on this, a simple one-dimensional stress wave model has been proposed to understand the Gen. III sample [16]. Figure 10 shows the principle of the model: the areas 1 and 2 of the sample in Fig. 3 are unified as beam I in Fig. 10, area 3 as beam II, areas 4 and 5 as beam III, area 6 as beam IV and area 7 as beam V.

The beams have different cross sections $A_I - A_V$. They may have different elastic or elastic-plastic properties. Beams I, III and V should always be in elastic state (characterized by Young's modules E), while beams II and IV are initially in elastic state and change into elastic-plastic state when the specimen is loaded (characterized by work hardening $d\sigma/d\varepsilon$. The impulse load comes from left side (beam I), and beam V on the right side is fixed on the load cell.

As the lower part of Fig. 10 shows, the incident stress wave σ_I^{left} passes though beam I and is transmitted into beam Sect. 2 at the boundary between the two beams. This $\sigma_{IT}^{\text{left}} = \sigma_{II}^{\text{left}}$ can be easily determined using Eqs. (6), (8a) and (8b). Parallel to the wave transmission, σ_I^{left} is also reflected on the same boundary as $\sigma_{IR}^{\text{left}}$ which can be calculated by Eqs. (7), (8a) and (8b).

The same transmission and reflection happens on the boundary between beams II and III as $\sigma_{IIT}^{\text{left}} = \sigma_{III}^{\text{left}}$ and $\sigma_{IIR}^{\text{left}}$, between beams III and IV as $\sigma_{IIIT}^{\text{left}} = \sigma_{IV}^{\text{left}}$ and $\sigma_{IIIR}^{\text{left}}$ and between beams IV and V as $\sigma_{IVT}^{\text{left}} = \sigma_{\text{V}}^{\text{left}}$ and $\sigma_{IVR}^{\text{left}}$.

There are also many second to N-order reflections, such as $\sigma_{IIR}^{\text{left}}$ reflected on boundary II to I as $\sigma_{IIRR}^{\text{left}}$ and $\sigma_{IIIR}^{\text{left}}$, reflected on boundary III to II as $\sigma_{IIIRR}^{\text{left}}$. The same thing happens in beam IV. When considering beam Sect. 3, $N = 6$ times reflections are drawn, with the last one as $\sigma_{IIIRRRRRR}^{\text{left}}$.

Due to the assumptions that plastic deformation in beams II and IV absorbs the stress waves [13, 14] (see also Sect. 3), the second-order reflections $\sigma_{IRR}^{\text{left}}$ in beam I and the $\sigma_{IIRR}^{\text{left}}$ in beam II are not further followed, which is the same as the second-order reflected waves in beams IV and V.

With a number of additional simplifications [16] and the condition that all reflected and transmitted stress waves on the beam boundaries in Fig. 10 should be smaller or much smaller than the incident stress waves, as well as the fact that the transmitted and reflected stresses in beam III $\sigma_{IIIR\ldots R}^{\text{left}}$ are captured in beam III due to the very fast stress wave attenuation in beams II and IV, the number of reflections N for $\sigma_{IIIR\ldots R}^{\text{left}}$ can be calculated until a certain percentage p of the incident stress σ_I remains in beam III. If p is small, the oscillation in beam III is negligible. The design target for the Gen. III sample should be the minimization of N-value.

This analytical one-dimensional model was thus coupled with mathematical optimization (here a sequential quadratic programming SQP [17]), which can predict the sample geometry [16]. Starting with $A_I = A_V = 50\ \text{mm}^2$ and $p = 3\%$, $5 < A_{II} < 7\ \text{mm}^2$, $10 < A_{III} < 60\ \text{mm}^2$, $6.5 < A_{IV} < 7.5\ \text{mm}^2$, the optimization software developed in [16] shows the optimal results with $N = 1$ at $A_{II} = 6.27\ \text{mm}^2$, $A_{II} = 32\ \text{mm}^2$ and $A_{IV} = 6.5\ \text{mm}^2$. These geometric sizes are very close to the Gen. III sample sizes of $A_{II} = 6.5\ \text{mm}^2$, $A_{II} = 25\ \text{mm}^2$ and $A_{IV} \approx 7.5\ \text{mm}^2$.

For the original Gen. III sample sizes of $A_I = A_V = 50\ \text{mm}^2$, $A_{II} = 6.5\ \text{mm}^2$, $A_{II} = 25\ \text{mm}^2$ and $A_{IV} \approx 7.5\ \text{mm}^2$, a reflection number $N = 7$ was produced, which corresponds to the reflection time of 0.06 ms. The experimental results on a ferritic steel FSS439 show that the force oscillation is negligible after approximately 0.12 ms (10–12 reflections), and for a DC04 steel it is almost zero. Therefore, the reflection number N is dependent on steel grade if the same sample geometry is used.

It is also possible to adapt the sample geometry slightly to achieve a minimum N value.

The Gen. III sample can thus be well described and understood by a one-dimensional stress wave model.

6 Summary and Conclusion

Through the FEM modeling of the entire servo-hydraulic test system in combination with physical mechanical ideas, a novel Gen. III specimen geometry with a corresponding measurement method was developed in this work. This allows for an oscillation-free force measurement at strain rates of up to 5000/s. The geometry of the sample can be approximately predicted by a one-dimensional stress wave model which also explains the physical background of the new sample. Using SQP which is implemented in MATLAB tools, the optimal sample geometry for different materials can be predicted.

This new sample can be used for the entire strain rate range of 4.4×10^{-4}–10^{3}/s and enables a continuous determination of material properties for crash calculation. Measurements on steel materials confirm the method and show a clear strain rate dependence.

Tribological Conditions in Hot Bending of 22MnB5 Tubes

Enrico Simonetto, Andrea Ghiotti, and Stefania Bruschi

Abstract Thanks to the high stiffness-to-weight ratio given by the closed-section geometry, tubular components are particularly suitable for automotive applications that require extreme lightness to reduce energy consumption and increase crash-worthiness. Tube bending processes are traditionally performed in cold conditions, but to overcome the dramatic problems of accuracy and formability that the new high-strength steels present, a novel draw bending set at high temperature has been proposed. This paper presents the results of the investigations carried out on the tribological conditions of the hot draw bending of 22MnB5 tubes to obtain tubular parts with tailored mechanical properties. Investigation about the process thermal cycle has been performed with focus on the influence of the contact pressure on the heat transfer. The results show the practicability of the new process chain to obtain hot stamped tubular parts.

Keywords Tube draw bending · High-strength steels · Heat transfer

1 Introduction

The most recent trends of sustainable mobility require the reduction of the hazardous pollutants related to engine emissions. To this aim, the reduction of vehicle weight to decrease the fuel consumption and to increase their autonomy still represents a challenge due to strong requirements in terms of frame stiffness and passenger safety [1]. The last decade saw the development of several manufacturing technologies to further fulfil these needs. The hot stamping of High-Strength Steel (HSS) sheets was one of the most successful ones as it allowed increasing the geometrical complexity

of the components and, at the same time, tailoring their final microstructure [2]. In this way, it made it possible to significantly reduce the thickness of body-in-white sheet components and therefore their weight [3]. A further improvement may be achieved by changing the design of many vehicle parts by substituting sheet-based components with tubular profiles. This could increase the component strength-to-weight ratio, thanks to the better mass distributions allowed by closed hollow cross-sections [4]. Tube bending processes are traditionally carried out at room temperature showing strong limits when applied to HSS such as (i) high forming loads, (ii) low formability, and (iii) high springback. While the former point can be solved by increasing the power of the bending machine actuators, the others limit both the complexity of the obtainable shapes and the accuracy of the processes and their repeatability. As of now, there are not any industrially available technologies to produce bent HSS tubes hardened during the process [5, 6] and with tailored microstructure and mechanical properties [7]. This paper presents experimental investigations carried out to assess the feasibility of new Direct Hot Bending (DHTB) processes of 22MnB5 tubes with focus on the thermal cycle and on the thermal boundary conditions that affect the final workpiece mechanical properties. Experimental measurements of the cooling rates that can be achieved in typical DHTB processes are carried out to evaluate the Heat Transfer Coefficients (HTC) with the tools. The results of the bends performed in hot conditions show that the proposed apparatus allows bending the HSS workpiece exploiting the increased formability of the austenite microstructure. Furthermore, the bent tubes show that different microstructures were obtained on different points according to the applied thermal boundary conditions.

2 Materials

The material used in the investigation is the 22 MnB5 steel grade, provided a sheet with 2 mm thickness and straight tubes having an outer diameter of 40 (±0.1) mm and a thickness of 2 (±0.05). The chemical properties are reported in Table 1.

The tool steel grade is the EN X38CrMoV5-1 alloyed steel, commercially available with the name Böhler W300 (nominal chemical composition in Table 2). To

improve its wear resistance at the hot stamping temperatures, the tool steel is heat-treated to the hardening temperature of 1040 °C and then oil-quenched to obtain a surface hardness of 51 (±1) HRC.

3 Direct Hot Tube Bending (DHTB)

A novel apparatus specifically developed for the rotary draw bending at high temperature of 22MnB5 tubes is hereafter presented. The apparatus is based on a traditional cold tube Rotary Draw Bending (RDB) machine, see Fig. 1, to assess the feasibility of the tube Direct Hot Tube Bending (DHTB) process. Figure 1 shows the main tools and kinematics of RDB.

3.1 DHTB Equipment

A resistance heating system is embedded within the bending machine, in order to limit the thermal loss during the handling stage, and to have the maximum flexibility in the application of thermal cycles to different zones of the tube. A DC generator with a maximum power of 60 kW (6000 A at 10 V) is used as a heating device as shown by Fig. 2a. Two couples of copper electrodes connect the tube with the DC generator; these can be opened or closed to grip the tube, by means of two pneumatic actuators with a maximum force of 950 N each. A couple of electrodes is mounted on a fixed frame (see Fig. 2b), positioned near the pressure die to limit the distance between the heating zone and the dies, to decrease both the handling time and the

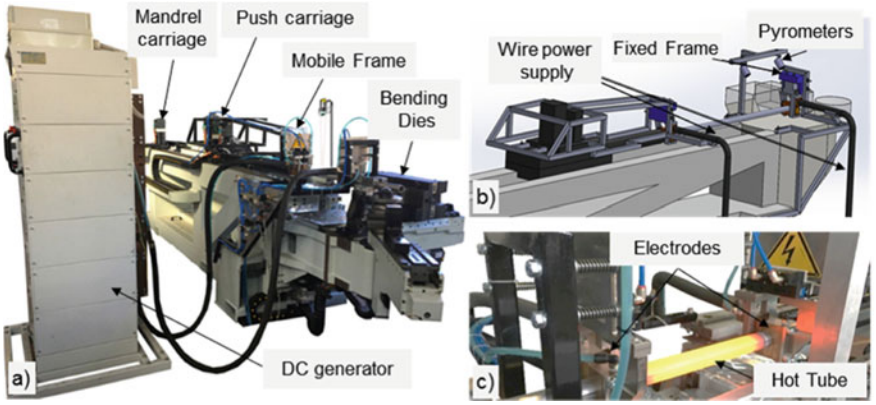

Fig. 2 **a** Overall view of the bending machine equipped with the heating apparatus for DHTB process, **b** model of the heating electrodes, and **c** hot tube heated by resistance heating. (Color figure online)

minimum distance between two subsequent bends. The other couple of electrodes is mounted on a mobile frame linked to the push carriage. This design allows moving the electrodes along the tube axis to change the heated length and adjust the length of the heat-treated zone to the bend angle. The tube temperature is monitored in-line by means of a pyrometer during the heating and holding stages allowing to control the applied electrical power in a closed-loop configuration. Figure 2c shows the copper electrodes and the tube heated at 950 °C during the austenitization stage. This solution has been preferred to others, such as induction heating, since it allows greater flexibility in terms of heating length without hindering the handling stages. The equipment has been tested, by heating the 22MnB5 tubes up to 950 °C, with a heating rate of 5.25 °C/s and a holding time of 60 s with different heated length, namely 200, 300, 400, and 500 mm, to assess the temperature gradient along the treated zone.

3.2 Thermal Cycle

By applying a thermal field to the workpiece, it possible to (i) increase the material formability to obtain more complex shapes, (ii) to reduce the springback angles, and (iii) modify the steel microstructure and so the mechanical properties. To achieve these results, the thermal cycle applied to the tube must be controlled. Figure 3 shows the proposed thermal cycle for the DHTB process, which includes the following steps:

i. Austenitization stage: the tube is heated up until (T_{Aust}) over the Austenitization temperature (Ac1) to obtain an austenitic structure. The heating rate can be increased and so the heating time reduced according to the capabilities of the power supply, in order to reduce the overall process time, while the holding

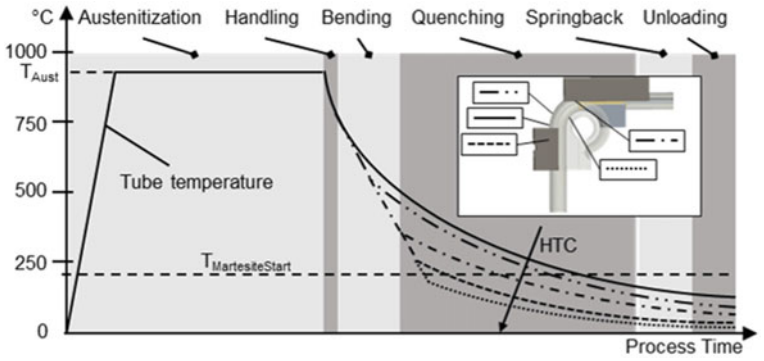

Fig. 3 Thermal cycle applied during the subsequent DHTB process stages. (Color figure online)

time at T_{Aust} is a function of the material properties in order to obtain a partially or fully austenitic structure according to the desired final mechanical properties of the component.

ii. Handling stage: the heated zone is moved from the heating system to the dies group in order to bend the tube. This stage is particularly critical as it is necessary to limit heat loss.

iii. Bending stage: the tube is bent while its temperature is still inside the process temperature window. In fact, all the forming stage should be completed while the tube microstructure is sitll austenite in order to allow an increased formability. At the end of the process, the mandrel is withdrawn from the bending zone.

iv. Quenching stage: after the bending stage is over, the tube is not unloaded as the tools are kept closed in order to maintain higher cooling rates.

v. Springback: when the tube cools down under the lower martensite transformation temperature, in order to reach the highest mechanical strength, the forming loads are released and the tube undergoes the springback phenomenon. However, the springback effect is greatly reduced by the thermal effects.

vi. Unloading: the bent zone is unloaded from the bending machine.

3.3 Boundary Conditions

As shown from the process model in Fig. 1, the thermal boundary conditions during the bending and quenching stages are not constant along the bent zone as the tools move during the process. Consequently, the thermal boundary conditions are not constant during the process forming stage. The chart in Fig. 3 shows different cooling paths that different points along the bending zone undergo during the process according to the evolution of the thermal boundary conditions. Figure 4 shows the contact conditions along several sections of the bending zone, in different moments of the bending stage. At the beginning of the bending stage, as shown by Section

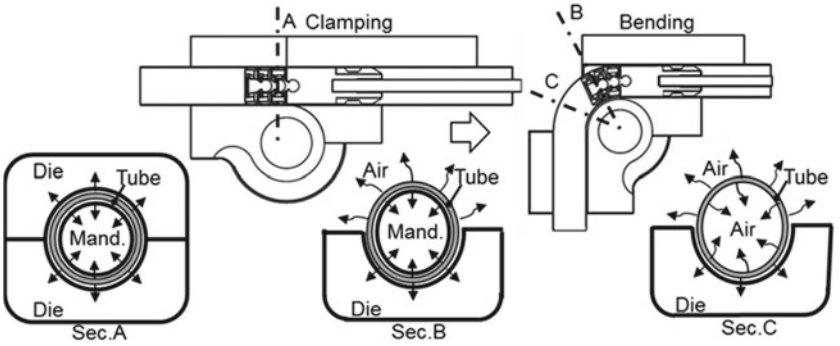

Fig. 4 Main boundary conditions during the quenching stage

A, the thermal exchange is mainly due to conduction since both the inner and outer tube surfaces are in contact with the dies or with the mandrel. Sections B and C are considered after the bending: in the former, the tube inner surface is still in contact with the mandrel and the tube intrados is in contact with the bend die but it is exposed to the air at the extrados. In the latter, the tube is in contact only with the bend die at the intrados, while there is air at the extrados and inside the tube. Therefore, the thermal conditions change during the bending stage and are different point by point, making the process difficult to control.

3.4 HTC Equipment

Figure 5a shows the developed experimental setup to test the different heat transfer conditions between the boron steel specimens and the dies, and between the boron

Flow per channel (l/s)	–	–	–	–	0.3	0.3	0.3

steel specimen and the air. A 22MnB5 flat sample (size equal to 45 × 50 × 2 mm) is heated by a frontal inductor head, according to the thermal cycle shown in Fig. 5b. The volume and the thickness of these flat samples are consistent with the dimension of the tube bent zone, to replicate a sample with similar thermal inertia and thermal boundary conditions.

Both the die temperature (T_D) and the specimen temperatures (T_S) are measured during the entire test by K-type thermocouples. To replicate the air cooling on the inner surface and with the bending tool on the outer surface, an insulating layer of trathermic® Silcem 1300 is interposed between the specimen and the lower die. Both dies are manufactured with the Böhler W300 steel as indicated in Sect. 2, with embedded cooling channels. The dies are mounted on a hydraulic press MTS322®, capable of a maximum load of 50 kN. The equipment was used to perform different cooling tests, according to Table 3, applying different levels of normal pressure consistent with the values undergone by the tube during the process. The tests were carried out with and without water flow on the upper die channels.

4 Numerical Model

To determine the heat transfer coefficients between the 22MnB5 sheet and the dies, a numerical inverse analysis was performed [8]. Figure 6a shows the 3D numerical model, developed with the commercial software Forge Nxt™, while Fig. 6b shows the temperature profile of the 22MnB5 sheet when the measured temperature T_S reaches the T_M value for a pressure of 2 MPa without water cooling. The thermal exchange between the sheet and the cooled die has been determined in order to fit the simulated temperature with the cooling paths measured during the real tests.

5 Results

5.1 Thermal Profile

The typical austenitization process for the 22MnB5 requires a temperature of 950°C, and so the electrodes are water-cooled below 100 °C to avoid excessive oxidation. As the cooled electrodes are in contact with the tube, also the tube is cooled down leading to a certain thermal gradient along the heated length as shown in Fig. 4c. A FLIR^{TM} A40 infrared thermal-camera (measurement range 20–1200 °C) was used to assess the temperature distribution along the tube axis for different heating lengths. Figure 7 shows its distribution for different lengths: 200, 300, 400, and 500 mm. It is possible to notice that the central part of the heated zones has a constant and uniform temperature, with a maximum deviation of ±5 °C, while the end zones of the tubes are at lower temperature due to the presence of the cooled electrodes. The length of these transient zones near the electrodes has a constant value of 50 (±10) mm.

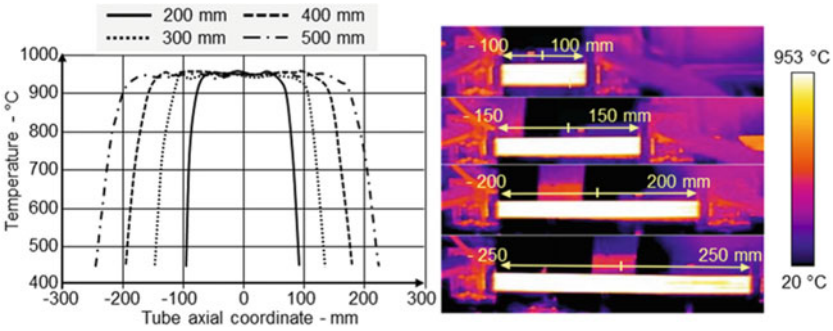

Fig. 7 Temperature profile along the tube axis at the end of the austenitization stage for different heated length. (Color figure online)

5.2 HTC Determination

Figure 8 shows the cooling rate obtained in still air. Figure 8a shows the bent tube at the end of the forming process, where the outer tube surface in the extrados cools down in still air, as shown by Sections B and C in Fig. 3. The cooling path in still air starts from T_A, see Fig. 8b, which is the temperature after the heating. It is worth noticing that the slope change around 600 °C is due to the latent heat release during the bainitic transformation.

The cooling paths measured during the die cooling tests are shown in Fig. 9. The first part of the cooling corresponds to the transfer time from the heating zone to the bend dies, starting from T_A down to the bending starting temperature T_{BS}. Then the dies are closed, with different pressures, leading to a faster temperature drop until T_M. The dies are then kept closed until the unloading temperature T_U is reached. In the case of water-cooled dies, the contact pressure between the dies and the specimen is less influential as shown in Fig. 9b.

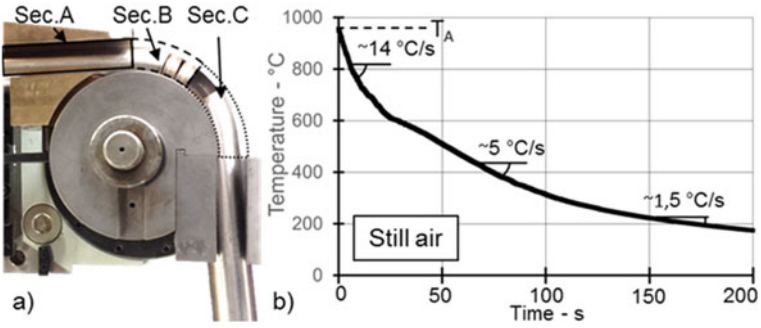

Fig. 8 **a** Tube and tool position at the end of the bending step, **b** specimen cooling path in still air from austenitization temperature. (Color figure online)

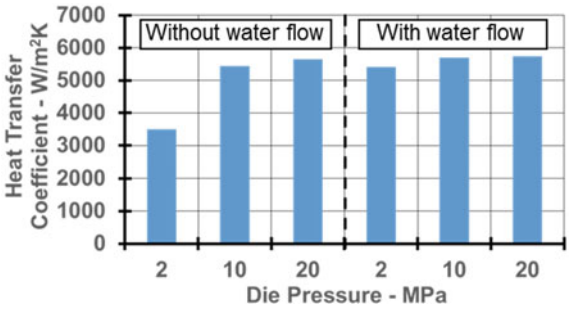

Fig. 11 Heat transfer coefficient obtained from the inverse analysis from T_{BS} to T_U for the die cooling conditions. (Color figure online)

The measured cooling paths were used to calculate the cooling rate varying both the contact pressure and the cooling conditions of the dies. Figure 10a shows the different cooling rates measured before the martensitic transformation while Fig. 10b shows the cooling rate down to T_U.

The experimental data were used to calculate the HTCs, see Fig. 11, between the die and the specimen by the numerical reverse analysis as discussed in Sect. 4. It was seen that HTC is almost stable for contact pressure values over 10 MPa without water flow, while it appears almost negligible with proper water flow.

5.3 Process Time

The duration of each process stages affects the thermal cycle and leads to changes in the workpiece final properties. As discussed in Sect. 3, the tube must be bent before any changes in the microstructure occur in order to avoid any loss of formability or increase in forming loads due to the presence of Martensite or Bainite. Figure 12 shows the position of the bending machine main axes during the process, starting

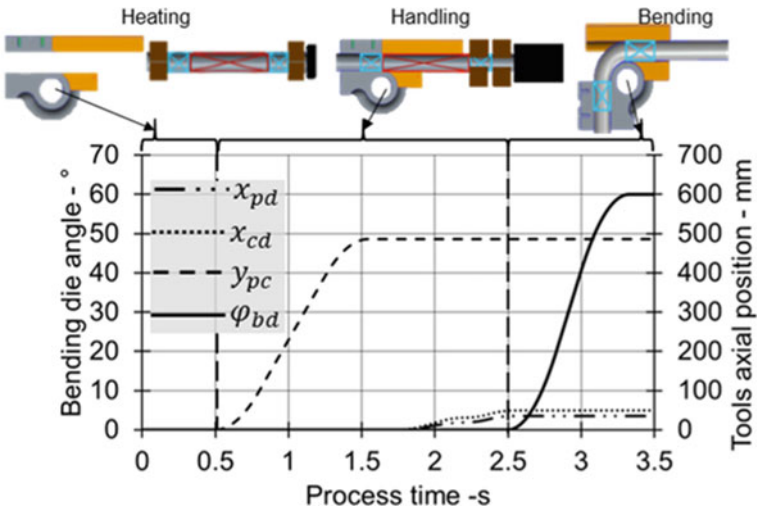

Fig. 12 Position of the bending machine main axes during the DHTB process. (Color figure online)

from the end of the Austenitization stage when the workpiece reaches the thermal profile shown in Fig. 7. During the handling stage, the pneumatic actuators open the copper electrodes and the tube gripped by the push carriage is moved along the axial direction to take the heated zone in the bending position; this operation requires 1.25 s. As shown in Fig. 4, the tube is gripped by the bend and clamp dies in the transient zones as this part is not deformed during the process, while the zone of the tube uniformly heated at 950 °C is positioned between the pressure and the wiper die to be bent. When the tube is in the right axial position, the dies are bought in contact with it, in 0.75 s as shown in Fig. 12. Then the tube is bent with an angular rate of 80°/s, taking 0.75 s to perform a 60° bend as reported in the chart. The cooling rate in still air for a 2 mm thickness tube can be estimated around 15 °C/s while in the case of cooling rate due to conductivity with a die, the cooling rate reaches maximum values of 200 °C/s for a pressure of 20 MPa. Therefore, as the tube is cooled in still air for 0.75 s and then it is in contact with the dies for 1.5 s until the end of the bending state, it is possible to say that the bending operation can be safely carried out before any microstructural changes occurs within the tube.

5.4 Mechanical Properties

After the bending stage the tube is cooled inside the dies, but during the quenching stage different zones of the bent tube undergo different cooling rates. The differences between the thermal boundary conditions on the tube intrados and extrados lead to non-uniform cooling rates and so different final microstructures are obtained. Figure 13a shows a bent tube by means of the DHTB process and highlights two

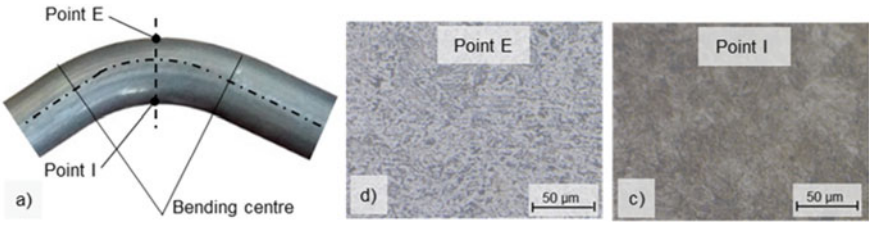

Fig. 13 **a** Tube bent with DHTB process, **b** microstructure at the extrados side, and **c** microstructure at the intrados side. (Color figure online)

different points on the extrados (Point E) and intrados (Point I). The microstructures of these two points were analysed showing that on the extrados side (Point E) a ferrite-perlite-based structure is still present due to the low cooling rate (Fig. 13b). On the other hand, Fig. 13c shows the martensitic microstructure obtained in point I, thanks to the highest cooling rate, greater than the 27 °C/s required to obtain the martensitic transformation.

6 Conclusions

This paper presents an investigation about the Tribological conditions in Direct Hot Bending of a hollow profile. In particular, it focuses on the thermal cycle and on the influence of the thermal boundary conditions between the workpiece and the machine tools. A DHTB prototype was developed to bend 22MnB5 after heating them up to the austenitization temperature, and a simplified experimental equipment was developed to determine the cooling rates and the HTCs as a function of different process parameters. The developed prototype uses a DC generator linked to the workpiece by means of two couple of cooled copper electrodes to apply the thermal field using the Joule effect. The thermal profiles measured at the end of the heating stage, using an infrared thermal-camera, show how the developed system allows to heat up different workpiece lengths in a homogeneous way, with a transition zone of 50 ($\pm$10) mm near the electrodes. Furthermore, the cooling rate and HTCs between the workpiece, the environment, and the dies were determined using the experimental equipment presented in Sect. 5.2 as a function of the contact pressure and of the die cooling channel water flow. These data, together with the process time measured in the DHTB operation allowed to estimate the process temperature windows. The process time was minimized to perform the forming operation at high temperature avoiding any phase transformation and any related formability decrease due to microstructural changes. Then the final microstructures of two different reference points were analysed to evaluate the influence of the different thermal boundary conditions, along the bent tube. The results show that two different microstructures are obtained, as a consequence of the different thermal boundary conditions, in particular a martensitic

structure was obtained on the intrados side, while a ferrite-perlite-based structure was obtained on the bend outer side. The technology proved to be promising to manufacture bent tube with tailored microstructure and mechanical behaviour.

In Search of the Perfect Sheet Metal Forming Tribometer

L. Schell and P. Groche

Abstract Due to increasing variant diversity and mass customization, time and cost-efficient process design has gained importance for several years. Tribological investigations are playing a key role as part of the process design. In particular, the desires for extended process limits, reduction of lubricant amount, and reliable determination of friction coefficients for FE simulations place high requirements on tribometers in sheet metal forming. For quite some time, the strip drawing test with several variations has been considered as an efficient and meaningful method for tribological investigations. This paper summarizes the development of the strip drawing test to date. In particular, design principles for experimental modelling of tribological conditions of deep drawing processes and approaches for friction measurement are described. Moreover, the current state and future requirements for the development of the "perfect" tribometer are discussed in this review paper.

Keywords Strip drawing test · Bending under tension · Tribometer · Friction coefficient · COF · Tribology · Sheet metal forming · Deep drawing

1 Introduction

A trend to shorter product life cycles and increased variant diversity can be observed for various industries [1] especially for the automotive industry [2]. Simultaneously, the growing demand for customized goods is boosted by manufacturing processes like additive manufacturing [3]. These trends are particularly challenging for forming technologies like deep drawing, which typically shine in high volume manufacturing [4]. To address these challenges, production flexibility [1] thus time and cost-efficient process design are important optimization methods. In deep drawing, tribological investigations play a key role in efficient and accurate process design [5]. In particular,

the desires for extended process limits, reduction of lubricant amount, and reliable determination of friction coefficients for FE simulations place high requirements on tribometers in sheet metal forming.

Tribological investigations of sheet metal forming processes are the main topic of many scientific publications. A recent overview of sheet metal forming tribometers is given in a review paper from Trzepiecinski et al. [6]. Comprehensive treatise with analyses of the individual tribometers can be found in dissertations of different research institutes [7–13]. This paper provides an extensive overview of the individual methods in form of a literature review including specific comparisons of the individual testing methods. The focus is on both design principles for modelling tribological conditions with tribometers and approaches for the determination of friction coefficients for deep drawing processes. Moreover, the current state and future requirements for the development of the "perfect" friction-focused sheet metal forming tribometer are discussed.

2 Tribological Test Methods

Tribological test methods can be classified into four different groups shown in Fig. 1 [14]: There is a contradiction between metrological accessibility and transferability to real forming processes.

Test methods of category 6 can be used to investigate basic tribological phenomena in a wide range of applications from gasoline engines [15] to prosthetics in the human body [16]. The main advantages of category 6 tribometers are their level of standardization (DIN 51350, DIN 51834, ASTM D5707, ASTM D1894, ASTM G99), although even results from category 6 tribometers with the same operation principle can show different results [17]. Disadvantages are the low transferability to sheet metal forming processes due to different contact conditions [18]. The contact area is typically small, which affects friction coefficients under lubricated conditions [19,

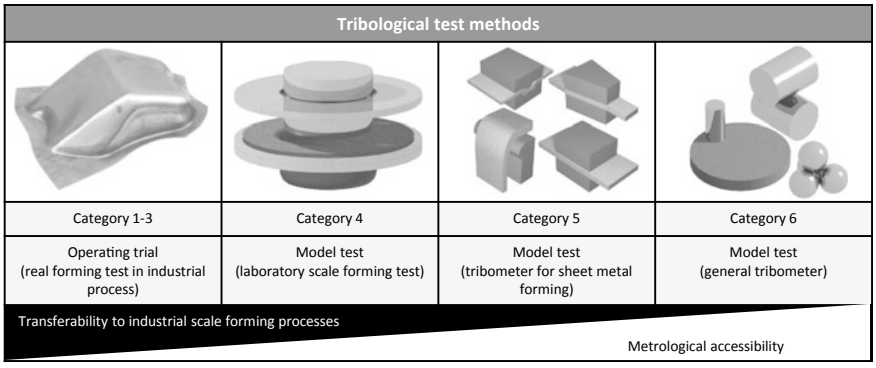

Fig. 1 Categories of tribological test methods for sheet metal forming (cf. [14] and DIN 50322)

20]. Additionally, sliding contact usually occurs repeatedly at the same surface area which is normally not the case in sheet metal forming processes [12]. Last but not least, plastic deformation of sheet metal affects its tribological boundary conditions (e.g., increasing surface roughness [21]) which is not considered in tribometers of category 6.

In contrast, "tribometers" of category 1 to 3 are rather in-situ test methods integrated in press shop forming operations of real parts under conditions of series production. Since the real forming operation is used in the test procedure, there is no need to transfer results. Disadvantages are both the limited options to change tribological loads and the implicit measurement of tribological variables like friction coefficients [12]. Furthermore, expenses of such tribological tests are typically high and should not affect current serial production [14].

Due to the extreme characteristics and distinct disadvantages of the mentioned test methods (categories 1-3 & 6), these test methods cannot be considered as perfect sheet metal forming tribometers. To select the most promising candidates from the remaining categories, it must be clarified what exactly is the objective of the investigation. When it comes to sheet metal forming, two different investigation objectives are conceivable, cf. [14, 22]:

(A) Investigation of tribological systems (e.g., lubricants) concerning their suitability in certain forming processes. Such studies mainly aim at qualitative comparisons and proof of feasibility.
(B) Investigation of frictional behaviour under specific tribological conditions (contact pressure, sliding velocity, temperature, …). Such studies mainly aim at quantitative results in form of friction coefficients.

For objective A, tests from category 4 (e.g., deep drawing of cylindrical cups) can be used but typically lack direct measurement of friction forces or friction coefficients [23]. Friction coefficients have to be derived from FE-based inverse analysis [23] or analytically using Siebel's formula [24]. In both cases, material models directly influence the determined friction coefficients which leads to inaccuracies [11]. For objective B, tests from category 5 are most suitable (e.g., various tests utilizing metal strips). A big advantage of category 5 tribometers over category 4 is the ability to easily adjust tribological conditions independently of each other [12]. Additionally, most category 5 tribometers are independent from material modelling. In order to decide whether the perfect sheet metal forming tribometer is searched in either category 4 (objective A) or category 5 (objective B), the current role of tribometers in sheet metal forming has to be discussed.

3 The Current Role of Tribometers in Sheet Metal Forming

Increasing importance of FE simulations in sheet metal forming results in higher demands for FE modelling accuracy and reliability. Advances in computational power enable more detailed thus more complex FE models; but even a complex

FE model can only be as accurate as its assumptions and input variables. Important and powerful input variables are friction coefficients [5] which, among others, affect simulation results regarding spring back [25], punch force, and sheet thinning [26]. Additionally, numerical modelling of friction gains importance in the industrial use of FE simulations for sheet metal forming [27]. In spite of the promise, friction models could "reduce the demand for experimental friction testing" [28], those numerical models are developed with the help of experiments, either for fitting or for validation purposes [28, 29]. Current publications show that there is still a scientific [18, 30, 31] and commercial [32] interest in sheet metal forming tribometers.

4 Discussion

To determine reliable friction coefficients, tribometers should meet exact requirements concerning homogeneous and stationary conditions (e.g., contact pressure, temperature, sliding velocity, and lubrication regime). In a perfect tribometer, it should be possible to adjust all conditions independently and therefore determine friction coefficients as function of these conditions. Furthermore, models for both sheet deformation or material behaviour should not be necessary when deriving friction coefficients from other measurement parameters [11]. The mentioned requirements are best met by the diverse types of strip drawing tests from category 5. These tests stay as close as possible to the sheet metal forming process (e.g., reproduction of forming conditions). An overview of different category 5 tribometers is shown in Fig. 2. The most promising ones are presented in the top row and will be discussed in detail in this paper.

The reasons to exclude the four tribometers in the bottom row of Fig. 2 are as follows. The draw bead test features both a highly inhomogeneous contact pressure at the draw beads [12] and differences in sliding velocity due to thinning of the strip [11]. It resembles three bending under tension tests connected in series while tribological conditions (e.g., lubrication, sheet surface roughness, contact pressure) are different in each contact zone. The strip-tension test also resembles a bending under tension test, though it shows transient contact pressure with a limited adjustment range and varying sliding speed in the contact zone [11]. The fundamental characteristics of both the draw bead test and the strip-tension test can be checked in the bending under tension paragraph. Hemispherical stretching resembles the strip-tension test though its three-dimensional design leads to even more inhomogeneous and transient contact conditions. Last but not least, the strip reduction test simulates tribological conditions in ironing and is typically used to investigate both lubricant break down [33] and onset of galling [34]. Investigation of friction coefficients in the strip reduction test is difficult [35] and coefficients are given as a function of pulling force rather than a homogeneous contact pressure.

The intention of the following paragraphs is not to list all variants of tribometers from different research institutes (cf. [6]) but to focus on both design principles to reproduce tribological conditions and approaches for the determination of friction

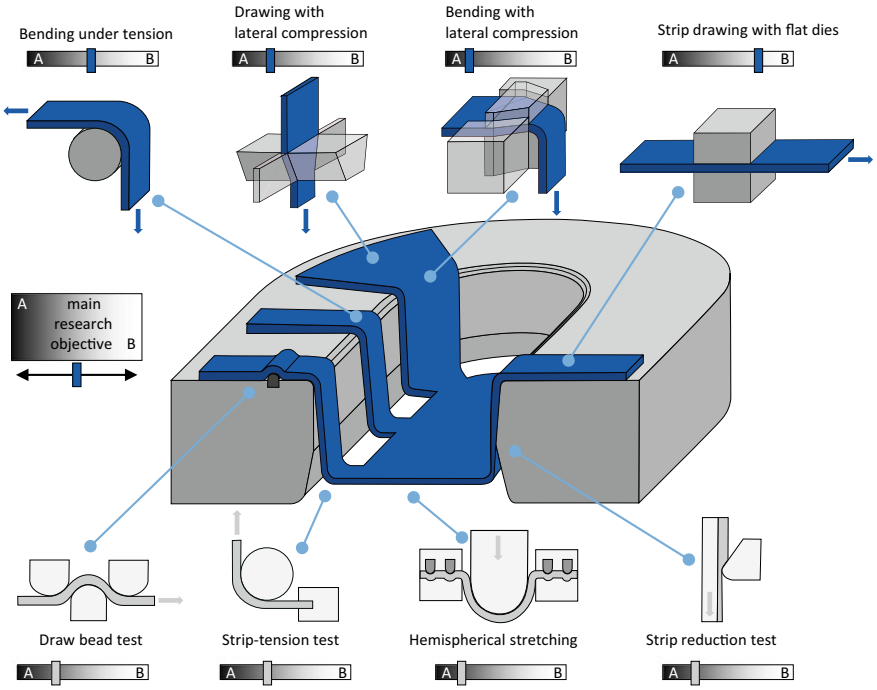

Fig. 2 Overview of sheet metal forming tribometers from category 5 (pictures after [36]). The main research objective is rated by the authors based on theoretical assessment, literature research, and actual experience with various tribometers. (Color figure online)

coefficients. The evaluation is ordered from the tribometer closest to the deep drawing process to the tribometer with the best metrological accessibility.

5 Bending with Lateral Compression

In a critical review of tribometers, Schey [22] tends to assign higher transferability to the more complex tribometers which include some sort of plastic deformation. One of the most complex tests of this kind is based on bending with lateral compression, which is rarely used, because of its complex dies.

Investigations from Lassen and Bay [37] show that besides complex dies, three different experimental setups are necessary to calculate the friction coefficient at the die radius based on the belt friction theory (Fig. 3). A downside of this approach is that measuring errors and variations in boundary conditions are added up. Furthermore, friction at the die radius affects both the bending procedure and forces for plastic deformation. This leads to the demand to derive friction coefficients from one single experiment [11]. Since bending with lateral compression is a combination of both

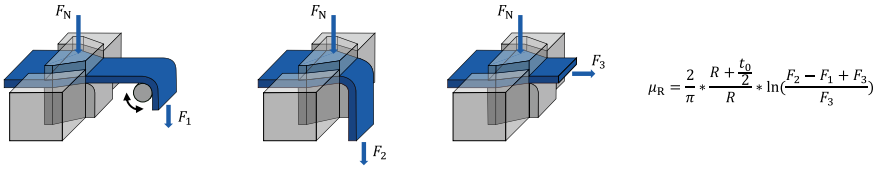

Fig. 3 Bending with lateral compression – test principle and calculation of friction coefficients based on the belt friction theory (cf. [37]). μ_R = friction coefficient at the die radius R, t_0 = initial sheet thickness, $F_\#$ = pulling forces in the different experimental setups, F_N = normal force. (Color figure online)

drawing with lateral compression and bending under tension, an in-depth analysis is performed separately in the respective paragraphs.

6 Drawing with Lateral Compression (Wedge Drawing Test)

The wedge drawing test was first published by Sachs in 1930 [38]. He investigated the drawability of different sheet materials and lubricants without measuring or calculating friction coefficients. His investigations were pursued by Loxley and Swift [39] and taken up again by Reihle [7]. Reihle extensively investigated the influence of contact pressure, lubricant, sheet material, surface roughness, and plastic deformation on the friction coefficient. Although he had a wedge drawing test available, he performed most of his tests with narrow strips without lateral compression because of the difficult to perform experimental procedures. The few tests with lateral compression yield the same friction coefficients as his flat die tests.

Around 20 years later, Ng [40] and Bluemel [41] took up the wedge test again. Bluemel used big diameter rollers to minimize friction and wear at the sheet edges (Fig. 4a), but both authors used the wedge test to investigate maximum drawing ratios but without dedicated studies of the frictional behaviour. In contrast, Kawai et al. developed a complex apparatus to separate friction forces from forming forces and

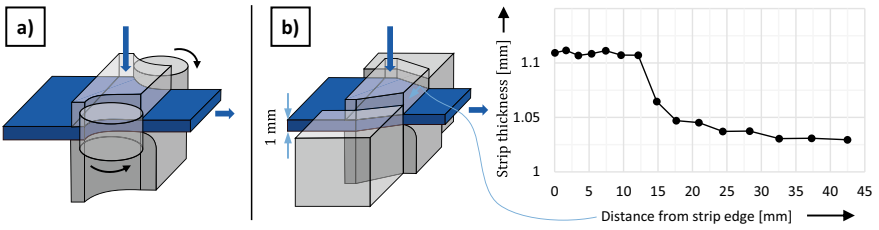

Fig. 4 Wedge drawing test: **a** Test principle from Bluemel (cf. [41]); **b** Numerical investigation of the sheet thickness distribution from Recklin (cf. [21]). (Color figure online)

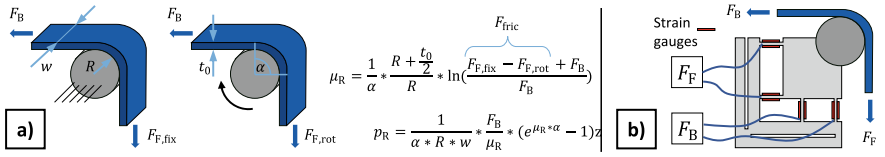

Fig. 5 **a** Test Principle of the traditional BUT test (pictures after [51]) and calculation of the friction coefficient μ_R and the mean contact pressure $\bar{p}_R$ at the die radius (cf. [8]); **b** force measuring method in the BUT test (cf. [49, 50]). (Color figure online)

claimed to quantify friction coefficients with high accuracy [42]. However, occurrence of bulging indicates that homogeneous distribution of contact pressure is not ensured [43]. In the 90 s, Netsch [10] describes problems in the wedge drawing test execution due to canting of thin sheets in the edge region. Miguel et al. developed a wedge test to reproduce deep-drawing-like flange stresses [44] and to investigate formability in pure shear deformation [45]; again, friction coefficients have not been evaluated in the flange region under lateral load. Recklin [21] summarizes the problems in the practical application of the wedge test with severe wear at the sheet edges and tools as well as an uneven sheet thickness distribution (Fig. 4b).

Reviewing all characteristics and disadvantages, the wedge drawing test is not eligible to be a perfect sheet metal forming tribometer. As alternative Recklin et al. [46] used an in-situ method to measure friction in the wedge-shaped blank holder region.[1] They showed that plastic deformation affects sheet roughness and friction in the blank holder region. Although they determined friction coefficients it was not possible to ensure a homogeneous contact pressure distribution.

7 Bending Under Tension (BUT Test)

The BUT test was introduced by Littlewood and Wallace [48]. They investigated friction coefficients dependent on lubricant viscosity and sheet surface roughness. The widely used procedure in the BUT test consists of two successive tests: Drawing both over a rotating cylindrical pin and a fixed cylindrical pin [36] (Fig. 5a). The difference in the front pulling forces $F_{F,fix}$ and $F_{F,rot}$ is assumed to be the friction force F_{fric}. Disadvantages of this dual-test-procedure are stated in the paragraph "Bending with lateral compression". The friction coefficient μ_R at the die radius R is derived from the theory of belt friction using the calculated friction force F_{fric} and the back pulling force F_B (Fig. 5a). A disadvantage of this approach is the assumption that the sheet material behaves as a membrane without resistance to bending [11] which simplifies the assumed contact pressure distribution. An approach from Witthueser [8] to investigate the mean contact pressure $\bar{p}_R$ is also shown in Fig. 5a.

[1] A similar in-situ measurement of friction in the blank holder region was conducted previously by Kasuga et al. [47].

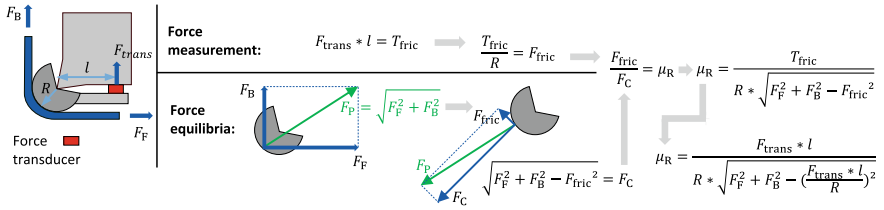

Fig. 6 Test principle of the integrative BUT test after Sniekers and calculation of the friction coefficient μ_R at the die radius (cf. [Sni96]), T_{fric} = friction torque at the die radius, F_{fric} = friction force tangential to the die radius. (Color figure online)

Advancements in the measurement of the front and back forces were achieved by Kernovsky and Weinmann [49, 50]. Strain gauges on the horizontal webs measure vertical forces and strain gauges on the vertical webs measure horizontal forces (Fig. 5b).

A different so-called integrative approach to investigate friction coefficients is presented by Sniekers [11]. He uses a BUT test with integrated force measurement to measure frictional load F_{trans} (cf. Figure 6). The calculation of the friction coefficient μ_R requires the determination of a contact force F_C by force equilibria. Additionally the friction force F_{fric} tangential to the die radius R is derived from the friction torque T_{fric}. Sniekers [11] compares the integrative approach with the belt friction approach in a numerical validation and concludes that the results from the integrative approach are superior to those of the belt friction approach. A big advantage of the integrative approach is the investigation of friction coefficients in a single experiment.

Another single-experiment BUT test was developed by Andreasen et al. [51]. Their approach uses the force measurement from Fig. 5b and a torque transducer in combination with a cylindrical tool pin (Fig. 7). The derivation of the friction stress τ and the mean surface pressure $\bar{p}$ is described by Andreasen et al. [51] and Sulonen et al. [52].

When reviewing the BUT test, it is noticeable that the calculation procedures to quantify the friction coefficients are relatively complicated (compared to the flat die test from a following paragraph). Additionally, the investigation of the mean normal pressure differs from author to author (cf. Figs 5a and 7) or is not made

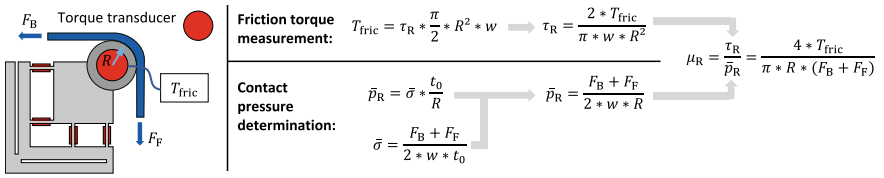

Fig. 7 Test principle of the BUT test after Andreasen (cf. [51, 52]) and calculation of the friction coefficient μ_R at the die radius, $\bar{\sigma}$ = mean tensile stress in the strip, $\bar{p}_R$ = mean contact pressure at the die radius, w = strip width, t_0 = initial strip thickness, τ_R = friction stress at the die radius. (Color figure online)

at all (cf. Fig. 6). Haruff et al. performed a mathematical sensitivity analysis of the calculation procedures in the traditional BUT test. Taking into account the uncertainty in force and geometrical measurements, they ascribe an inaccuracy of $+-0.01$ to the evaluated friction coefficients [53]. However, their investigations do not question the use of the belt friction theory and inhomogeneous conditions in general.

A BUT test procedure that differs from the previous ones is presented by Wenzloff et al. [54]. They use a linearly increasing back force in combination with normalized force values (normalized via dividing measured forces with the strip tensile yield load) to calculate friction coefficients. This approach assumes that the friction coefficient is independent of the contact pressure. According to the author of this paper, this is an unacceptable assumption (cf. [5]) and therefore the test method is not described here in detail.

All the above-mentioned BUT test setups have in common that contact pressure can be adjusted via the back force. Alternatively, contact pressure can be adjusted via changing the die radius, though changing the die radius also changes the contact length [51] and thus the lubrication regime. Speaking of contact pressure: One major concern of the BUT test is inhomogeneous pressure distribution [10, 11]. Netsch found that the degree of homogeneity depends on the bending angle, the die radius, and to a lesser extent on the friction coefficient. He recommends performing BUT tests at a 90° angle and with a die radius of at least 10 mm to achieve acceptable homogenity [10]. Sniekers, however, attributes a much worse contact pressure homogeneity to the BUT test [11], while Witthueser [8] is more confident in a homogeneous distribution. Though, Witthueser's analytical verification is based on the belt friction approach (no bending resistance) and still ascertains a deviation of 9.5% between mean- and calculated local surface pressure.

In further investigations of the BUT test Hortig states that contact pressure distribution at the drawing radius varies depending on whether a back pulling force is applied as a pure tensile force or by a blank holder [55]. Woska developed a variant of the BUT test with a flat blank holder [56] while Reissner used a tensile force in combination with two rollers to reproduce realistic contact pressure distribution [57]. Compared to the traditional BUT test, the tests by Reissner and Woska are more accurate in simulating contact pressure distribution of real forming processes but extraction of friction coefficients is more difficult [22]. Furthermore, contact pressures are highly inhomogeneous over the die radius compared to the traditional BUT test [12, 55].

All in all, the BUT test enables the investigation of average friction coefficients at the die radius, but it has disadvantages in homogeneous contact pressure distribution. Furthermore, it is unfavourable that contact pressure cannot be adjusted directly by a dedicated actuator. The average contact pressure is limited by the yield strength of the strip [10, 11]. The strip drawing test with flat dies, depending on its version, can address these disadvantages and is reviewed in the following paragraph.

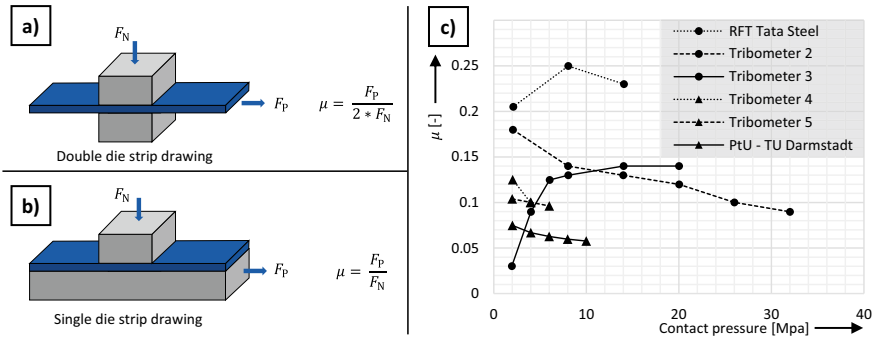

Fig. 8 **a**, **b** Test principles of the strip drawing test with flat dies; **c** round robin test of seven flat die strip drawing tests (from [28] after [59], F_p = pulling force, F_N = normal force, μ = friction coefficient between strip and die(s). (Color figure online)

8 Strip Drawing with Flat Dies (FD Test)

One can assume that the FD-test is the most basic and straightforward sheet metal forming tribometer from Fig. 2. Two basic variants of the FD test are shown in Fig. 8a and b. This depiction emphasizes the simplicity of the test method, especially the derivation of friction coefficients. Still, results are transferable to actual forming processes [58]. Parameters like contact size, contact pressure, drawing speed, tool surface configuration, and drawing length can be adjusted easily and directly. However, in-depth analyses show that a meticulous test stand design is key for reliable tribological investigations with the FD test [13]. Even recently developed FD tests reveal challenges in providing consistent results [18]. A round robin test of seven different FD tribometers in 2013 shows a large scatter of the investigated friction coefficients (Fig. 8c). Possible reasons for such a large scatter are reviewed in the following paragraphs. Most of the considerations and some of the design principles can be transferred to the design process of all kinds of tribometers.

Early tribological investigations with the FD test were performed by Wojtowicz in the 1950s [60]. Wojtowicz investigated several lubricants with different sheet materials and quantitatively described the influence of lubricant viscosity to friction coefficients. His test apparatus worked according to the double die principle (Fig. 8a) and was mounted on a tensile testing machine which provided the pulling force. The normal force on the dies was applied by a screw which was loaded with a torque wrench. Despite the simple test setup, friction coefficients were within 5% of the mean value in consecutive tests.

A short review of design-based limitations of the FD test was performed by Emmens [13] and is supplemented with possible solutions below. Most of the solutions have already proven to be useful in the strip drawing test of the PtU[2] at the TU Darmstadt, which (in its first version) is described by Frontzek [9] and Netsch [10]

[2]Institute for Production Engineering and Forming Machines.

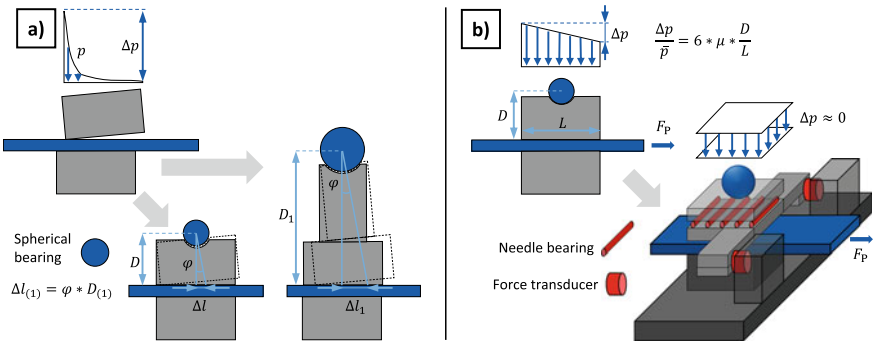

Fig. 9 **a** Misalignment of the dies in the FD test and compensation with a spherical bearing, **b** possible measuring system for friction forces (equation from [13]), p = contact pressure distribution, $\bar{p}$ = mean contact pressure. (Color figure online)

and has been continuously developed since then. The test stand has good transferability to actual forming processes and thus was used to build the testing guideline of the VDA (Federation of the German Automobile Industry) for prelubes [58, 61].

Misalignment of the dies in the FD test (Fig. 9a) causes uneven contact pressure distribution p [8], which leads to wrong contact pressure-dependent friction coefficients. Severe flaws in test results can be evoked by ploughing of the die edges through the strip material. Misalignment should be less than the roughness depth of the contacting surfaces (e.g., 1 μm), even during elastic deformation of the construction caused by the pulling force [13].

A proven solution is provided by spherical bearings to enable self-alignment of the dies (Fig. 9a). When using spherical bearings, it is worthwhile to arrange them as close as possible to the sheet surface in order to reduce the movement of the dies Δl during the aligning process. In other words, the distance D should be minimized without negatively affecting the stiffness of the device. Additionally, the deviation of the contact pressure distribution Δp decreases with decreasing D and increasing die length L (Fig. 9b). To minimize Δp even further, it is favourable to support the dies on the level of the sheet, where the friction force occurs. Thus a tilting of the dies caused by the friction force is avoided. In combination with a linear bearing, the die support can be used as a friction force measuring system (Fig. 9b).

Figure 10a shows the basic influence of the thickness of the dies on the contact pressure distribution. In general, the whole construction of a tribometer should be as stiff as possible. Besides positive effects on uniform contact pressure distribution, high stiffness reduces the appearance of stick slip effects [13]. Especially the design of spring-loaded elements should be done with great care considering possible oscillation effects (cf. [18]). The limitation of the maximum examinable mean contact pressure $\bar{p}_{\max}$ in the double die FD test is shown in Fig. 10b. Possible solutions to increase $\bar{p}_{\max}$ are both the single-sided FD test and the use of two or more stacked strips in the double die FD test (Fig. 10b). However, due to different tension stresses in the strips, both solutions represent a greater abstraction of sheet forming

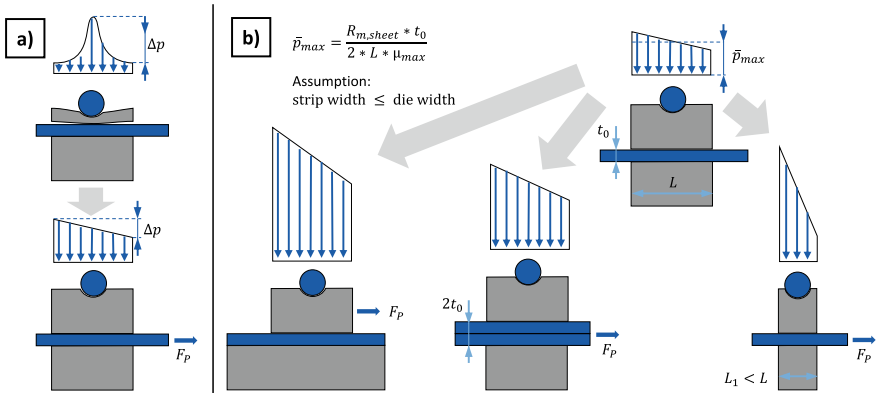

Fig. 10 **a** Effect of the die thickness in the FD test; **b** possibilities to raise the maximum mean contact pressure $\bar{p}_{max}$ in the FD test, L-R single-sided FD test, FD test with stacked strips, FD test with smaller dies. $R_{m,sheet}$ = sheet tensile strength, μ_{max} = maximum friction coefficient. (Color figure online)

processes than the double die FD test with a single strip. Another possibility to increase maximum contact pressure is using smaller dies, though independent investigations from several authors on different FD tribometers show that die size affects results from the FD test [10, 13, 20, 62]. The authors conclude that friction coefficients increase with decreasing die size (only under lubricated conditions [20]). However, Emmens and Netsch do not agree on whether die width or die length is the more pronounced factor of influence. Recklin et al. [62] use an analytical model to describe die size dependent lubricant behaviour in the FD test. The model was validated by measuring the lubricant amount on the dies after the FD experiments. In their investigation, smaller dies lead to increased volume flow and squeezing of lubricant out of the contact zone. Choosing the die size for a FD tribometer should be under consideration of the real forming process. It is important to keep in mind that smaller dies (especially dies with shorter length L or L_1 tend to cause tilting and uneven contact pressure distribution (Fig. 9b and Fig. 10b).

All in all, the FD test makes it possible, like no other sheet metal forming tribometer, to set parameters separately and to ensure homogeneous and stationary conditions. However, despite its apparent simplicity, a thorough dimensioning is necessary. Since one can assume that not every FD test is well designed, it is no surprise that in some publications transferability is rated rather low [22].

9 Conclusion

The search for the perfect sheet metal forming tribometer gathered pace in the mid-twentieth century. Since then, two test methods, namely, the bending under tension

Fig. 11 Logos of the sponsors of the "RAmP" project, in which a tribometer for aluminium hot forming is further developed. (Color figure online)

test (BUT) and the strip drawing test with flat dies (FD test), have proven to be the most promising candidates, although their transferability is controversially discussed [22, 58, 63]. Much of the difference in opinion about these and other tribometers is assumed to be due to poor tribometer design and sloppy execution of experiments. A quote from 1997 is still valid: "Tribotesting suffers from the problem that a result is always obtained, but its relevance to real situations is open to doubt. […] The design and construction of equipment […] have vital importance." [22]

This statement should be kept in mind when designing and using tribometers of any kind at any time. The aim in the development of the "perfect" sheet metal tribometer should be to reproduce the forming process conditions in the tribometer as precise as possible while ensuring metrological accessibility. This paper mainly summarizes different variants of the BUT test and gives advice for the design of FD tests that can be transferred to other tribometers. Furthermore, an orientation is given which test method fits to which research goal.

Future tribometer developments are aimed at the investigation of forming processes like hot stamping which offer demanding tribological challenges [64, 65]. Especially hot forming die quenching of aluminium requires complex tribometer designs, since non-steady-state temperature profiles add "time" as a new investigation dimension. At the PtU of the TU Darmstadt, an aluminium hot forming tribometer is under development as part of the "RAmP" project. Besides friction coefficients, it is planned to investigate wear phenomena of high strength aluminium alloys. These kinds of investigations complicate the search for the perfect sheet metal forming tribometer which will not be over anytime soon (Fig. 11).

The analyses in this paper were carried out as a part of the "RAmP" project. This project (HA project no. 822/19-142) is financed with funds of LOEWE – Landes-Offensive zur Entwicklung Wissenschaftlich-ökonomischer Exzellenz, Förderlinie 3: KMU-Verbundvorhaben (State Offensive for the Development of Scientific and Economic Excellence).

A Contact and Friction Model for Forming of Galvanized Steel Sheet Based on Fractal Theory

Yao Huang, Leigang Wang, Mingxiao Shi, and Xiang Ma

Abstract Galvanized steel sheets are increasingly used in the automotive industry due to excellent corrosion resistance, sufficient weldability, and formability. During sheet forming of galvanized metals, material failures such as exfoliation and cracking can be found in the zinc coated layers of the sheet under severe friction. Thus, the evaluation of the influences of surface topography, pressure, and lubrication on friction could provide valuable guidance in forming of galvanized metals. A hot-dip galvannealed sheet and a hot-dip galvanized sheet are chosen in this tribology study. The surface topographies of the materials are measured using profile meter and the fractal parameters are calculated using the fractal theory. The contact model between the sheet and the die is established using the real contact area. The friction model concerning the surface topography of galvanized sheet and the pressure is thus formulated. The friction coefficients of the theoretical values are in reasonable agreement with the experimental.

1 Introduction

Galvanized steel sheets are widely used in the automotive industry to make car panels and bodies due to good weldability and formability, excellent corrosion resistance, and superior coating properties [1–3]. Especially the Japanese cars have been mostly using galvanized steel sheets [4]. Their applications in the United States and Europe are constantly increasing as well. Currently, there is increasingly demanding on durability performance of cars by auto consumers. This requires higher quality and superior performance of galvanized sheets, which is calling for more research focusing on the galvanizing process, the surface quality, and friction characteristics during sheet stamping.

The galvanized sheet refers to the sheet made of ordinary cold-rolled sheet coated with a layer of zinc, so that steel corrosion can be prevented and the lifetime of the material can be extended [4]. Galvanized sheets are consisted of three parts: the steel sheet substrate, the buffer layer, and the galvanized layer. With dissimilar mechanical properties in elastic modulus and yield limits of the coated zinc layer to that of the substrate steel, not only the formability of galvanized steel sheets is more difficult, but also the contact and friction between the galvanized steel and the die tool is more complex than seen in forming ordinary cold-rolled steels. The conditions of contact and friction directly influence the surface quality, the springback, and forming limit of galvanized sheets. At present, more finite element-based numerical simulations have been applied to the sheet plastic deformation analysis. To obtain reliable simulation results, it is necessary to employ an accurate contact model and friction model in examining the formability of galvanized steels.

Depending on the galvanizing process, galvanized sheets can mainly be classified as hot galvanized, electro-galvanized, and mechanically galvanized. Among them, most widely used in industries are hot-dip galvanized and electro-galvanized [5]. Hot dip galvanized coating can be made thick, with very good corrosion resistance and formability at low cost. But the uniformity of coating surface might be quite poor, easily creating zinc tumor and other defects. On the other hand, electro-galvanized coating can provide a superior surface quality and a better coating uniformity. However, the coating is relatively thin with a high production cost. With fast technology development of hot-dip galvanizing, it is possible to produce a more homogeneous zinc coating. Thus, the hot-dip galvanizing process has been widely applied to make galvanized sheets for automotive industry. In this study, two different hot-galvanized coated sheets were chosen for tribology study, i.e., a hot-dip galvannealed sheet and a hot-dip galvanized sheet.

Any friction pair surface is rough at micro-scale. This surface feature has a significant impact on the phenomena such as micro-contact, friction, abrasion, thermal conductivity, and lubrication [6, 7]. As a result, research on the influences of parameters of rough surfaces in tribology is always of immense importance. During the earliest study, Hertz elastic contact theory was used in the contact surface to study a single point contact behavior. Hertz then simplified the contact surface asperities into two elastic spheres contact problem, thus solving the problem of the distribution

of pressure after the compression. Hertz contact model is by far the most classical contact mechanics model, up to now still being used to analyze the two surfaces contact. An elastic-plastic contact model was established in 1954 by introducing the statistical theory [8]. Another classical elastic contact model was further developed by including statistical theory and standard contact mechanics [9]. Their study showed that the actual contact area and the number of asperities were closely linked to the density distribution function of profile height of the contact surface. The applications of these models, however, are limited by the resolution of the measuring instruments and the sample length, as well as uncertainty [10, 11]. Until 1990s, a modified Weierstrass fractal function was introduced and the fractal contact model, i.e., Majumdar-Bhushan or M-B model was established, in which the deformation properties of the contact surface could be determined with a more proper relationship between the real contact area and the load [12].

With the development of the fractal theory in tribology, fractal parameters have been widely used in characterization of rough surface topography and establishment of contact model with self-similarity and scale invariance. A complicated contact model of fractal rough surfaces was developed later [13]. The results showed that the relationship between the contact load and the real contact area was linear. The plastic deformation region decreased, and the contact stiffness increased as the contact area increased. Another modified elastic-plastic contact model with a single fractal asperity was established [14]. The revised model showed that as the load and contact area increased, a transition from elastic to plastic contact mode took place. Furthermore, a fractal contact model was developed based on base length considering asperity deformation properties, fractal theory, and friction effect [15]. The relationship between the fractal dimension, contact force, and real contact area was studied as well by using numerical simulation analysis.

In this study, the surface topography of the galvanized sheet was measured by using optical profile meter. Based on the fractal theory, the fractal parameters were calculated using MATLAB. The real contact between the galvanized sheet and the die was then simplified in order to establish a fractal contact model. Eventually, the friction model was developed and experimentally verified.

2 Surface Topographies and Fractal Features of Galvanized Sheets

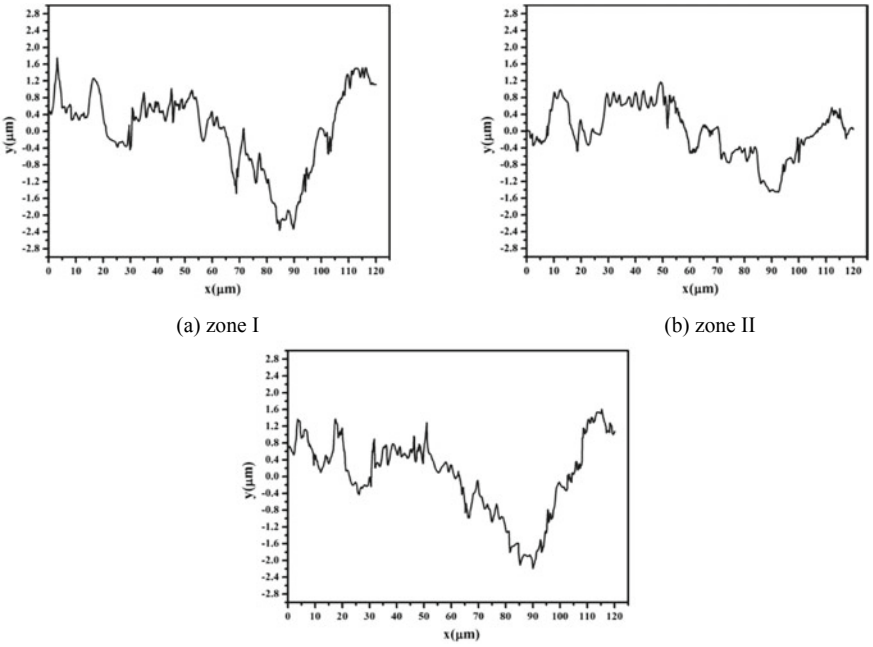
2.1 Materials and Methodology

Two different hot-dip galvanized coated sheets are chosen for tribology study, i.e., a hot-dip galvannealed (GA) sheet and a hot-dip galvanized (GI) sheet, supplied by Shanghai BaoSteel Group Corporation. Their product identifications are given as *SP781BQ* for GA sheet and *HC420/780DPD* + *Z* for GI sheet. The coating material in GA sheet is a zinc-iron alloy, while in GI is pure zinc. This gives a much

shinier surface in GI than in GA sheet. A Veeco Wyko NT1100 optical non-contact profile meter is used to measure the surface topography of the galvanized sheets. A rectangular sheet sample in dimension of $30 \times 100\ mm^2$ is cut from the original large sheet for such purpose. All samples are treated with anhydrous ethanol to keep surface finish. In the sample, three micro areas are selected randomly as the measurement area for plotting of the surface profile curve and determining the surface roughness value, as well as the 3D surface topography.

To study the friction behavior of the galvanized sheet, a sliding friction test under flat die is carried out using a testing device from Shanghai BaoSteel Group Corporation. Each of the contact surface areas of the sheet interfacing with the top and bottom of the flat dies is approximately $2 \times 30\ mm^2$ (more details can be found in Figs. 2.3, 2.4, 2.5, 2.6 and 2.7 of [16]). The material is pulled with a sliding speed of 150 mm/min, under a normal load of 1000 N. The surface roughness values (Ra) of the dies are varied between 0.4 μm, 0.8 μm, and 1.2 μm. Both dried and lubricated frictions are applied, while only the results under dry conditions are reported in this paper.

To reduce the experimental errors, each sample and each measurement are repeated three times. An average value of the measured data is given correspondingly.



2.2 *Surface Profiles and 3D Topographies of Galvanized Sheets*

The typical surface profile curves of the GI and GA sheets from the three randomly chosen regions on each sample sheet are shown in Figs. 1 and 2, respectively. This clearly shows that a larger fluctuation of surface roughness is seen in the GA sheet than in the GI sheet. The surface roughness values (Ra) of the GA sheet and the GI sheet are measured as 0.889 μm and 0.525 μm, respectively, based on averaging the measured data. This difference might be due to the fact that in the GA sheet, the zinc layer is formed with hard and brittle Zn-Fe alloy; while in the GI sheet, the coating is composed of a relatively soft zinc. Thus, the surface of the GA sheet is much rougher than the GI sheet.

Figure 3 shows the three-dimensional topographies of the galvanized steels. Clearly more uneven asperities are found in the GA sheet surface, while the hot-dip pure zinc coated surface is much smoother.

2.3 *Fractal Characterization of Galvanized Sheets*

In Majumdar-Bhushan model [12], two rough contact surfaces can be simplified by an equivalent rough surface and an ideal rigid flat surface. The height of the asperity on the rough surface is defined as

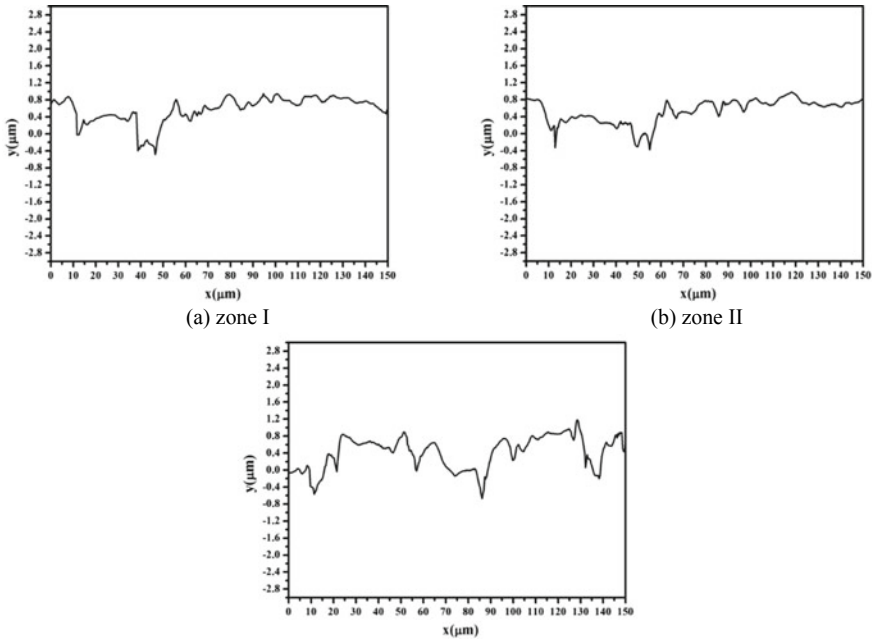
(a) zone I (b) zone II

(c) zone III

Fig. 1 The surface profiles of GA sheet (SP781BQ) at three zones

$$\delta = G^{(D-1)} a^{\left(\frac{2-D}{2}\right)} \tag{1}$$

where D is fractal dimension, G is the fractal roughness parameter, and a is the contact area.

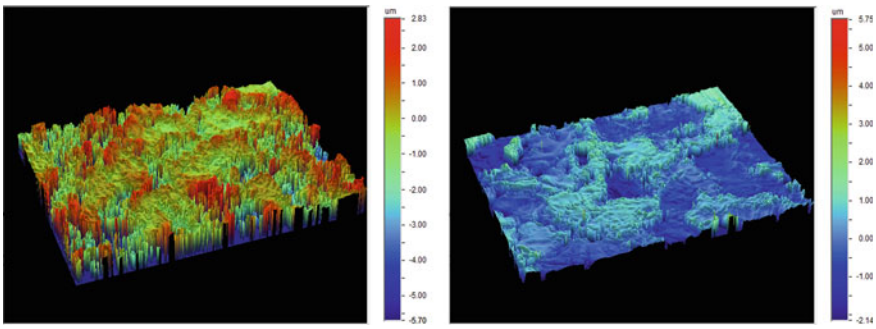


The surface profile curves are used to assess if the fractal characteristics is found in the galvanized sheets, i.e., at the level $1 < D < 2$ when the surfaces have fractal features. Thus the group of the points in the surface profile curves in Figs. 1 and 2 are processed and computed using the root-mean-square method [17].

The calculations are carried out in the MATLAB platform using the relation below:

$$\sigma(\tau) = C\tau^{(2-D)} \tag{2}$$

where the correlation length τ is similar to the discrete values of the displacement variable x in Figs. 1 and 2; $\sigma(t)$ is corresponding to the Weierstrass-Majumdar fractal function [12]; and C is a constant.

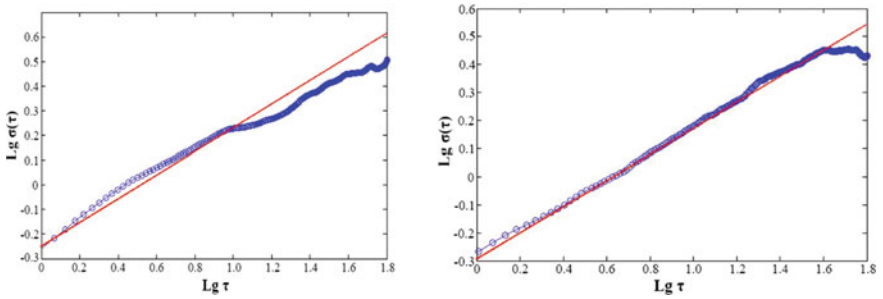


The double logarithm charts of the covariance of the measurement $\sigma(t)$ versus the correlation length τ are given in Fig. 4. It can be seen that the logarithm of root-mean-square measurement is in near linear relation with the logarithm of correlation length. Denoted α as the slope of this linear line, the fractal dimension D is thus determined by [17]:

(a) zone I (b) zone II

(c) zone III

Fig. 2 The surface profiles of GI sheet (HC420/780DPD + Z) at three zones



(a) GA sheet (b) GI sheet

Fig. 3 Initial 3D surface topographies of galvanized sheets. (Color figure online)

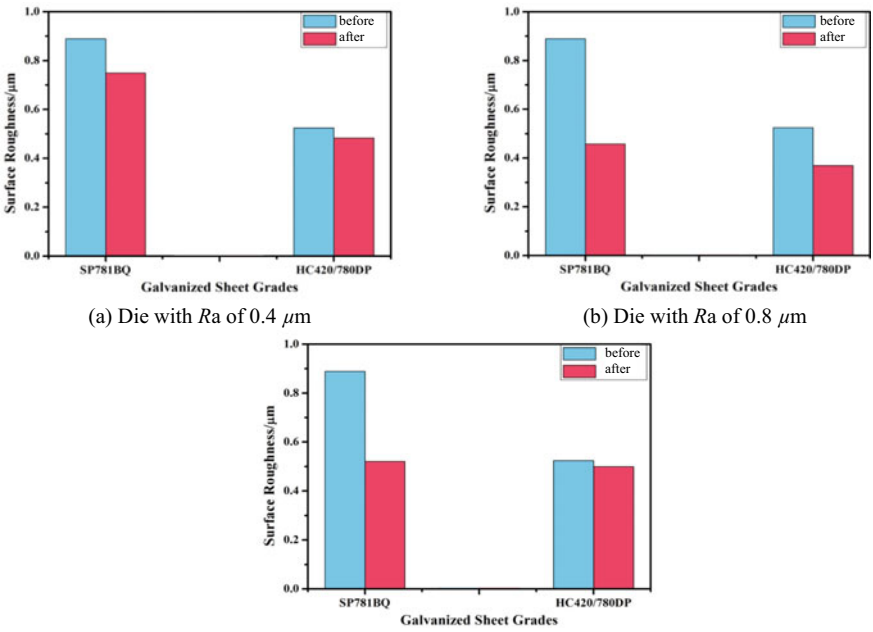
$$D = 2 - \alpha \tag{3}$$

The calculated fractal dimension and fractal roughness parameter based on Figs. 1 and 2 are given in Table 1. It can be seen that both of the fractal dimensions meet the range $1 < D < 2$. Hence, the surfaces of galvanized sheets have fractal characteristics. The average fractal dimension seen in the GA sheet is smaller than in the GI sheet,

(a) GA sheet (b) GI sheet

Fig. 4 The double logarithm chart of galvanized sheets. (Color figure online)

Table 1 The fractal parameters of galvanized steels



Types of sheet	Fractal dimension D	Fractal roughness parameter G (μm)	Average of D	Average of G (μm)
GA (SP781BQ)	1.522	0.227	1.52	0.23
	1.528	0.229		
	1.497	0.232		
GI (HC420/780DPD+)	1.597	0.114	1.6	0.11
	1.604	0.111		
	1.601	0.112		

while the fractal roughness parameter is obviously larger in the coarse surface of the GA sheet. This may be due to that a smooth surface is generally more delicate, with a deep self-similar fine structure which gives a higher fractal dimension.

2.4 Fractal Change of Galvanized Sheets After Friction

After the sliding friction experiments under a normal load of 1000 N, similar measurements of the surface profile curves and topographies are made using Wyko NT1100 optical profiler meter. The fractal dimension parameter can thus be calculated as before the friction tests. Figure 5 compares the changes in the surface roughness of the sheets before and after friction test. The surface roughness value is less than that before the test. And with the die surface roughness increasing, the surface roughness of the sheets reduces first before increasing again. This is because that the high peaks are worn out after friction.

The roughness of the GA sheet (*SP781BQ*) decreases more than that of the GI sheet (*HC420/780DP*), as seen from Figs. 5 and 6, shows that the fractal dimension of galvanized sheets after friction is greater than that before tests.

(a) Die with *R*a of 0.4 μm

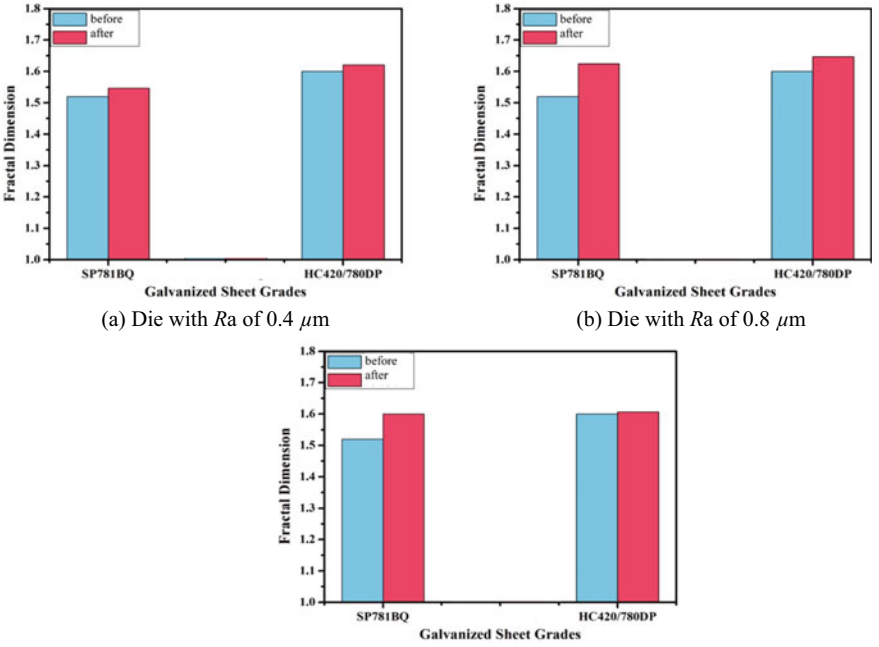
(b) Die with *R*a of 0.8 μm

(c) Die with *R*a of 1.2 μm

Fig. 5 Changed roughness of galvanized sheets before and after friction test. (Color figure online)

3 Fractal Contact Models of Galvanized Sheets

When the largest contact area a_l is larger than critical contact area a_c (i.e., plastic deformation occurs), Majumdar-Bhushan model [12] gives a relation between the real contact area and the pressure or the total contact load P as



(a) If $D \neq 1.5$:

$$P^* = \frac{4}{3}\sqrt{\pi}\left(G^*\right)^{(D-1)} g_1(D)\left(A_r^*\right)^{\frac{D}{2}} \left\{\left[\left(\frac{D-2}{D}\right)A_r^*\right]^{\frac{3-2D}{2}} - \left(a_c^*\right)^{\frac{3-2D}{2}}\right\} + K\phi g_2(D)\left(A_r^*\right)^{\frac{D}{2}}\left(a_c^*\right)^{\frac{2-D}{2}} \tag{4}$$

(b) If $D = 1.5$:

$$P^* = \sqrt{\pi G^*}\left(\frac{A_r^*}{3}\right)^{\frac{3}{4}} ln\left(\frac{A_r^*}{3a_c^*}\right) + \frac{3}{4}K\phi\left(\frac{A_r^*}{3}\right)^{\frac{3}{4}}\left(a_c^*\right)^{\frac{1}{4}} \tag{5}$$

In Eqs. (4) and (5), the parameters are non-dimensional, i.e.,

(a) Die with *R*a of 0.4 μm

(b) Die with *R*a of 0.8 μm

(c) Die with *R*a of 1.2 μm

Fig. 6 Changed fractal dimension of galvanized sheets before and after friction test. (Color figure online)

$$P^* = \frac{P}{A_a E};\ G^* = \frac{G}{\sqrt{A_a}};\ A_r^* = \frac{A_r}{A_a};\ a_c^* = \frac{a_c}{A_a} = \frac{(G^*)^2}{\left(\frac{K\phi}{2}\right)^{\frac{2}{D-1}}};$$

$$g_1(D) = \frac{D}{3-2D}\left(\frac{D-2}{D}\right)^{\frac{D}{2}};\ g_2(D) = \left(\frac{2-D}{D}\right)^2 \tag{6}$$

where A_a is the nominal contact area, E is the equivalent Hertzian elastic modulus; K is defined as a factor related to the hardness H as well as yield strength σ_y, namely, $K = H/\sigma_y$; ϕ is a factor related to the yield strength σ_y and the elastic modulus E by $\phi = \frac{\sigma_y}{E}$; and A_r is the total real contact area.

Similarly, if $a_1 < a_c$, the contact load is given as

$$P^* = K\phi A_r^* \tag{7}$$

3.1 Contact Model of Hot-Dip Galvannealed (GA) Sheet

The mechanical properties and the surface morphology parameters of the GA sheet can be determined as follows.

For mechanical properties, the collective Young's modules is described as

$$E = \left(\frac{1-\upsilon_2^2}{E_1} + \frac{1-\upsilon_2^2}{E_2}\right)^{-1} \tag{8}$$

where E_1 and υ_1 are Young's modules and Poisson's ratio of the galvanized surface (the values are 0.27 and 130 GPa, respectively); and E_2 and υ_2 are Young's modules and Poisson's ratio of the die surface (the values are 0.3 and 200 GPa, respectively). Inserting these values into Eq. (8) gives Young's modules of 85.6 GPa. Please be noted that the values of the basic material properties (such as Youngs's modules and Poisson's ratio) are provided by the supplier, i.e., Shanghai BaoSteel Group Corporation.

The parameter of material performance is given as

$$K\phi = \frac{H}{E} = 0.022$$

The surface morphology parameters can be determined as follows.

The fractal dimension D is 1.52, the fractal roughness parameter G is 0.23 μm, and the nominal contact area $A_a = 2 \times 30$ mm^2.

Based on the mechanical properties and surface morphology parameters of the GA sheet, the relevant parameters can be calculated using the equations above as

$$G^* = \frac{G}{\sqrt{A_a}} = \frac{0.23 \times 10^{-3}}{\sqrt{2 \times 30}} = 0.0000296$$

$$P^* = \frac{P}{A_a E} = \frac{P}{2 \times 30 \times 85605} = \frac{P}{5136300}$$

$$a_c^* = \frac{a_c}{A_a} = \frac{G^{*2}}{\left(K\phi/2\right)^{2/(D-1)}} = 0.03$$

$$g_1(D) = \frac{D}{3-2D}\left(\frac{D-2}{D}\right)^{\frac{D}{2}} = -15.82$$

$$g_2(D) = \left(\frac{2-D}{D}\right)^{\frac{2-D}{2}} = 0.7583$$

After substituting above parameters into Eq. (4), the relation between the real contact area A_r^* and the load P can be obtained in the following form:

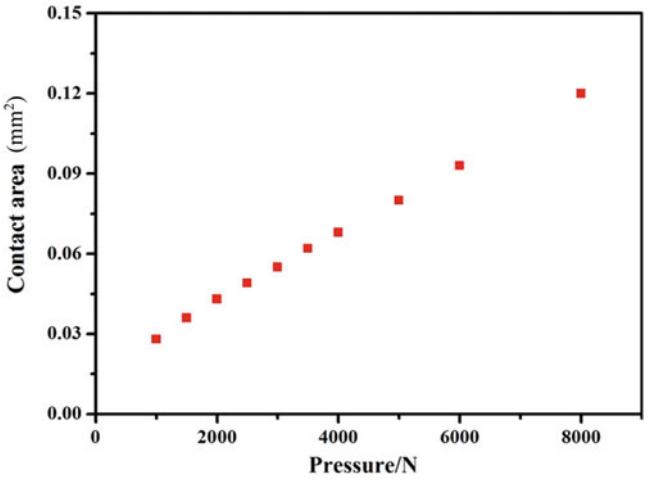


Fig. 7 Relation of real contact area and pressure between the galvanized sheet and the die (GA sheet). (Color figure online)

$$P = 948202A_r^{*0.76} - 869061A_r^{*0.74} \tag{9}$$

The relation between the real contact area and the pressure is shown in Fig. 7, from which it can be concluded that the real contact area rises as the pressure increases.

3.2 Contact Model of Hot-Dip Galvanized (GI) Sheet

The collective Young's modules is 85.6 GPa, same as the GA sheet.

With a different hardness, the parameters of material performance are $K\phi = 0.013$.

Considering that the fractal dimension D is 1.60, the fractal roughness parameter G is 0.11 μm, and the nominal contact area $A_a = 2 \times 30$ mm^2, the other parameters can be calculated as

$$G^* = \frac{G}{\sqrt{A_a}} = \frac{0.11 \times 10^{-3}}{\sqrt{2 \times 30}} = 0.0000142$$

$$P^* = \frac{P}{A_a E} = \frac{P}{2 \times 30 \times 85605} = \frac{P}{5136300}$$

$$a_c^* = \frac{a_c}{A_a} = \frac{G^{*2}}{(K\phi/2)^{2/(D-1)}} = 0.00393$$

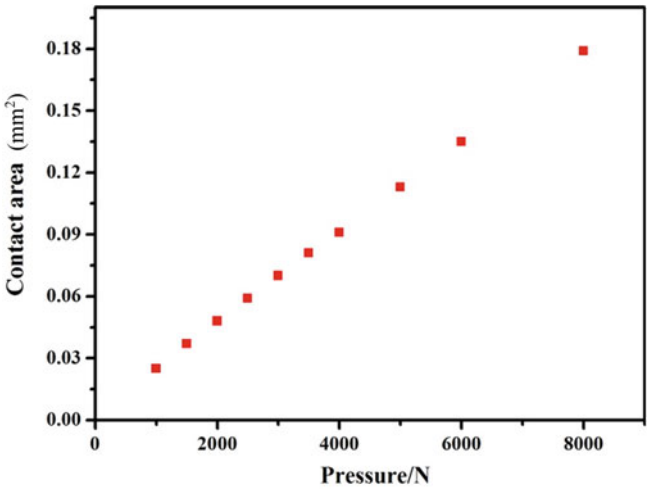

Fig. 8 Relation of real contact area and pressure between the galvanized sheet and the die (GI sheet). (Color figure online)

$$g_1(D) = \frac{D}{3-2D}\left(\frac{2-D}{D}\right)^{\frac{D}{2}} = -2.6391$$

$$g_2(D) = \left(\frac{2-D}{D}\right)^{\frac{2-D}{2}} = 0.75785$$

After above parameters are substituted into Eq. (4), the relation between real contact area A_r^* and the load P can be given in the following form:

$$P = 84460A_r^{*0.8} - 4531A_r^{*0.7} \tag{10}$$

Similarly, the relation between the real contact area and the pressure is shown in Fig. 8 for this GI sheet.

4 Friction Models of Galvanized Sheets

According to the theory of adhesive friction, the friction can be described as

$$F = F_a + F_e = A_r\tau_b + F_e \tag{11}$$

where F is the friction resistance, F_a is the adhesion force, and F_e is the plowing force, A_r is the real contact area, and τ_b is the shear strength of softer material. With

a relatively smooth material surface and a moderate contact pressure, the contribution of plowing force to friction could be neglected. In consequence, the simplified formula of friction coefficient μ is given as

$$\mu = \frac{F}{P} = \frac{A_r \tau_b}{P} \tag{12}$$

4.1 Friction Model of the Hot-Dip Galvannealed (GA) Sheet

When the shear strength of zinc coating is 113 MPa, the friction coefficient according to Eq. (11) is given as

$$\mu = \frac{\tau_b A_r}{P} = \frac{113 A_r}{P} \tag{13}$$

4.2 Friction Model of the Hot-Dip Galvanized (GI) Sheet

When the shear strength of HC420/780DPD + Z zinc coating is 90 MPa, the friction coefficient is

$$\mu = \frac{\tau_b A_r}{P} = \frac{90 A_r}{P} \tag{14}$$

The relation between friction coefficient and positive pressure is shown in Fig. 9, which indicates that the friction coefficient decreases with the increasing pressure. Moreover, the friction coefficient of hot-dip galvannealed sheet shows a massive decline at first. Then tendency of decline becomes slow as the pressure reaches 3000 N. By contrast, the friction coefficient of hot-dip galvanized sheet is slightly decreased.

4.3 Experimental Verification of Friction Model

Flat plate sliding friction experiment is conducted to measure friction coefficients of galvanized sheets under different pressures. The friction coefficients are calculated using the friction model and details of the experiment are shown in Tables 2 and 3.

It can be seen from Tables 2 and 3, friction coefficients of theoretical values are close to experimental values, and the error between them is less than 10%. Due to the ignored plowing force, theoretical values are slightly smaller than experimental

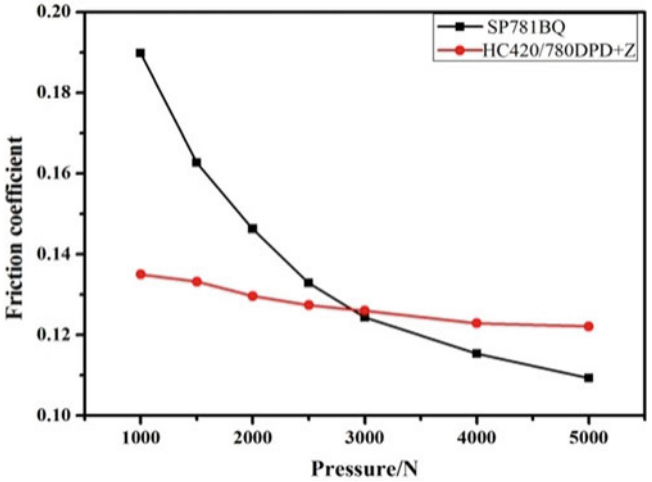

Fig. 9 Friction coefficient calculated by friction model under different pressures. (Color figure online)

Table 2 Friction coefficients of theoretical and experimental value (for SP781BQ sheet)

Pressure/N	1000	1500	2000
Theoretical value	0.1898	0.1627	0.1463
Experimental value	0.2055	0.1793	0.1584
Error	7.6%	9.2%	7.6%

Table 3 Friction coefficients of theoretical and experimental value (for HC420/780DPD + Z sheet)

Pressure/N	1000	1500	2000
Theoretical value	0.135	0.1332	0.1296
Experimental value	0.1501	0.1439	0.1375
Error	10%	7.4%	5.7%

values. It should be noted that in the experiment with a medium normal force, no full adhesion is expected. However, the theoretical model assumes a full adhesion for simplicity.

5 Conclusions

The following conclusions can be drawn from the study:

(1) It has been shown that the galvanized sheet has fractal characteristics. The fractal dimension and fractal roughness parameter for the SP781BQ hot-dip galvannealed sheet are 1.52 and 0.23 μm, respectively. Likewise, the fractal

dimension and the fractal roughness parameter for the HC420/780DPD + Z hot-dip galvanized sheet are 1.6 and 0.11 μm accordingly.

(2) Based on the fractal theory, the elastic-plastic contact model has been developed and the relation between real contact area and pressure has been obtained. The model shows that the real contact area rises with the increase of contact pressure.

(3) Friction model is established based on the fractal contact model. Experimental verification is carried out using the flat plate sliding friction experiment. The results indicate that the error between theoretical and experimental friction coefficients is within 10%. Thus, the friction model developed is relatively accurate.

On the Characterization of Fracture Loci in Thin-Walled Tube Forming

J. P. Magrinho, M. B. Silva, and P. A. F. Martins

Abstract This paper is focused on the formability limits by fracture of thin-walled tubes. It provides, for the first time ever, the fracture forming limit lines associated with crack opening by tension (mode I), by in-plane shear (mode II) and by mixed-mode consisting of crack opening by modes I and II of fracture mechanics. This is accomplished by an experimental methodology that combines digital image correlation (DIC) and determination of gauge length strains in double notched tensile test (DNTT) specimens, staggered DNTT specimens and shear test specimens. Results are plotted in principal strain space and the crack opening modes are confirmed by fractography analysis performed with a scanning electron microscope (SEM). DNTT specimens are also used to determine fracture toughness in specimens that failed by tension. Results show that the use of DNTT, staggered DNTT and shear tests allow obtaining the strain loading paths and fracture loci across a wide range of forming conditions, ranging from plane strain to pure shear. The fracture forming limit (FFL) line, the shear fracture forming limit (SFFL) line and the transition region between these two lines are similar to those recently published for sheet and strip materials, and their use is of paramount importance for the design and optimization of tube forming processes.

1 Introduction

Growing demand for the design and fabrication of high-strength lightweight structures is pushing forward the utilization of thin-walled tubes in transportation vehicles, buildings and design appliances, among other applications. This trend combined with the development of new tube forming processes has been driving the need to perform accurate characterization and determination of the formability limits by necking and fracture in thin-walled tubes [1].

In recent years, several experiment-based investigations have been carried out to determine the forming limits of thin-walled tubes by means of tube bulging [2, 3] and tube hydroforming [4, 5]. However, none of these studies analyzed the crack opening modes associated with the formability limits.

In contrast, the formability limits in sheet metal forming are nowadays well-understood. Failure by necking in principal strain space is characterized by the forming limit curve (FLC), which was originally proposed by Keeler [6] and Goodwin [7]. Failure by fracture is characterized by the fracture forming limit line (FFL), originally proposed by Embury and Duncan [8] for cracks opening by tension (mode I of fracture mechanics [9]) and by the shear fracture forming limit line (SFFL), recently disclosed by Isik et al. [10] for cracks opening by in-plane shear (mode II of fracture mechanics). The mechanics and physics behind these two fracture lines are comprehensively discussed by Martins et al. [11].

The attempt to extend the methods and procedures that are commonly utilized in sheet metal forming to tube forming leads the authors to recently propose an experimental methodology to obtain the strains at fracture and to determine the critical values of ductile damage by means of tube expansion with rigid dies [12]. In a subsequent work, the authors enhanced their methodology by adding a broader range of testing conditions ranging from pure tension to biaxial stretching. This was done by performing additional experiments in tube expansion with elastomers [13] and allowed determining, for the first time ever, the formability limits of thin-walled tubes by necking and fracture. The resulting FFL was recently confirmed in a numerical and experimental independent investigation focused on the utilization of external inverted tubes as energy absorbers [14].

Despite the above-mentioned advances in the characterization of fracture in thin-walled tubes, the determination of the SFFL (mode II) and of the transition between the FFL and the SFFL (mixed-mode, consisting of crack opening by combination of tension and in-plane shear), is still an open research topic.

Similar to what was previously said about the limited number of research publications on the formability limits by fracture of thin-walled tubes, there are almost no publications connecting fracture toughness and formability testing. In fact, the prevalence is on the determination of fracture toughness in specific applications such as the work of Leitch [15], who analyzed fracture in axially cracked pressure tubes by means of compact fracture toughness test specimens cut out from the tube wall. As a result of this, the number of publications in manufacturing is surprisingly low despite

the importance of fracture toughness [16] and its relationship to fracture loci in principal strain space [17]. This is important because fracture toughness and fracture forming limits are basically two different approaches of the same phenomenon.

Under these circumstances, this paper is focused on thin-walled tubes and has a two-fold objective: (i) to extend the previous methods and procedures developed by the authors [18] for the characterization of the SFFL and the transition between the FFL and the SFFL in principal strain space, and (ii) to propose a new methodology for the determination of the fracture toughness in crack opening by tension (mode I). The first objective made use of new double edge notched tension [19], staggered [20] and shear test specimens [21] with geometries adapted from sheet metal tests and cut-out from the supplied tubes in the longitudinal and transversal directions. The second objective was accomplished by determining the essential work of fracture and made use of double edge notched test specimens cut out and loaded by tension in the longitudinal and transversal tube directions.

2 Experimentation

2.1 Material Characterization

The experimental work was performed on commercial AA6063-T6 aluminum tubes with an outer radius $r_0 = 20$ mm and an average thickness $t_0 = 1.9$ mm. The mechanical properties and flow curve of the material were determined by means of tensile tests along the longitudinal and transversal tube directions. The longitudinal tensile test specimens were prepared in accordance to the ASTM E8/E8M-16 standard [22] and the transversal tensile test specimens were prepared in accordance to a sub-size geometry of the same standard in order to avoid bending effects [23]. Both tests were performed at room temperature in a universal testing machine Instron 5900R.

The longitudinal tensile tests utilized special fixing clamps at the extremities of the specimen to prevent deformation. The transversal tensile test specimens made use of two 'D-shaped blocks' to allow tension in the transverse direction. The specimens were lubricated with polytetrafluoroethylene (teflon®) sheets to reduce friction [13]. The mechanical properties obtained from the tensile tests performed in the longitudinal and transversal directions are summarized in Table 1.

Table 1 Summary of the mechanical properties and constants of Swift's material strain hardening model for the AA6063-T6 aluminum tubes in the longitudinal and transversal directions

Test geometry	Thickness (mm)	σ_Y (MPa)	σ_{UTS} (MPa)	A (%)	r_{avg}	K (MPa)	n	ε_0
TL - Longitudinal	1.90	164.4	204.1	44.10	0.58	300.0	0.125	0.002
TT - Transversal	1.90	163.5	238.2	58.60	1.19	408.5	0.216	0.008

In Table 1, the symbol σ_Y denotes the yield stress, σ_{UTS} is the ultimate tensile strength and A is the elongation at fracture. The anisotropy coefficients ($r = \varepsilon_{width}/\varepsilon_{thickness}$) were directly obtained from the principal strains provided by the digital image correlation system (DIC) for a point located at the center of the tensile specimens. The r_0 and r_{90} coefficients correspond to r_{avg} in the longitudinal (L) and transversal (T) directions, respectively.

The flow curves resulting from the longitudinal and transversal tensile tests were approximated by Swift's material strain hardening model with pre-strain $\tilde{\sigma} = K(\bar{\varepsilon} + \varepsilon_0)^n$. The constants are provided in Table 1.

The formability limits by necking (FLC) and fracture in opening mode I (FFL) were determined by means of tensile tests (TT), expansion with rigid punches (EP), inversion with rigid punches (IP) and bulging with elastomers (BE). Figure 1 shows the results in principal strain space and the light gray dashed lines defined for $\beta = d\varepsilon_2/d\varepsilon_1$ equal to $-1/2$ and 1 are included for reference purposes.

Figure 1a presents the analytical expression of the FFL and the limiting necking ε_1^{*n} and fracture ε_1^{*f} strains in plane strain deformation that resulted from the experiments. Details on the methods and procedures that were utilized to obtain the formability limits and the failure strains are available in previous publications by the authors [13, 14].

2.2 Tube Formability Tests

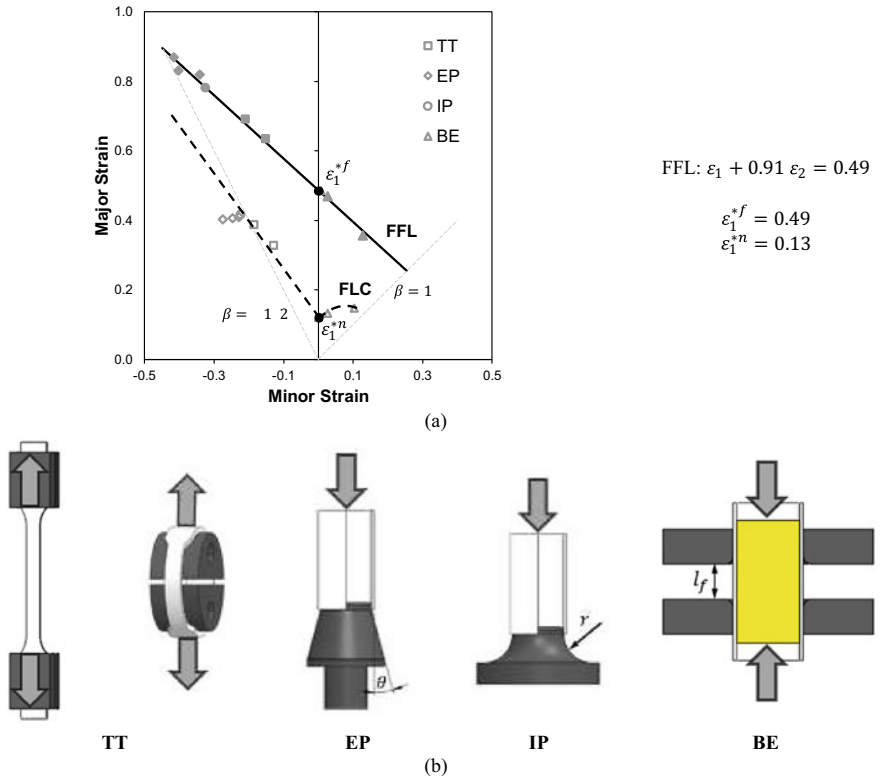
The formability limits of the tube material by fracture were determined by means of double notched tension (DNTT), staggered DNTT and shear tests. The specimens were cut out from the longitudinal (L) and transverse (T) directions of the tubes, and the tests were performed at room temperature with a cross-head speed of 5 mm/min (quasi-static operating conditions) in the same testing machine where the mechanical characterization had been performed.

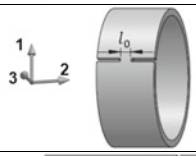
Table 2 summarizes the experimental work plan and includes schematic drawings of the different test specimens with information on the geometries, dimensions and corresponding states of stress and strain.

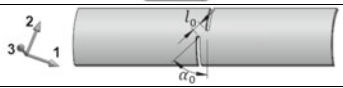
3 Methodology

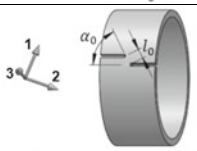
The strain measurements on the fracture surface of the specimens that were needed to characterize the formability limits and to determine fracture toughness of the tube material were obtained by using a digital image correlation (DIC) system from Dantec Dynamics—model Q-400 3D (Fig. 2).

The surfaces of the specimens were sprayed with a stochastic black speckle pattern on a previously painted uniform white background. The specimens were illuminated









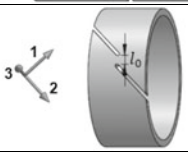


Fig. 1 **a** Formability limits by necking (FLC) and fracture (FFL) of AA6063-T6 aluminum tube in principal strain space obtained from **b** longitudinal and transversal tensile tests (TT), expansion with rigid punches (EP), inversion with rigid punches (IP) and bulging with elastomers (BE) [13, 14]. (Color figure online)

with a spotlight and the DIC system was equipped with 2 cameras with 6 megapixels of resolution and 50.2 mm of focal lenses with an aperture of f/8. The frequency of image acquirement was set to 20 frames per second, and the correlation algorithm was performed with the INSTRA 4D software. A facet size of 13 pixels with a spacing grid of 7 pixels was considered.

3.1 Fracture Strains

The surface strains obtained by DIC near the fracture cannot be considered the fracture strains due to inhomogeneous deformation at the neighborhood of the crack. In other words, the strains provided by DIC are very sensitive to the location of the selected measuring points. As a result of this, the experimental procedure for

Table 2 Experimental work plan with schematic representation of the experimental tube formability tests performed in the aluminum AA6063-T6 tube

Test			Dimensions (mm)	State of Stress	State of Strain
Double Notched Tension Test (DNTT)	L		$l_0 = 5\ to\ 14$	$\sigma_1 > 0$ $\sigma_2 < 0$ $\sigma_3 = 0$	$\varepsilon_1 > 0$ $\varepsilon_2 = 0$ $\varepsilon_3 < 0$
	T		$l_0 = 3\ to\ 7$		
Staggered DNTT	L		$\alpha_0 = 45°\ to\ 80°$ $l_0 = 3\ to\ 7$	$\sigma_1 > -\sigma_2$ $\sigma_3 = 0$	$\varepsilon_1 > -\varepsilon_2$ $\varepsilon_3 < 0$
	T		$\alpha_0 = 45°\ to\ 80°$ $l_0 = 2\ to\ 4$		
Shear Test	L		$l_0 = 2\ to\ 6$	$\sigma_1 = -\sigma_2$ $\sigma_3 = 0$	$\varepsilon_1 = -\varepsilon_2$ $\varepsilon_3 = 0$
	T		$l_0 = 1.5\ to\ 3.5$		

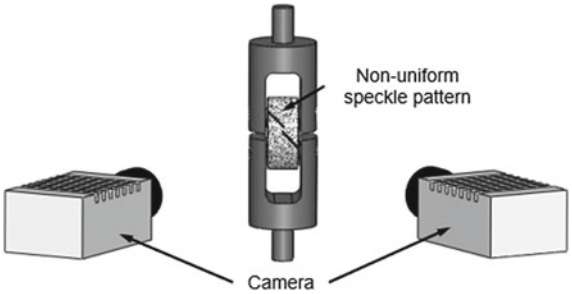

Fig. 2 Schematic representation of the experimental setup utilized by the DIC system for measuring the strains in a transversal shear test

constructing the formability limits by fracture cannot be solely based in DIC and requires additional information of the specimen's thickness at cracking in order to obtain the 'gauge length' strains [13]. For this purpose, individual measurements of thickness t_F were taken along the cracks with a stereomicroscope Mitutoyo TM-505B with a magnification of 30x.

The thickness strain at fracture ε_{tF} was calculated by

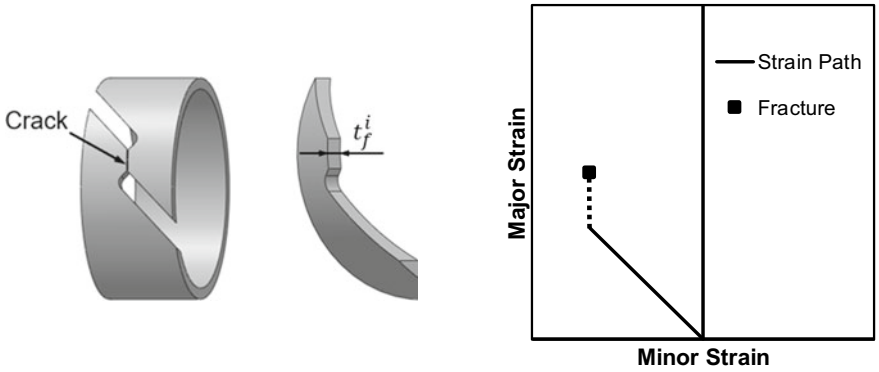

Fig. 3 Schematic representation of the methodology that was utilized to determine the formability limits by fracture. **a** Measuring the thickness along the crack. **b** Fracture strain pair with an indication of the strain loading path (solid line) up to the last measurement obtained by DIC

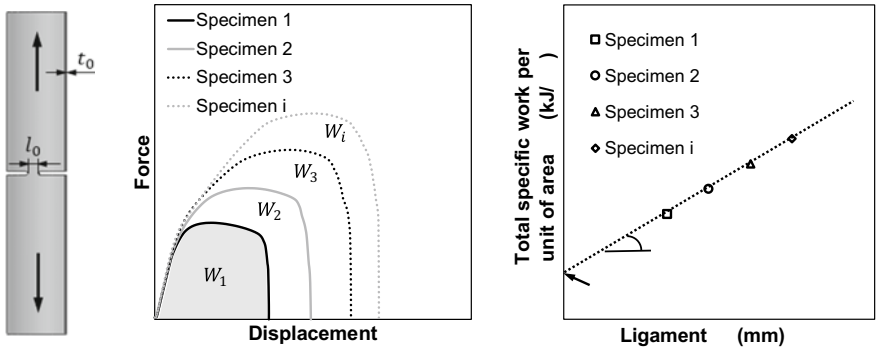
$$\varepsilon_{tF} = ln\left(\frac{t_F}{t_0}\right) \tag{1}$$

where t_0 was the initial thickness and $t_F = \frac{1}{n}\sum_{i=0}^{n} t_F^i$ was the average thickness at the center of the fracture surface of the specimens (Fig. 3a).



The minor strain ε_2 (meridional strain) was assumed to remain constant after the last measurement by DIC, and the major strain ε_1 (circumferential strain) and was obtained by incompressibility under plane strain deformation conditions,

$$\varepsilon_{1F} = -(\varepsilon_{2F} + \varepsilon_{tF}) \tag{2}$$

Figure 3b illustrates the overall procedure that was utilized to plot the fracture strain in principal strain space (refer to the solid square marker).

3.2 Fracture Toughness

The commonly utilized procedure for determining fracture toughness R requires calculating the total work W_T (Fig. 4b), the total specific work per unit of area w_T (Fig. 4c) and the specific essential work of fracture for DNTT specimens with several ligament sizes l_0 (Fig. 4a) [19]. The specific essential work of fracture (also known as fracture toughness, R) is obtained by extrapolating the total specific work per unit of area w_T to the limiting condition where the starting ligament length l_0 is zero, and the work related to plastic deformation is null (Fig. 4c).

(a) (b) (c)

Fig. 4 Schematic representation of the method utilized to determine fracture toughness R. **a** DNTT test specimen. **b** Typical force–displacement evolution for DNTT specimens with different ligaments sizes l_0. **c** Total specific work per unit of area w_T and extrapolation to obtain fracture toughness R

This paper extends, for the first time ever, the above-described methodology to DNTT specimens obtained from the thin-walled tubes in the longitudinal and transversal directions (Table 2).

4 Results and Discussion

4.1 Fracture Limits

Figure 5 presents the formability limits and the corresponding failure strains for the AA6063-T6 aluminum tubes. The formability limits by necking (FLC) and the fracture forming limit by tension (FFL) were retrieved from a previous work of the authors [13].

The strain paths for the DNTT, staggered DNTT and shear test specimens aligned in the longitudinal (L) and transversal (T) directions were obtained by DIC, and the fracture strain pairs were determined in accordance with the procedure that was described in Sect. 3.1.

As shown in the figure, the strain paths and fracture strain pairs of the longitudinal and transversal DNTT and shear test specimens revealed near-plane strain and pure shear deformation conditions, respectively.

The staggered DNTT specimens with different inclination angles α_0 allowed obtaining fracture strains at the transition zone between the FFL and the SFFL. Results also show that the minor fracture strain decreases with the increase of the inclination angle α_0, in good accordance with previous investigations in sheet formability [18].

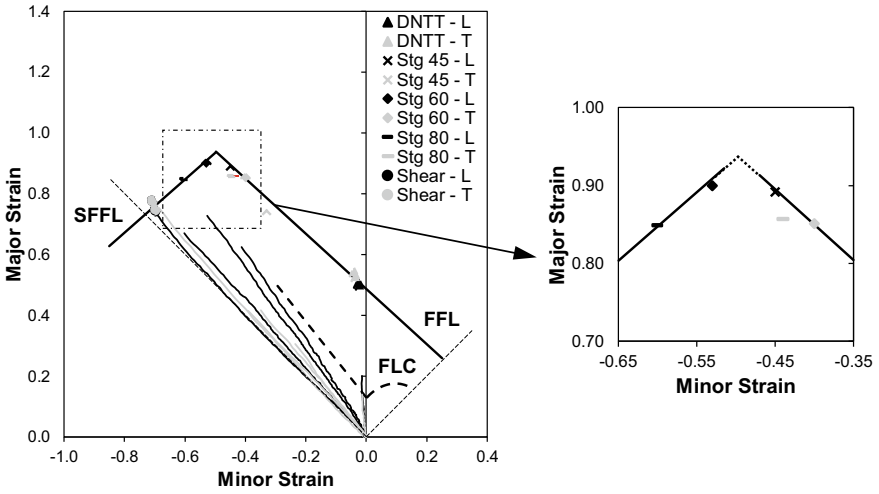


Fig. 5 Strain loading paths and formability limits of the AA6063-T6 aluminum tubes by necking (FLC) and fracture (FFL and SFFL) in principal strain space. The detail is a magnification of the transition region. (Color figure online)

Moreover, the longitudinal staggered DNTT specimen allowed obtaining fracture strains closer to pure shear than the transversal staggered DNTT specimen. This result is due to the strain hardening coefficient n obtained from tensile tests ($n = 0.125$ for the longitudinal direction and $n = 0.216$ for the transversal direction; refer to Table 1). In fact, a larger strain hardening coefficient gives rise to wider plastic deformation regions near the ligaments and, therefore, to smaller localization effects. In other words, a larger strain hardening coefficient gives rise to smaller absolute values of strain at the onset of fracture. A similar effect was recently observed in sheet formability tests [18].

The fractography analysis performed on the fracture surface of each test specimen allowed investigating the crack opening mode and correlating the experimental observations with the fracture forming limits shown in Fig. 5. The images were obtained in a scanning electron microscope (SEM) Hitachi S-2400 with a magnification of 1500X and are representative of the entire length of the fracture surface of the longitudinal and transversal DNTT, staggered DNTT and shear test specimens (Figs. 6 and 7).

As shown in both figures, the fracture surface evolves from a circular dimpled structure typical of a normal fracture caused by remote loading orthogonal to the fracture surface in case of the DNTT specimen, to an elongated parabolic dimpled structure typical of fracture by sliding caused by in-plane shear, in case of the shear test specimens. These results are consistent with the fracture strains of the DNTT and shear test specimens being located on the FFL and SFFL (Fig. 5) corresponding to crack opening modes I and II, respectively.

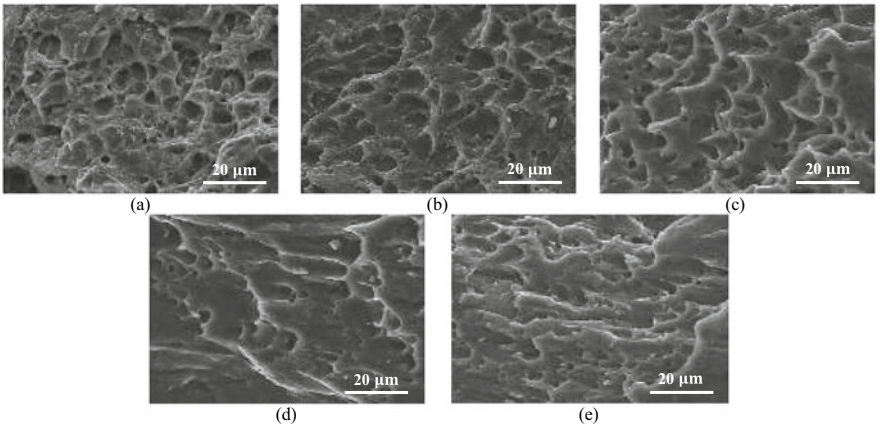

Fig. 6 SEM fractographies of the aluminum AA6063-T6 obtained for the longitudinal **a** DNTT, **b** staggered DNTT with $\theta = 45°$, (d) $\theta = 60°$, (e) $\theta = 80°$ and (f) shear test specimens

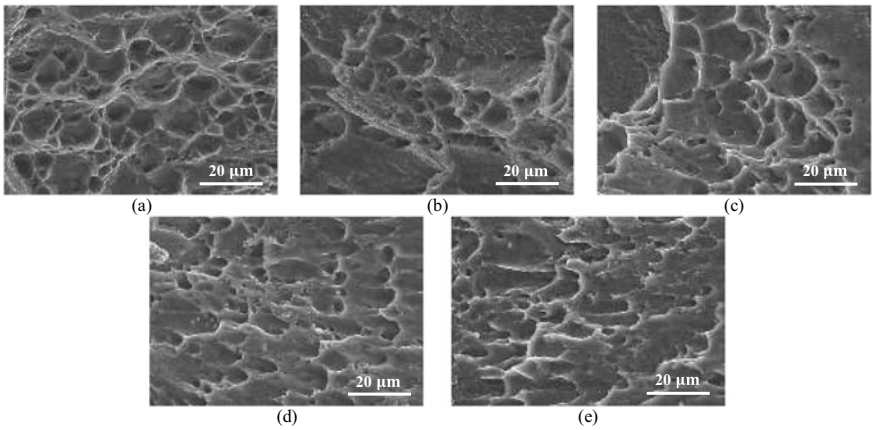

Fig. 7 SEM fractographies of the aluminum AA6063-T6 obtained for the transversal **a** DNTT, **b** staggered DNTT with $\theta = 45°$, (d) $\theta = 60°$, (e) $\theta = 80°$ and (f) shear test specimens

The SEM images included in Figs. 6 and 7 also confirm that staggered DNTT specimens with ligament angles α_0 varying from 45 to 80º have a fracture surface made of circular dimples that are progressively replaced by increasing elongated parabolic dimples. This result is consistent with the fracture strains of the staggered DNTT specimens being in the transition region between the FFL and SFFL (Fig. 5). In other words, the result is consistent with failure by means of a fracture mixed-mode consisting of crack opening by modes I and II.

Moreover, the fractography analysis of the longitudinal (Fig. 6) and transversal (Fig. 7) staggered DNTT specimens also confirms the influence of strain hardening in failure. This is because the fracture surfaces are closer to pure shear and mainly

consist of elongated parabolic dimples in case of the longitudinal DNTT specimens, which have the smallest strain hardening coefficient ($n = 0.125$).

Finally, it is worth mentioning that the experimental work plan allowed obtaining a wide range of strain paths and fracture strains, from plane strain ($\beta = 0$) to pure shear ($\beta = -1$) loading conditions. This allowed an independent confirmation of the FFL that had been previously obtained by the authors [13, 14] and the determination of the SFFL of thin-walled tubes for the first time ever,

$$\varepsilon_{1F} = 0.88\varepsilon_{2F} + 1.38 \tag{3}$$

The FFL and SFFL are approximated by straight lines with a negative slope -0.91 (Fig. 1) and a positive slope + 0.88, respectively. These slopes are different from the theoretical estimates of −1 and + 1 because the experimental conditions deviate from the simplifying assumptions proposed in the theoretical models proposed by Martins et al. [11]. However, the perpendicularity between the FFL and the SFFL maintains, despite these deviations.

4.2 Fracture Toughness

The determination of fracture toughness R followed the methodology that was previously described in Sect. 3.2. Different longitudinal and transversal DNTT specimens with varying ligaments were utilized and the resulting force versus displacement evolutions are shown in Fig. 8a.

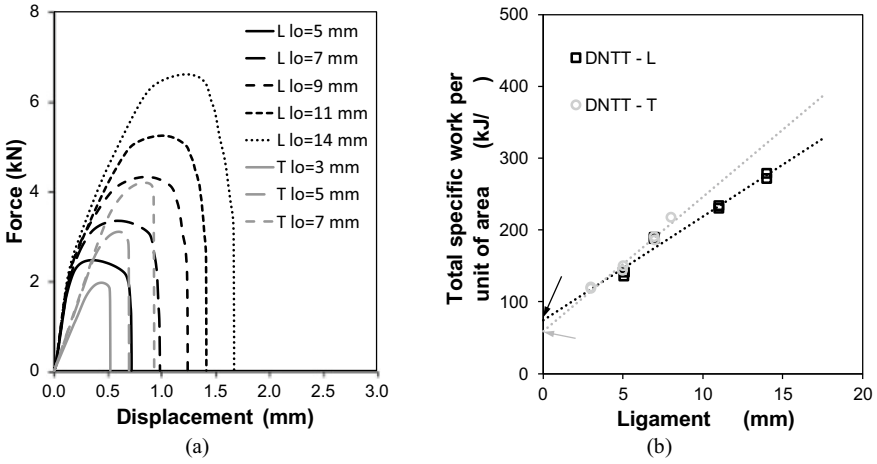

Fig. 8 Fracture toughness R in crack opening mode I for aluminum AA6063-T6 tubes obtained from DNTT specimens: **a** experimental force versus displacement evolution and **b** determination of fracture toughness in longitudinal (L) and transversal (T) directions

The total specific work of fracture per unit of area w_T obtained for several ligaments l_0 in the longitudinal and transversal directions are presented in Fig. 8b. The evolutions are linear, and the fracture toughness in the longitudinal and transversal directions are, respectively, equal to $R_L = 74.5kJ/m^2$ and $R_T = 60.0kJ/m^2$. The difference in the longitudinal and transversal fracture toughness values is related to the difference in strain hardening coefficients, which are higher for the transversal DNTT specimens. This also explains the larger slope γ of the linear fitting of the total specific work per unit of area of these specimens in Fig. 8b.

5 Conclusions

Methods and procedures that were recently developed for the characterization of the fracture limits and for the determination of fracture toughness in sheet metal forming can be easily extended to tube forming. In particular, the combination of digital image correlation (DIC) and thickness measurements at the cracked regions is suitable to determine the strain loading paths and the strains at fracture in double notched tensile test (DNTT) specimens, staggered DNTT specimens and shear test specimens.

Under these circumstances, the main conclusions associated with this investigation on the formability limits of thin-walled tubes are the following:

- Formability by fracture in thin-walled tube forming is limited by the fracture forming limit (FFL) line, the shear fracture forming (SFFL) line and the transition region between these two lines in principal strain space.
- Fractography analysis confirms that the fracture surfaces associated with the FFL consist of circular dimpled structures typical of normal fracture, whereas those associated with the SFFL consist of elongated parabolic dimpled structures typical of fracture by sliding caused by in-plane shear.
- Mixed-modes consisting of crack opening by modes I and II of fracture mechanics entail a combination of circular and elongated parabolic dimpled structures.
- Strain hardening influences the crack opening mode because of its influence on the relative size of the plastic deformation region near the fracture surface.
- Fracture toughness in thin-walled tubes can be determined by a methodology based on the total specific work of fracture per unit area and similar to that commonly utilized in sheet metal forming.
- Anisotropy influences the results and must be taken into account in future investigations on the formability limits of thin-walled tubes.

Deformation Mechanisms in Tool–Workpiece Asperity Contact in Metal Forming

Chris Valentin Nielsen, Xiaodan Zhang, Marcel Moghadam, Niels Hansen, and Niels Bay

Abstract The contribution to friction stemming from dissipation of plastic energy is studied by numerical simulations and experiments. The geometrical setup consists of a single model asperity, which is first flattened against a tool with grooves on a smaller length scale. Relative, tangential sliding between the model asperity and the tool is induced subsequently until a steady state is reached. The flank angle of the grooves on the tool is varied. Comparison between the simulations and the experiments leads to validation of the simulations at low tool flank angles, while the current numerical implementation cannot handle the complicated flow around the tool grooves with a large flank angle. At low flank angles, the simulated tangential tool force is in agreement with experiments when keeping one determined friction factor. This proves that the change in tangential force, corresponding to a change in apparent friction factor, is only due to the dissipated energy from the plastic waves. The validated numerical model can be used to determine a wider range of apparent friction factors for strain hardening materials.

Keywords Friction · Asperity contact · Plastic waves

1 Introduction

Bowden and Tabor [3] described the influence of asperity contact on friction and started the intense analysis on asperity flattening among several research groups over the following decades. One path goes through Shaw et al. [12], who suggested a smooth transition from Amontons–Coulomb's friction model to the constant friction model due to asperity flattening being individual at low normal pressures while

being interacting at higher normal pressures, and Wanheim and Bay [17] who quantified the development of real contact area by slip-line analysis under frictional sliding. Sutcliffe [14] also analyzed asperity flattening by slip-line analysis taking into account subsurface deformation but not the asperity interaction at high normal pressures. Lately, Wang et al. [15] and Nielsen et al. [10, 11] analyzed asperity flattening while taking both strain hardening and subsurface deformation into account by a combined experimental and numerical study.

Common for the majority of research on asperity flattening is the focus on model asperities that are scaled up for practical reasons when evaluating real contact area. The real contact area resulting from these analyses is, however, overestimating the true real contact area due to the existence of multiple orders of asperities. In fact, the typical flat plateaus of the first-order asperities contain second-order asperities, and hence, the true real contact area is smaller than that estimated by first-order asperities. Such an approach can continue on the flat plateaus of the second-order asperities, and so forth. Steffensen and Wanheim [13] did such an analysis and concluded that the reduction of the true real contact area due to second-order asperities on the first-order plateaus is rather insensitive to normal pressure and friction on the plateaus. This is justifying the analyses that are being done on model asperities, which represent the first-order asperities of a real surface. It is justified by the higher order effects on the real contact area being rather constant, which leaves the possibility of having this effect hidden in the friction factor that is assumed on the flat plateaus of the first-order asperities.

A number of mechanisms have been proposed as contributions to the friction that appears in the real contact. Bay and Wanheim [1] presented an overview of the origins of friction. Bowden and Tabor [3] identified the shearing of layers due to adhesion and micro welds as well as dragging or plowing of a harder material through a softer material. Wanheim and Abildgaard [16] later added the mechanism of plastic waves in the softer material induced by the roughness of the harder tool material upon relative sliding. They showed the existence of the plastic wave mechanism by an experiment and gave by slip-line analysis the apparent friction factor as function of the real friction factor along the tool grooves and the groove angle on the harder tool material.

Plastic waves have also been analyzed by other groups. Challen and Oxley [4] modeled one hard asperity in relative sliding against a softer material. Depending on the angle of the hard asperity, this gave rise to a steady-state standing wave, wear, or cutting. Challen et al. [5] presented experiments verifying the modeling, and Challen and Oxley [6] presented slip-line analyses with more than one hard asperity and in the full range from zero to full filling of the grooves in the hard material.

Luo et al. [8] applied upper bound analysis to the moving wave mechanism by assuming contact with the tool only on one side. They found that for low flank angles, the wave may disappear after some sliding and confirmed that by experiments. Bin and Luo [2] applied finite element analysis to the analysis of one hard asperity sliding against a softer workpiece material and found good agreement with their simulation and experiments previously published by Challen and Oxley [4].

In the present paper, the focus is on the deformation mechanisms due to plastic waves on top of workpiece asperities that are flattened by a hard tool and subjected to relative sliding against it. First-order asperity flattening is considered by imposing the plastic waves on top of a model asperity. The deformation mechanisms are analyzed by experiments, numerical simulation, and metallurgical analysis.

2 Experimental Setup

The tool–workpiece contact in metal forming is considered by taking into account first-order asperities on the workpiece surface and a tool surface, which in comparison to the workpiece, is smooth. Such an interface is illustrated in Fig. 1a with the identification of a single asperity that is taken out for analysis. The single asperity is shown in a schematic illustration of an experiment in Fig. 1b. At this scale, the tool surface is assumed to have asperities as well, but with a wavelength much smaller than that of the workpiece surface. The experiment illustrated in Fig. 1b has a single model asperity (A) with flank angle γ in contact with a tool (T) with many, smaller asperities with flank angle β. A normal pressure between the asperity and the tool can be induced by the punch (P) resulting in asperity flattening against the tool under plane strain deformation (zero strain perpendicular to the figure due to tool blocks that are not shown in the illustration).

The tool (T) can move tangentially to emulate relative sliding in the tool–workpiece interface. The tangential force will be the sum of the apparent friction against the model asperity and the friction against the base (B), which is minimized by a

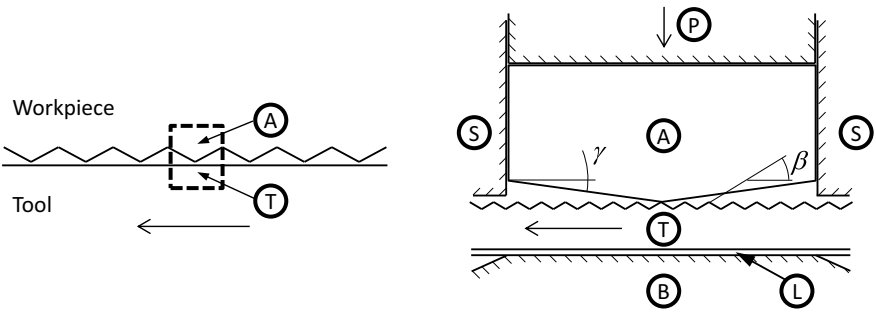

Fig. 1 Schematic illustration of the asperity contact. **a** Workpiece and tool interface represented by first-order workpiece asperities in contact with a smooth tool with relative movement given by the arrow. The dashed rectangle identifies a single asperity (A) and the contacting tool (T). **b** Experimental setup with a single model asperity (A) supported against rotation by (S) and pressed towards a tool (T) by the punch (P). Notice that the tool in this magnification also has asperities. The tool (T) is separated from the base (B) by a layer of Teflon (L) to minimize friction when moved tangentially to the asperity

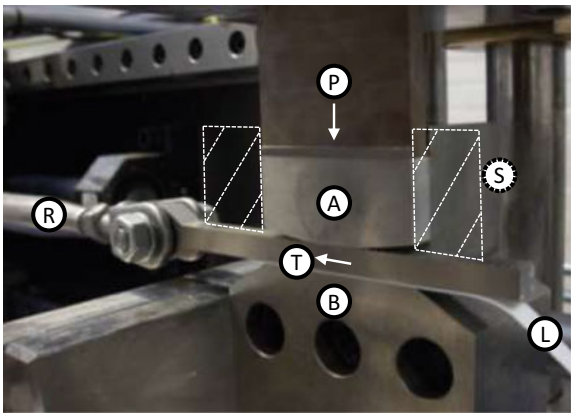

Fig. 2 Experimental setup with labels corresponding to Fig. 1 with the addition of (R) identifying the rigging screw connected to a movable horizontal axis that is used to pull the tool (T). The support is given by four blocks surrounding the model asperity. The two blocks indicated by white dashed lines were removed for taking the photograph. Of the two other blocks, which are used to ensure plane strain deformation, one was also removed for taking the photograph. (Color figure online)

separating layer of Teflon (L). The apparent friction against the model asperity is due to true friction, where workpiece material is in relative sliding along the tool asperities, and due to plastic power dissipation in the plastic waves that the tool induces in the workpiece model asperity.

Figure 2 shows a photograph of the real experiment after having removed a few supporting blocks to allow the photograph to show the model asperity and tool contact. The photograph is taken after an experiment and therefore Fig. 2 shows a flattened model asperity. The normal load applied by the punch (P) is measured by a piezoelectric load cell above the punch. The tangential load on the tool (T) is measured through a pre-compressed piezoelectric load cell connected to the rigging screw (R). Both load cells are outside the photograph.

The model asperity (A) is machined with a flank angle $\gamma = 10^\circ$ and a width $w = 60\,\text{mm}$ representing the model asperity wavelength. The thickness of the specimen is $t = 10\,\text{mm}$ (in the direction of plane strain). The model asperities are made from aluminum 1050, while the tool (T) is made of cold work tool steel, hardened and tempered to 58–60 HRC. Three tools were made with flank angles $\beta = 5^\circ$, $\beta = 10^\circ$, and $\beta = 15^\circ$, respectively. The wavelength of the tool asperities is $l = 1.5\,\text{mm}$. The tool asperities were polished to a roughness $R_a \leq 0.25\,\mu\text{m}$ and the tool asperity tip radii were measured to around $R = 1.4\,\text{mm}$. Zinc stearate was used for lubrication by applying a thin layer to both the workpiece and tool surfaces. The aluminum workpieces were pickled in a NaOH bath prior to rubbing zinc stearate to the surface.

Aluminum 1050 used for the model asperities is characterized by the flow stress curve shown in Fig. 3. The flow stress has been tested at large strains due to heavy local deformation in the experiments. The flow stress curve is based on simple upsetting until an equivalent strain of 0.5. In order to achieve experimental data at large strains,

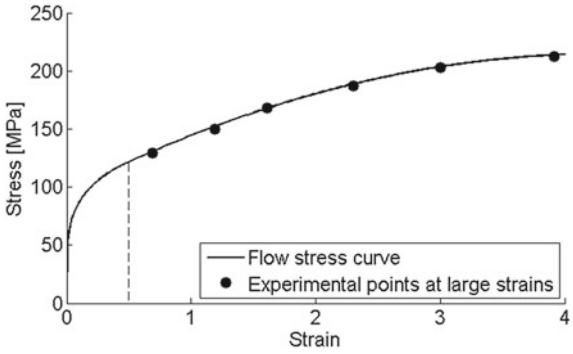

Fig. 3 Flow stress curve based on simple upsetting below an equivalent strain of 0.5 and scaled tensile tests of rolled samples above 0.5

the original 1050 plate was rolled with different thickness reductions and tensile samples were cut from the rolled plates. The yield stress found by tensile testing gave rise to a flow stress at the equivalent strain dictated by the amount of rolling. The data points stemming from rolling and subsequent tensile testing have been multiplied by an estimated factor of 1.18 [7] taking into account the strength anisotropy of the lamellar structure, especially formed at the medium and large strains in the present study. The strength in the normal direction is typically higher than that of the lamellar direction when a lamellar microstructure forms with surface deformation by different processing methods, e.g. due to friction or particle bombardment [18]. By doing this, comparison to compression stress from aluminum 1050 cylinders in our previous research [19] revealed good agreement with the compression stress from the aluminum 1050 cylinders at strains up to 2. The flow stress between equivalent strains of 0.5 and 3.9, which was the maximum strain obtained by rolling, is a best fit by a second-order polynomial through the end point of the upsetting test and the experimental data points at large strains after scaling. Above an equivalent strain of 3.9, the flow stress is assumed constant. The flow stress curve used for numerical modeling can be summarized as

$$\sigma[MPa] = \begin{cases} 141\varepsilon^{0.21} & \text{for} \quad \varepsilon \leq 0.5 \\ 96.1 + 54.7\varepsilon - 6.31\varepsilon^2 & \text{for } 0.5 < \varepsilon \leq 3.9 \\ 214 & \text{for} \quad \varepsilon > 3.9 \end{cases} \tag{1}$$

3 Numerical Model

The deformation mechanisms on the flattened model asperity are simulated by the numerical model shown in Fig. 4. The initial mesh for one model asperity with flank angle $\gamma = 10°$ is shown in Fig. 4a with boundary conditions on the sides that only allow vertical movement and with a nominal normal pressure q stemming from the applied load by the punch. After plain strain asperity flattening against the tool, which

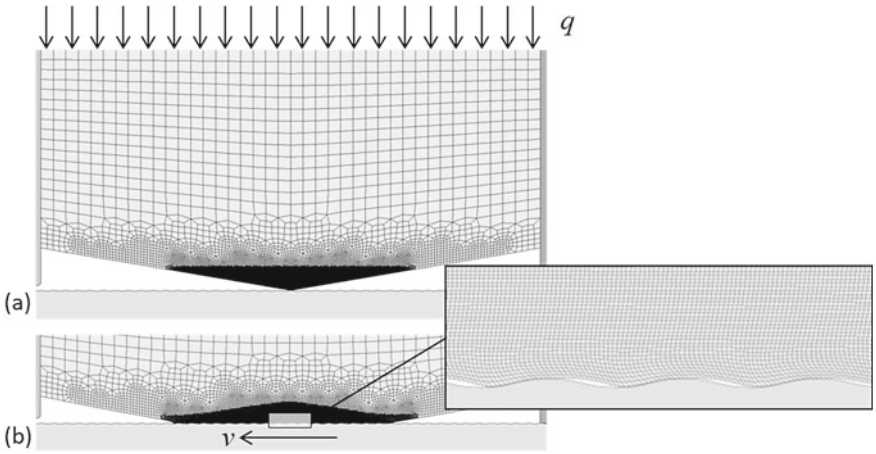

Fig. 4 Finite element mesh consisting of 26,084 quadrilateral elements for simulation of model asperity shown **a** in initial condition and **b** after flattening due to normal pressure q and after sliding with relative velocity v against the hard, rough tool

is shown for the case having tool asperities with flank angle $\beta = 15°$ and wavelength $l = 1.5\,\text{mm}$, relative sliding by a constant velocity $v = 1\,\text{mm/s}$ is imposed. The mesh refinement on the asperity tip allows an initial element size being 3% of the tool asperity wavelength.

The numerical calculations are based on discretization by quadrilateral finite elements and an underlying irreducible flow formulation by minimization of the following functional

$$\Pi = \int_V \bar{\sigma}\dot{\bar{\varepsilon}} dV + K \int_V \dot{\varepsilon}_v^2 dV + \int_{S_f} \left(\int_0^{|u_r|} \tau du_r \right) dS \tag{2}$$

where the energy rate due to plastic deformation is integrated over volume V in the first term consisting of the effective stress $\bar{\sigma}$ and the effective strain rate $\dot{\bar{\varepsilon}}$. Incompressibility is enforced by penalizing volumetric strain rate $\dot{\varepsilon}_v$ by the penalty factor K in the second term. The last term includes the frictional stress τ between the workpiece and the tool by integration over relative sliding velocity u_r on the shared surface S_f. The applied finite element computer program is iform, which is an in-house numerical code shared between the University of Lisbon and the Technical University of Denmark. Additional information is given by Nielsen et al. [9].

4 Results and Discussion

The resulting tangential load from the experiments with flank angle $\beta = 5°$ is shown in Fig. 5 as function of the sliding length. Corresponding simulation results are included in the figure for a variation of the friction factor m in the sliding along the tool grooves. A friction factor $m = 0.1$ in the simulations is found appropriate when comparing to the experiments. Increasing the tool flank angle β, while keeping the friction factor constant will increase the necessary tangential load due to additional dissipation of plastic energy by plastic waves. This is shown by the results in Fig. 6 by simulation results and experiments. The results for $\beta = 5°$ are the same as in

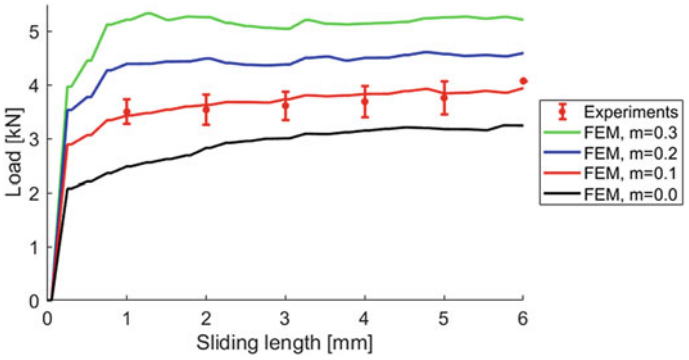

Fig. 5 Tangential load as function of sliding length in case of tool asperity flank angle $\beta = 5°$ for experiments and numerical simulation with variation of the friction factor m. The error bars correspond to one standard deviation based on three repetitions, except for the last point which was only obtained in one of the experiments. (Color figure online)

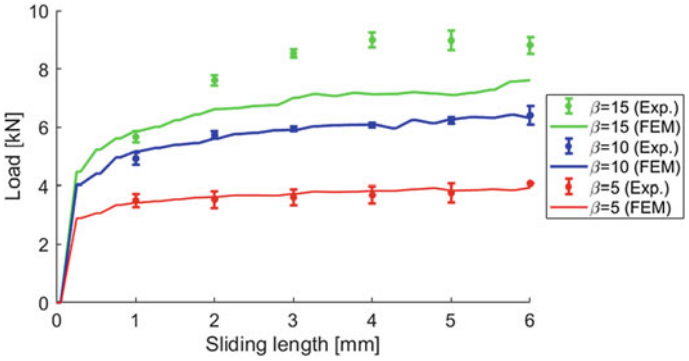

Fig. 6 Tangential load as function of sliding length for different flank angles including experimental results and numerical simulation with friction factor $m = 0.1$. The error bars correspond to one standard deviation based on three repetitions, except for the last point with $\beta = 5°$ which was only obtained in one of the experiments. (Color figure online)

Fig. 5. The simulations with $m = 0.1$ are seen also to match the experiments well for $\beta = 10°$, indicating that the only contribution to the increase of the tangential force is the plastic waves. When increasing the tool flank angle further to $\beta = 15°$ the simulation does not match the experiments any longer. This difference is explained by a difference in the local flow along the grooves. The finite element discretization still results in a smooth and continuous flow, while the experiments reveal workpiece material sheared off and deformed as a third body between the remaining workpiece and the tool. This gives rise to a higher tangential force than the ideal force predicted by simulation of an ideal flow.

All cases show that the tangential force is building up to a rather constant level corresponding to steady-state sliding. From Fig. 6 it is noticed that steady state is obtained later for larger tool flank angle due to larger extend of the deformation field. During the initial transient build-up of the tangential force, the first-order real contact area increases due to the change in stress state. The induced shear on the flattened workpiece asperity reduces the necessary yield pressure, which is compensated by further deformation of the overall asperity as the normal load is kept constant. For the different tool flank angles, Fig. 7a shows the first-order real contact area ratio after deformation due to the applied normal load (dashed curves) and after additional sliding until steady state (solid curves). Both experimental results (blue curves) and simulated results (black curves) are included in the figure for comparison. A slight overestimation of the contact area is noticed for all the simulations. In order to focus on the effect of the additional sliding, Fig. 7b shows the relative change in first-order contact area for the three tool flank angles. Here, the simulations match the experiment for the tool flank angles $\beta = 5°$ and $\beta = 10°$, while the simulation underestimates the relative change for $\beta = 15°$ in agreement with the differences between simulation and experiment discussed in relation to Fig. 6.

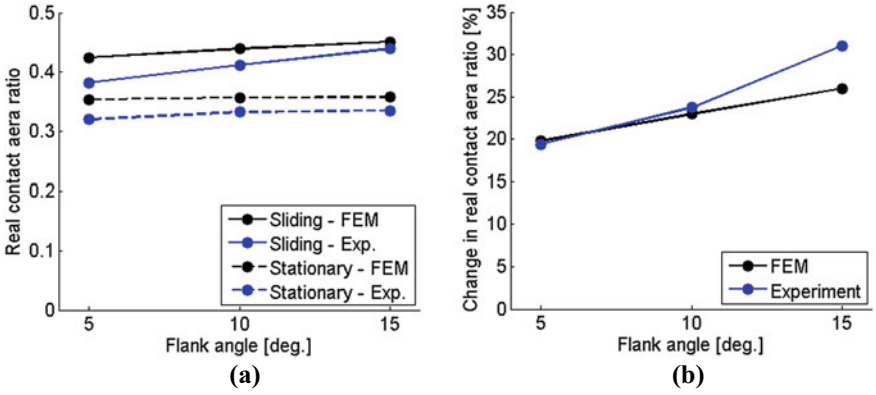

Fig. 7 First-order real contact area between model asperity and tools with three different flank angles by experiments and numerical simulations. The contact area corresponding to stationary contact and to the developed contact area during sliding are shown in (**a**), while the change from stationary to sliding contact area is shown in (**b**). (Color figure online)

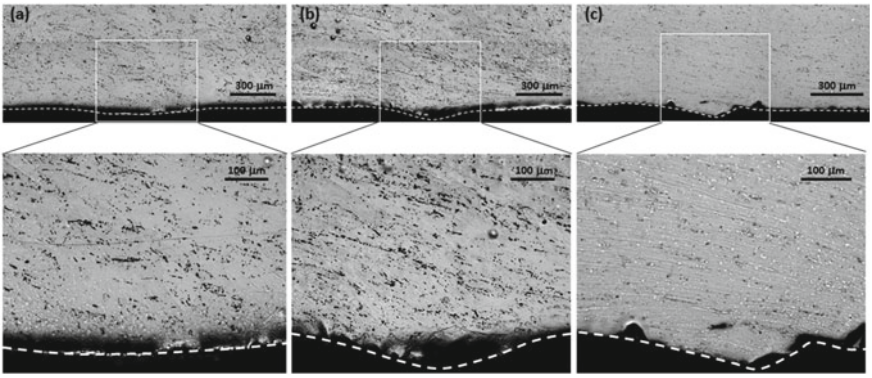

Fig. 8 Cross-sectional LOM pictures of the workpiece material after reaching steady state sliding for tool flank angles **a** $\beta = 5°$, **b** $\beta = 10°$ and **c** $\beta = 15°$. Enlarged pictures are shown from the workpiece tips of the pictures above. Tool movement is in this figure from left to right

Cross-sectional photographs of the deformed workpiece surfaces are shown in Fig. 8 based on light optical microscopy (LOM). For each tool flank angle, a corresponding cross section of the workpiece is shown from the center of the flattened plateau of the first-order asperity. The photographs span just above one wavelength of the tool asperity, while the enlarged photos span around 40% of a tool asperity wavelength near a local tip of the workpiece (valley of the tool). The edges are unfortunately unclear after the grinding, polishing, and etching. White dashed lines have therefore been added manually along the edges. The identified edges for the cases with tool flank angles $\beta = 5°$ and $\beta = 10°$ are smooth waves, while the edge identified for the tool flank angle $\beta = 15°$ is a non-smooth wave due to a flow with much more shear and also induced cracks in the surface. This difference supports the above discussion, where simulations represent the results for the low tool flank angles, $\beta = 5°$ and $\beta = 10°$, while the simulations cannot be validated for the larger tool angle, $\beta = 15°$. It would require both further mesh refinement and handling of microcracks with resulting new contacts in the simulations to deal with the larger flank angle.

5 Conclusions

Plastic waves, as a suggested deformation mechanism in the contact between workpiece asperities and tool surfaces by Wanheim and Abildgaard [16], have been studied by numerical simulations and experiments by an enlarged asperity which is flattened against a tool with smaller grooves representing tool surfaces asperities. The simulations have been successfully validated for low tool flank angles, $\beta = 5°$ and $\beta = 10°$, while the metal flow around the tool grooves for the larger tool angle, $\beta = 15°$, was too complicated for the present numerical implementation as it involved heavy shear

and microcracks with new surfaces getting under compression. This paper leaves the numerical model ready for studying a wider range of friction factors along the tool grooves, a wider range of workpiece materials in terms of strain hardening behavior and a higher resolution of tool flank angles up to at least 10°. Wanheim and Abildgaard [16] already mapped the apparent friction factor as a function of the local friction factor and the tool flank angle for ideal plastic materials. Further work with the presented numerical model allows extending that mapping to include strain hardening materials. Variations of workpiece flank angle is another future extension to the present work. Experiments at smaller scales and numerical modeling based on crystal plasticity with effects of grain sizes and orientation to account for real surface scales are also future work.

Welding of Aluminium in Chip Extrusion

André Schulze, Oliver Hering, and A. Erman Tekkaya

Abstract The reduction of energy consumption and CO_2 emissions in aluminium profile production can be achieved by solid-state recycling. By direct hot extrusion, aluminium chips can be directly processed into semi-finished or near-net-shape products requiring relatively low energy and having a high material yield. Since the mechanical properties of the extruded profiles highly depend on the welding of the individual chips, the main focus is to achieve a sufficient bonding between the chips. For this, the oxide layer covering the aluminium surface has to be broken. In order to predict the welding of the individual chips and estimate the process success a weld prediction model is developed. The influence of process parameters such as extrusion ratio, temperature, and speed is analysed. The weld model is applied to further profiles and validated by experimental tryouts.

Keywords Solid-state bonding · Chip extrusion · Aluminium

1 Introduction

Currently, most aluminium scrap, including machining swarf, i.e. small chips, is remelted in furnaces and recycled into ingots or die-casting products. However, the conventional recycling method is associated with two main disadvantages. The remelting process requires significantly large amounts of energy, which is unfavourable in terms of energy conservation. In addition, the metal yield rate is very low. These limitations drive the development of alternative technologies for the recycling of aluminium scrap [1]. Recently, solid-state recycling, which involves direct recycling of metal scrap into bulk material by using severe plastic deformation (SPD), has emerged as a potential alternative to the conventional remelting and recycling techniques [2]. Different processes using severe plastic deformation to recycle aluminium scrap of different alloys, mainly AA6XXX alloys, were developed. Examples are cyclic extrusion compression [3], high-pressure torsion [4], compressive

torsion [5], or equal channel angular pressing (ECAP) [6]. The direct recycling of aluminium chips using hot extrusion was first proposed and patented by Stern in 1945 [7]. Gronostajski et al. investigated the production of aluminium and aluminium-based composites using this methodology [8]. Additional works were carried out by Fogagnolo [9] who extruded AA6061 reinforced with Al_2O_3 or Allwood [10] who analysed the recycling of aluminium scrap by cold bonding during cold extrusion and rolling processes. Tekkaya et al. reported on the influence of chip type and compaction strategy on the mechanical properties of hot extruded profiles based on AA6060 chips when using a porthole die [11]. The process parameters extrusion ratio, die design (material flow), and temperature have the most significant influence on the microstructure and the mechanical properties [12]. The underlying mechanism of the chip consolidation is the solid-state welding which due to its importance for different manufacturing processes has been investigated in detail to understand the ongoing physical relationships. In order to be able to make predictions about the welding, two types of weld models are considered in the literature: On the one hand, qualitative models based on the *energy barrier theory*, which are also known as welding criteria, on the other hand, physically motivated models based on the *film theory* for the prediction of an absolute weld strength.

In order to predict the quality of the longitudinal weld seam in porthole die extrusion, weld criteria based on the energy barrier theory were developed. First of all, Akeret assumed that the ratio between the normal contact pressure and the local flow stress of the material in the welding zone must be larger than a critical threshold value [13]. Plata and Piwnik proposed that the value should be integrated over the contact time [14]. Donati and Tomesani introduced the local velocity as an additional variable to the existing model [15]. In the Yu model, the strain rate is integrated over the time considering pressure and local flow stress and a weighing factor which takes diffusion into account [16]. There is only one criterion solely dedicated to the prediction of chip weld quality in hot extrusion of aluminium chips. Güley et al. assumed that an accumulation of bond strength increments starts after a certain critical shear stress is reached, which leads to breakage of the oxide layers [12].

Most of the before-mentioned weld criteria do not take into account the local surface expansion in the contact region. This is, however, an important influencing factor for metal-to-metal solid bonding which was identified by Bay [17]. He developed a physically motivated model to predict the bond strength. The metallic surfaces have to come into direct contact to reach bonding. Concerning aluminium, the oxides covering the surface must be broken. An expansion of the two contacting surfaces is required for this. After local breakage of the oxides, the presence of contact pressure leads to micro extrusion of base metal through the cracks in the broken layers. This leads to the bonding of two contacting surfaces (Fig. 1) [17].

The latest development of the model by Bay was conducted by Cooper and Allwood [18]. This model allows for a prediction of the absolute bond strength σ_b as a function of the normal stress σ_n, shear stress τ and strain, according to

$$\frac{\sigma_b}{\sigma_f} = \left(\frac{0.8}{\sigma_f}\sqrt{\sigma_n^2 + 3\tau^2}\right) \cdot v \cdot \left(0.8\frac{\sigma_n - p_{ex}}{\sigma_f}\right) \tag{1}$$

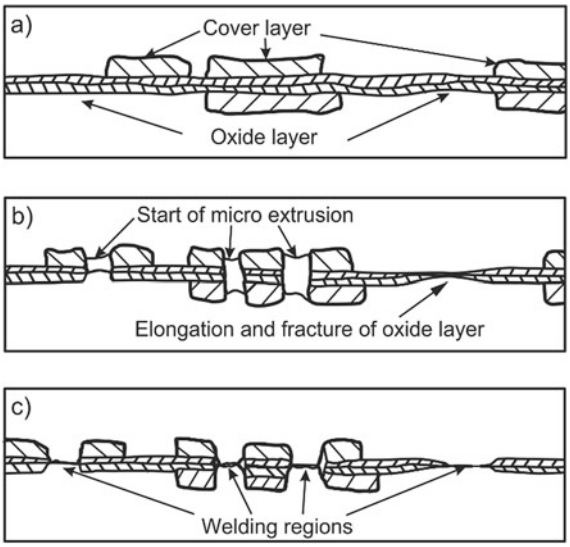

Fig. 1 Schematic steps in solid bonding: **a** Initial contact situation, **b** Elongation and cracking of cover and oxide layer, **c** Local welding (adapted from Bay [17])

The model can be divided into three terms:

1. The first term considers the true microscopic contact surface of the two contacting partners. It is affected by the normal stress σ_n and the shear stress τ, because of microscopic plastic deformations at the interface.
2. The necessary strain to initiate oxide fracture of the oxide layer, so the base material can get into direct contact is included by the second term v.
3. By means of the third term, the microextrusion pressure p_{ex} which is essential for the micro extrusion of base metal through the cracks in the fractured oxide layer is regarded. It depends on a number of geometric and material parameters.

The Cooper and Allwood model was chosen to be adapted for weld quality prediction in aluminium chip extrusion for AA6060 alloy due to its physically motivated background by Kolpak et al. [19]. Some changes have been made in order to apply the model in chip extrusion:

1. The welding between the individual chips is a complex three-dimensional process. Thus, to homogenize the local weld quality, the effective plastic strain ε is set as the relevant strain. The hydrostatic pressure p, which is responsible for the densification of material is defined as the relevant stress measure for welding.
2. Due to the high porosity of the chip-based billets, the encapsulated amount of oxygen drastically increases. Since this is the main driving factor to break oxides and allow base metal to flow through the resulting cracks, an additional factor is added to calculate the additional surface expansion necessary to fully turn the oxygen captured in the pores into oxides on the chip surface.

3. Since no additional oxygen is introduced in the system, it is assumed, that the amount of oxygen captured in the pores of the billets during compaction does not change during the extrusion.

The above-mentioned changes have been implemented in the model leading to the weld quality calculation model given in Fig. 2.

The model works as follows: conventional FE simulation is conducted utilizing the standard material behaviour used for as-cast material because investigations suggest that the material has a density of nearly 100% before flowing in the die cavity (Fig. 2a). Particles are defined on the profile cross-section in order to extract the necessary field quantities. The particles are tracked to calculate their path during the extrusion (Fig. 2b). All necessary field quantities are extracted along each investigated particle line (Fig. 2c). Along each particle line, the weld quality is calculated individually for n points. The weld quality can only increase because within the container no negative pressure (positive hydrostatic stress) exists. This was implemented by assuming the local weld quality to be the maximum weld quality achieved up to the current point i (Fig. 2d) [19].

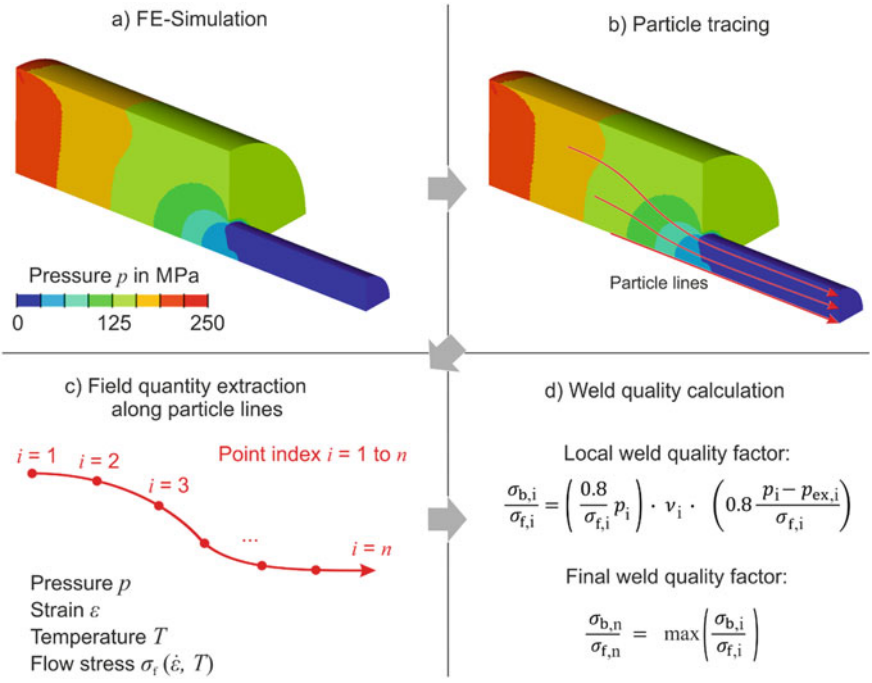

Fig. 2 Adjusted weld model for application in hot extrusion of chip-based billets [19]. (Color figure online)

2 Influence of Process Parameters on the Weld Quality Factor

To verify the model capability different extrusion process parameters which, according to literature influence, the welding of the chips and thus the process success was varied in the simulations. The major parameters are extrusion ratio R, billet temperature T, and ram speed v. For this, an initial diameter of $d_0 = 66$ mm, an initial length $l_0 = 78$ mm, and the extrusion of a round bar were assumed. Starting from a reference set (Fig. 3), the process parameters were varied within a range of industrially relevant limits. For three points over the cross-section, the chip weld quality factor was calculated. The weld quality model is shown to explain the influence of the variation of the extrusion parameters. The influence is indicated with a green arrow if it is positive and with a red arrow if it is negative. As known from the literature the extrusion ratio shows a major influence on the weld quality factor. Starting from a low weld quality factor of $0.5 < \sigma_b/\sigma_f < 0.75$ for $R = 6$, with increasing extrusion ratio the weld quality saturates towards the maximum achievable value of $\sigma_b/\sigma_f = 1$, for all three investigated points. The increase in the weld quality is due to the simultaneous increase in local strain and pressure. The higher strain leads to a higher surface expansion and thus to a larger region where welding is possible. An increase in the billet temperature has no significant influence on the welding of the chips. The local flow stress is reduced by the temperature increase which facilitates the material to flow through the cracked oxide layer. The reduced flow stress also leads to a decrease in the pressure. Since these two effects balance out, the calculated weld quality shows no influence for all three investigated points. Similar observations are made for the influence of the ram speed. The increase of the strain rate would lower the weld quality but, in contrast, the pressure is increased. These two

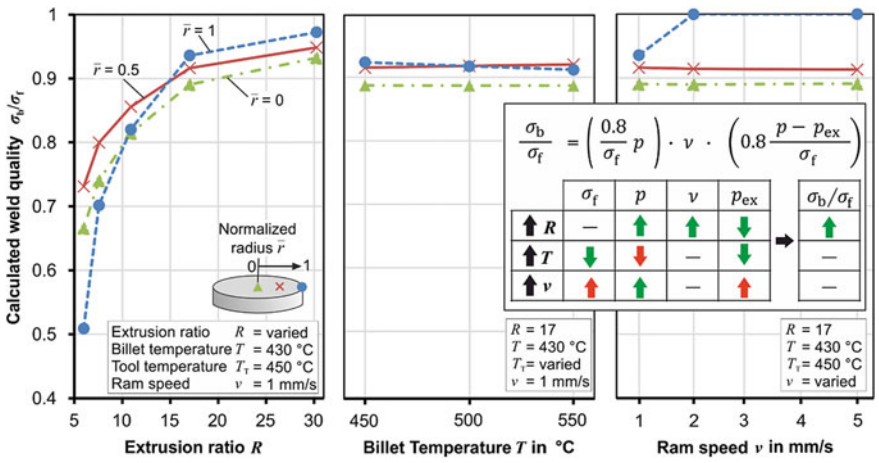

Fig. 3 Influence of extrusion ratio R, extrusion temperature T, and ram speed v on the weld quality factor [19]. (Color figure online)

opposing effects balance out for the inner points of the profile. However, the weld quality is increased in the surface region because the material which ends up at the profile surface, has travelled along the dead metal zones, which leads to large shear strains.

The calculated weld quality resulting in the weld model was validated against a variety of literature results as well as against the results of additional hot extrusion experiments utilizing flat-face dies to produce round bars. Additionally, the stresses at the die exit have to be considered since a velocity gradient leads to positive normal stresses and shear stresses which can cause a delamination of the chips on the profile surface. To withstand the given die exit stresses and to ensure the process success, a minimum weld quality factor of $\sigma_b/\sigma_f > 0.95$ is required. The minimum weld quality factor depends on the chip size and also chip shape because the amount of oxygen captured in the billet is a function of the ratio between the overall chip surface and volume as well as on the (unknown) amount of dissolved oxygen in the pores.

3 Weld Quality Prediction and Experimental Validation

To further validate the weld model and verify the influence of the strain on the welding of the chips during the extrusion process, it was applied to predict the weld quality for the extrusion of two profiles. Both profiles were simulated with HyperXtrude and then the weld quality model was used to calculate the weld quality. The experimental tryouts have been carried out with a hydraulic extrusion press Collin PLA250 t with a maximum ram force of 2.5 MN. The aluminium alloy AA6060 was used for all investigations. The chips were produced by turning of cast bars and then cleaned and cold compacted with a maximum force of 550 kN into chip-based billets with a diameter of 60 mm and an average length of 90 mm resulting in an overall density of 78%. Prior to extrusion the chip-based billets were homogenized at 550 °C for 6 h and then extruded through preheated dies with a temperature of 450 °C.

The first profile is a cross profile with a low extrusion ratio of $R = 7$. A flat-face die with a small pre-chamber was used resulting in low strains during the extrusion. This can be seen in the simulation results (Fig. 4 left). Due to the homogenous material flow through the flat-face die only low strains are achieved over the profile cross-section which means the surface expansion of chips is low and thus the areas of pure aluminium being able to be welded. Solely at the inner edges, higher strains occur. Using the weld quality model to generate a contour plot of the calculated weld quality similar observations can be made indicating a strong correlation between strain and weld quality since the strain has a high influence on the welding of the chips. The contour plot shows insufficient welding for the majority of the profile cross-section solely the inner edges show a calculated weld quality of over 95% (Fig. 4 right).

By evaluating the calculated weld quality along two paths of the cross-section, it can be seen that the calculated weld quality is very low in the centre of the profile (Fig. 5 left). It increases drastically towards the inner edges of the cross (Path 2), however, along Path 1 a sufficient value is not reached. Due to the low calculated

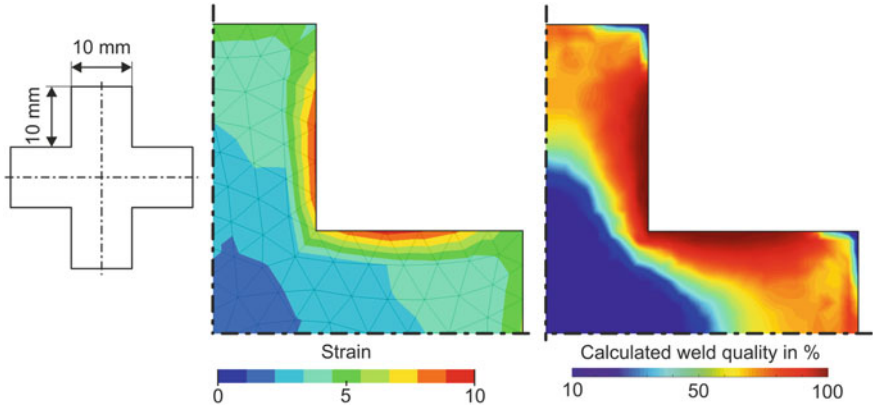

Fig. 4 Cross profile, simulation, and calculated weld quality for a quarter profile. (Color figure online)

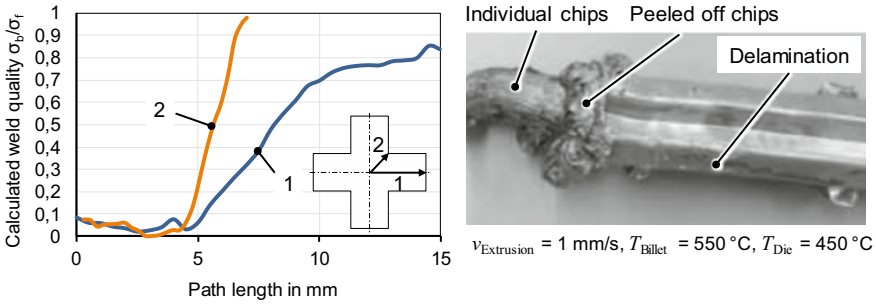

Fig. 5 Calculated weld quality along path 1 and 2, delamination of chips in experimental tryouts. (Color figure online)

weld quality, an insufficient welding will be expected. The experiment shows a strong delamination of the chips because of the poor welding in the profile centre. As a consequence of friction at the die bearing, the outer chips which are welded are peeled off from the centre where individual chips can be detected. Moreover, minor delaminations occur at the profile surface. The experiment corresponds to the calculated weld quality according to Fig. 5 in which a strong delamination of the chips can be observed which validates the weld quality model.

The second profile is an asymmetrical rectangular hollow profile with different wall thicknesses (Fig. 6). A porthole die with two inflows is used in order to divide the material flow and create the profile cross-section. The profile has an extrusion ratio of $R = 14$ which in combination with the porthole die leads to higher strains. The effect of the strain on the welding of the chips can be estimated comparing the contour plot of the simulation (Fig. 6 left) to the weld quality model (Fig. 6 right). In the areas of high strains (near the surface), a good welding of the chips is estimated.

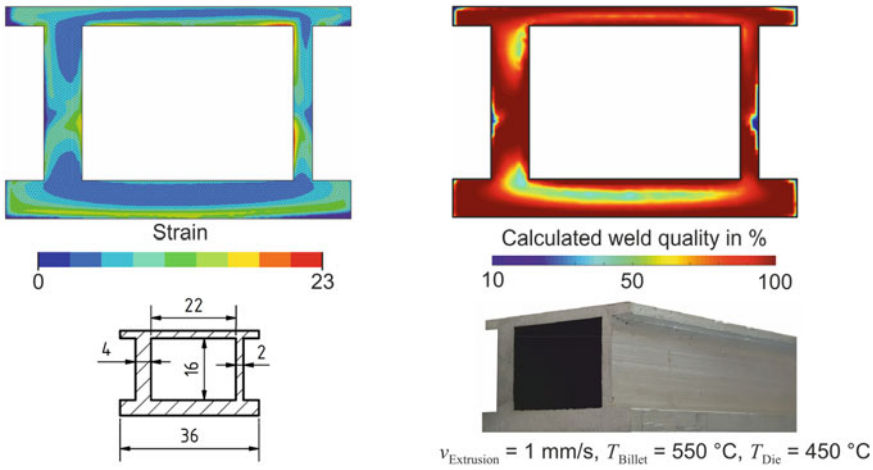

Fig. 6 Asymmetrical rectangular hollow profile: simulation, calculated weld quality and experiment. (Color figure online)

In the middle of the horizontal bridges, the values decrease. Overall a good welding of the chips is predicted which results in profiles without delamination during the experiments (Fig. 6 bottom right). It can be concluded that the distribution of the strain correlates with the calculated weld quality. Nevertheless, the calculation of the weld quality is inevitable to estimate the process success. Despite the strain also the pressure has a major influence on the welding of the chips. Hence, to take all influencing field quantities into account, only the calculated weld quality can give an indication of the welding of the chips during extrusion.

4 Conclusion

In order to numerically predict the process success, a weld model was developed which allows for an estimation of the local chip weld quality depending on the die type and hot extrusion parameters for different profile geometries. In general, a process success is assumed if a minimum weld quality factor of about 95% is reached and the stresses at the die exit region are minimized. For the process success, high strain and pressure are needed to cause oxide breakage and thus welding of the individual aluminium chips. A strong correlation between strain and weld quality is given since high strains lead to high surface expansions of the chips which enable welding of the bare aluminium. The weld model can be used to assess the process success in chip extrusion when designing new profile geometries and dies. In further investigations, it has to be proofed that the weld model also works for other alloys for example AA2XXX, AA5XXX, or AA7XXX series.

Bulk Microforming from Sheet Metal—A Promising Approach for the Mass Production of Cold-Formed Metallic Micro Parts

Martin Kraus and Marion Merklein

Abstract Every year billions of micro parts are produced. In mass production, cold bulk forming offers considerable technological, economical, and ecological potentials compared to alternative production methods. Due to the occurrence of scale effects, high tool stresses, and handling problems, cold bulk forming is not used for the mass production of multi-stage formed metallic micro parts. Within this paper, multi-stage bulk microforming from sheet metal is investigated on the laboratory scale with the material Cu-OFE. Throughout this process, the sheet metal strip serves both as a semi-finished product and as a handling aid. In the first forming stage, a pin is extruded from sheet metal, which is then extruded in a cup during the second stage. For the identification of size effects and the evaluation of such effects on the part quality, the tests are carried out on macro- and micro-scale. In the first step, the process-influencing variable of the blank holder pressure is investigated in the first forming stage in order to derive measures for the highest possible material utilization. The two-stage forming of the pin with cup is compared with a single-stage process to assess the part quality and material utilization depending on the process strategy. Using the correct geometric scaling, size effects are identified and their effects on the forming process are evaluated. The experimental results reveal that it is possible to fabricate micro parts with a diameter of 470 μm and a minimum wall thickness of 36 μm reproducible by using the presented cold bulk microforming process strategy.

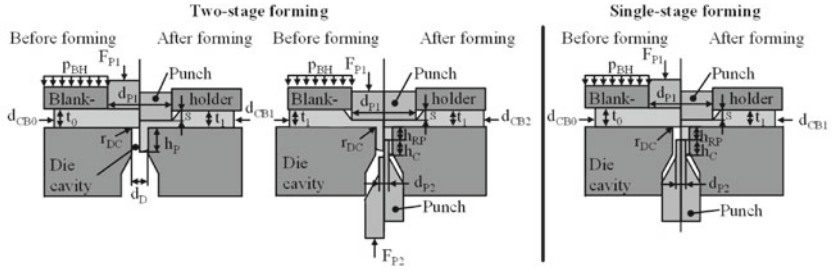
1 Introduction

The ongoing miniaturization and the continuous development of microproduction technologies enable the production of ever smaller products with an extended functional range. This applies especially to microcomputers, electronics, telecommunication devices, and microelectromechanical systems (MEMS). The MEMS include, for example, acceleration and pressure sensors, which have a wide range of applications in the automotive industry [1]. Further applications of MEMS sensors are in the energy industry, medical technology, and consumer electronics, like flow meters, blood pressure monitors, or video game consoles [2]. Due to the numerous possible applications, the market share is growing continuously [3] and the demand for metallic microcomponents increases rapidly. Besides MEMS, typical examples of metallic micro parts are IC carriers, fasteners, micro-screws, leadframes, sockets, and any kind of connecting elements [4].

In mass production, metal forming processes offer economical, technological, and ecological advantages compared to other production methods. However, scaling down forming processes into the micro-scale can result in the occurrence of size effects, which may have a negative impact on the part quality as well as on the repeat accuracy of the process [5]. Size effects are classified into physical and structural causes. Despite these size effects, high volumes of metallic micro parts, such as leadframes, springs, and micro cups, are nowadays produced in industry using metal forming technology [6]. These components are mainly produced by sheet metal forming processes, as here the transport of the micro parts between the forming stages in multi-acting tool can be realized precisely with the help of the sheet metal strip. For the identification, understanding, and minimization of size effects, numerous of research projects were carried out in the past [7]. A major challenge in micro sheet metal forming is the high, unpredictable springback during bending due to scale effects. Ruan's research group [8] has investigated the influence of size effects on bending thin metal foils with different grain sizes. By using a simplified constitutive model, it was possible to predict the springback angle after microbending.

At present, cold bulk microforming is mainly used in industry for wire bending to produce filaments and springs in large quantities, as it allows to form directly from the wire [6]. For complex, multi-stage formed micro parts, cold bulk microforming is barely used in industry since additional handling challenges arise due to the small part size. As a result of the relative large surface area in relation to the part volume, adhesive forces dominate, which is why the micro parts stick to the gripper systems [6]. To meet these challenges, handling devices, which reduce the contact surface between the gripper and the workpiece, and thus the adhesion force, have been developed. These handling devices are based on vacuum pipettes and iris grippers [6]. The use of such systems improves the micro part transport but reduces the production rate considerably. Another challenge consists in the occurrence of size effects, which have a negative influence on the forming processes and the part quality [9]. Bulk microforming of metallic micro parts from sheet metal strip offers the potential to meet the handling challenges by using the strip as a transport aid between the forming



steps in a multi-acting tool system, like in sheet microforming [10]. Size effects might be reduced by a grain refinement during the multi-stage forming process. The principle feasibility of bulk microforming from sheet metal has already been demonstrated in numerous studies by Meng et al. [11], Ghassemali et al. [12], Hirota [13] und Merklein et al. [14]. In the first forming stage, material is extruded, e.g. in the shape of a pin, which is then formed further in several subsequent forming stages. In the last forming stage, the micro part is separated from the metal strip by blanking. One major challenge of this process is the material utilization. Due to the lack of lateral boundaries, a large amount of the displaced material flows laterally into the sheet metal plane and is not available for further forming steps. Ghassemali et al. [12] have shown that the pin height does not increase linearly with the punch stroke. At the end of the process, extrusion is dominant and the pin height in relation to the punch stroke increases rapidly. Hirota [13] has observed with aluminum and Merklein et al. [14] with cooper that the material utilization can be significantly increased by a harder material state. It was also shown that the use of thinner sheets improves the material utilization. The effects of different punch and die diameters on the material flow and the mechanical properties of the pins have been investigated by Ghassemali et al. [15]. Despite a low material utilization, the process has the potential to contribute resource savings if it is integrated into existing progressive processes and uses the offcuts [13].

Within this study, the basic feasibility of the production of micro parts by multi-stage bulk microforming from sheet metal is analysed. For this purpose, a single-stage and two-stage forming strategy for the extrusion of a pin with cup is fundamentally investigated. In order to identify size effects and to evaluate their impact on the process and the micro part, the experiments are carried out in macro- and micro-scale. In the single-stage variant, the micro part is directly formed by a combination of direct impact extrusion (DIE) and direct impact cup extrusion (DICE). For the two-stage variant, a pin is formed by direct impact extrusion (DIE) in the first forming stage and the material is then provided for indirect impact cup extrusion (IICE) in the second forming stage. Additionally, a process-influencing variable on the pin forming is investigated with the blank holder pressure in order to enable recommendations with respect to the material utilization and the process quality.

2 Experimental Setup and Material Characteristics

2.1 Experimental Setup

Figure 1 shows schematically the extrusion processes from sheet metal plane with all relevant process parameters, which are analysed experimentally in this study. A multi-action tool system, which allows a separate control of the blank holder pressure and the extrusion punches, is used for the tests. For the identification of size effects, the processes are investigated in the macro- and micro-scale. Thus, all tool

Scaling factor: $\lambda = \frac{Micro\ sheet\ thickness}{Macro\ sheet\ thickness} = 0.356$

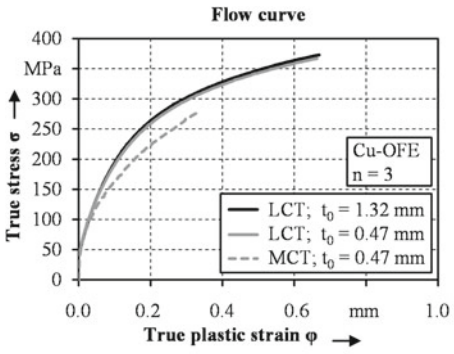
Fig. 1 Process schematics and process parameters for cold bulk macro- and microforming from sheet metal

geometries are scaled down according to the similarity theory of Geiger et al. [16]. The scaling factor is based on the ratio of the available sheet thicknesses and is $\lambda = 0.356$. The dimensions of all active tool elements are given in Fig. 1. Since the grain size of the metallic structure cannot be scaled exactly geometrically, the occurrence of size effects is expected. For all tests, the extrusion oil Dianol ST in a ratio of 10 g/m^2 is used for lubrication. A constant forming speed of 5 mm/min is chosen for all forming steps, analogous to the upsetting tests for material characterization. The process sequences for single-stage and two-stage forming of a pin with cup are described below.

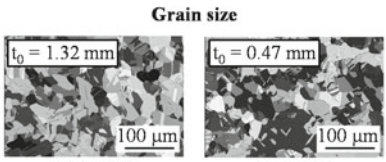
2.2 Two-Stage Forming (1. DIE; 2. IICE)

DIE. In the two-stage forming process for fabricating the demonstrator part (pin with cup), the first forming stage uses DIE to accumulate material in form of a pin. The pin provides the material for the following forming stages. In this forming stage (DIE), the tooling system consists of a die, a blank holder, and a DIE-punch. At the beginning of the process, the workpiece is axially constrained by the blank holder to prevent the sheet metal from bulging. Afterwards, the DIE-punch is moved downwards, causing a material flow axially and radially into the die as well as radially outwards into the sheet metal plane. The aim of this forming stage is to increase the material flow into

the die cavity in order to provide as much material as possible for further forming stages. For this reason, the effects of different blank holder pressures on the pin and blank shape, process quality, and stability are investigated in this work.



IICE. In the second process stage, a cup is extruded on the pre-formed pin from the first process stage by IICE. For this purpose, the tool system remains closed after the first forming stage. During the process, an IICE-punch is moved up until the desired residual pin height (h_{RP}) is reached. As a result, the cup is formed due to the displaced material of the pin.



2.3 Single-Stage Forming (DIE/DICE)

DIE/DICE. In the single-stage forming, the demonstrator part is formed by a combination of DIE and DICE. The process sequence is similar to the DIE. The only difference is the fixed positioning of the DICE-punch in the forming zone at the position of the desired residual pin height (h_{RP}). By forming the pin, a cup is formed when it reaches the DICE-punch. The single-step variant is investigated in this study to determine if the material utilization and the mould filling can be increased by multi-stage bulk microforming from sheet metal.

2.4 Material Characteristics

For all the tests, the copper material Cu-OFE is used. Due to its high purity, the absence of oxide inclusions and its single-phase microstructure, this material is well suited as a model material for the fundamental investigation of the multi-stage bulk microforming process from the sheet metal. Moreover, the material is widely used for electrical components due to its high conductivity of at least 101% IACS. In order to exclude the influence of batch fluctuations on the material properties, the sheet metal is taken from the same melt for the investigations in the macro- and micro-scale. For macro-scale, the material was available with a sheet thickness of 1.32 mm and 0.47 mm for micro-scale. Due to the different pass reductions, the material properties, such as pre-hardening, anisotropy, or grain size, are not identical for the two sheet thicknesses in the as-rolled delivery condition. As the different material states may result in incorrect interpretations during the detection of size effects, the material is heat-treated prior to testing. The heat treatment is carried out in a tube furnace under a protective gas atmosphere (argon) at a temperature of 650 °C. This temperature is held for one hour. The cooling took place slowly over several hours in the furnace keeping the protective gas atmosphere. Through heat treatment, it is possible to reduce the anisotropy of the grains almost completely. The heat treatment resulted in cubic grains with almost no measurable anisotropy. The grain size is 24.0 ± 13.8 µm for $t_0 = 1.32$ mm and 27.5 ± 18.0 µm for $t_0 = 0.47$ mm. Thus, the grain size is almost identical and comparable for both sheet thicknesses (Fig. 2). Due

Initial true stress

	LCT	LCT	MCT
t_0 [mm]	0.47	1.32	0.47
σ_{ys} [MPa]	41.1	40.8	35.7
r_b	0.9	1.0	0.9

Fig. 2 Flow curves from LCT and MCT, grain sizes and grain structure as well as the initial yield stress and biaxial anisotropy for both sheet thicknesses

to the similar stress state to the investigated forming process, the strain hardening behaviour is analysed by layer compression tests (LCT) according to Merklein and Kuppert [17]. The evaluated flow curves and the initial yield stresses are shown in Fig. 2. The diagram confirms that the strain hardening behaviour is approximately identical for both sheet thicknesses.

Additional micro compression tests (MCT) are carried out for a better understanding of the forming behaviour of the material in micro-scale. The specimen diameter and height are each 0.47 mm. The samples are produced with the TruMark3020 Nd: YAG laser from Trumpf. The contour of the samples is exposed in several successive cycles, which results in a removal of the surface. Due to the focused laser beam, with a focus diameter of 30 µm and the short recurring pulses, no measurable heat penetration on the grain structure can be detected in micrographs, since the heat of the laser beam is immediately dissipated into the surrounding material. Figure 2 shows that the work hardening decreases for a smaller sample size at a constant grain size. Thus, the strain hardening behaviour is not only dependent on the grain size itself, there is also a dependence on the sample geometry. Ruan's research team already documented this finding in 2006 [18]. The reason for the decrease of the work hardening due to the miniaturization of the samples can be explained by the surface layer model [4]. Due to miniaturization, the proportion of surface grains gets larger in relation to the sample volume. The surface grains on the curved surface area are not subject to any external compatibility conditions and can thus be more easily displaced radially outwards during upsetting. As a result, the required forming force is reduced. In addition, the number of grains in the micro-sample and thus the absolute grain boundaries are lower. This means that fewer dislocations accumulate at the grain boundaries resulting in a softening effect.

3 Results

The influence of the blank holder pressure on the mould filling (pin height) and the material utilization is investigated in a first step. Based on these results, an appropriate blank holder pressure is selected to analyse the single-stage and two-stage forming strategies.

3.1 Influence of the Blank Holder Pressure

The blank holder pressure is investigated in five gradations between 0 MPa and 200 MPa (Fig. 1). After forming, the pin height is measured tactile by a digital absolute digimatic indicator from Mitutoyo. Figure 3a displays the resulting pin height in relation to the blank holder pressure. It is evident that the pin height increases in the macro- as well as in the micro-scale with increasing blank holder pressure.

According to the Coulomb friction law (1), the friction force increases linearly as a result of the increase of the blank holder pressure and thus the contact force (F_N). Due to the higher friction force between the blank holder and the die in the passive forming zone, the lateral material flow outside in the sheet metal plane is inhibited, which leads according to the condition of continuity to an increase of the lateral material flow towards the die cavity and thus to an increase of the pin height.

$$F_{\text{Friction}} = \mu \times F_N \,(\text{Coulomb fricton law}) \tag{1}$$

The further processing of the pin in subsequent forming stages in a progressive die requires not only the greatest possible material utilization but also the lowest possible deformation of the sheet metal strip in order to realize a precise handling of the strip. The qualitative influence of the blank holder pressure on the sheet metal geometry is presented in Fig. 4 by micrographs. Without the use of a blank holder

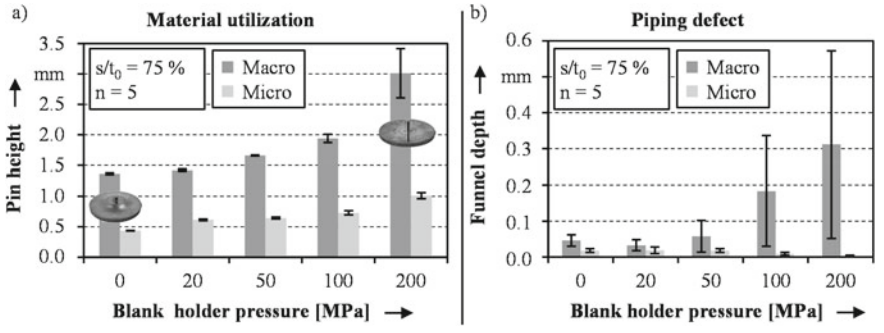


Fig. 3 Influence of the blank holder pressure on pin height and piping defect

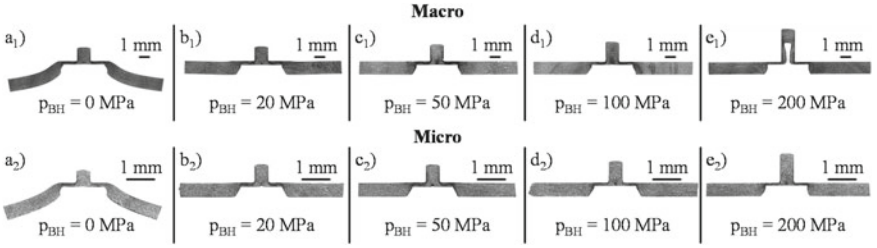

Fig. 4 Micrographs of the pin cross section after DIE in macro- and micro-scale for different blank holder pressures

Table 1 Average blank diameter after forming in relation to the blank holder pressure; n = 5

p_{BH} [MPa]	20	50	100	200
d_{CB1} [mm] (Macro)	15.411	15.462	15.615	15.927
d_{CB1} [mm] (Micro)	5.508	5.521	5.557	5.645

(0 MPa) or if the blank holder pressure is too low (20 MPa), the sheet metal strip is bulging strongly outside the forming zone.

The bulge is reduced with an increasing blank holder pressure and can be completely avoided if the blank holder pressure is sufficient. Regarding the qualitative evaluation of the bulge, there are no differences and thus no size effects between macro- and micro-scale detectables.

For blank holder pressures $p_{BH} > \sigma_{ys}$ the sheet is compressed and plastically deformed by the blank holder. This results in a larger radial expansion of the blank, as shown in Table 1. This enlargement of the blank has a negative effect on the handling in progressive tools. Thus, the blank holder pressure should be selected as high as possible, but always slightly below the yield stress. For the subsequent experiments in this paper, the blank holder pressure of $p_{BH} = 50$ MPa is chosen, as it is the closest to the initial yield stress of Cu–OFE and prevents bulging of the sheet.

The extrusion of pins from sheet metal can result in unwanted piping defects if the process parameters are not selected appropriately [13]. This is the case when the axial material flow velocity (DIE-punch velocity) is lower than the lateral material flow velocity towards the die cavity. As a result, the material detaches from the DIE-punch and a funnel is formed. Figure 3b quantifies the resulting piping defect by the funnel depth in relation to the blank holder pressure. The funnel depth is measured by confocal microscopy on the μSurf from NanoFocus. In macro-scale, the funnel depth increases with rising blank holder pressure. This is not the case in micro-scale. A size effect is present due to the decrease of the funnel depth with increasing blank holder pressure. Besides this, generally smaller funnel depths are observed in micro-scale than in macro-scale, even considering the scaling factor. The shape of the funnel and thus the funnel depth is strongly dependent on the grain structure. Hence, there are also size effects which result in increasing scattering for greater funnel

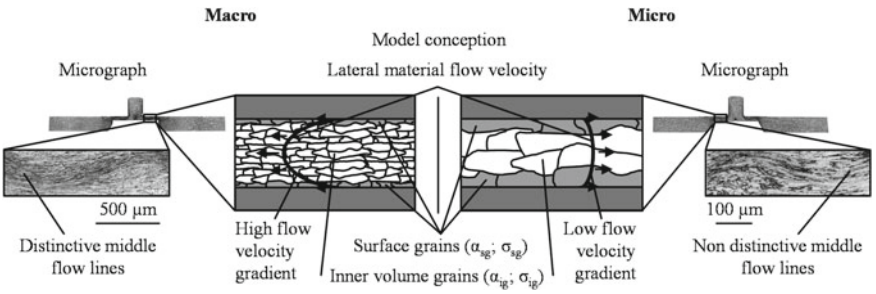

Fig. 5 Surface layer model for the validation of size effects regarding the piping defect

depth. In Fig. 4, the effect of funnel formation is also compared qualitatively for the marco- and micro-scale. Figure 4e_1, e_2 show a large piping defect in macro-scale and no piping defect in micro-scale. This size effect can be explained by transferring the surface layer model [4] to the investigated bulk microforming process from sheet metal. Figure 5 illustrates the surface layer model for the analysed process in macro- and micro-scale as well as the plausibility check based on micrographs of the cross section. Due to the same grain size for macro- and micro-scale, the ratio of surface grains in relation to the total volume is smaller in macro- than in micro-scale, according to the scaling factor.

Surface grains are in direct contact with the forming tools. Thus, the surface friction is transferred into the workpiece through these grains. This results in a large material flow velocity-gradient across the sheet thickness, which can be also observed in conventional DIE-processes. The surface-near grains flow slower than the grains in the middle of the sheet due to the frictional force transferred from the surface grain over the grain boundaries. In micro-scale, the ratio of surface grains is significantly higher than in macro-scale due to the lower grain count. Since there are only a few grains over the cross section, the middle grains are stronger influenced by the surface friction and thus the material flow velocity-gradient is significantly lower than in the macro-scale. As a result, the material flows more homogeneously radially towards the die cavity and does not flow ahead at higher speed in the middle. The more homogeneous material flow results in a reduced piping defect, since there is sufficient material available for an entire mould filling. The described material flow behaviour can be checked for plausibility using the micrographs in Fig. 5. In macro-scale, distinct flow lines in the middle of the sheet can be observed in the micrograph. This indicates a greater deformation in the middle of the sheet and thus a higher material flow velocity. In micro-scale, the flow lines are homogeneously distributed over the entire sheet thickness. The reason for the increase of the funnel depth in macro-scale and the decrease in micro-scale can also be explained by the grain count using the surface layer model. As already mentioned, the lateral material flow outwards into the sheet metal plane is inhibited by increasing blank holder pressure. Thus, the lateral material flow towards the die cavity is enhanced in accordance to volume constancy. The DIE-punch force (active forming zone) increases as a consequence

of the laterally higher flow restriction outwards into the sheet metal plane (passive forming zone). Due to the higher DIE-punch force, the frictional force in the active forming zone increases according to the Coulomb friction law (2). This results in an increase of the lateral material flow velocity-gradient in macro-scale towards the cavity, which favours the forming of piping defects (Fig. 3b). In micro-scale, funnel formation is less than in macro-scale and decreases further with increasing blank holder pressure. This size effect can also be explained by the surface layer model. As less grains are located over the pin cross section and thus the wall friction at the die has a greater influence on the material flow in the centre of the pin, the axial material flow velocity-gradient is also lower in micro-scale than in macro-scale. This is why the funnel depths of the piping defects are relatively smaller in micro-scale. Additionally, the deflection of the grains at the die radius into the die cavity is inhibited in micro-scale due to the lower number of grains. With increasing blank holder pressure and thus higher DIE-punch force, the compatibility condition of the surface grains in the transition area between die/punch and cavity/punch rises. Thus, the deflection and the entry of the material into the die cavity are impeded additionally. This result in a decrease of the funnel depth with increasing blank holder pressure (Fig. 3b).

Figure 6 displays the force–displacement curves for DIE in relation to the punch surface and the sheet thickness in macro- and micro-scale. Without size effects, both curves should be identical. At the beginning of the process, the contact pressure at the DIE-punch is lower in micro-scale than in macro-scale. It can also be observed that the contact pressure increases stronger in micro-scale than in macro-scale during the forming process, causing both curves to converge. At the end of the process, the maximum related punch force in micro-scale is 1238 MPa even slightly higher than in macro-scale with 1212 MPa.

The characteristic of the force–displacement curves can also be explained by the theory of the surface layer model. According to Meßner [19], the yield stress in the surface layer model is calculated by accumulating the yield stresses of the surface and inner volume grains (2). In micro-scale, the yield stress is initially lower due to the fact that the surface grains have lower compatibility conditions due to their free surface and therefore lower yield stresses than the inner grains, which are completely surrounded by neighbouring grains (Fig. 2). Thus, the related process force at the beginning of the process is lower in micro-scale. During the forming process, the contact pressure and thus the frictional force in the process increases. This leads to higher compatibility conditions of the surface grains between workpiece

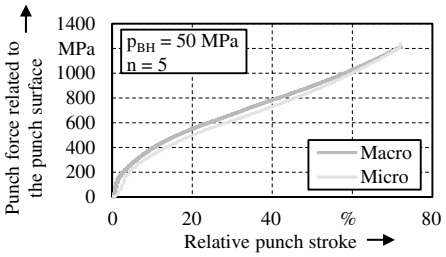

Fig. 6 Force–displacement curves for DIE in relation to the punch surface and the sheet thickness

and tool. In this state, the rigid tool at the contact workpiece-to-tool is more resistant to dislocations than inner grain boundaries. Thus, the related punch force is greater in micro-scale than in macro-scale at the end of the process.

$$\sigma = \alpha_{ig} \times \sigma_{ig} + \alpha_{sg} \times \sigma_{sg} \text{(Surface layer model)} \quad (2)$$

α = Volume share; σ_{ig} = True stress of inner grains; σ_{sg} = True stress of surface grains;

3.2 *Influence of the Process Strategy*

The influence of the process strategy on the material utilization and the mould filling during DIE of a pin with cup is investigated in this study in macro- and micro-scale. The specimens are formed by a single-stage (DIE/DICE) and a two-stage (DIE and IICE) process strategy. The cup height and the residual pin height are measured with the confocal laser-scanning microscope VK-X210 from Keyence. The position of punch 2 (DICE; IICE) is set identically for all configurations. The residual pin height is fixed at $h_{RP} = 1.004 \pm 0.015$ mm in macro- and at $h_{RP} = 0.379 \pm 0.018$ mm in micro-scale according to the scaling factor. Figure 7 compares the measured total heights (cup and residual pin heights) depending on the process strategy and the wall thickness (WT).

First, it can be seen that clearly higher cup heights are achieved for the two-stage process strategy in macro- as well as in micro-scale. In macro-scale, the two-stage process control strategy increases the cup height by 295% for WT = 200 µm and by 264% for WT = 100 µm. In micro-scale, the cup height can be increased by 266% for WT = 71 µm and by 291% for WT = 36 µm. Thus, the increase in material utilization due to the two-stage process strategy is comparable in macro- and micro-scale. Based on this assumption, size effects can be excluded in relation to the process strategy. The reason for the significantly higher material utilization by the two-stage forming process can be traced back to the narrow flow gap between the DICE-punch and

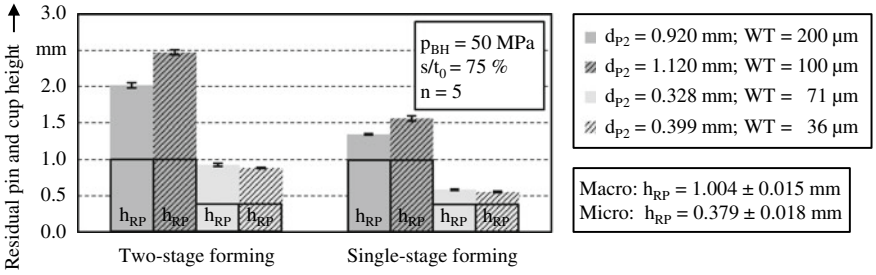

Fig. 7 Total heights (cup and residual pin height) depending on the process strategy and the WT

the die cavity. This gap is clearly smaller than the residual sheet thickness between DIE-punch and the die during forming. Additionally, the wall friction (static friction) caused by the DICE-punch changes the position of the neutral plane radially towards the cavity. Consequently, more material flows radially outwards into the sheet metal plane during single-stage forming. In the two-stage process, the IICE starts after the pin extrusion process (DIE) is completed. At this point, the flow gap between the DIE-punch and the die is $0.25*t_0$, which is significantly smaller than for DIE/DICE (single-stage). The narrow flow gap between DIE-punch and die and the deflection of the axial material flow from the pin by 90 ° into the sheet metal plane cause the material to flow dominantly into the cup wall. Furthermore, the relative velocity of the IICE-punch favours the cup forming in the two-stage process, as the sliding friction at the inner cup wall is lower than the static friction at the die and DIE-punch. As a result, almost the entire displaced material in the pin is used to form the cup.

In the following, only the two-stage process will be discussed, since no size effects occur with regard to the process strategy for the investigated material. In macro-scale, the highest cup height of $h_C = 1.475 \pm 0.028$ mm is achieved for the lower WT = 100 µm. For the WT = 200 µm the cup height is $h_C = 1.013 \pm 0.025$ mm. This is due to the fact, that the used IICE-punch has a larger diameter for smaller WT and thus more material is displaced. Furthermore, due to the small WT, the annular cross-section of the cup is smaller, which is why the cup height is greater in accordance to the volume constancy. In micro-scale, the cup height for the smaller WT = 36 µm is with $h_C = 0.517 \pm 0.009$ mm lower than for the WT = 71 µm with $h_C = 0.561 \pm 0.020$ mm. In contrast to the macro-scale, higher cups for larger WTs are achieved in micro-scale. Thus, a size effect is present here, which can be explained with the aid of the micrographs of the cross sections in Fig. 8 and the surface layer model. In macro-scale, there are 4–11 grains located across the minimum WT = 100 µm. In micro-scale there are only 1–5 grains at WT = 36 µm. Due to the small grain count in micro-scale there are nearly exclusively surface grains through which the frictional force at the active surfaces is transferred into the material. Due to the

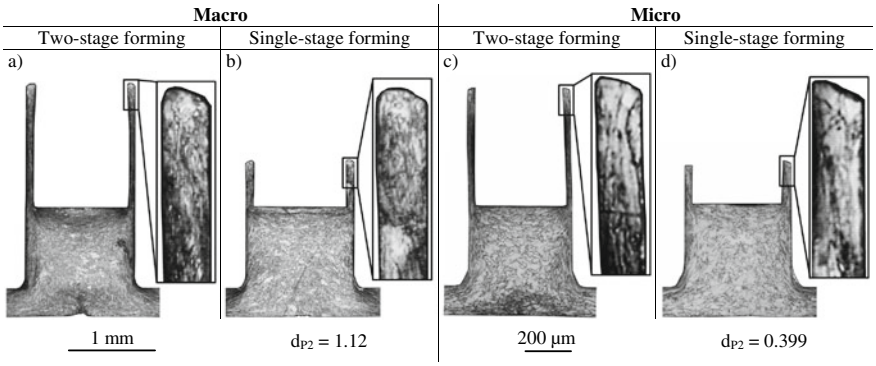

Fig. 8 Micrographs of the cup cross-section after two-stage and single-stage extrusion in macro- and micro-scale

few or non-existent grain boundaries in the material and the very strong hindrance to surface deformation at the rigid tool, the required forming force to fill the cup increases. This means, that the lower the WT and thus the grain count, the higher is the flow resistance to form the cup. Thus, the material is increasingly displaced laterally into the sheet metal plane by the flow gap between DIE-punch and die in micro-scale as the WT decreases. This results in lower cup heights for smaller WTs.

The process standard deviation of the total component length is with 1.52% (macro) and 1.60% (micro) low. Besides, the percental deviation with regard to the cup shape is almost identical in the macro- and micro-scale. In this context, it is shown that the identified size effects do not affect the process variation and thus the process stability. In earlier research studies, uneven cup edges were observed as a size effect during micro cup forming [4]. Due to the process-related grain orientation, the cup edge is formed homogeneously with a maximum tolerance of 0.3 μm (micro). On behalf of the low process variation and the homogeneous forming of the micro part, the investigated process is in principle suitable for the mass production of metallic micro parts.

4 Summary and Outlook

Within this research, extrusion processes from sheet metal plane are investigated in order to produce a micro pin with a cup. To identify size effects, the investigations are carried out in macro- and micro-scale under consideration of a correct geometric scaling. The influences of the blank holder pressure, the single-stage and two-stage process strategies as well as different cup wall thicknesses on the forming of the micro part and the process variation are investigated. The key findings of this study can be summarized as follows:

- The pin height and thus the material utilization increases with increasing blank holder pressure. This also makes it possible to react to fluctuating process parameters such as the sheet thickness or different strengths by adjusting the blank holder pressure.
- The blank holder pressure should be selected as high as possible, but always just below the yield stress in order to prevent plastic deformation of the sheet metal by bulging or thinning.
- In macro-scale, a larger piping defect occurs with increasing blank holder pressure. In micro-scale, the funnels become smaller. This size effect is explained in the article by using the surface layer model.
- The work-hardened pin from the first process stage can be further formed to a cup in macro- and micro-scale.
- The two-stage process strategy enables an increase of the cup heights up to 295% and thus a significant higher material utilization. Single-stage forming results in low cup heights, which is why the multi-stage version with material accumulation in form of a pin and further forming steps is more effective.

- The process strategies have no influence on the occurring size effects.
- In micro-scale, deeper cups are obtained for greater wall thicknesses due to size effects.
- The size effects have no impact on the process variation. The standard deviation is in average 1.52% (macro) and 1.60% (micro). Thus, the process is in principle suitable for the mass production of metallic micro parts for the investigated part dimensions.

In future research work, the investigations will be extended to other materials such as steel and aluminium to ensure the transferability of the scientific findings of this study. Furthermore, the shearing of the micro part by blanking will be studied in a third forming stage. Further studies will focus on the forming of more complex geometries. In this context, the cold bulk microforming process from the sheet metal will be analysed in order to produce metallic micro gears below the current module limit for cold bulk forming.

Acknowledgments The authors would like to thank the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) which founded this work within the project DFG ME 2043/79-1 'Basic research and determination of process limitations in bulk forming processes of microgears from sheet metal'. The authors would also like to show their gratitude to Mr. Manuel Backer, who participated in this experimental study within the scope of his master thesis.

Machine Learning (ML)-Based Prediction and Compensation of Springback for Tube Bending

J. Ma, H. Li, G. Y. Chen, T. Welo, and G. J. Li

Abstract Bent tubes are extensively used in the manufacturing industry to meet demands for lightweight and high performance. As one of the most significant behaviors affecting the dimensional accuracy in tube bending, springback causes problems in tube assembly and service, making the manufacturing process complex, time-consuming, and difficult to control. This paper attempts to present an accurate, efficient, and flexible strategy to control springback based on Machine Learning (ML) modeling. An enhanced PSO-BP network-based ML model is established, providing a strong ability to account for the influences of material, geometry, and process parameters on springback. For supervised learning, training sample data can be collected from the historical production process or, alternatively, finite element simulation and laboratory-type experiments. Using the cold bending of aluminum tubes as the application case, the ML model is evaluated with high reliability and efficiency in springback prediction and compensation strategy of springback.

1 Introduction

As one of the crucial structures for mass/heat transferring and load bearing with enormous quantities and diversities, bent tubular parts have attracted increased application in most industrial fields, such as automobile, aerospace, energy, and so on [1–3]. Springback is a significant issue for tube bending. It refers to the changes of both angles and curvatures after removing the applied tools, leading to a series of problems such as increased tolerance limit, variabilities in assemble, and, sometimes, service performance [3, 4]. From the point of the manufacturing system, springback makes the forming process complex, significantly affecting the process flexibility [5] as well as the adaptive design of control strategies [6]. In addition, this critical problem becomes more dramatic in the manufacturing of complex 3D structures, as well as small production batches with diverse bending angles and curvatures [7]. Thus, achieving accurate control of springback is of importance to high-precision products and integrated design of smart manufacturing systems. However, springback is the "closing work" in a forming process, meaning that all possible factors from the aspects of material property, geometry, and processing conditions can make an impact on springback, thus making it difficult to control dimensional accuracy in tube bending.

Accurate prediction is the premise to achieve effective control of springback. In the past decades, analytical, experimental, and numerical methods have been widely used to estimate springback in metal forming [3, 4]. The analytical method allows fast springback calculation for simple forming cases, offering an advanced understanding of springback characteristics and mechanisms. The finite element (FE) numerical approach can simulate the actual forming process, in particular, with modeling of the complex contact/friction conditions and nonlinear material properties, thus providing accurate predictions of forming defects, such as thinning, distortion as well as springback once high reliability can be ensured. FE-assisted optimization of tooling and process parameters is widely used in the design stage of the forming process. The experimental approach, however, is generally based on "trial-and-error" to search for a satisfactory result. Furthermore, in recent years, several Deep Learning (DL) methods also emerge in springback analysis to explore the control of dimensional accuracy [8–10].

To this date, most FE-based works and DL-based attempts on springback are focused on sheet metal forming, yet with much less concern on the tube bending processes. The "trial-and-error" approach still acts as the main strategy for springback compensation in tube bending production [1, 3], in which at least 2–3 times bending trials are commonly needed to find out an acceptable compensation solution. It causes some critical problems, including production downtime, high costs, waste of materials, scrap, and increased process uncertainties. This is particularly true for the industrial production of bent tubular parts with small batches and multiple part configurations. Even though FE simulation can be used as the virtual "trial-and-error" to reduce the physical trials, it is also a non-added value operation to simulate all the possible forming conditions. In addition, FE simulation with the deterministic target

springback problem can hardly meet the need for process flexibility. To address these problems, it is a need to develop a feasible and effective strategy that can provide a reliable and fast evaluation of compensation for springback, at the same time, with the possibility for the integrated design of closed-loop-control to improve the product accuracy and enhance the process flexibility for tube bending.

To this aim, this work attempts to develop a flexible strategy for springback prediction and compensation in tube bending based on the ML modeling framework. Training datasets for supervised learning can come from the historical production process, alternatively laboratory-type experiments, and FE simulation. Using the cold bending of aluminum alloy (Al-alloy) tubes as the application case, the ML model is verified in both springback prediction and compensation. Based on this research, an outlook on the future development and industrial application of the ML-based springback control strategy is presented.

2 Methodology

2.1 Overview of ML-Based Modeling for Springback

As mentioned above, almost all the possible factors throughout the forming process can make a difference in springback. In fact, as shown in Fig. 1, in addition to springback, the other geometry dimensions, such as wall thickness, ovalization, etc., as well as product performance, such as working pressure, fatigue, etc., are closely related to the above-mentioned influential factors from the aspect of material, geometry, and process. To this end, a "bridge" can be built to link the various input and/or in-process

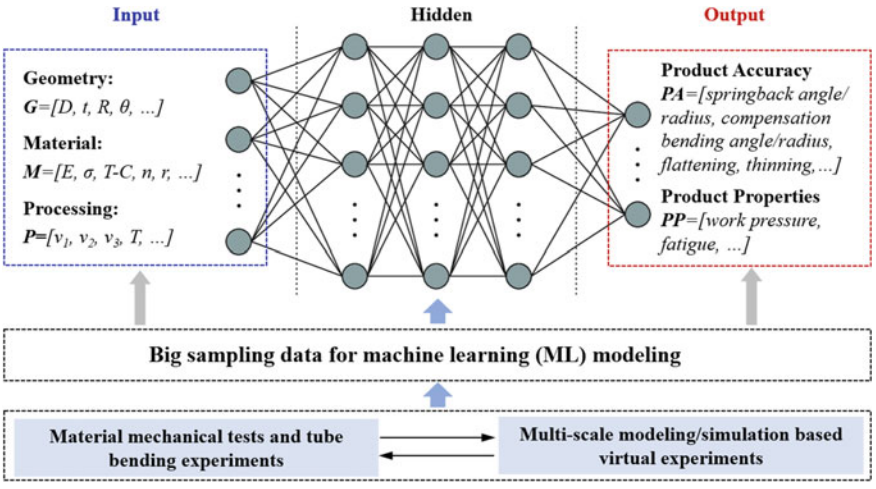

Fig. 1 Overview of the ML-based modeling for tube bending

variables and different output indexes based on big-data mining and analysis, thus achieving better control of product quality and forming process, as well as reducing the manufacturing investment.

However, the accuracy and reliability of the "bridge" model highly depend on the number and quality of sampling data. If the data is all from physical experiments, it will uncourtly cause dramatic time consumption and high cost, especially in small production batches with diverse angles, radius, and spatial structures. Therefore, the idea of this model is to establish the sampling data source by combining typical experiments, such as material property tests and forming experiments, and the multi-scale simulation-based virtual experiments, such as through-process FE simulation of bending–springback. Based on the big-data analysis, a machine learning model can be constructed to map the relation between multiple input variables and springback, thus achieving accurate compensation for springback in tube bending.

2.2 *Rotary Draw Bending and Springback*

Rotary draw bending (RDB) is taken as the forming process in the application. RDB is the most commonly used method for the manufacturing of bent tubes with high dimension accuracy. As shown in Fig. 2a, the whole tube is subjected to the multi-tool constraints; viz., bend die, clamp die, pressure die, wiper die, and flexible mandrel die. Under the joint action of a multi-tool, the tube is drawn around the bending center to form a bent tube with a certain bending radius and angle. Then, the tube is unloaded upon removal of the tools, and springback occurs, as shown in Fig. 2b. Springback in tube bending can cause both changes of released bending angle and radius. For a targeted bending geometry, the processing conditions are always pre-determined after optimization.

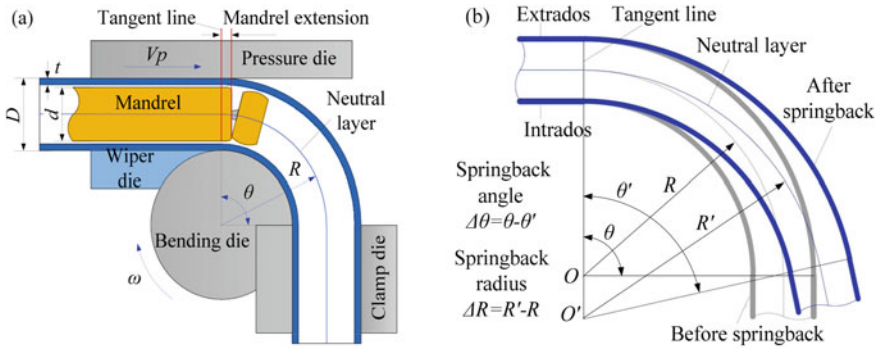

Fig. 2 Schematic view of rotary draw bending: **a** forming principle and tooling system; **b** unloading springback. (Color figure online)

In order to characterize the springback under different bending angles, a springback ratio coefficient is defined as follows:

$$\eta = \Delta\theta \big/ \theta_{\mathrm{b}} = (\theta_{\mathrm{b}} - \theta_{\mathrm{a}}) \big/ \theta_{\mathrm{b}} \tag{1}$$

where η is the springback ratio coefficient, $\Delta\theta$ denotes the amount of springback angle, θ_{b} and θ_{a} represent the bending angle before unloading and actual angle after springback, respectively.

As for springback compensation, a compensation coefficient is also defined as shown in Eq (2):

$$C = \Delta\theta_{\mathrm{c}} \big/ \theta_{\mathrm{t}} = (\theta_{\mathrm{c}} - \theta_{\mathrm{t}}) \big/ \theta_{\mathrm{t}} \tag{2}$$

where C is the compensation coefficient, θ_{t} is the targeted bending angle, and $\Delta\theta_{\mathrm{c}}$ is the amount of compensation angle. Here, θ_{c} is the compensated bending angle, which can further be calculated as follows:

$$\theta_{\mathrm{c}} = (1 + C)\theta_{\mathrm{t}} \tag{3}$$

If the compensation coefficient can be identified, the springback compensation thus can be realized. However, achieving this coefficient presumes an accurate prediction of the springback angle under different bending conditions.

3 Machine Learning Modeling

A myriad of ML algorithms has been developed to address the problems with different features. Among these algorithms, the backpropagation (BP) neural network is the most widely used due to its advanced algorithm structure, which shows a strong ability and potential in recognizing the underlying complicated patterns in engineering tasks [11]. Furthermore, there is a number of successful experiences with utilizing the BP neural network in manufacturing processes, such as stamping, additive manufacturing [12]. Therefore, in this work, the BP neural network is employed as the base to model the relationship between the input variables and springback for tube bending process.

3.1 BP Neural Network

The BP neural network is a multi-layer feedforward network algorithm that is trained according to an error backpropagation scheme [13]. A three-layer BP network with the input layer, the hidden layer, and the output layer is selected as the baseline to construct the ML model. The Hecht–Nelson method is used to determine the node

number of the hidden layer; that is, the node number of the hidden layer is (2n + 1) times the node number of the input layer. For the output, only the springback ratio or compensation coefficient is the objective in this work, which implies that the node number is just set as one.

The basic procedure of the BP network is described as follows:

Step 1: Calculation of hidden layer output:

$$H_j = f\left(\sum_{i=1}^{n} w_{j,i} \cdot x_i + a_j\right) \tag{4}$$

where $w_{j,i}$ represents the connection weight from input node i to hidden node j, a_j is the bias of the neuron j, H_j is the output of hidden layer node j, and f is the activation function of a node.

Step 2: Calculation of the final output:

$$O_k = f_{\mathrm{o}}\left(\sum_{k=1}^{m} w_{k,j} \cdot H_j + b_k\right) \tag{5}$$

where $w_{k,j}$ represents the connection weight from hidden node j to output node k, b_k is the bias of the neuron k, O_k is the output data, and f_{o} is the activation function of output layer nodes.

Step 3: Global minimization of error by training the algorithm:

$$e_k = \sum_{k=1}^{m} |y_k - O_k| \tag{6}$$

where e_k is the error and y_k represents the experimental result of output node k.

Step 4: Check of error tolerance and update of weight coefficients.

3.2 PSO Algorithm

Particle swarm optimization (PSO) was proposed by Kennedy and Eberhart [14], representing an evolutionary computation algorithm inspired by the flocking behavior. In the PSO algorithm, a swarm of particles keeps moving around in a problem space according to the best-known positions of each particle and the entitle swarm, in searching for the optimal solution. The position and moving velocity of the particles in the D-dimensional space are described as follows:

$$\begin{cases} V_i^{t+1} = w^t V_i^t + c_1 r_1 \left(p_{\mathrm{best},i}^t - X_i^t\right) + c_2 r_2 \left(g_{\mathrm{best},i}^t - X_i^t\right) \\ X_i^{t+1} = X_i^t + V_i^{t+1} \end{cases} \tag{7}$$

where X_i^t is the position of particle i in at the t^{th} iteration, V_i^t represents the velocity of this particle, c_1 and c_2 are the learning factors controlling how far a particle can move in a single iteration, and r_1 and r_2 are two random number within [0, 1]. In Eq. (7), $p_{\text{best},i}^t$ and $g_{\text{best},i}^t$ are the optimal position of the particle and the global optimal position of all particles at the tth iteration, respectively, and the w^t is the inertia weight coefficient that makes a balance of the local and global search ability.

In the PSO algorithm, the linearly decreasing inertia weight is commonly used. However, the linear decreasing weight has two drawbacks; viz., the low velocity of convergence when the best point can be detected at an early computation state, and the decreased global search ability with decreasing the weight [15]. Thus, in this model, a nonlinear inertia weight is used to improve the search ability, as shown in Eq. (8):

$$w^t = w_{\max} - \left(w_{\max} - w_{\min}\right) \cdot \tan\left(t \Big/ t_{\max} - \pi \Big/ 4\right) \tag{8}$$

where $w_{\max}$ and $w_{\min}$ are the maximum and minimum inertia weight, and $t_{\max}$ is the maximum iteration, respectively.

In addition, to further improve the global search ability of the PSO algorithm, a crossover operator can be applied after each iteration [16]. According to a given crossover probability, a certain number of particles will be chosen for random hybridization, and then the same number of offspring particles are generated. The position of the offspring particle is determined as

$$X^t = r X_I^t + (1 - r) X_{II}^t \tag{9}$$

where r is a random value within [0, 1], and the subscript "I" and "II" are two parent particles.

The velocity of the offspring particle is calculated by Eq. (10) from their parent particles.

$$V^t = \left|V_I^t\right|\left(V_I^t + V_{II}^t\right) \Big/ \left|V_I^t + V_{II}^t\right| \tag{10}$$

Through the crossover operator, the offspring particles can avoid falling into the local optimization, thus improving the global search ability.

3.3 Enhanced PSO-BP-Based ML Model

By combining the BP neural network and the PSO algorithm with a crossover operator, an enhanced PSO-BP-based machine learning model is thus established. Figure 3 demonstrates the computation flowchart of the proposed ML model. Based on Matlab, the model is numerically implemented for the application in the next section.

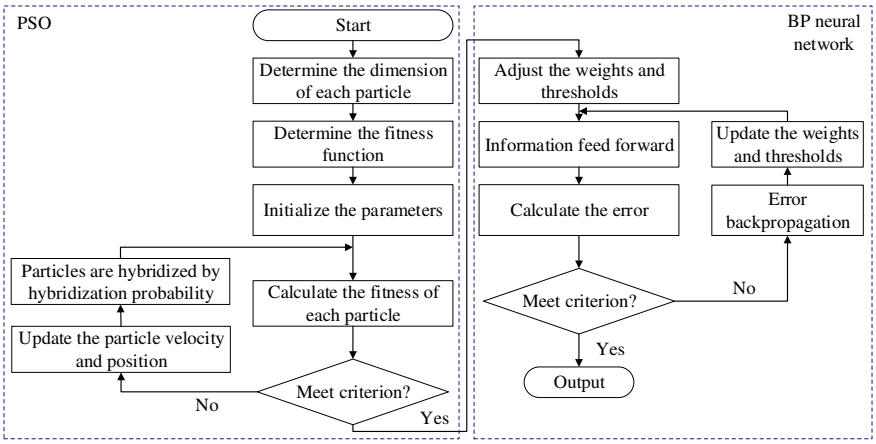

Fig. 3 Flowchart of the enhanced PSO-BP neural network model. (Color figure online)

4 Application and Evaluation

In this application, AA5052-O tubes with eight types of specifications (diameter and thickness) are used. Even though the material grades are the same, variations exist in the mechanical properties between different specifications. Table 1 shows the mechanical properties obtained by uniaxial tension tests, indicating a significant variation in the elastic modulus, yield strength, working hardening, etc. Springback magnitude is determined by the bending moments, elastic modulus, and residual stress after unloading, etc. All the mechanical parameters listed in Table 1 can cause an influence on the stress/strain distribution, further affecting the springback. Therefore, the above material parameters are set as the independent input variables in the ML model. Besides, the geometry parameters—viz., outer diameter, thickness, the

ratio of bending radius to outer diameter, and bending angle—are also set as independent input variables. As the tooling/process parameters are generally determined after optimization and then keep constant in production, these parameters are not considered in this work. Figure 4 shows the rotary draw bending process and the typical experimental part.

For the supervised machine learning of this model, the training sample set should be first established. In this application case, only the experimental data collected from the historical tube bending production in a company be used to establish the big-data source, and further to explore the feasibility of the ML model. The training sample data source is comprised of 46 sets of experimental input and springback data, which is acquired from the industrial production process in the company. The training set covers different bending geometries of the above-described eight types of tubular materials, in which the range of bending angle is $\theta = 9$~$122.2°$, and the range of relative bending radius is $R = 2$~$3D$. As shown in Table 2, five sets of experimental inputs are chosen as the test samples to evaluate the prediction accuracy. According to the description in Sect. 3, the parameters related to the ML model are determined

Table 2 Springback prediction based on the ML model

Table 3 Springback compensation based on the ML model

Input				Sp. compensation output + actual result			
D [mm]	t [mm]	Relative bending radius, R/D	Target bending angle, θ_t [°]	Exp. comp. angle, $\Delta\theta_{c,exp}$ [°]	Pred. comp. angle, $\Delta\theta_{c,pred}$ [°]	Absolute error [°]	Relative error [%]
10	1.0	3	32.00	2.20	2.11	0.09	3.91
16	1.0	2	33.40	1.10	0.81	0.29	26.10
22	1.0	2	64.90	1.30	1.21	0.09	7.08
30	1.0	2	89.50	1.70	1.91	0.21	12.53
70	1.5	2	50.80	1.70	1.65	0.05	2.82

as follows: the number of particles: 40, learning coefficient: 2.05, maximum weight: 0.9, minimum weight: 0.4, maximum velocity: 1, hybrid probability: 0.7.

After 34 iterations within 300 s, the prediction results can be calculated, as shown in Table 2. It can be found that the maximum absolute error is 0.188°, the average relative error is 6.29%. Compared with the traditional PSO-BP model, by introducing the crossover operator, not only the prediction accuracy is greatly improved but also the computation time is significantly reduced from 1.5 h to 300 s. For the springback compensation, the computation is completed after 32 iterations within 200 s. As shown in Table 3, the predicted compensation angles can agree with the experimental ones except for one abnormal case. The average absolute error and relative of the compensation angle are 0.15° and 10.49%, respectively. The maximum absolute error is 0.29°, which also meets the tolerance of $\pm$ 0.3° in many application cases.

However, we can find from the predictions of both springback angles and compensation angles, as shown in Tables 2 and 3, that there is still a pronounced variation in the prediction errors, which indicates a probability that an unacceptable prediction occurs. The reason for this variation might be attributed to the sample data used for training the ML model. In this application, the tube specifications (i.e., outer diameter and thickness), and bending geometries (i.e., bending angle and bending radius) vary significantly, however, training data only comprise 46 sets of experimental data from the historical production process. The accuracy of machine learning is sensitive to the number of samples and enlarging the high-quality datasets with a certain range can improve the performance [10, 17]. Thus, for the problem in this work, increasing the size of high-quality training datasets may be helpful to the improvement of springback prediction and compensation. However, it does not mean that the more data of samples, the better performance of the model. The large size of datasets always means an increased computation time. Besides, machine learning can show effectiveness when it is applied to limited types and size of data and well-defined tasks [10]. It needs further exploration to find an optimal size of datasets, thus ensuring the performance as well as balancing the efficiency of the ML model.

5 Conclusions and Outlook

This paper presents a Machine Learning framework for springback prediction and compensation in tube bending towards the improvement of product dimensional accuracy, and process flexibility. The model is based on an enhanced PSO-BP algorithm, which enables a strong ability to address the complex influences of material properties, bending geometries and process parameters on springback, at the same time, has a high computation efficiency. Using the cold rotary draw bending process of Al-alloy tubes, the ML model is verified with high accuracy and efficiency in both springback prediction and compensation. In this application case, the experimental data that are collected from the historical production process in a company is applied for model training. Both the flexible bending geometries (i.e., tube diameter, thickness, bending radius, and bending angle) and the variations of material properties (elastic modulus, yield strength, work hardening exponent, etc.) of the Al-alloy tubes with respect to different specifications are considered to accommodate their influences on springback. The process parameters, however, are not yet considered due to the limited real-time data collection in the forming process.

In future research work, FE simulation-based virtual experiments in combination with typical physical experiments will be used to provide a big-data source for supervised learning of the model, thus improving the prediction/compensation accuracy and reducing the manufacturing investment. In addition, the model will be integrated into the manufacturing system of tube bending, thus seeking a self-adaptive enhancement of the model capability by training with the real-time production data. Finally, a close-loop-control strategy of springback in tube bending will be explored based on the ML model with both offline and online learning.

Ductile Fracture Prediction of Hot-Stamped Boron Steel 22MnB5 with Modified Mohr–Coulomb and Hosford–Coulomb Models

Fangxing Wu, Bingtao Tang, Ning Guo, Huiping Li, and Qiaoling Wang

Abstract With the increasing demand for the reduction in energy consumption and enhancement of automobile safety, ultra-high-strength steel are widely used in the automobile industry. Due to the high achievable strength, hot stamping process can be used to supply promising automobile components. The increasing use of high-strength steels provides particular challenges to fracture modeling due to their microstructures and processing conditions. This paper is concerned with plasticity and ductile fracture modelling of hot-stamped boron steel 22MnB5, where martensite phase with high yield strength, work hardening, and ductility are present. The modified Mohr–Coulomb criteria as well as Hosford–Coulomb criteria are implemented using VUMAT in ABAQUS. Parameters of the selected fracture criteria are determined using calibration tests with various kinds of specimen. Fracture properties and flow curves up to large strains are determined from single-phase tensile experiments using digital image correlation. The final hole expansion test shows that the Mohr–Coulomb ductile fracture criterion is more suitable to model ductile fracture in metal forming proc

Keywords Ductile fracture · Boron steel · Hot stamping

1 Introduction

It is critically important to accurately model and predict the failure and fracture behavior with the increased use of high-strength steel components of automobile body structure [1]. Ductile fracture is widely believed to be the main reason for failure

during forming of advanced high strength steels, aluminum alloys, titanium alloys, and magnesium alloys [2, 3]. Similarly, it is critical to ensure accurate prediction when modeling crash loading sequences [4, 5]. More and more ductile fracture criteria were proposed in the last decade to model ductile fracture behaviors of these advanced metals [6–8].

In this study, the plasticity and ductile fracture of hot-stamped boron steel 22MnB5 are modeled. Four different fracture criteria including two modified Mohr–Coulomb (MMC) and two Hosford–Coulomb (HC) have been implemented in ABAQUS/Explicit using users' subroutine VUMAT. Experiments are conducted on hot-stamped boron steel 22MnB5 (t = 1.8 mm) to calibrate ductile fracture criteria under various stress states, including in-plane shear, uniaxial tension, plane strain tension, and verified by hole expansion test. Digital Image Correlation (DIC) method is applied to monitor the surface pattern and record the strain evolution of the specimen surface during the experiment. Testing of dogbone specimens made in various directions shows that the von Mises criterion with isotropic strain hardening criterion is a simple and accurate choice [9]. Fracture strains of these specimens are calculated by hybrid numerical-experimental method [7] and used to calibrate the parameters of the four different fracture criteria. The calibrated criterion is then utilized to model the dependence of ductile fracture under various loading conditions. Finally, different ductile fracture criteria are compared with experimental results to evaluate their accuracy.

2 Modified Mohr–Coulomb Fracture Criterion

Three-dimensional principal stress vector $(\sigma_{1,}\sigma_{2,}\sigma_3)$ is used to define the stress state. Two stress invariants η and $\overline{\theta}$ are usually used to identify the stress state. The stress triaxiality η is defined as the ratio of the mean stress σ_m to the von Mises equivalent stress $\overline{\theta}_{VM}$:

$$\eta = \frac{\sigma_m}{\overline{\theta}_{VM}} \text{with} \sigma_m = \frac{tr(\boldsymbol{\sigma})}{3} \text{and} \overline{\theta}_{VM} = \sqrt{\frac{3}{2}\boldsymbol{\sigma}' : \boldsymbol{\sigma}'} \tag{1}$$

where $\boldsymbol{\sigma}'$ is the deviatoric stress and the normalized Lode angle $\overline{\theta}$ ranging from -1 to 1 is expressed as

$$\overline{\theta} = 1 - \frac{2}{\pi}\arccos\left(\frac{27}{2}\frac{det(\boldsymbol{\sigma}')}{\overline{\theta}^3_{VM}}\right) \tag{2}$$

Bai and Wierzbicki [10] modified the Mohr–Coulomb (MC) criterion to describe ductile fracture behavior of metals. The modified MC (MMC) criterion was expressed in the space of $\left(\eta, \bar{\theta}, \bar{\varepsilon}^p\right)$. The modified Mohr–Coulomb criterion (MMC4) with four fracture parameters c_1, c_2, $c_3$and c_θ to be calculated by experimental data is expressed

in Eq. (3):

$$\bar{\varepsilon}_f = \left\{ \frac{K}{c_2} \left[c_3 + \frac{\sqrt{3}}{2-\sqrt{3}} (c_\theta - c_3) \left(\sec\left(\frac{\pi \bar{\theta}}{6} \right) - 1 \right) \right] \times \left[\sqrt{\frac{1+c_1^2}{3}} \cos\left(\frac{\pi \bar{\theta}}{6} \right) + c_1 \left(\eta + \frac{1}{3} \sin\left(\frac{\pi \bar{\theta}}{6} \right) \right) \right] \right\}^{-\frac{1}{n}} \tag{3}$$

In case of $c_\theta = 1$, the MMC4 criterion is reduced to MMC3 in a form shown below:

$$\bar{\varepsilon}_f = \left\{ \frac{K}{c_2} \left[c_3 + \frac{\sqrt{3}}{2-\sqrt{3}} (1 - c_3) \left(\sec\left(\frac{\pi \bar{\theta}}{6} \right) - 1 \right) \right] \times \left[\sqrt{\frac{1+c_1^2}{3}} \cos\left(\frac{\pi \bar{\theta}}{6} \right) + c_1 \left(\eta + \frac{1}{3} \sin\left(\frac{\pi \bar{\theta}}{6} \right) \right) \right] \right\}^{-\frac{1}{n}} \tag{4}$$

with K and n related to strain hardening properties.

3 Hosford–Coulomb Fracture Criterion

Mohr and Marcadet [11] modified the Mohr–Coulomb criterion by expressing it as a linear combination of the Hosford equivalent stress and the normal stress acting on the plane of maximum shear stress reaching a critical value b [12]:

$$\bar{\sigma}_{HF} + c(\sigma_1 + \sigma_3) = b \tag{5}$$

Here σ_1,σ_2, and σ_3 are the principal stresses ($\sigma_1 \geq \sigma_2 \geq \sigma_3$), c is the friction coefficient in the Mohr–Coulomb criterion. The Hosford equivalent stress can be expressed as

$$\bar{\sigma}_{HF} = \left\{ \frac{1}{2} \left((\sigma_1 - \sigma_2)^a + (\sigma_1 - \sigma_3)^a + (\sigma_2 - \sigma_3)^a \right) \right\}^{\frac{1}{a}} \tag{6}$$

Equation (6) can be transformed to the space of $\left(\eta, \bar{\theta}, \bar{\varepsilon}^p\right)$. Thus, Hosford–Coulomb fracture criterion for a strictly proportional loading can be expressed as

$$\bar{\varepsilon}_f^{pr}\left[\eta, \bar{\theta}\right] = b(1+c)^{\frac{1}{n_f}} g\left[\eta, \bar{\theta}\right] \tag{7}$$

With

$$g\left[\eta,\bar{\theta}\right]=\left(\left\{\frac{1}{2}\left((f_1-f_2)^a+(f_1-f_3)^a+(f_2-f_3)^a\right)\right\}^{\frac{1}{a}}+c(2\eta+f_1+f_3)\right)^{-\frac{1}{n_f}} \tag{8}$$

The Lode angle parameter-dependent functions can be written as

$$f_1\left[\bar{\theta}\right]=\frac{2}{3}\cos\left[\frac{\pi}{6}\left(1-\bar{\theta}\right)\right] \tag{9}$$

$$f_2\left[\bar{\theta}\right]=\frac{2}{3}\cos\left[\frac{\pi}{6}\left(3+\bar{\theta}\right)\right] \tag{10}$$

$$f_3\left[\bar{\theta}\right]=-\frac{2}{3}\cos\left[\frac{\pi}{6}\left(1+\bar{\theta}\right)\right] \tag{11}$$

In this paper, if the transformation coefficient n_f is always set to 0.1, the criterion is named HCI, while if it is involved in the calibration of the fracture criterion, the criterion is called HCII. Therefore, there are three parameters, a, b, and c to be identified for HCI, while four parameters, a, b, c, and n_f to be determined for HCII.

The two uncoupled fracture models assume that the evolution of damage has no effect on the effective stress–strain response of the material before fracture occurs. Within this framework, damage is depicted using the scalar variable D, and its increase $dD \geq 0$ is defined through the increment of the equivalent plastic strain $\overline{\varepsilon}^p$ with respect to a stress-dependent reference failure strain $\hat{\varepsilon}$ [13].

$$dD=\frac{d\overline{\varepsilon}^p}{\hat{\varepsilon}(\boldsymbol{\sigma})} \tag{12}$$

It is assumed that the material is in its unreformed state in case of $D = 0$ and in fracture initiation process when $D = 1$.

4 Experiments for Hot-Stamped Boron Steel 22MnB5

Experiments are conducted for hot-stamped boron steel 22MnB5 to characterize the plastic and fracture behaviors of the alloy. The in-plane shear specimens are used in experiments to figure out the stress–strain curve. The material work hardening behavior at large strain is obtained by the reverse engineering approach.

The fracture behavior is investigated by five types of specimens: specimens with a central hole, notched specimens (R2.5, R5, R10), in-plane shear, and equi-biaxial test specimens. Stretching processes are recorded by a three-dimensional GOM Aramis

Table 1 Fracture stains of hot-stamped boron steel 22MnB5 and its Lode parameter and stress triaxiality by hybrid method

Specimens	Lode parameter (L)	Lode angle (θ)	Normalized lode angle ($\bar{\theta}$)	Stress triaxiality (η)	Fracture strain (ε_f)
Central hole	− 0.8460	0.0692	0.8678	0.4826	0.6904
Notched R5	− 0.0515	0.4939	0.0568	0.6891	0.5155
In-plane shear	− 0.0457	0.4972	0.0504	0.0183	0.8516
Equi-biaxial	0.9741	1.0359	− 0.9784	0.6330	0.3765

system for the experimental measurement of fracture strains. The von Mises equivalent plastic strains are calculated right before the onset of ductile fracture for these tests and considered as the fracture strains. The normalized Lode parameter and stress triaxiality as well as the ductile fracture strain are recorded in Table 1 for various specimens.

5 Application of the Ductile Fracture Criterion to Hot-Stamped Boron Steel 22MnB5

According to the experimental data shown in Table 1, four different fracture loci are constructed in Fig. 1a–d, respectively in the coordinate of Lode parameter and stress triaxiality. The related experimental data is also plotted in the

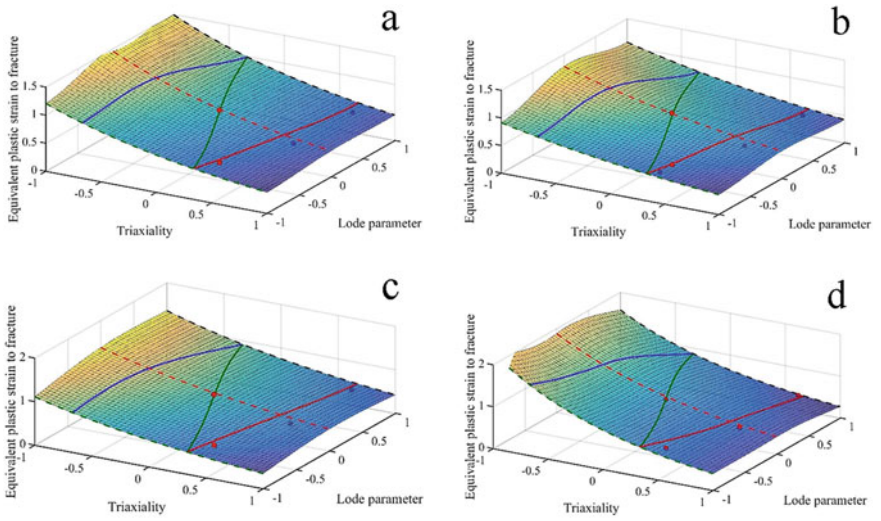

Fig. 1 The constructed fracture loci optimized with the fracture strains **a** HCI; **b** HCII; **c** MMC3; **d** MMC4. (Color figure online)

figures. The constructed fracture loci meet most of the experimental data. The fracture parameters for MMC3 are optimized as K = 1710.8MPa, n = 0.05, c_1 = 0.0133, c_2 = 843.44and c_3 = 0.8624, while for MMC4 are optimized as K = 1710.8MPa, n = 0.05, c_1 = 0.0219, c_2 = 866.27, c_3 = 0.8830and c_θ = 1.0428, and for HCI are optimized as $a = 2.5036, b = 0.5466, c = 0.0295$. Finally, the parameters for HCII are optimized as $a = 2.2542, b = 0.4892, c =$ 0.0077and $n_f = 0.0328$.

The calibrated and constructed fracture loci are implemented using user's subroutine VUMAT in ABAQUS/Explicit. The evolution of ductile fracture is simulated for the central hole, notched R5, in-plane shear as well as hole expansion test specimens. The evolution of load–stroke curves for experiments and numerical simulations for specimen of hot-stamped boron steel 22MnB5 are described in Fig. 2. Table 2 shows the comparison of the calculated fracture displacement with the averaged experimental displacement with four types of fracture criteria. The error functions can be written as

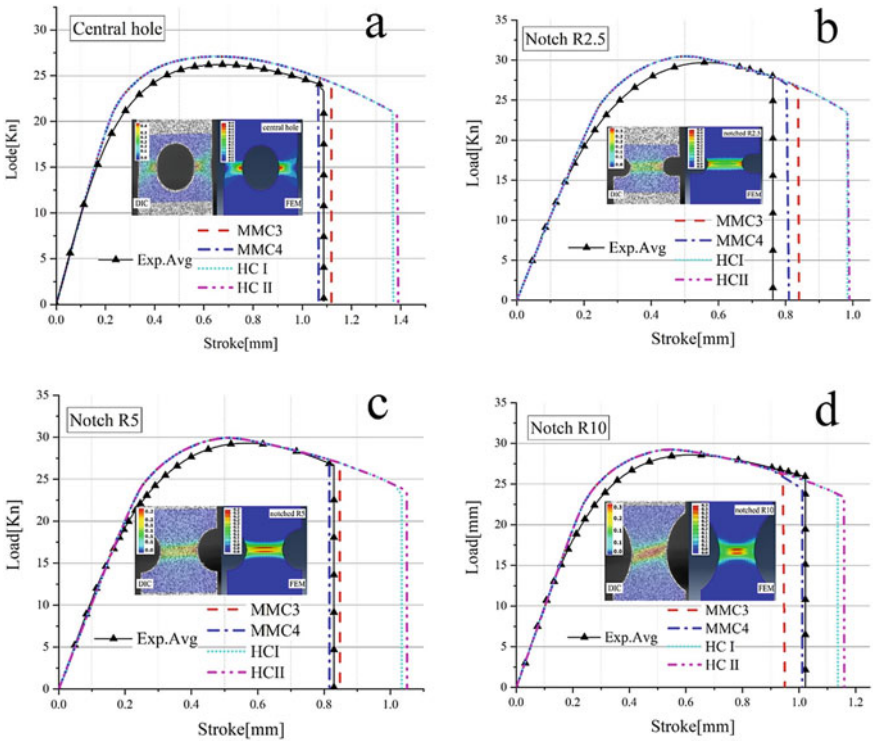

Fig. 2 FE simulation results of tensile process for **a** central hole; **b** notched R2.5; **c** notched R5; **d** notched R10; **e** in-plane shear; **f** hole expansion test. (Color figure online)

Table 2 Comparison of the calculated fracture displacement with the averaged experimental displacement

Specimens	Exp. average (unit:mm)	MMC3(Err)	MMC4(Err)	HCI(Err)	HCII(Err)
Central hole	1.105	1.118(1.19%)	1.066(3.51%)	1.366(23.64%)	1.384(25.27%)
Notched R2.5	0.751	0.840(11.82%)	0.810(7.83%)	0.984(31.03%)	0.983(30.89%)
Notched R5	0.814	0.848(4.24%)	0.816(0.30%)	1.034(22.00%)	1.049(28.87%)
Notched R10	1.072	0.950(11.40%)	1.011(5.69%)	1.137(6.06%)	1.159(8.12%)
In-plane Shear	1.547	1.390(10.18%)	1.440(6.94%)	2.179(40.85%)	2.410(55.79%)
Hole expansion	20.553	21.232(3.30%)	20.514 (0.19%)	38.090(85.33%)	34.906(69.83%)

$$Err = \frac{\left|d_{Expave} - d_f\right|}{d_{Expave}} \tag{13}$$

where d_{Expave} is the averaged experimental displacement,d_f is calculated displacement by fracture criterion.

The plastic deformation and fracture evolution of central hole specimen, three notched specimens, in-plane shear specimen as well as hole expansion test specimen are simulated with four ductile fracture criteria. The comparison of load–stroke curves between FE simulation and experimental data in Fig. 2 shows that the MMC3 and MMC4 ductile fracture criteria meets the experiments quite well. In case of the fracture displacement predicted by the MMC4 fracture criterion, its Err is less than 8%. For the MMC3 fracture criterion, the prediction accuracy is not as good as the MMC4 fracture criterion and its Err is less than 12%. Figure 2 shows that the stroke predicted by two HC models is significantly exceeding the one of the experiment. The reason is due to the overestimation of fracture strains shown in Table 2. It shows that two HC models are not proper to predict the fracture evolution of hot-stamped boron steel 22MnB5.

In case of in-plane shear specimen, the fracture stoke is slightly underestimated by the calibrated ductile fracture models even using MMC4 fracture model. The reason is that, for in-plane shear specimen, the used shear strain to calibrate the fracture criterion is not the true equivalent plastic strain at fracture stroke. Because the change of the Lode parameter and the triaxiality is more severe, the predicted ductile fracture strain by hybrid numerical–experimental method is of a little discrepancy compared with that of experimental data. But the predicted load–stroke evolution of the specimens is still acceptable, showing the wide applicability of the MMC4

fracture model when the stress state ranges from uniaxial tensile to plane strain tensile state.

6 Conclusions

In this paper, four types of fracture criteria, MMC3, MMC4, HCI, and HCII, are applied to predict the fracture behavior of hot-stamped boron steel 22MnB5. Five types of specimens are used to determine the parameter values of fracture criteria and evaluate the their prediction accuracy under different stress states. Hole expansion tests are carried out to investigate their accuracy in case of non-proportional loading conditions. It proves the modified Mohr–Coulomb criteria, especially MMC4 can accurately predict the fracture of high strength steels such as hot-stamped boron steel 22MnB5 under a wide range of stress condition not only in proportional but also in non-proportional loading process.

Understanding the Microscale Plastic Behavior and Deformation Mechanism of Magnesium Alloy via Ex Situ Experiments and Full-Field Crystal Plasticity Modeling

Haiming Zhang, Shuai Xu, Xiaoqing Shang, and Zhenshan Cui

Abstract Magnesium alloys have been of growing interest for their low density and high specific strength, but their applications are impeded by their poor formability at room temperature. This work employs the state-of-art experimental and modeling techniques to understand the joint effect of thickness and grain size on the plastic behavior and deformation mechanism of wrought Mg alloy. Equal channel angle pressing was applied to AZ31 Mg alloy to fabricate billets with different grain sizes but the similar basal texture. Interrupted micro-tensile tests combined with ex situ EBSD characterizations were carried on the fine-polished specimens with different grain sizes and thicknesses. It shows that mechanical twinning is significantly affected by both grain size and thickness. In particular, the volume fraction of extension twins decreases with the number of grains in the thickness. Full-field crystal plasticity simulations demonstrate that both the contributions of basal slip and twinning are rather sensitive to grain size.

Keywords Size effect · Deformation twinning · Crystal plasticity · Magnesium alloys · Ex situ EBSD

1 Introduction

For their high specific strength and excellent biocompatibility, magnesium (Mg) alloys are of great application in fabricating micro-parts using in the fields of biological medicine and MEMS, etc. [1, 2]. However, it is challenging to form Mg alloy parts at room temperature, as Mg alloys generally exhibit poor room temperature formability and strong anisotropy for their low-symmetric hexagonal close-packed (HCP) crystal structure. Compared with the cubic metals, e.g., aluminum and copper, Mg alloys show more complex plasticity behaviors. Mg alloys essentially have two types of deformation modes, i.e., dislocation slip and deformation twinning [3]. As regards dislocation slip, the deformation of Mg alloys is mainly accommodated by

basal $\langle a \rangle$ slip and conditionally by prismatic $\langle a \rangle$ slip, pyramidal $\langle a \rangle$ slip, and non-basal $\langle c + a \rangle$ slip. For deformation twinning at room temperature, Mg alloys have $\{10\bar{1}2\}\langle 10\bar{1}\bar{1}\rangle$ extension twinning (ET) accommodating the resolved tensile deformation in $\langle c \rangle$ axis and $\{10\bar{1}1\}\langle 10\bar{1}\bar{2}\rangle$ contraction twinning (CT) accommodating the compressive deformation in $\langle c \rangle$ axis [4]. The deformation mechanism of Mg, therefore, is a complex association of the slip systems with $\langle a \rangle$ and $\langle c+a \rangle$ Burgers vectors as well as various twin systems.

Grain refinement is an important way to overcome the strength–ductility dilemma of Mg alloys. Many works have been carried out to study the grain size effect on mechanical property and deformation mechanism concerning the competition and interaction between dislocation slip and deformation twinning [5, 6]. Barnett et al. [7] reported the inhibition of twinning in an AZ31 alloy with sub-micron grain size. It is attributed to the decrease of the pile-up dislocations, which reduces the local stress at grain boundaries below the threshold of twin nucleation. Based on crystal plasticity (CP) simulations, Jian et al. [8] explained that the Hall–Petch relationship of an AZ31B sheet is primarily due to the grain size dependence of the CRSS of the prismatic slip systems.

Except the grain size effect, the geometrical constraints, such as thickness of foils/sheets, also significantly affect the plastic behaviors and mechanical responses of polycrystalline metals when the dimension of components/specimens decreases to microscale. Understanding the influence of microstructures and geometrical constraints on the deformation mechanism of Mg alloys hence is important for the design of alloys and forming processes. Unlike the cubic metals, for HCP metals, the joint effect of the intrinsic/extrinsic constraints on the deformation and failure mechanisms are still not well understood. In this study, ex situ EBSD characterizations combined with full-filed crystal plasticity (CP) simulations were employed to explore the influence of grain sizes (d) and specimen thicknesses (t) on the plastic behaviors and deformation mechanisms of Mg alloy foils subjected to micro-tensile deformation.

2 Experiment and Modeling Framework

2.1 Micro-Tensile Tests and Ex Situ EBSD Characterizations

The studied material is a commercial extruded AZ31 Mg alloy. The equal channel angular pressing (ECAP) process followed by annealing processing was used to obtain billets with different grain sizes but similar texture. The ECAP was operated with a multi-temperature step-down technology under the Bc route. The refined billets then were annealed under different heat treatments and cut into lath-shaped specimens with length of 28 mm and width of 6 mm, but different nominal thicknesses

Table 1 Average grain size and thickness of the studied AZ31 Mg alloy foils machined from ECAP billets underwent different annealing operations

No.	Annealing temperature (°C)	Annealing time (hour)	Grain size (d) (μm)	Thickness (t) (mm)	λ (t/d)
1	450	10	40	0.2	5
2				0.5	13
3				1.0	25
4	250	2	7	0.2	28
5				0.5	71

($t = 0.2$, 0.5 and 1.0 mm). Table 1 presents the details of the annealing treatments and the obtained grain size (calculated from EBSD maps subsequently) of the studied AZ31 Mg alloy foils.

Uniaxial tensile tests at room temperature were performed on the specimens listed in Table 1 via an in-house micro-tester system with the load cell of 5000 N, as shown in Fig. 1a; the speed of the crosshead is 0.3 mm/min. The tensile direction is along the extrusion direction (ED) of the ECAP operation. The tensile tests were interrupted at the design strain levels, i.e., $\varepsilon_{ED} = 2, 4, 8, 12, 16\%$, and up to fracture. Figure 1b shows the miniature rectangular specimens for the interrupted tensile tests and ex situ EBSD characterizations of microstructure evolution. The microstructure evolution in the region of interest was observed using a MIRA3 field emission SEM equipped with an Oxford EBSD system operating at 20 kV. The region of interest was ground with 600, 1200, 2000, 3000, and 5000 grit SiC papers, and then electro-polished at 15 V voltage in a solution of 3% perchloric acid and ethanol solution chilled to −40 °C. The region of interest was examined again when the specimens were deformed to the designed strain levels.

Figure 2 shows the initial microstructures of the specimens in the form of EBSD maps with ED inverse pole figure (IPF) coloring and (0001) pole figures (PFs). Figure 2a shows the representative microstructure of the coarse grain (CG) specimens (No. 1, 2, and 3 shown in Table 1), and Fig. 2b the fine-grain (FG) specimens (No.4 and 5). The average grain size (d) of the CG specimens is 40 μm and that of the FG

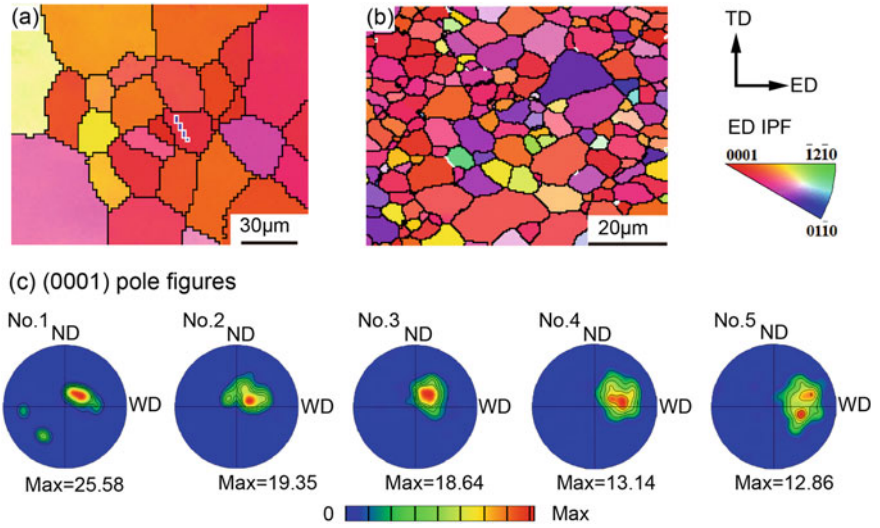

Fig. 2 The initial microstructures of the specimens in form of EBSD maps with ED inverse pole figure (IPF) coloring, **a** the coarse grain specimen and **b** the fine grain specimen. **c** shows the (0001) pole figures (PFs) of all the studied specimens. (Color figure online)

specimens is 7 μm. The (0001) PFs shown in Fig. 2c tells that both the CG and FG specimens show strong basal texture, i.e., a strong ED fiber texture along the basal (0001) pole. It means that extension twinning can be easily activated to coordinate the elongation along *c* axis during the tension deformation. Because of the fewer grains in the region of interest, the texture intensity of the CG specimens is slightly higher than that of the FG specimens.

2.2 CP Constitutive Model Incorporating Dislocation Slip and Deformation Twinning

Full-field CP simulations were complementally used to study the micro-mechanical behaviors of the Mg alloy foils. The CP constitutive model incorporates the plastic deformation models of both dislocation slip and deformation twinning. The twinning model formulating in the form of pseudo slip, referring to Salem et al. [9]. The plastic velocity gradient resulted from both dislocation slip and twinning is expressed as

$$L^p = \sum \dot{\gamma}^{\alpha}_{sp} S^{\alpha}_{sp} + f_{tw} \sum \dot{\gamma}^{\beta}_{tw} S^{\beta}_{tw} \tag{1}$$

Here, S^{α}_{sp} and S^{β}_{tw} are the Schmid tensors of the potential slip systems and twinning systems, $\dot{\gamma}^{\alpha}_{sp}$ and $\dot{\gamma}^{\beta}_{tw}$ denote the plastic shear rates associated with the slip and

twinning on the αth slip system and the βth twinning system, respectively. f_{tw} is the accumulated volume fraction of the twinned areas.

The power-law constitutive relation was adopted to describe the plastic shear rates resulted from both slip and twinning. It is written as

$$\dot{\gamma}_{sp}^{\alpha} = \dot{\gamma}_{sp}^{0} \left| \frac{\tau_{sp}^{\alpha}}{g_{sp}^{\alpha}} \right|^{1/m_{sp}} \operatorname{sign}\left(\tau_{sp}^{\alpha}\right), \text{ and } \dot{\gamma}_{tw}^{\beta} = \dot{\gamma}_{tw}^{0} \frac{\tau_{tw}^{\beta}}{g_{tw}^{\beta}}^{1/m_{tw}} \tag{2}$$

where $\dot{\gamma}_{sp}^{0}$ and $\dot{\gamma}_{tw}^{0}$ are the reference shearing rate, m_{sp} and m_{tw} the rate sensitivity parameters, g_{sp}^{α} and g_{tw}^{β} the slip resistance and twinning resistance. The evolutions of g_{sp}^{α} and g_{tw}^{β} are formulated as follows [9]:

$$\begin{cases} \dot{g}_{sp}^{\alpha} = h_{sp}^{0}(1 + c_1 \cdot f_{tw}) \sum_{\xi} \left(1 - \frac{g_{sp}^{\xi}}{g_{sp}^{\infty}}\right)^{n} \dot{\gamma}_{sp}^{\xi} \\ \dot{g}_{tw}^{\beta} = h_{tw}^{0}(f_{tw})^{c_2} \sum_{\zeta} \dot{\gamma}_{tw}^{\zeta} + h_{tw-sp}^{0} \left(\sum_{\alpha} \gamma_{sp}^{\alpha}\right)^{c_3} \sum_{\xi} \dot{\gamma}_{sp}^{\xi} \end{cases} \tag{3}$$

The material parameter h_{sp}^{0} represents the initial hardening modulus of slip systems, and g_{sp}^{∞} denotes the saturated slip resistance. h_{tw}^{0} and h_{tw-sp}^{0} denote the initial twin hardening moduli due to twin-twin interactions and slip-twin interactions, respectively. The parameters n, c_1, c_2, c_3, and s_{pr} are estimated constants. In particular, c_1 describes the effect of the Basinski mechanism on the slip resistance. Mg alloys have various slip systems and twinning systems to coordinate the plastic deformation. In this work, the CP constitutive model considers $\{0001\}\langle 11\bar{2}0\rangle$ basal $\langle a\rangle$ slip, $\{10\bar{1}0\}\langle 11\bar{2}0\rangle$ prismatic $\langle a\rangle$ slip, $\{1\bar{2}12\}\langle \bar{1}2\bar{1}3\rangle$ pyramidal $\langle c+a\rangle$ slip, and $\{10\bar{1}2\}\langle \bar{1}011\rangle$ extension twinning. The material parameters for the alloy are listed in Table 2.

The CP model was implemented into the open-source spectral method solver DAMASK. The EBSD data of the initial structures shown in Fig. 1 were directly used to construct the studied representative volume elements (RVEs); the periodic boundary condition of uniaxial tension was enforced on the RVEs [10].

Table 2 The material parameters of the CP model for AZ31 Mg alloy. The unit of the stress-type parameters is MPa

3 Results and Discussion

Figure 3 present the EBSD maps of specimens No. 1 (the smallest λ), No. 3, and No. 5 (the largest λ) strained to 0.04 and 0.08, respectively. The white lines depict twinning boundaries (TBs), while the black lines grain boundaries (GBs). It should be noted that all the twins characterized in Fig. 3 are $\{10\bar{1}2\}\langle 10\bar{1}\bar{1}\rangle$ extension twins (ETs), as the reorientation angles are found around 86.3°. Plentiful twins are clearly seen in CG specimens No. 1 and No. 3; this is consistent with the report of Jiang et al. [11] that ETs occur firstly in the deformation of 0.02 ~ 0.04. By contrast, twins are scarcely found in FG specimen No. 5 only few twin embryos appear at GBs. When the specimens were strained to 0.08, the CG ones experienced prominent twinning, especially for specimen No.1 in which most grains are occupied by large ETs. InFG specimen No. 5 the extension twinning is still significantly suppressed. Another observation is that the width of twins in the CG specimens is much larger than that is the FG specimens.

To explore the size effects on the twin behaviors quantitatively, the twin area fractions of the specimens at different deformation stages were counted and are shown in Fig. 4. Both grain size and specimen thickness (or λ) significantly affect the evolution of ETs. The fraction of ETs increases with the decrease of λ. At strain level of 0.08, the twin area fraction of the specimen No.1 is about 17 times that

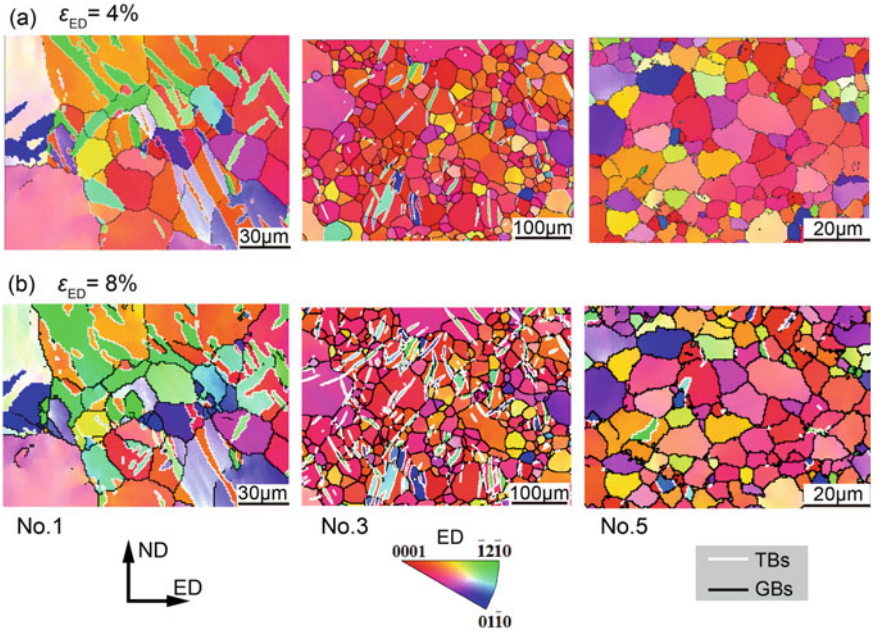

Fig. 3 The microstructures of the specimens No. 1, No. 3, and No. 5 strained to 0.04 and 0.08. (Color figure online)

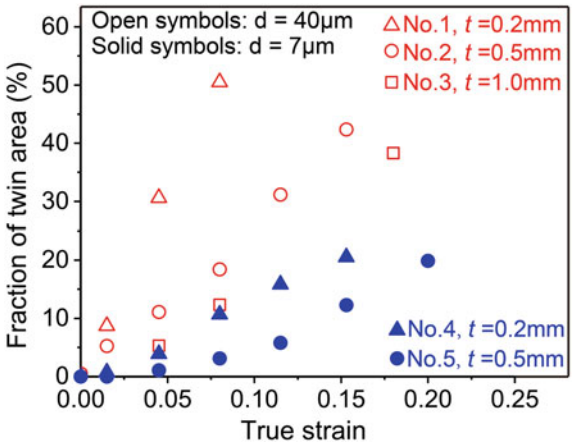

Fig. 4 The evolution of the area fraction of extension twins with respect to the global strain. (Color figure online)

of the specimen No. 5. For the specimen No. 5, even at a relative large fracture strain, the twin area fraction occupies only about 20%, and the activation of ETs is significantly suppressed in the early deformation stage. Consequently, both grain size and thickness soundly affect the extension twinning of the studied AZ31 foils, and it is concluded that λ plays an important role in affecting the nucleation and growth of deformation twinning.

Figure 5 shows the simulated results obtained from the CP simulations; the volume fraction (f_{tw}) of ETs and the total shear of basal slip of the specimens No.1, No. 3, and No. 5 at the strain levels of 0.04 and 0.08, respectively. Since the extension twinning was treated as a pseudo slip in this work, the instantaneous transformation of ETs is viewed to accomplish gradually; $f_{tw} = 1.0$ means that the twinning process has been completed. The predicted ETs essentially agree well with the experimental results shown in Fig. 3, which verifies the accuracy of the full-field CP model. Figure 5 shows that there is obvious competition between the activation of basal slip and extension twinning in the early stage of deformation, i.e., $\varepsilon_{ED} = 0.04$. The activation of ETs is significantly suppressed by the activation of basal slip. However, at the strain level of 0.08, as the work hardening of basal slip the localized shear strain due to the activation of basal slip are changed dramatically. Shear localizations appear in the grains with high volume fraction of ETs, which implies the micromechanical cooperation between basal slip and extension twinning.

To analyze the contribution of individual deformation modes, shear strain due to three slip systems with respect to the total shear of dislocation slip as well as shear strain due to extension twinning were counted, respectively, as shown in Fig. 6. As shown in Fig. 6a, b, basal slip is the dominant slip system to coordinate the plastic deformation of the studied specimens, while the contribution of non-basal slips is distinctly limited. Moreover, the activation of basal slip is influenced by grain size. The contribution ratio of basal slip in the FG specimens is slightly less than that in the CG specimens, while the contribution ratio of non-basal slips is higher which complementally coordinates the plastic deformation effectively. Figure 6a

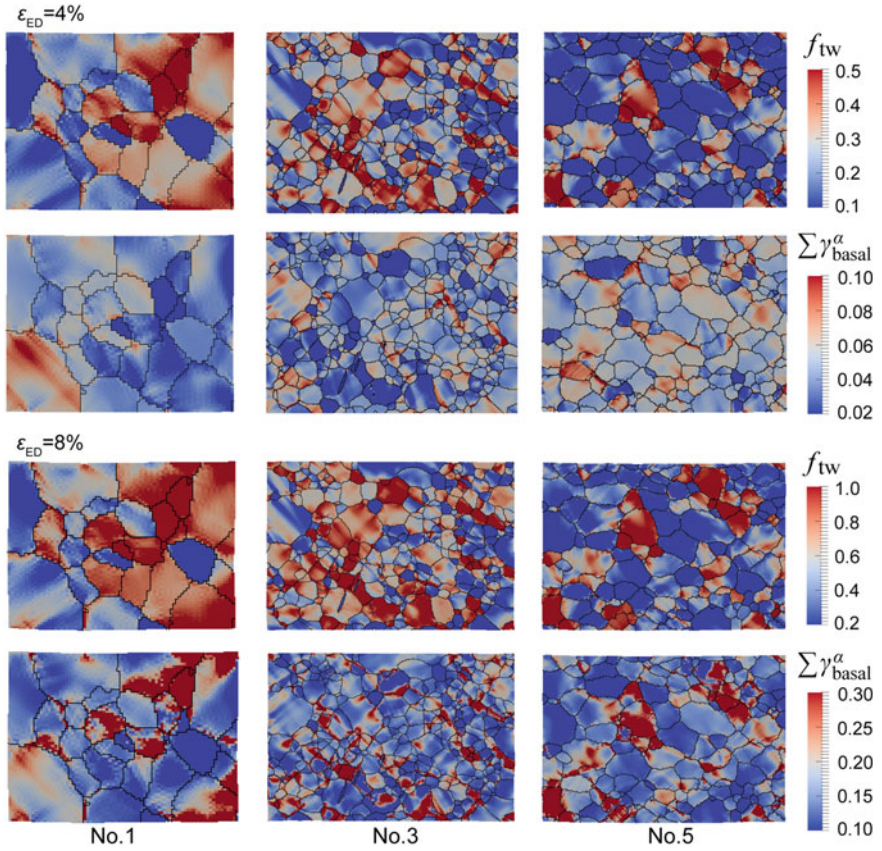

Fig. 5 The simulation results of the volume fraction of extension twins in the specimens at the strain level of 8%. (Color figure online)

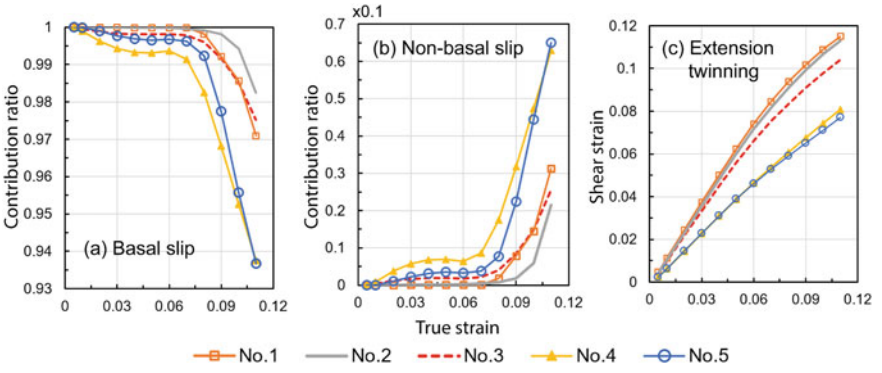

Fig. 6 The contributions of the different deformation modes during the tension deformation. **a** basal slip, **b** non-basal slip, and **c** extension twinning. (Color figure online)

further shows that the contribution ratio of basal slip for both FG specimens and CG specimens, decreases abruptly as the deformation exceeds a threshold strain (i.e. $\varepsilon_{ED} = 0.07–0.09$); Meanwhile, the contribution ratio of prismatic slip increases rapidly to compensate for the decrease of basal slip. Figure 6c shows the evolution of shear strain due to extension twins which agrees well with the experimental results that more extension twins are activated to coordinate the deformation in the CG specimens. Figure 6 also verifies that basal slip and extension twin are two main deformation mechanisms to coordinate the plastic deformation in this study.

4 Conclusion

A series of micro-tensile tests and ex situ EBSD characterizations combined with full-field crystal plasticity (CP) simulations were performed to study the deformation mechanism and microstructure evolution of AZ31 Mg foils with different grain size and thickness. The grain size and thickness distinctly affect the evolution of deformation twins. The twins observed in all the studied foils are $\{10\bar{1}2\}\langle 10\bar{1}\bar{1}\rangle$ extension twins. The area fraction of extension twins increases with deformation, and the increase rate decreases with the number (λ) of grains in thickness. For the coarse grain foils with small λ, extension twins nucleate early and grow quickly. For the fine-grain specimens with large λ, extension twinning is significantly suppressed in the early deformation stage. The full-field CP simulations successfully capture the evolution of extension twinning and show that the dislocation slip is affected by λ. The simulation results confirm that the basal slip contributes mostly to the shear deformation of dislocation slip, while the non-basal slip contributes little even at large deformation.

A Plasticity Framework for Forming Applications

Frédéric Barlat and Toshihiko Kuwabara

Abstract This presentation reviews the key features of a macroscopic plasticity framework applicable to numerical simulations of practical forming processes in industry. The constitutive relationships are developed for anisotropic materials with an anisotropic hardening assumption. The framework relies on mathematical concepts, physical understanding of deformation mechanisms, and experimental results. Lower scale simulation results are essential for the introduction of relevant features in the macroscopic framework. The experimental investigations on plasticity conducted by Professor Tozawa in the 1960s and 1970s is of fundamental importance for the development and validation of the theory.

Keyword Plasticity · Yield condition · Yield surface · Flow rule · Hardening behavior

1 Background

In sheet metal forming simulations for process design and optimization, a plasticity theory is necessary to model the material deformation behavior. The flow theory of plasticity is a well-established and reliable approach to model the inelastic behavior of materials with a yield condition defined by an effective stress and a hardening function, and a flow rule. For each material, these three characteristics should be defined mathematically and measured experimentally, as explained in [1]. Since plasticity is a highly non-linear phenomenon, assumptions are needed to define suitable mathematical descriptions. For metals, the isotropic hardening assumption is often adopted with an anisotropic yield condition and the associated flow rule. The latter indicates that the strain increment is normal to the yield surface. Isotropic hardening means that

the yield surface associated with the yield condition, expands while keeping the same shape. This approach is reasonably accurate for linear or pseudo-linear strain paths. However, when drastic strain path changes occur, additional hardening phenomena are observed such as the Bauschinger effect during strain reversal. This behavior is often captured using the kinematic hardening assumption, in which the yield surface translates in stress space. Sometimes, kinematic hardening is supplemented by distortional plasticity effects. In this article, the isotropic hardening approach for pseudo-linear strain paths, and a purely distortional plasticity description for non-linear strain paths are outlined. In both cases, the work of Professor Tozawa was essential to validate the concepts with high levels of confidence.

2 Linear Strain Path

Tozawa [2] developed a biaxial compression testing device to deform cubic specimens made of stacked sheets. By applying various compressive stress states on specimens with different orientations and assuming that the hydrostatic pressure had no influence on yielding, he determined the yield surfaces of many materials over the entire deviatoric plane, with axes corresponding to the normal stresses in the three characteristic directions of a sheet, namely, rolling (RD), transverse (TD), and normal (ND). As an example, the yield surfaces of commercially pure aluminum alloys, determined with a 0.2% offset strain, are represented in Fig. 1a&b for different amounts of plastic strain [2, 3]. This figure indicates that all the contours have similar

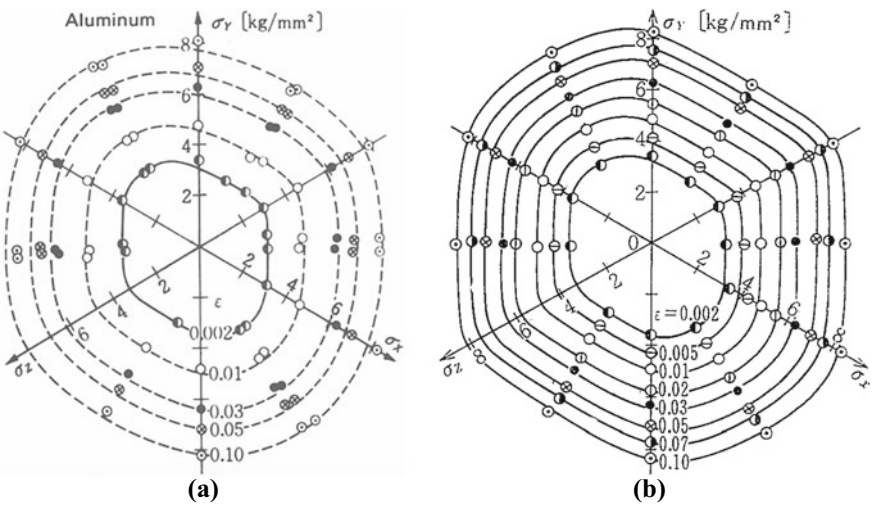

Fig. 1 Yield surfaces of commercial purity aluminum sheet samples measured using biaxial compression tests and projected in the deviatoric plane with the normal stresses σ_x, σ_y, and σ_z in the RD, TD, and ND directions, respectively; **a** from Ref. [2] and **b** from Ref. [3]

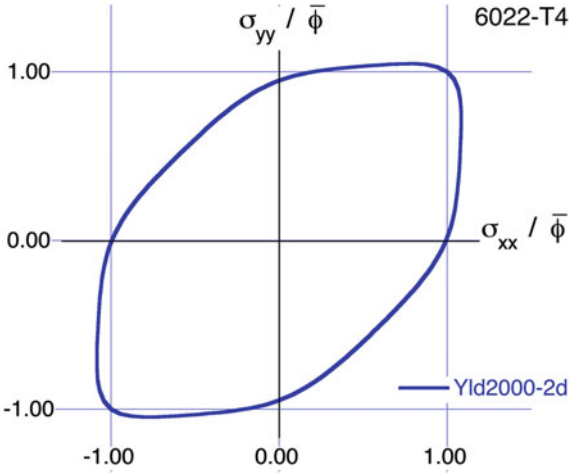

Fig. 2 Normalized plane stress yield surface for 6022-T4 aluminum alloy represented in plane of variables $\sigma_{xx}/\overline{\phi}$ and $\sigma_{yy}/\overline{\phi}$ (normal stresses in rolling and transverse directions, respectively). (Color figure online)

shapes, which is consistent with the isotropic hardening assumption. In addition, each contour exhibits areas with high and low curvatures. Note that Kuwabara [4] observed similar behavior using biaxial testing with cruciform and tubular specimens.

In the flow theory of plasticity, under the assumption of isotropic hardening, the yield condition is defined as

$$\overline{\phi}(\mathbf{s}) = \sigma_r(\overline{\varepsilon}) \tag{1.}$$

where $\overline{\phi}$ is an effective stress that accounts for plastic anisotropy, $\mathbf{s}$ the stress deviator, σ_r a reference stress–strain curve and $\overline{\varepsilon}$ the work-equivalent effective strain. A number of effective stresses or the corresponding anisotropic yield functions are described in [1]. Figure 2 represents the yield surface of a 6022-T4 aluminum alloy sheet sample calculated using the plane stress Yld2000-2d yield condition (see [1] for a brief review). The line represents the intersection of the normalized yield surface with the plane of the ND stress $\sigma_{zz}/\overline{\phi} = 0$. This line is unique because isotropic hardening is assumed and Eq. (1) implies that all the subsequent yield surfaces are superimposed. In Fig. 2, the material of the Al-Mg-Si series is not the same as in Tozawa's work. In addition, the intersection plane is different from the deviatoric plane featured in Fig. 1. In spite of these drawbacks, it is clear that areas of high and low yield surface curvatures can be observed in Fig. 2, in qualitative agreement with Fig. 1. However, the isotropic von Mises and anisotropic Hill [5] yield conditions would not show these features because the curvature would be more uniform, while the yield condition of Tresca would lead to sharp corners. The anisotropic Yld2000-2d yield condition was developed to provide a good representation of crystal plasticity simulation results, which also show the presence of curvature effects on the yield surface [6]. Therefore, it may be said that Yld2000-2d qualitatively captures important features observed

either experimentally by Tozawa or predicted by crystal plasticity simulations, which provide a strong support for its validity.

3 Pre-strained Material

Tozawa [2] conducted experiments similar to those described above for pre-strained materials. For instance, Fig. 3 show the yield surfaces, determined using a 0.2% offset strain, of an Al-stabilized steel that was first subjected to various amounts of pre-strains in uniaxial tension in the rolling direction. This figure shows that the subsequent yield surfaces flatten roughly in the direction opposite to the pre-load, i.e. towards a plane indicated by the dashed line in Fig. 3. In fact, a more accurate description of the distortion is that the yield surface flattens towards a plane parallel to the plane tangent to the yield surface during pre-straining, which corresponds to the two parallel solid lines in Fig. 3.

Kinematic hardening is commonly used to account for the effects of a pre-strain on plastic flow as, for instance, in the modeling of the Bauschinger effect after a load reversal. However, in this article, a pure distortional plasticity model, called HAH, is employed to capture the additional hardening effects due to a strain path change. In the HAH model, the yield condition in Eq. (1) was extended to [7]

$$\overline{\sigma}(\mathbf{s}) = \left\{\overline{\phi}(\mathbf{s})^q + \phi_x(\mathbf{s})\right\}^{\frac{1}{q}} = \sigma_R(\overline{\varepsilon}) \tag{2.}$$

with

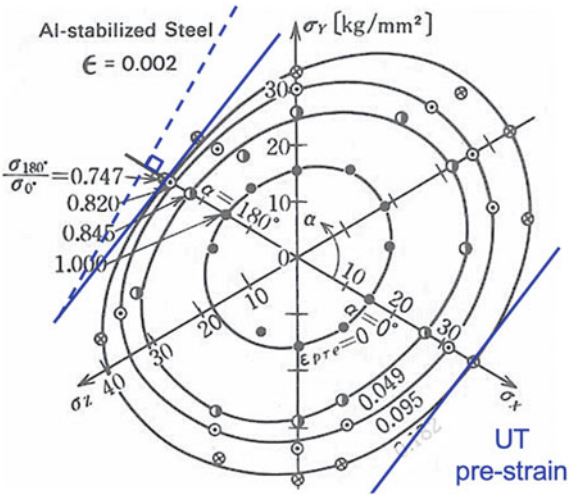

Fig. 3 Yield surfaces for an anisotropic steel pre-strained in RD uniaxial tension by various amounts, showing the yield surface flattening in a region at the opposite side of the load during pre-strain, toward a plane orthogonal to the pre-strain increment. (Color figure online)

$$\phi_x(\mathbf{s}) = \phi_h(\mathbf{s}) = f_-^q \left| \widehat{\mathbf{h}} : \mathbf{s} - \left| \widehat{\mathbf{h}} : \mathbf{s} \right| \right|^q + f_+^q \left| \widehat{\mathbf{h}} : \mathbf{s} + \left| \widehat{\mathbf{h}} : \mathbf{s} \right| \right|^q \tag{3.}$$

and q a constant exponent. An alternate form of $\phi_x(\mathbf{s})$ was proposed later [8]

$$\phi_x(\mathbf{s}) = \phi_\varepsilon(\boldsymbol{s}) = f_-^q \left| \frac{\hat{\dot{\boldsymbol{\varepsilon}}}_h : \mathbf{s} - \left| \hat{\dot{\boldsymbol{\varepsilon}}}_h : \mathbf{s} \right|}{\hat{\dot{\boldsymbol{\varepsilon}}}_h : \widehat{\mathbf{h}}} \right|^q + f_+^q \left| \frac{\hat{\dot{\boldsymbol{\varepsilon}}}_h : \mathbf{s} + \left| \hat{\dot{\boldsymbol{\varepsilon}}}_h : \mathbf{s} \right|}{\hat{\dot{\boldsymbol{\varepsilon}}}_h : \widehat{\mathbf{h}}} \right|^q \tag{4.}$$

Equation (2) is a generalization of Eq. (1), with an additional term $\phi_x(\mathbf{s})$ to introduce the distortion of the yield condition described by Eq. (1). In fact, the material responses obtained by Eqs. (1) and (2) are exactly the same if the boundary conditions applied to Eq. (2) leads to a linear strain path. $\widehat{\mathbf{h}}$, the so-called microstructure deviator, is a tensorial state variable indicating the distortion orientation and $\hat{\dot{\boldsymbol{\varepsilon}}}_h$ the associated yield surface normal. f_+ and f_- are two scalar state variables that control the amount of distortion. In this article, the role of $\widehat{\mathbf{h}}$ is only to define the direction of the pre-strain. The expression of $\phi_x(\mathbf{s})$ in Eq. (3) was selected because it is simpler and contains only stress terms in addition to $\widehat{\mathbf{h}}$. However, this function leads to a distortion with $\hat{\dot{\boldsymbol{\varepsilon}}}_{-h}$ parallel to $\widehat{\mathbf{h}}$ where $\hat{\dot{\boldsymbol{\varepsilon}}}_{-h}$ is the yield surface normal corresponding to $-\widehat{\mathbf{h}}$. In contrast, the expression of $\phi_x(\mathbf{s})$ in Eq. (4) leads to a distortion with $\hat{\dot{\boldsymbol{\varepsilon}}}_{-h}$ parallel to $\hat{\dot{\boldsymbol{\varepsilon}}}_h$. Figure 4 shows, in the deviatoric plane, the yield surfaces calculated using either Eq. (3) or Eq. (4) in the yield condition of the HAH model. This work indicates that Eq. (4) leads to a flattening orientation, which is in excellent qualitative agreement with Tozawa's experimental results.

Note that the complete HAH model requires additional state variable evolution equations. However, this detailed description is out of the scope of the present article, which concentrates on the yield condition only.

4 Discussion

For isotropic hardening, Hershey [9] proposed an isotropic yield condition leading to regions of low and high curvatures that were reintroduced later by Hosford [10]. Logan and Hosford [11] generalized this yield condition to restricted cases of plastic anisotropy. More importantly, using crystal plasticity simulations, they firmly established the existence of high and low curvature areas in the yield surface of a cubic metal. Both Tozawa's experimental results and crystal plasticity simulations led to consistent yield surfaces curvature variations that motivated the development of well-formulated non-quadratic yield conditions such as Yld2000-2d for anisotropic materials.

The so-called HAH distortional plasticity model was developed to describe the plastic behavior of metals subjected to arbitrary loading histories. The first version [7] was constructed on the basis of Eq. (3), mostly to capture the Bauschinger effect.

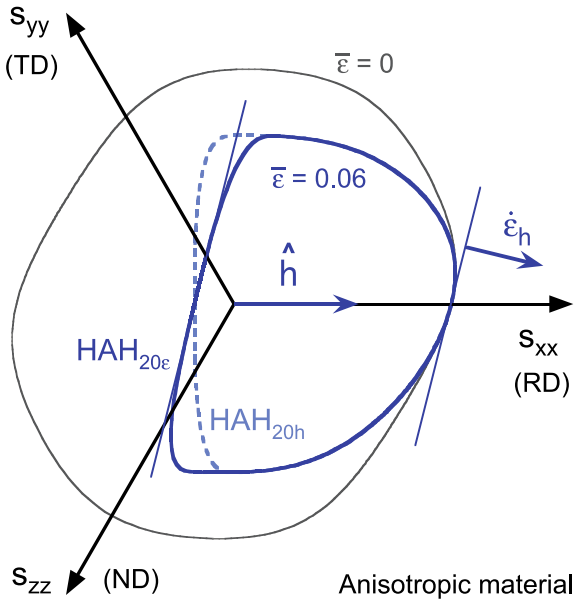

Fig. 4 Illustration of the yield surface of metallic material in deviatoric plane after a pre-strain of about 0.06 in RD uniaxial tension using either Eq. (3) [labeled HAH_{20h}] and Eq. (4) [labeled] $HAH_{20\varepsilon}$ in distortional plasticity model. (Color figure online)

The most recent version, called HAH_{20} [12] offers Eq. (4) as an alternative, as well as better state variable evolution equations to describe a number of anisotropic hardening effects. In fact, Eq. (4) was suggested as a result of crystal plasticity simulations coupled with strain path-dependent dislocation density evolutions to model strain hardening. The excellent qualitative agreement between Eq. (4) and Tozawa's results was observed in retrospect after the crystal plasticity simulations were analyzed. The HAH_{20} model was implemented in finite element (FE) code [13] and used successfully for the forming simulations of the B-pillar of an autobody structure [14]. Nevertheless, the qualitative agreement between Tozawa's experiments, the results of crystal plasticity simulations, and this new distortional plasticity model sets a direction paving the way to future macroscopic constitutive description of plasticity that will lead to even more accurate forming process simulation results.

Hole Expansion Simulation of Steel Sheet Considering Differential Hardening

Shunya Nomura and Toshihiko Kuwabara

Abstract Finite element analysis (FEA) of hole expansion forming is investigated to clarify the effects of material models on the predictive accuracy of the FEA. The multiaxial plastic deformation behavior of a hot rolled steel sheet with a tensile strength of 440 MPa was measured using biaxial tensile tests with cruciform specimens (ISO 16842, 2014) and tubular specimens subjected to servo-controlled axial force and internal pressure. Many linear stress paths in the first quadrant of stress space are applied to the specimens to measure the contours of plastic work (CPW) and the directions of plastic strain rate (DPSR) up to a reference plastic strain of 0.22. It is found that the Yld2000-2d yield function (Barlat et al., 2003) accurately reproduces both the CPW and DPSR. Isotropic (IH) and differential hardening (DH) models are determined using the Yld2000-2d yield function; in the DH model the values of exponent and eight material parameters of the Yld2000-2d yield function change as functions of reference plastic strain. Moreover, a hole expansion forming experiment was performed. The thickness strain distribution along the hole edge was measured and compared with the FEA results obtained using selected yield functions. The DH model correctly predicts the minimum thickness position that matches the fracture position of the specimen in experiment. It is concluded that the yield function best capturing both the plastic work contours and the directions of plastic strain rates leads to the most accurate FEA results.

1 Introduction

The establishment of trial-and-error-less manufacturing enhanced by numerical forming simulations has been strongly desired in industry to shorten the product development period and reduce costs for prototype manufacturing. The accuracy of forming simulations is significantly affected by the material models used in the simulation [1]. Therefore, it is crucial to use a proper material model that accurately reproduces the deformation behavior of the material in finite element analysis (FEA) in order to improve the accuracy of the simulation [2].

The authors investigated the effects of material models on the predictive accuracy of hole expansion forming simulation of steel sheet [3–5]. In particular, Kuwabara and Ichikawa [5] performed biaxial tensile tests using cruciform specimens [6, 7] and multiaxial tube expansion tests (MTET) with tubular specimens subjected to servo-controlled axial force and internal pressure [8, 9] for the test material to identify proper material models to be used in the FEA of the hole expansion forming. Both isotropic hardening (IH) model and differential hardening (DH) model, which can reproduce the change in the shapes of plastic work contours with work hardening, were applied to the FEA. It was found that the Yld2000-2d yield function [10] gives a more accurate description of the biaxial deformation behavior of the test material than the von Mises and Hill's quadratic yield functions. However, even the calculated results by the Yld2000-2d yield function showed some deviation from the measured thickness strain distribution in the vicinity of the hole edge.

The objective of this study is to further investigate the effects of material models on the accuracy of the hole expansion forming simulation. The test material used in this study is a hot rolled steel sheet with a tensile strength of 440 MPa. An objective function is introduced and the parameters of the Yld2000-2d yield function are determined so that the difference between the measurement and prediction for both the plastic work contours and the directions of plastic strain rates, $\mathbf{D}^{\mathrm{p}}$, can be minimized. Both IH and DH models based on the Yld2000-2d yield function are applied to the FEA of the hole expansion forming. It is found that the DH model correctly predicts the minimum thickness position that matches the fracture position of the specimen in experiment.

2 Experimental Methods

The test material used in this study was a 1.6-mm-thick hot rolled steel sheet with a tensile strength of 440 MPa. The rolling (RD), transverse (TD), and normal to the sheet plane (ND) directions of the sheet sample are referred to as the x-, y-, and z-axes, respectively.

Biaxial tensile tests using cruciform specimens and tubular specimens were performed to measure the plastic deformation behavior of the test material under biaxila tension. Figure 1a shows a schematic of the cruciform specimen used for the

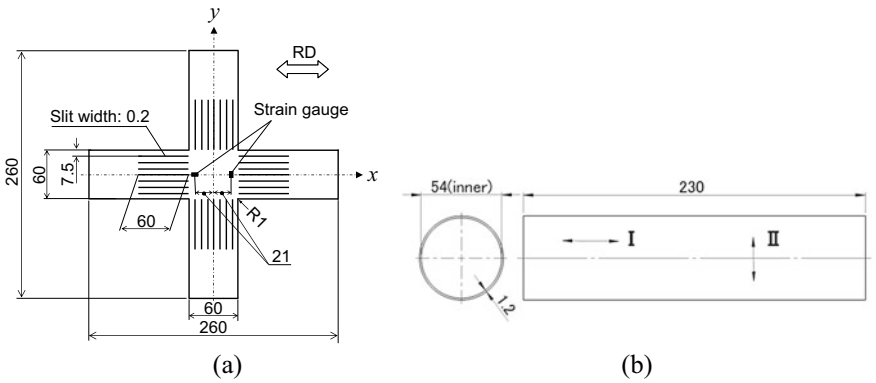

Fig. 1 Specimens used for the biaxial tensile tests (dimensions in mm). **a** Cruciform specimen. **b** Tubular specimen. The mark ↔ indicates the RD of the original sheet sample

biaxial tensile tests of the as-received sheet sample. The geometry of the specimen was the same as that developed in [6] and followed ISO 16842 [7]. The specimen arms were parallel to the RD and TD of the material. The slits were fabricated by laser machining. A couple of strain gauges (YFLA-2, Tokyo Sokki Kenkyujo Co.) were mounted at ± 21 mm from the center along the maximum loading direction and measure the normal strain components, ε_x and ε_y. See [7] for the details of the experimental methods. Using FEAs, Hanabusa et al. [11, 12] estimated that the stress measurement error is less than 2% when the strain components are measured at the positions shown in Fig. 1a.

Figure 1b shows the tubular specimen used for the MTETs. The specimens were fabricated by bending and laser welding into a cylindrical shape with an inner diameter of 54 mm and a length of 230 mm. Two types of tubular specimens were fabricated; type I specimen had the RD in the axial direction and type II specimen had the RD in the circumferential direction. Type I specimens were used for the tests with $\sigma_x \leq \sigma_y$ and type II for the tests with $\sigma_x \geq \sigma_y$; the maximum principal stress direction was always taken to be in the circumferential direction of the specimen. See [9] for the details of the experimental method. Both the cruciform and tubular specimens were subjected to linear stress paths with true stress ratios $\sigma_x : \sigma_y = 4{:}1$, 2:1, 4:3, 1:1, 3:4, 1:2, and 1:4. Standard uniaxial tensile specimens (JIS 13 B-type) were used for the uniaxial tensile tests with $\sigma_x : \sigma_y = 1{:}0$ and 0:1.

The concept of the contour of plastic work in stress space [13] was introduced in order to evaluate the work hardening behavior of the test material under biaxial tension. The stress–strain curve obtained from a uniaxial tensile test along the RD was selected as a reference datum for work hardening; the uniaxial true stresses σ_0 and the plastic work per unit volume W_0 corresponding to particular values of offset logarithmic plastic strains $\varepsilon_0^{\mathrm{p}}$ were determined. The uniaxial tensile true stress σ_{90} in

the TD and the biaxial true stress components (σ_x, σ_y) obtained from biaxial tensile tests were then determined at the same plastic work as W_0. The stress points $(\sigma_0, 0)$, $(0, \sigma_{90})$, and (σ_x, σ_y) form a contour of plastic work associated with a particular value of $\varepsilon_0^{\mathrm{p}}$.

3 Material Testing Results and Material Modeling

Figure 2a, b shows the measured stress points forming contours of plastic work and the direction of the plastic strain rate for $\varepsilon_0^{\mathrm{p}} = 0.22$. In Fig. 2(a), the stress values are normalized by the σ_0. Also depicted in Fig. 2 are the data calculated using the von Mises, Hill's quadratic (Hill'48) [14], and the Yld20000-2d yield functions [10]. The anisotropic parameters of the Hill'48 were determined using r_0,r_{45}, r_{90}, and σ_0, where r_θ is the r-value measured by a tensile test at an angle of θ from the RD. The anisotropic parameters α_i $(i = 1\text{–}8)$ and exponent M of the Yld2000-2d yield function were determined to minimize the cost function given by Eq. (1):

$$F = \frac{1}{N}\sum_{i=1}^{N}\left\{w_{\sigma,i}\left(l_{\mathrm{M},i} - l_{\mathrm{C},i}\right)^2 + w_{\beta,i}\left(\beta_{\mathrm{M},i} - \beta_{\mathrm{C},i}\right)^2\right\}, \tag{1}$$

where N $(= 14)$ is the number of linear stress paths for the biaxial tensile tests with linear stress paths of $\sigma_x : \sigma_y = 4{:}1$, 2:1, 4:3, 1:1, 3:4, 1:2, 1:4, and the uniaxial tensile tests for every 15° from RD. $l_{\mathrm{M},i}$ is the distance between the origin of the normalized principal stress space and the stress point on the i th stress path and $l_{\mathrm{C},i}$ is the distance between the origin of the normalized principal stress space and

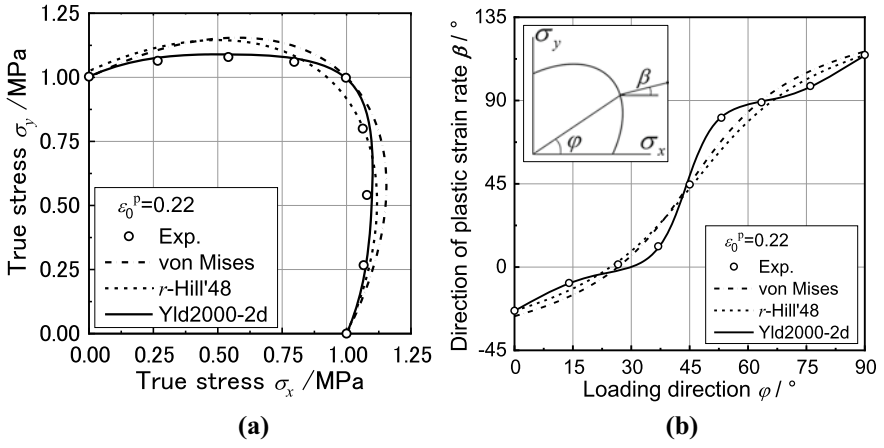

Fig. 2 Measured data of **a** the stress points forming contours of plastic work, and **b** the directions of plastic strain rate

the calculated yield locus along the i th stress path. $\beta_{M,i}$ is the direction of the $\mathbf{D}^p$ measured for the i th stress path and $\beta_{C,i}$ is the value of β calculated using the yield function and the normality flow rule at the i th stress path. $w_{\sigma,i}$ and $w_{\beta,i}$ are the weighting factors for l_i and β_i, respectively. Real-coded genetic algorithm (GA) was used to minimize the cost function and to avoid a local optimum solution. Details of the calculation procedures for minimizing F are given in [15]. The calculated results by the Yld2000-2d yield function are consistent with the experimental data for both work contour and β.

Moreover, a DH model was made using the Yld2000-2d yield function, in which the variation of α_i ($i = 1$–8) and M with the increase of ε_0^p were taken into account as functions of ε_0^p.

4 Hole Expansion Forming Experiment and FEA Simulation

Hole expansion forming experiments using a flat-headed punch were performed to quantitatively evaluate the effect of the material models on the predictive accuracy of the hole expansion forming simulation. The tool geometry used for the hole expansion forming is shown in Fig. 3a. The punch and die hole diameters were 100 mm and 130 mm, respectively. The initial hole with a diameter of 30 mm was fabricated at the center of a circular blank using a wire-electrical discharging machine. The periphery of the blank was clamped using a triangular draw-bead with a diameter of 195 mm. The interface between the blank and punch head was lubricated with Vaseline and 0.3-mm-thick Teflon sheet, while no lubricant was applied to the interfaces between the blank and the die/blank holder. The punch velocity was approximately 0.1 mm/s, which gave an average strain rate of 10^{-3} s^{-1} to the hole edge, and is comparable to those for the biaxial material tests. The forming was terminated at a punch stroke of $h = 28$ mm. The sheet thickness along the hole edge (at positions 2 mm distant from the hole edge on the undeformed blank) was measured using a digital micrometer with a minimum readout of 0.001 mm.

FEA of the hole expansion forming was carried out using Abaqus/Standard Ver. 6.14. Figure 3b shows the initial mesh division of a blank used in the FEA. The increment of element divisions in the circumferential direction was 3.0° The increment of element divisions in the radial direction was 1 mm. One quarter of a blank was analyzed, owing to the orthotropic material symmetry. Reduced 4-node shell elements (S4R) with five integration points in the thickness direction were used for the blank.

The punch, die and blank holder were defined as rigid bodies. The coefficients of friction were assumed to be 0.03 between the punch and blank and 0.15 for the other contact areas, as no lubricant was applied to the surfaces of the die and blank holder. The displacement of the blank edge (a diameter of 195 mm) was fixed at the bead

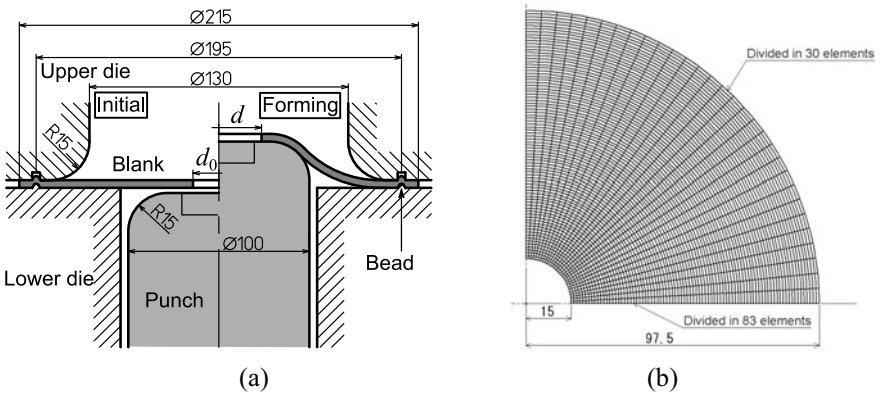

Fig. 3 Schematic illustration of the hole expansion test: **a** tool geometry, and **b** initial mesh division of a blank used in the FEA of the hole expansion forming

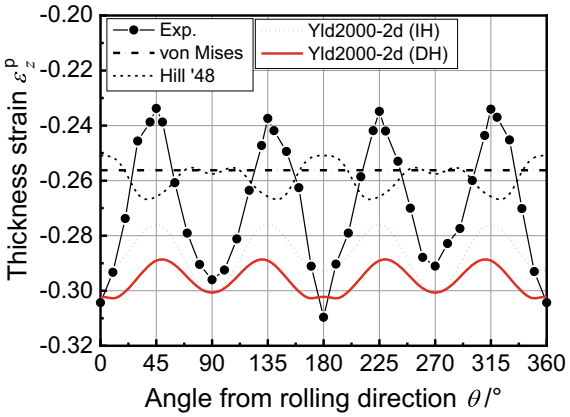

Fig. 4 Thickness strains along the hole edge compared with those calculated using selected yield functions. The thickness strains were measured at positions 2 mm away from the hole edge. (Color figure online)

position. The material was unloaded when the punch stroke reached 30 mm, and the FEA was terminated.

The material models used in the FEAs were the IH models based on the von Mises and Hill'48 yield functions shown in Fig. 2a, and those based on the Yld2000-2d shown in Fig. 2b.

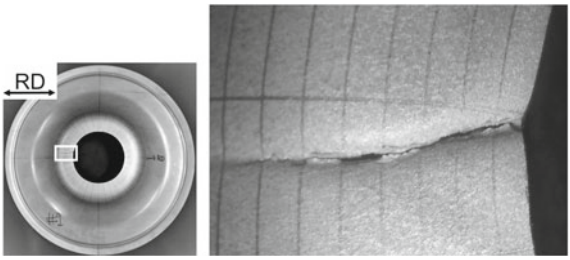

Fig. 5 Top view of a specimen with fracture at the hole edge

5 Results of the FEA of Hole Expansion Forming

Figure 4 shows the experimental results of the logarithmic thickness plastic strains $\varepsilon_z^{\mathrm{p}}$ along the hole edge at a punch stroke $h = 28$ mm. They take a minimum in the RD, a second local minimum in the TD, and a maximum in 45° (DD) from the RD. The figure also shows the FEA predictions calculated using the IH and DH models based on the Yld2000-2d yield function. Both the DH and IH models predicts that a maximum is in DD, which is consistent with the expriment. The DH model shows a good agreement with the measurement in the vicinity of the RD and TD and it also correctly predicts that $\varepsilon_z^{\mathrm{p}}$ becomes minimum in the RD. On the otherhand, the IH model predicts a minimum in the TD. The Hill'48 predicts that they take a minimum in the vicinity of the DD and a maximum in the RD; therefore, the prediction is the exact opposite of the experimental trend.

In the hole expansion experiment fracture occurred at a punch stroke of 32 mm near the hole edge along the RD, see Fig. 5. The position of fracture is consistent with the minimum thickness position as prediction by the DH model. The DH model correctly predicts the minimum thickness position that matches the fracture position of the specimen in experiment. It is concluded that the yield function best capturing both the plastic work contours and the directions of plastic strain rates leads to the most accurate FEA results.

6 Conclusions

Hole expansion forming of a 440 MPa hot-rolled steel sheet is investigated both experimentally and analytically to clarify the effects of material models on the predictive accuracy of the FEA of the forming process. The DH model correctly predicts the minimum thickness position that matches the fracture position of the specimen in experiment. It is concluded that the yield function best capturing both the plastic work contours and the directions of plastic strain rates leads to the most accurate FEA results.

Surface Quality of Extruded Sidewall in Cold Backward Cup Extrusion with Low-Frequency Torsional Oscillation

Ryo Matsumoto, Seiji Takatsuka, and Hiroshi Utsunomiya

Abstract The effect of torsional oscillation on the surface quality of an extruded sidewall of a workpiece was investigated in backward cup extrusion with an extrusion ratio of 2.0 at room temperature. In this extrusion process, a cylindrical aluminum workpiece lubricated with mineral oil was extruded in the axial direction and simultaneously twisted in the circumferential direction between extrusion and knockout punches. The two punches were controlled with an axial speed of 0.1 mm/s, an alternating amplitude of 5°, and a maximum angular speed of 0.5 rpm. The torsional oscillation tilted the traction direction at the container–workpiece from the radial direction to the circumferential direction with approximately 25% lower contact pressure on the container. As the result, the surface of the extruded sidewall was uniformly smoothed.

Keywords Forging · Extrusion · Torsion · Friction · Surface

1 Introduction

To reduce axial load in the forging process, the authors developed forging process with torsional oscillation. In this process, torsional oscillation around the forging axis was superposed with axial deformation. According to the theory of plasticity, plastic deformation of metals can be promoted by the combination of normal and shear stresses [1]. In our previous studies, the maximum reduction in axial load was attained with larger than 20% under torsion/axial speeds higher than 60°/mm in cold forging and cold backward cup extrusion [2, 3].

On the other hand, the authors aim not only to reduce the axial load but also to improve the properties of the forged products such as surface qualities, shape accuracy, and microstructure in forging process with torsional oscillation. This is because the superposition of torsional moment during axial deformation is a well-known method to change the stress and strain distributions in the workpiece. For

example, crystallographic grain refinement of workpiece by applying large shear strain was reported in KOBO-type forming with torsional moment in die forging [4]. The superposition of torsional moment during axial deformation was also applied to friction test [5, 6] because the contact and sliding conditions between die and workpiece can be controlled. In forging process, the application of torsional moment is expected to change friction, lubrication, and surface qualities of the forged product.

In this study, the effect of torsional oscillation on surface quality of extruded workpiece was investigated in cold backward cup extrusion. The relationship between the torsional oscillation conditions and the surface qualities is investigated through extrusion experiment on an originally designed equipment. The change in contact state between the die and the workpiece is discussed using the results of finite element simulation.

2 Extrusion Process with Torsional Oscillation and Procedures of Experiment

Figure 1 shows the schematic illustration of the die layout, the punch shape, and the surface groove of the punches for backward cup extrusion with torsional oscillation. A cylindrical workpiece inserted in the container was extruded by the extrusion punch in the z-direction (the axial direction or height direction) and simultaneously twisted by the knockout punch in the θ direction (the circumferential direction) around the z-axis. The extrusion punch was moved downward in the z-direction, while the knockout punch was rotated or rotationally oscillated in the θ direction (not moved in the z-direction). The diameter of the workpiece, the inner diameter of the container, and the diameter of the extrusion punch were ϕ 13.9 mm, ϕ14 mm, and ϕ10 mm, respectively. The extrusion ratio was 2.0.

Backward cup extrusion with torsional oscillation was performed using originally designed equipment. Due to the capacities of the maximum load and torque of the

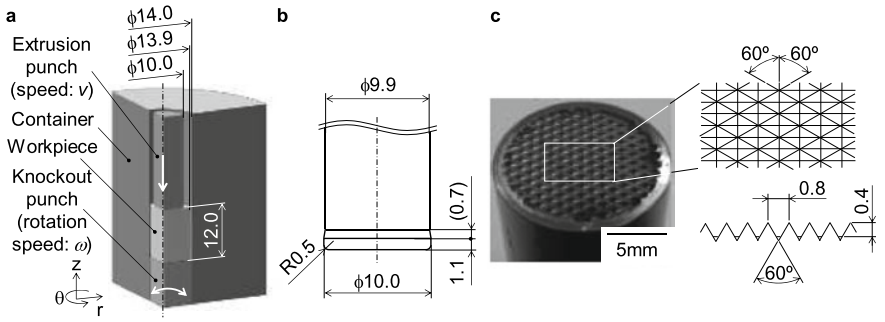

Fig. 1 **a** Layout of dies and workpiece, **b** Detail of end shape of extrusion punch, **c** Groove on end surface of punches

apparatus, JIS A1070 aluminum cylinder was selected as the workpiece. The initial surface roughness of the outer surface of the workpiece was $Ra = 0.30$–0.50 μm. The mineral oil with a kinematic viscosity of 32 mm^2/s (at 313 K) was applied with a thickness of approximately 90 μm to the outer surface of the workpiece. The dies were made of JIS SKH51 high-speed tool steel (63 HRC). In the experiment, when the axial extrusion stroke reached 0.5 mm, the knockout punch started to rotate circumferentially around the extrusion axis. To grip and twist the workpiece by the two punches, knurled grooves with a depth of 0.4 mm and a vertical angle of 60° were prepared with a crossing angle of 120° and a pitch of 0.8 mm on the end surfaces of the punches, as shown in Fig. 1c. From our previous report of upsetting with torsional oscillation [2], the axial extrusion speed was set to $v = 0$–0.1 mm/s, while the rotation speed and amplitude were set to $\omega = 0$–0.5 rpm (0–0.05 rad) and 5° (π/36 rad), respectively. The maximum frequency of the torsional oscillation was 0.15 Hz.

3 Experimental Results

3.1 Appearance and Surface Roughness of Outer Surface of Extruded Workpiece

Figure 2 shows the appearance of the outer surface of the extruded workpiece. The surface defects of the extruded workpiece were caused by turning marks in the initial workpiece because the adhesion of the workpiece was not observed at the surface

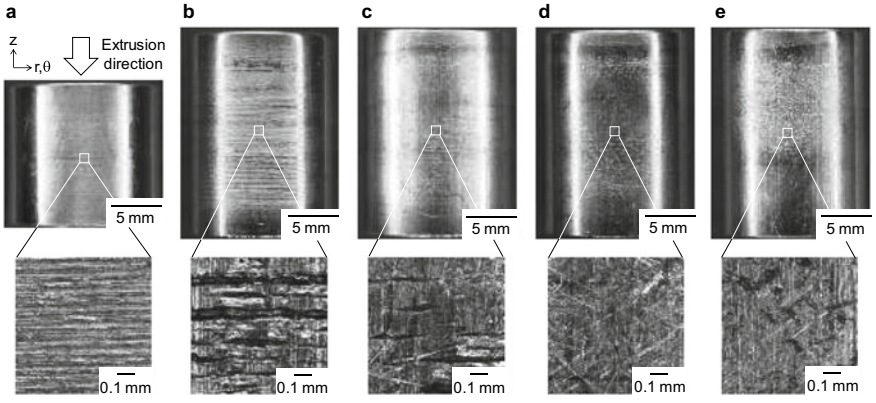

Fig. 2 Photographs of outer surface of the extruded workpiece in backward extrusion with torsional oscillation ($v = 0.1$ mm/s, axial stroke: 6.0 mm), **a** Initial workpiece, **b** $\omega = 0$ rpm, **c** $\omega = 0.3$ rpm ($\theta_{acc} = 83°$), **d** $\omega = 0.5$ rpm ($\theta_{acc} = 165°$), **e** $\omega = 0.5$ rpm ($\theta_{acc} = 165°$, one-way) (θ_{acc}: accumulative rotation angle of knockout punch)

of the container. The surface defects were stretched in the extrusion (z)-direction of the workpiece in extrusion without torsional oscillation. On the other hand, the length of the surface defects was shortened in the circumferential direction and was tilted from the radial direction to the diagonal direction in extrusion with torsional oscillation. It means that the surface defects are elongated and shallowed by the torsional oscillation.

The surface profile of the outer surface of the extruded workpiece in the circumferential direction is shown in Fig. 3. The surface profile was measured by a 2D stylus type profilometer along the extrusion direction. The surface was roughened due to the stretching of the surface defects as above described in extrusion without torsional oscillation, while the surface was smoothed as the rotation speed increased in extrusion with torsional oscillation.

Figure 4 shows the relationship between the surface roughness on the outer surface of the extruded workpiece and the accumulative rotation angle of the knockout punch (accumulative twisted angle of the workpiece, θ_{acc}). The surface roughness was measured at 16 locations of which four places every 4.0 mm in the extrusion direction of the extruded workpiece and four places every 90° in the circumferential direction. The average and standard deviation of the surface roughness decreased with increasing accumulative rotation angle in the range of $0° < \theta_{acc} < 360°$. The average and standard deviation of the surface roughness were lower than the initial in the range of $200° < \theta_{acc} < 360°$. It was confirmed that the outer surface of the workpiece was flattened and the unevenness of the surface roughness was reduced by applying torsional oscillation during extrusion. This implies that torsional oscillation was effective for reducing the unevenness of the lubrication state because the lubricant was squeezed not only in the extrusion direction but also in the circumferential direction between the container and the workpiece. However, excessive torsion deteriorated the surface qualities of the extruded workpiece because the average and standard deviation of the surface roughness increased with increasing accumulative rotation angle in the range of $\theta_{acc} > 360°$.

3.2 *Deformation Behavior of Indentation of Outer Surface of Workpiece During Extrusion*

To investigate the sliding behavior of the workpiece at the container–workpiece interface, four hemispherical indentations were prepared at a height of 6.0 mm from the bottom and 90° intervals in the circumferential direction in the outer surface of the initial workpiece using a Rockwell hardness tester. The diameter and depth of the indentation were approximately 0.56 mm and maximum 0.13 mm, respectively.

Figure 5 shows the photograph of the indentation of the extruded workpiece. The indentation was deformed to ellipse slightly stretched in the extrusion direction in extrusion with/without torsional oscillation (Fig. 5b, c). The indentation was deformed to an ellipse with a high aspect ratio tilted toward the torsional direction in extrusion with a one-way torsional moment (Fig. 5d). The relationship between the indentation shape of the extruded workpiece and the accumulative rotation angle of the knockout punch is shown in Fig. 6. Here, the indentation shape was measured

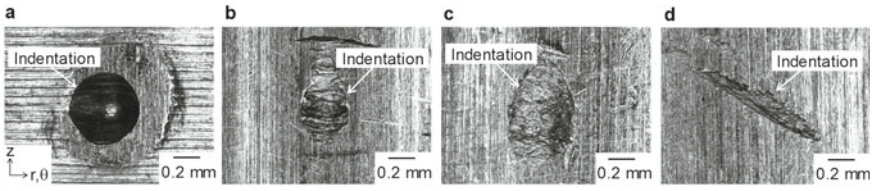

Fig. 5 Photographs of hemispherical indentation at outer surface of extruded workpiece in backward extrusion with torsional oscillation ($v = 0.1$ mm/s, axial stroke: 6.0 mm), **a** Initial workpiece, **b** $\omega = 0$ rpm, **c** $\omega = 0.5$ rpm ($\theta_{acc} = 165°$), **d** $\omega = 0.5$ rpm ($\theta_{acc} = 165°$, one-way)

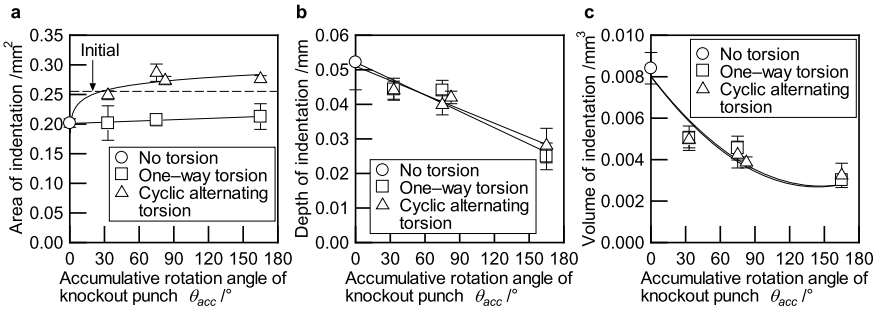

Fig. 6 Relationship between hemispherical indentation shape at outer surface of extruded workpiece and accumulative rotation angle of knockout punch in backward extrusion with torsional moment ($v = 0.1$ mm/s, axial stroke: 6.0 mm), **a** Cross-sectional area, **b** Maximum depth, **c** Volume

by a laser microscope with an image processing function. The accumulative rotation angle of the knockout punch was equal to the accumulative twisted angle of the workpiece because the workpiece was twisted by the knurled grooves of the punches without slipping. The cross-sectional area of the indentation became large in extrusion with torsional oscillation, while the depth of the indentation became shallow with increasing accumulative rotation angle. As the result, the volume of the indentation decreased with increasing accumulative rotation angle. It was confirmed that the outer surface of the workpiece was smoothed by applying torsional oscillation during extrusion.

4 Discussions by Finite Element Analysis

4.1 Finite Element Analysis Conditions

The elastic–plastic deformation and temperature change of the workpiece in extrusion were analyzed by a commercial three-dimensional finite element code, Simufact Forming ver. 15.0 (MSC Software Company). In the analysis, the material properties of the aluminum workpiece were employed from the built-in database of material properties in Simufact Forming ver. 15.0. The model of the flow stress was an isotropic hardening model. The temperature dependences of the flow stress, Young's modulus, the thermal conductivity, and the specific heat were taken into account in the analysis, and the strain rate sensitivity of the flow stress was also taken into account.

The dies were treated as rigid bodies under an isothermal state, and the end surfaces of the punches were assumed to be flat (no knurled grooves). To grip the workpiece for circumferential twisting, the frictional condition at the end surface of the punch–workpiece interface was assumed to be sticking (no sliding), while the frictional condition at other parts of the container–workpiece interface was shear

friction factor $m = 0.2$. The heat transfer coefficients on the die–workpiece interface and the free surfaces of the workpiece were assumed to be 5000 W/(m^2·K) and 50 W/(m^2·K), respectively.

4.2 Rotation Speed and Contact Pressure Between Container and Workpiece

Figure 7 shows the calculated circumferential rotation speed of the outer surface of the workpiece in backward extrusion with the one-way torsional moment. The rotation speed of the workpiece gradually decreased from the bottom of the workpiece to the height position of the end surface of the punch, while the rotation speed of the extruded sidewall of the workpiece (the distance from the bottom of the workpiece: longer than 8 mm) was constant at 20–40% of the rotation speed of the knockout punch. It is found that the part of the workpiece sandwiched between the extrusion and knockout punches were circumferentially twisted during extrusion, while the sidewall part of the extruded workpiece was not twisted during extrusion.

The calculated contact pressure between the container and the workpiece in backward extrusion with torsional moment was shown in Fig. 8. The contact pressure in extrusion with torsional moment was reduced by approximately 25%. This is due to the traction direction at the container–workpiece is tilted from the radial direction to the circumferential direction by torsional moment during extrusion.

The above circumferential sliding of the workpiece and the reduction in contact pressure at the container–workpiece are suggested to influence the surface quality of the outer surface of the extruded workpiece. It was also reported that surface

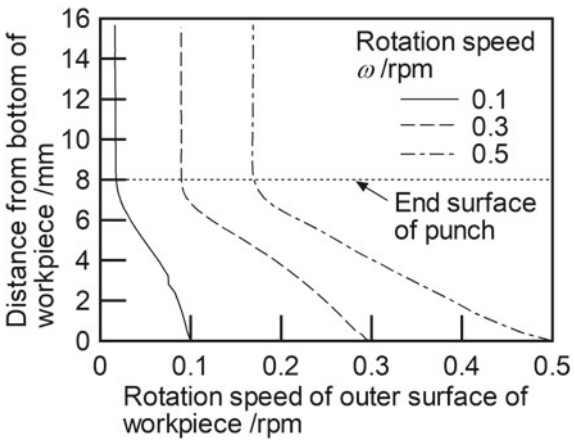

Fig. 7 Circumferential rotation speed of the outer surface of workpiece in backward extrusion with one-way torsional moment (axial stroke: 4.0 mm, FEM)

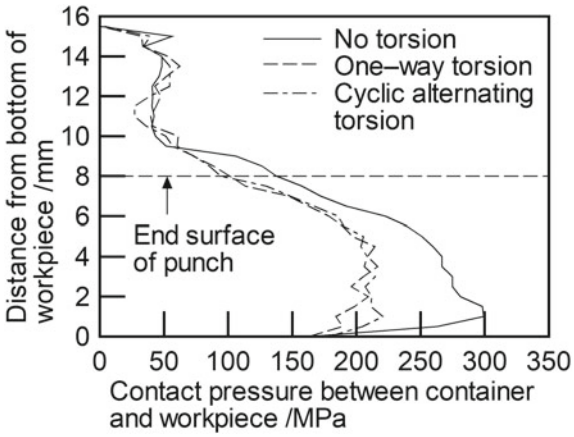

Fig. 8 Contact pressure between container and workpiece in backward extrusion with torsional moment (axial stroke: 4.0 mm, $\omega = 0.5$ rpm, FEM)

roughness of JIS A1050 aluminum was smoothed to approximately 10% in sliding with longer than 0.25 mm under contact pressure with higher than 150 MPa [7]. Therefore, the changes of the indentation shape in Sect. 3.1 and the surface roughness in Sect. 3.2 are reasonable.

5 Conclusions

In this study, the effect of torsional oscillation on surface quality of extruded workpiece was investigated in cold backward cup extrusion. Torsional oscillation with a maximum frequency of 0.15 Hz around the extrusion axis was applied on axial extrusion. The relationship between the torsional oscillation conditions and the surface properties was investigated by experiment and the finite element simulation. The following remarks were obtained.

(1) The torsional oscillation tilts the traction direction at the container–workpiece from the radial direction to the circumferential direction. The contact pressure between the container and the workpiece is reduced by approximately 25%.
(2) The average and standard deviation of the surface roughness of the outer surface of the extruded workpiece are lower than the initial by applying the torsional oscillation with accumulative torsion angle of 200°–360°.

Anisotropic Ductile Fracture Estimation of Diagonal Cracks in Flange-Shaped Parts

Atsuo Watanabe, Kunio Hayakawa, Shinichiro Fujikawa, Tatsumi Takeshita, and Mika Furutani

Abstract Inclined rotary forming (IRF) combines bending and axial compression with rotation and is employed for forming flange shaft-structured parts from round rod billets. Although the forming load is smaller than the one in conventional processes, cracks may develop during this process. However, it is difficult to predict the onset of cracks using conventional ductile fracture prediction equations. In this paper, an equation for predicting ductile fractures is proposed, which considers anisotropic ductile damage. The proposed equation is expressed as a second-rank tensor resulting from the inner product of the stress tensor and the strain increment tensor. Referring to the previously published results on the compression of cylindrical specimens, the difference between diagonal and longitudinal sidewall cracks was clarified by considering the anisotropy of ductile damage. The proposed equation was then applied to the IRF process, wherein diagonal cracks developed at the outer rim of flange. Consequently, it was possible to estimate the requirements for reducing diagonal cracks by controlling lubrication conditions.

1 Introduction

Cold forging processes of complex parts offer weight and cost reduction and are widely used in the automotive industry [1, 2]. Ductile fracture defects often define the forming limit of cold-forged parts. Therefore, accurate prediction of ductile fractures using the tools of the finite element analysis is necessary; this can help reduce the cost associated with trial-and-error design.

As the near-net shaping of forged parts progresses and material deformation becomes increasingly complicated, it is necessary to further improve the prediction accuracy of ductile fractures. Considering anisotropic damage associated with ductile fractures, the generation and growth of microscopic voids and cracks in the material depends on the direction of the applied stress and/or strain. In other words, the damage profile is essentially anisotropic. Therefore, prediction accuracy can be likely improved by accounting for this damage anisotropy.

In this paper, we propose to use damage anisotropy during the evolution of ductile fractures to improve the prediction accuracy of ductile fractures. The proposed equation is validated for the inclined rotary forming (IRF) process, wherein diagonal cracks develop at the outer rim of flange. Consequently, requirements for reducing diagonal cracks by controlling lubrication conditions were identified.

2 Ductile Fractures in IRF

IRF as a forming process is shown schematically in Fig. 1. In this process, the free part of the shaft is thickened by setting a steel billet to both the pushing and receiving dies, and by rotating the dies while inclining the receiving die [3–5]. This process allows thickening of the free part of the billet using a lower load, owing to a locally high forming pressure caused by the inclined rotary forming, such as orbital forming. The authors have been developing this method to apply to a part called a pulley that constitutes a part of the automatic transmission mechanism in modern automobiles [5].

The studied material was SCr420H (JIS) and spheroidizing annealing was performed before forming. The spheroidizing annealing was performed at the holding temperature of 690 °C and for the holding time of 10 h. After that, phosphate coating was applied for lubrication. Cold multi-stage forward extrusion was conducted before the IRF process, to shape the product (Fig. 2). In the IRF process, the forming force was 2600 kN, the rotation speed was 60 rpm, and the angle of the inclining die was 4°. During the forming, oil was poured for the auxiliary lubrication. The diameter expansion ratio, which is the ratio of the final diameter to the initial diameter, was 2.8.

Figure 2 shows the formed samples during the IRF process. After the process, diagonal cracks at the outer rim of flange (Fig. 2) were observed. When investigating factors that could suppress these diagonal cracks, it was confirmed that these

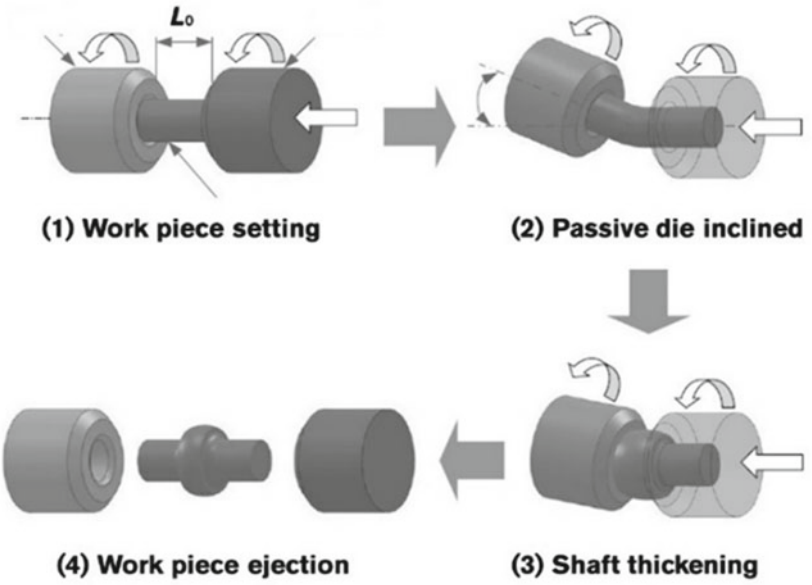

Fig. 1 Inclined rotary forming process

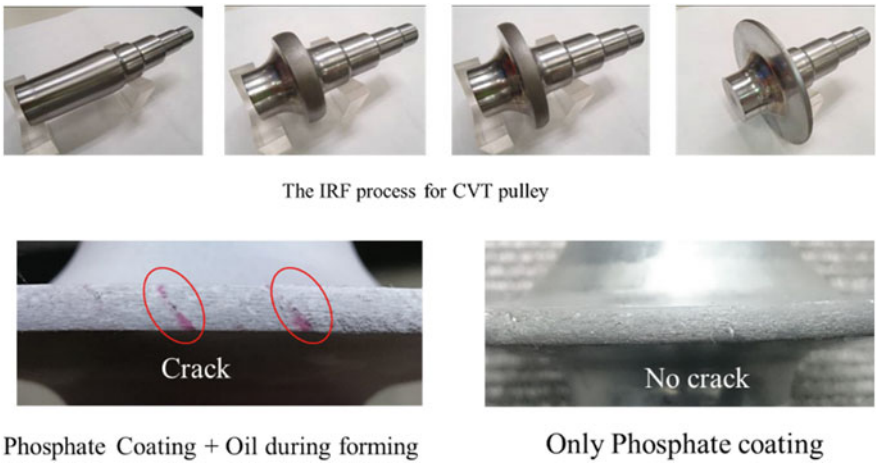

Fig. 2 Cracks in flange-shaped parts. (Color figure online)

diagonal cracks could be alleviated by stopping the oil supply for lubrication during the forming. In this paper, the occurrence and suppression of the diagonal cracks were clarified using the anisotropic ductile fractures theory and finite element analysis. The finite element analysis was performed using the dedicated finite element software DEFORM-2D, DEFORM-3D (SFTC), and their user subroutine functions.

3 Proposed Equations for Ductile Fracture Prediction Using Anisotropic Ductile Damage

Isotropic ductile fractures criteria by Cockcroft and Latham [6] in Eq. (1) were used for the ductile damage evaluation; these criteria are widely used in the finite element analysis of cold forging. I_1 is the threshold on the ductile fracture, $\sigma_{\max}$ is the maximal principal stress, $\bar{\sigma}$ is the equivalent stress, and $d\bar{\varepsilon}$ is the equivalent strain increment. Equation (1) assumes isotropic damage and cannot capture the damage direction. To capture the damage direction, the anisotropic ductile fracture theory was proposed and applied to ductile fractures in the forward extrusion [7].

The inner product of the stress tensor and the strain increment tensor represents the specific strain energy increment, as given by Eq. (2), where σ_{ij} is the stress tensor, $d\varepsilon_{ij}$ is the strain increment tensor, and δ_{ij} is the Kronecker delta. Based on Eq. (2), a ductile damage model of the second-order tensor is given by Eq. (3), which can be considered as a possible modification of Eq. (1).

Equations (1) and (3) are based on the idea of evaluating the accumulation of the strain energy expressed by the product of the stress and strain increments as material ductile damage. In the case of Eq. (3), the effect of the stress/strain direction on the ductile damage evolution can be considered.

When discussing anisotropic ductile damage, it is often convenient to use principal values. However, because Eq. (3) features an asymmetric tensor, the principal values may be complex numbers, in which case physical interpretation is difficult. Therefore, with reference to the effective stress method [8] in the framework of continuum damage mechanics, symmetrized variables were adopted as the proposed equation, as shown in Eq. (4). In the cylindrical coordinate system O-$r\theta z$, the principal values $\bar{\bar{D}}_{\mathrm{I}}$, $\bar{\bar{D}}_{\mathrm{II}}$, and $\bar{\bar{D}}_{\mathrm{III}}$ are calculated according to Eq. (5).

$$D_{\mathrm{CL}} = I_1,\ D_{\mathrm{CL}} \equiv \int \left(\frac{\sigma \max}{\bar{\sigma}} \right) d\bar{\varepsilon} \tag{1}$$

$$dE = \sigma_{ij} d\varepsilon_{ij} = \delta_{ij} \left(\sigma_{ik} d\varepsilon_{kj} \right) \tag{2}$$

$$\bar{\bar{D}}_{ij} = \int \frac{\sigma_{ik}}{\bar{\sigma}} d\varepsilon_{kj} \tag{3}$$

$$\bar{\bar{D}}_{ij} = \frac{1}{2} \int \left(\frac{\sigma_{ik}}{\bar{\sigma}} d\varepsilon_{kj} + \frac{\sigma_{jl}}{\bar{\sigma}} d\varepsilon_{li} \right) \tag{4}$$

$$\left. \begin{matrix} \bar{\bar{D}}_{\mathrm{I}} \\ \bar{\bar{D}}_{\mathrm{II}} \end{matrix} \right\} = \frac{1}{2} \left(\bar{\bar{D}}_r + \bar{\bar{D}}_z \right) \pm \sqrt{\left(\frac{\bar{\bar{D}}_r - \bar{\bar{D}}_z}{2} \right)^2 + \bar{\bar{D}}_{rz}^2},\ \bar{\bar{D}}_{\mathrm{III}} = \bar{\bar{D}}_\theta \tag{5}$$

4 Application of the Anisotropic Ductile Damage Model to Side Cracks in the Cylindrical Compression Test

4.1 Investigation of Diagonal Cracks in Compression Tests

To study the effect of the anisotropic damage model on diagonal cracks in flange-shaped parts as in the IRF process, we used the previously published result of the cylindrical compression test [9]; that study also reported the formation of diagonal cracks. In that experiment, when compression was performed using conical-type dies as in Fig. 3, diagonal cracks appeared on the side of the cylinder. When compression was performed using boundary-restrained dies as shown in Fig. 4, longitudinal cracks appeared. W and H are the initial diameter and the initial height. In this condition, the finite element analysis was conducted axisymmetrically using DEFORM-2D. The Coulomb friction coefficient was 0.1 for the compression test with conical-type dies, and the shear friction coefficient was 0.5 for the compression test with boundary-restrained dies, to match previously reported stress changes. The flow stress data were taken from the literature [9]. Figures 5 and 6 show the change in the stress at the center of the height of the cylinder side. The horizontal axis shows the compressive logarithmic strain, $\ln(H/h)$, where h is the current height. The direction of the maximal principal stress of both types was the θ direction in cylindrical coordinates. This

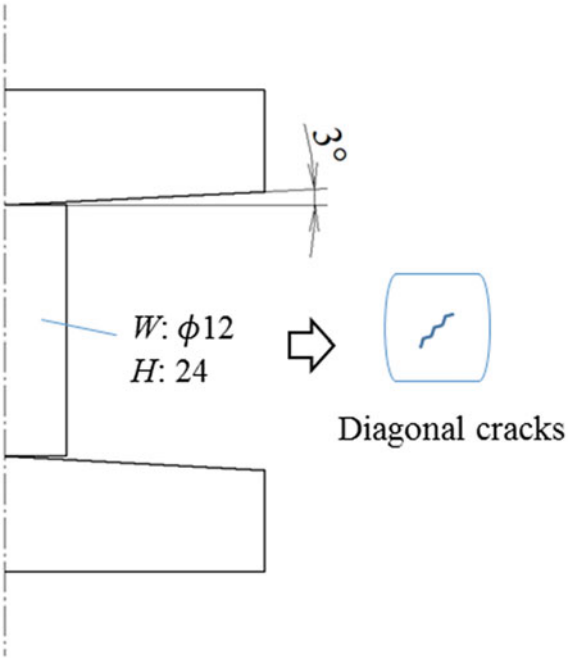

Fig. 3 Diagonal cracks in the compression test. (Color figure online)

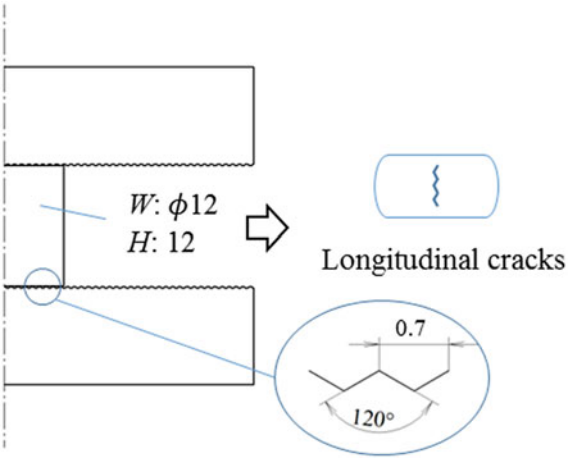

Fig. 4 Longitudinal cracks in the compression test. (Color figure online)

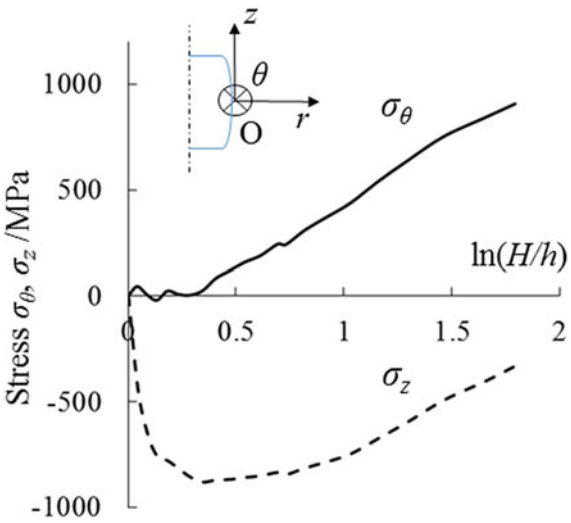

Fig. 5 Change in the stress in the compression test (Fig. 3). (Color figure online)

fracture formation model is based on the maximal shear stress theory in the literature [9].

The developed anisotropic damage model was applied to the results of this experiment. Equation (4) was implemented into the DEFORM-2D by using user subroutines. The value in Eq. (4) varies depending on the system of coordinates. D_θ quantifies the damage in the θ direction in cylindrical coordinates, that is, the direction perpendicular to the vertical crack. $D_{\theta 45^\circ}$ quantifies the damage in the direction of 45° around the r axis, that is, in the direction perpendicular to the diagonal crack. For the compression test with conical-type dies in which diagonal cracks occurred, $D_{\theta 45^\circ}$

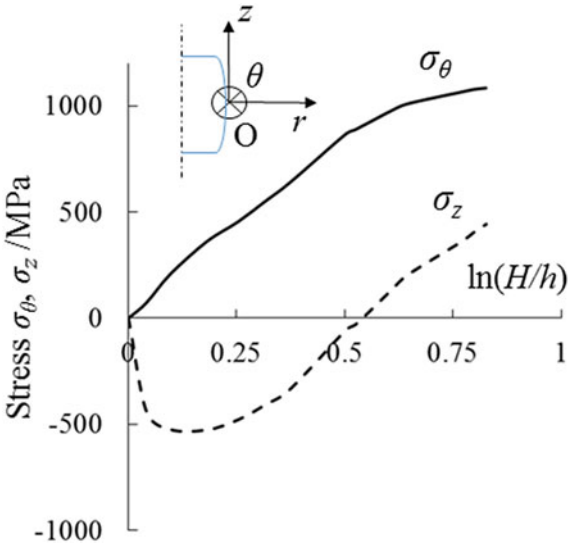

Fig. 6 Change in the stress in the compression test (Fig. 4). (Color figure online)

(perpendicular to the crack) was larger than D_θ, as shown in Fig. 7. For the compression test with boundary-restrained dies in which longitudinal cracks occurred, D_θ was larger than $D_{\theta 45^\circ}$, as shown in Fig. 8. It is confirmed that the proposed model can properly assume the direction of the damage on each compression condition.

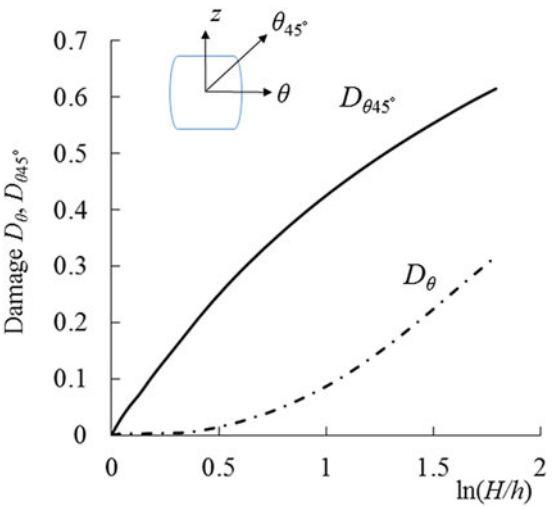

Fig. 7 Change in the damage in the compression test (Fig. 3). (Color figure online)

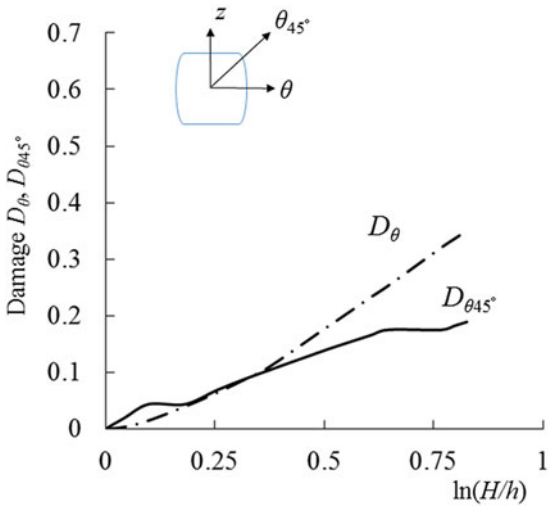

Fig. 8 Change in the damage in the compression test (Fig. 4). (Color figure online)

4.2 Application of the Anisotropic Damage Model in the Principal Direction

To study the formation of diagonal cracks using Eqs. (4) and (5), a principal value was added in the shear direction, in addition to the principal value in the vertical direction. The damage equation for the principal value in the shear direction was given in Eq. (7), based on the same concept as Mohr's stress circle. The concept underlying the damage energy in Eq. (2) is that the damage becomes positive when both the stress and strain rates are negative. As shown in Fig. 9, the stress in the z-direction at the diagonal crack is negative, but the damage is positive, and it is estimated to be small when calculating the principal value in the shear direction. Therefore, Eq. (6) is proposed for calculating the principal value in the shear direction. C_{ij} takes the value of -1.0 if

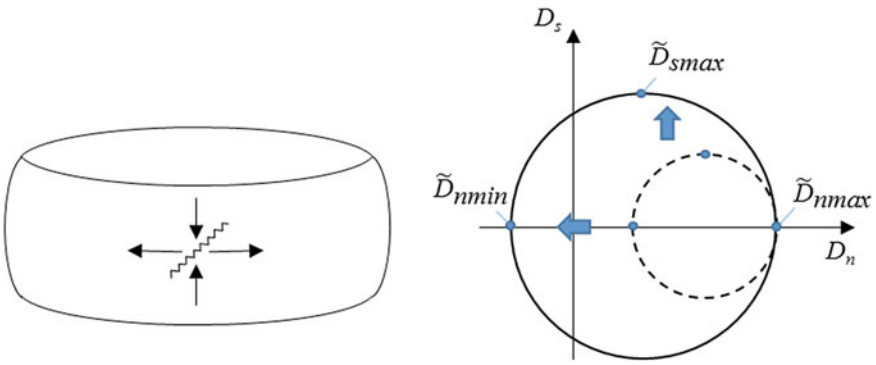

Fig. 9 Conceptual depiction of damage in the shear principal direction. (Color figure online)

the stress σ_{ij} is negative and 1.0 if the stress is positive. The damage value is basically a positive value with directionality, but only when calculating the principal value in the shear direction, and the principal value in the shear direction $\tilde{D}_{smax}$ is calculated from $\tilde{D}_{ij}$ as Eq. (7). This calculation model was applied to the compression test with conical-type dies (Fig. 3), and the principal value, $\tilde{D}_{smax}$ coincided with the change in $D_{\theta 45^\circ}$ in Fig. 7. The value of $\tilde{D}_{nmax}$ coincided with that of D_θ. The anisotropic damage model with principal values in the shear direction can be used for calculating actual parts.

$$\tilde{D}_{ij} = C_{ij}\bar{\bar{D}}_{ij} \cdot \text{no sum on } i \text{ and } j \tag{6}$$

$$\tilde{D}_{smax} = \frac{1}{2}\left(\tilde{D}_{nmax} - \tilde{D}_{nmin}\right) \tag{7}$$

5 Simulation of the IRF Process with the Anisotropic Ductile Damage Model

To reproduce the diagonal cracks in the outer rim of flange of the CVT pulley in the IRF process as described in Sect. 1, the finite element analysis using DEFORM-3D was performed. The material was SCr420H (JIS). Table 1 shows the chemical composition of the material. The spheroidizing annealing temperature was 690 °C. Microstructure is ferrite perlite structure. The flow stress was measured using a tensile test on the material and was used for calculations. Material constants of flow stress data are shown in Table 2. The forming force was 2600 kN, the rotation speed was 60 rpm, and the angle of the inclining die was 4°, the same as for the conditions for which crack generation was observed, as described in Sect. 1. The axial length of the bar was 243.0 mm and the maximal diameter was 48.2 mm before forming, as shown in the left panel of Fig. 10. The simulation terminated when the diameter expansion ratio reached 2.8. The element size was about 2 mm in the flange-formed

Table 1 Chemical composition of SCr420H

Material	C	Si	Mn	P	S	Cr
SCr420H	0.20	0.25	0.73	0.03	0.03	1.05

Table 2 Material constants of Swift's law of SCr420H

Plasticity coefficient F/MPa	Work hardening exponent n	Material constant ε_0
889	0.17	0.003
		$\sigma = F(\varepsilon + \varepsilon_0)^n$

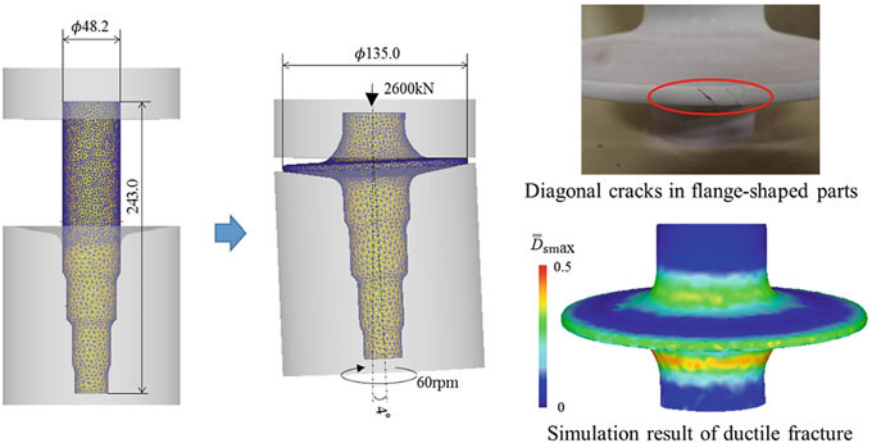

Fig. 10 CVT pulley in the simulation of the IRF process. (Color figure online)

part. The step was 2°, according to the rotating dies. To reproduce the formation of cracks owing to the difference in the lubrication state, as described in Sect. 1, the friction coefficient was set to 0.02, to capture phosphate coating and oil pouring, corresponding to the condition of good lubrication. The friction coefficient was 0.3 to capture phosphate coating only, corresponding to the condition of insufficient lubrication. Figure 10 shows the analysis model and the analysis results for damage calculation.

Equations (4)–(7) were incorporated into the DEFORM-3D user subroutine, to quantify the damage. Figure 11 shows the change in $\tilde{D}_{smax}$ at the outer rim of the flange, where diagonal cracks occurred. Because the calculation results exhibited

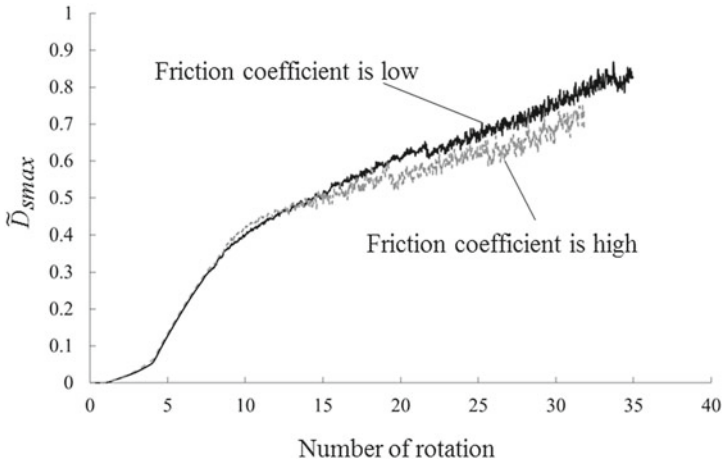

Fig. 11 Difference in $\tilde{D}_{smax}$ at the fracture point

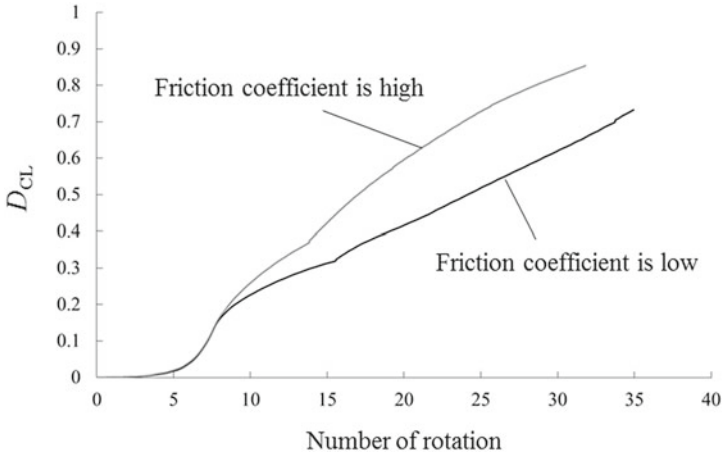

Fig. 12 Difference in D_{CL} at the fracture point

some dispersion along the circumferential direction of the outer rim, we averaged the 12 points on the outer circumference (every 30°). The damage value $\tilde{D}_{smax}$ was higher for the low friction coefficient. This demonstrates that diagonal cracks can be formed, similar to the experiment in Sect. 1. Because the coefficient of friction was lower, the material flow along the radial direction was larger. Because the axial compression at the outer rim of the flange was larger, the damage in the shear direction was stronger.

It is considered that ductile fracture occurs when the damage value reaches fracture threshold. This fracture threshold depends on the type of material and heat treatment condition, and is determined by tensile tests. In addition, the threshold must be verified whether it can be applied to the actual parts, which are complexly formed [7]. In this case, it is considered that fracture threshold was between 0.7 and 0.8, based on the actual occurrence of cracks in the parts and Fig. 11.

Figure 12 shows the change in the damage value, calculated using the normalized Cockcroft–Latham equation, Eq. (1), under the same conditions. In the conventional predictive equation that assumes isotropic damage, the contribution to the damage along the θ direction, which is the maximal principal stress, increases. Consequently, the damage value for the insufficient lubrication condition increases. This suggests that anisotropic predictive modeling is necessary to properly infer the formation of diagonal cracks owing to the shear of the flange phenomenon, as is the case here.

6 Conclusion

A novel equation for quantification of the ductile fracture-related damage, which accounts for anisotropy, was proposed in this paper. In the case of a complex material flow such as the IRF process, the conventional isotropic ductile failure damage equation does not accurately predict the position of the onset of ductile failures. In light of this, the conclusions of this study obtained are summarized as follows.

1. For the proposed equation of ductile fracture generation that accounts for anisotropy, the amount of damage was expressed as the inner product of the stress tensor and the strain tensor increment.

2. The proposed anisotropic ductile damage model was applied to the phenomenon of diagonal cracks and longitudinal cracks on the side of a cylinder, which were observed in cylinder compression experiments, as described in the literature. The effectiveness of this model was verified. The analysis concluded that the principal value of damage along not only the vertical direction but also the shear direction should be considered.

3. The anisotropic ductile damage model was applied to describe the onset of diagonal cracks in the IRF process. The effect of lubrication condition on the onset of diagonal cracks was properly predicted by employing the proposed model.

Prediction of Microstructure Behavior During Large-Scale Hot Forging of Ni-Based Superalloy

Nobuki Yukawa, Chihiro Osawa, Takayuki Yamada, and Eiji Abe

Abstract For the production of large heat-resistant components, improving the prediction accuracy of microstructural behavior by the finite element method leads cost and time reduction in process optimization. To perform this task, it is essential to predict the recrystallization behavior accurately, during hot forging and heat treatment of Ni-base superalloys. So far, many researchers have used the Avrami equation to predict the recrystallization behavior. However, this uses experimental coefficients determined empirically for each process, so it is not suitable for predicting the microstructure of large-scale hot forged parts with different complex deformation and thermal histories at different locations. Because the recrystallization behavior is considered to depend on the path, and on the temperature, strain, and strain rate at that time. Therefore, an incremental form of a prediction model based on the Avrami equation has been developed as a solution. Optimized parameters for the incremental model were obtained by using a genetic algorithm which is an adaptive heuristic search algorithm. At this time, it is not enough to use only the results of small tests at the laboratory level as training data for genetic algorithm. This is because the thermal histories and distributions have a large difference between the small specimens and the large parts. In this study, 1,500 and 50,000 t class forging tests were performed, and the parameters in the prediction model were determined using these results as learning data. As a result, the average error of prediction was reduced to about half.

1 Introduction

In recent years, the demand for aircraft has increased and there is a need to increase the combustion temperature of gas turbines in order to improve fuel efficiency. To achieve this, the gas turbine material must have high strength and fracture toughness

at high temperatures. Alloy 718 superalloy is a Ni-based superalloy that is used widely in gas turbines to satisfy these demands [1].

Alloy 718 turbine disks are manufactured through casting, multiple hot forging, and heat treatment. The microstructure changes induced during the manufacturing process affect the heat resistance of the alloy during the service. In order to guarantee the high-temperature strength, for example, it is necessary to control the grain size within a certain range. Alloy 718 is an austenite single-phase material, so grain refinement due to phase transformation cannot be expected [2]. Therefore, only grain refinement by recrystallization during hot forging and heat treatment is an effective means.

The recrystallization behavior has been studied so far. The Avrami equation is often used to predict softening phenomena caused by dynamic, post-dynamic, and static recrystallization [3]. In order to predict the fraction of recrystallization by the Avrami equation, it is necessary to determine some parameters in the equation. An assumption is made in recrystallization prediction by the Avrami equation using the Arrhenius plot method. The assumption is that the temperature, strain, and strain rate of the material does not change from the initial values during the process. The assumption has been used for simple forgings such as small free upsetting tests in the 10 t class.

However, in an actual hot forging, even if it is a small test piece in a modeled experiment, deformation at each location is complicated due to shape and friction, and the temperature is not constant and uniform due to heat release to the atmosphere and heat removal to the dies. This is even more pronounced in turbine disk forgings about 2 m in diameter. In the case of large forging, the temperature difference between the surface layer and the central part increases because the material to be forged is exposed to the cold atmosphere after it is removed from the heating furnace until the forging is completed. Also, the strain distribution inside the material is large because it is formed by multiple complex die forgings. In such complicated and non-uniform forging, the above assumption do not hold and it is difficult to accurately predict recrystallization using the parameters obtained on above assumption.

Therefore, in this research, a prediction model and a parameter optimization method that can respond to change and distributions during process were developed. Avrami equation is changed to an incremental form, and a genetic algorithm is used to determine the parameters in the prediction models. At this time, it is not enough to use only the results of small tests at the laboratory level as training data for genetic algorithm. This is because there is a difference in temperature change and deformation behavior during hot forging and heat treatment between small test specimens at the laboratory level and large real forgings. These differences are due to the difference in surface area to volume ratio of these materials. The volume that stores heat is the cube of the dimension, but the surface area that releases heat is the square. Specifically, the surface area/volume ratio of a large forging is about 1/60 of that of a small laboratory specimen, and the heat histories and distributions are completely different between the two.

In this study, in addition to the small forging test, tests using a 1,500 t class hot forging simulator (about 380 t) and tests using a 50,000 t forging press (about 13000 t)

Table 1 Chemical composition of tested material (mass %)

Ni	Cr	Mo	Fe	Nb(+Ta)	Ti	Al
54.0	18.0	3.0	18.5	5.1	0.9	0.5

were performed. Based on the results obtained from these tests, the parameters in the dynamic recrystallization prediction model and the post-dynamic/static recrystallization prediction model were determined using a genetic algorithm, respectively, and the recrystallization behavior of a large forging with a shape close to that of a turbine disk product was predicted. As a result of verifying the accuracy of the prediction model by comparing the experimental values and the prediction values, it is shown that the accuracy was improved by optimizing including the results of 1,500 and 50,000 t forging tests.

2 Experimental Procedure

2.1 Materials

Alloy 718 was used in the tests. The specimens were machined from a triple melted ingot (vacuum induction melting followed by electro-slag remelting and vacuum arc remelting). The chemical composition of the tested material is shown in Table 1.

2.2 Small Forging Test

Isothermal compression tests were done using THERMECMASTER-Z (FTZ-203A, Fuji Electric Industrial Co., Ltd). The shape of the specimen is a cylinder with 8 mm in diameter and 12 mm in height. The specimens were heated in a vacuum to the testing temperature in a few seconds by high-frequency induction heating, held for 60 s at the test temperature, and then compressed axially while maintaining temperature. At this time, the mica plates were used on the upper and the lower end surface as heat insulators. The ranges for test temperature, average strain rate, compression rate, and initial grain diameter is 960–1020 °C, 0.02–0.2 s^{-1}, 33–60%, and 18–539 μm, respectively.

After forging, cooling was performed in three different processes. Details are shown as small A test, small B test, and small C test, respectively.

- Small A test

In order to determine the parameters in the dynamic recrystallization prediction model, the specimens were cooled by N_2 gas immediately after hot forging to realize the quench condition.

- Small B test

In order to determine the parameters in the post-dynamic/static recrystallization prediction model, the specimens were held at the forging temperature after hot forging. The holding time was 15 s, 30 s, 60 s, and after holding, it was quenched with N_2 gas.

- Small C test

In order to determine the parameters in the post-dynamic/static recrystallization prediction model, the specimens were cooled to 500 °C at a rate of -15 °C $\cdot$ min^{-1} after hot forging. Then cooled with N_2 gas.

2.3 1,500 T Forging Test

Free upsetting hot forging tests were done using a large hot forging simulator installed at National Institute for Materials Science. This is a device that integrates an atmospheric furnace, a press (HCF-1,500, Sumitomo Heavy Industries, Ltd.), the cooling control devices, temperature measurement devices, and a manipulating robot. The shape of the specimen is a cylinder with 80 mm in diameter and 140 mm in height and has a corner radius of 3 mm at each end edge of the cylinder. The specimens were heated to the testing temperature in the furnace, held for 3600 s at the test temperature, moved to the compression die by the manipulator, and then compressed axially while maintaining temperature. At this time, glass lubricant was used between the specimen and the upper and lower dies. The testing temperature range, strain rate, compression rate, and initial grain diameter are 900 and 980 °C, 0.1 s^{-1}, 50%, and 160 μm, respectively. After compression, the specimens were removed from the die and cooled at a rate of -15 °C $\cdot$ min^{-1}.

2.4 50,000 T Forging Test

Two types of large forging tests were conducted using a 50,000 t hydraulic forging press. The first is the No.1 shape used for parameter determination, and the second is the No.2 shape used for accuracy verification. For both shapes, two-stage tests were conducted: rough forging and finish forging. The initial shape of the specimen for the No.1 test is a cylinder with 258 mm in diameter and 538 mm in height, and the

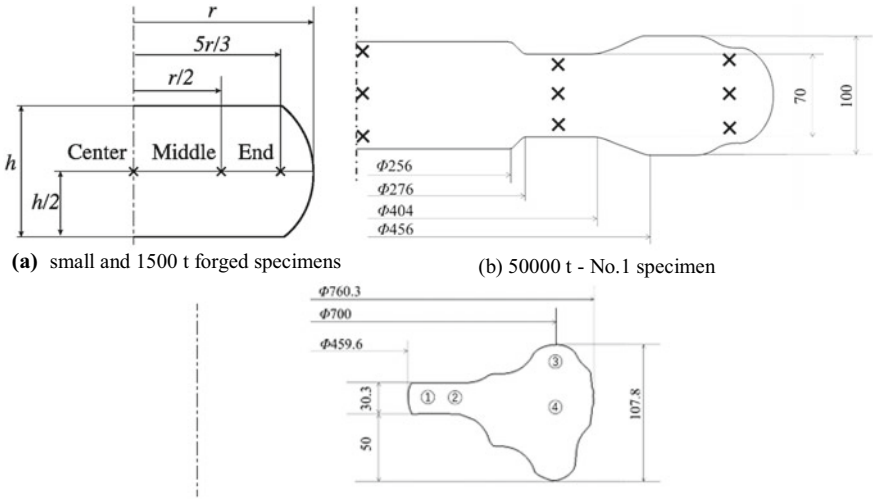

Fig. 1 Appearances of each shape specimens after rough forging and finish forging. (Color figure online)

No.2 test is a cylinder with 258 mm in diameter and 760 mm in height, before the rough forging. The No.2 shape specimen was machined to ring shape between rough forging and finish forging. Figure 1 shows the appearances of each shape specimen after rough forging and finish forging. The specimens before rough forging and finish forging were heated to 980 °C in a heating furnace in about 15 h, transported to the press machine by a robot arm, and then forged. After that, the forged specimens were taken out from the press machine with a robot arm and air-cooled on two metal bars.

2.5 Microstructure Observation

The microstructure of the specimen after cooling was observed in the vertical -section and the area fraction of recrystallization and recrystallized grain size was measured by EBSD method. In this study, the average grain size is calculated by the image processing method on the cut surface. Generally, grains have various shapes, and the average grain size is evaluated to be smaller than the actual size by image processing method on the cut surface as the grains have a shape that deviates greatly from the spherical shape. However, since the recrystallized grains are often equiaxed, the effect of shape-related errors in this study is considered to be small. On the other hand, it should be noted that even with equiaxed grains, the two-dimensional grain size is only a characteristic value of the cross section of the three-dimensional structure [5], and a value smaller than the three-dimensional grain size can be obtained.

The observation positions of small forged specimens and 1,500 t forged specimens are several areas of 1/2 in height, shown in Fig. 2a. The observation positions of 50,000 t No. 1 and No. 2 forged specimens are shown in Fig. 2b and c, respectively.

Fig. 2 Observation positions of each specimen

3 Prediction Model

3.1 Incremental Form of the Avrami Equation

In order to predict the fraction of dynamic recrystallization during the complex unstable deformation process, an incremental form of the Avrami equation was developed [4]. Equations (1) and (2) show the prediction model of dynamic recrystallization grain diameter.

$$D_{new} = a_3 \cdot \varepsilon^{p_1} \cdot Z^{-m_3} \tag{1}$$

$$Z = \dot{\varepsilon} exp(Q/RT) \tag{2}$$

where D_{new} is the nucleation particle size of dynamic recrystallization, ε is the amount of residual strain in the region, $\dot{\varepsilon}$ is the equivalent strain rate, T is the temperature, and a_3, p_1, m_3, Q are material constants. Total 21 parameters are contained in the equations. The parameters in these prediction models were optimized using the results of small A tests under 39 conditions as learning data.

Both post-dynamic recrystallization and static recrystallization are recrystallizations occurring after hot forging. Therefore, it is difficult to distinguish between post-dynamic recrystallized grains and static recrystallized grains in the microstructure observed after the small B, small C, 1,500 t and 50,000 t-No. 1 forging tests.

In this study, the recrystallization that occurs after hot forging is summarized as post-dynamic/static recrystallization.

Prediction models for area fraction of recrystallization after heat treatment, $X_{post,static}$, are shown in Eq. (3) [6].

$$X_{post,static} = 1.0 - exp\left[-\beta_s\left(\frac{t}{t_{0.5}}\right)^{K_s}\right] \tag{3}$$

where t is the holding time, $t_{0.5}$ is the time for 50% post-dynamic/static recrystallization, and β_s, K_s are material constants. The incremental form of this equation was expressed as shown in Eqs. (4)–(7).

$$X^{n+1}_{post,static} = X^{n}_{post,static} + d\left(X^{n}_{post,static}\right) \tag{4}$$

$$d\left(X^{n}_{post,static}\right) = \frac{\partial X}{\partial t}dt + \frac{\partial X}{\partial t_{0.5}}dt_{0.5} \tag{5}$$

$$\frac{\partial X}{\partial t} = \frac{-\beta_s \cdot K_s \cdot \left(\frac{t}{t_{0.5}}\right)^{K_s-1.0} \cdot exp\left[-\beta_s\left(\frac{t}{t_{0.5}}\right)^{K_s}\right]}{t_{0.5}} \tag{6}$$

$$\frac{\partial X}{\partial t_{0.5}} = \frac{-\beta_s \cdot K_s \cdot t \cdot \left(\frac{t}{t_{0.5}}\right)^{K_s-1.0} \cdot exp\left[-\beta_s\left(\frac{t}{t_{0.5}}\right)^{K_s}\right]}{(t_{0.5})^2} \tag{7}$$

For $t_{0.5}$, Eq. (8) has been proposed by previous research [6].

$$t_{0.5} = a_1 \cdot (d_0)^b \cdot \varepsilon^{-m_1} \cdot \dot{\varepsilon}^{-p_1} \cdot exp\left(\frac{Q_1}{RT}\right) \tag{8}$$

where d_0 is the initial grain diameter, $\dot{\varepsilon}$ is the equivalent strain rate during hot forging, and a_1, b, m_1, $p_1$and Q_1 are constants. The residual strain calculated by the dynamic recrystallization prediction model are used as initial values. In this equation, $t_{0.5}$ depends on the initial grain diameter. However, in this study, it is not appropriate to use a constant initial grain diameter when calculating $t_{0.5}$ at each calculation step because the calculation is performed in an incremental form. Therefore, the grain boundary length at each step was used instead of the initial grain diameter.

$$t_{0.5} = a_1 \cdot L^{-n_1} \cdot \varepsilon^{-m_1} \cdot \dot{\varepsilon}^{-p_1} \cdot exp\left(\frac{Q_1}{RT}\right) \tag{9}$$

L is the grain boundary length of the target region.

These equations contain a total of 17 parameters. The parameters in these prediction models were optimized using the results of small B (9 data), small C (3 data), 1,500 t (12 data), and 50,000 t-No. 1 tests (9 data) as learning data.

3.2 Overview of Parameter Optimization

The parameters in the dynamic and post-dynamic/static recrystallization prediction models were optimized by using genetic algorithm. First, the history of the temperature and the strain rate inside the material during forging and cooling was acquired by finite element analysis and used as input data. Next, using the input data and randomly generated parameters, the fraction of recrystallization and recrystallized grain size were calculated in a prediction model. Then, the calculated values were compared with the experimental values, the genetic operations were performed to reduce the error, and a new parameter group was generated. This operation was repeated, and the generation parameter group that is converged empirically enough was determined as the optimal value.

4 Results of Prediction Model

4.1 Calculation Accuracy

Figure 3 shows the calculation results when the parameters in the dynamic recrystallization prediction model were optimized using the results of the small A tests.

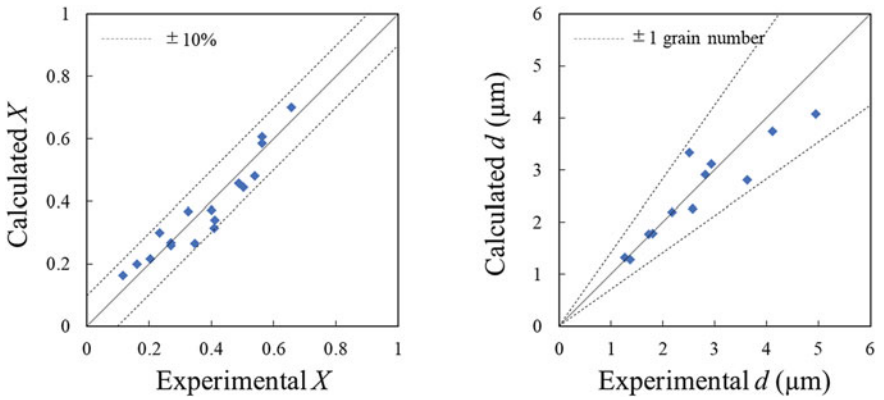

Fig. 3 Calculation results of dynamic recrystallization to decide parameters. **a** the fraction of recrystallization, **b** the recrystallized grain size. (Color figure online)

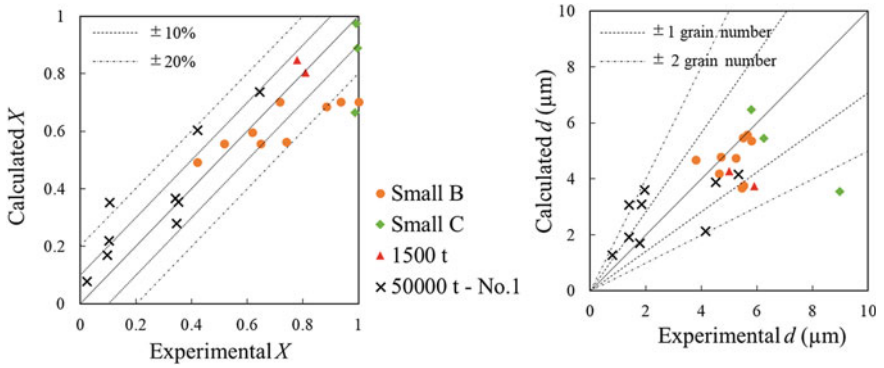

Fig. 4 Calculation results of post-dynamic/static recrystallization. **a** Fraction of recrystallization, **b** Recrystallized grain size. (Color figure online)

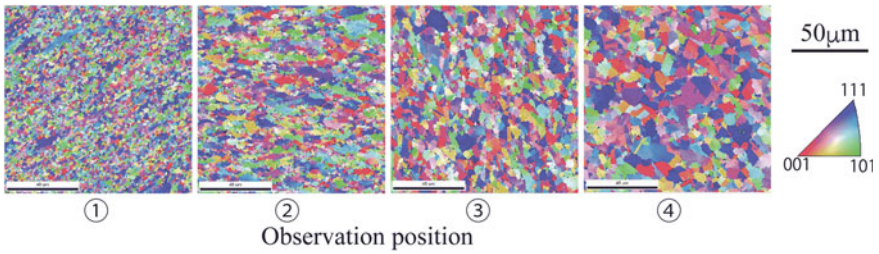
Figure 3a shows the fraction of recrystallization, and Fig. 3b shows the recrystallized grain size. The dotted lines in the figure indicate the range of the fraction of ± 10% for the fraction of recrystallization and ± 1 ASTM grain size number for the recrystallized grain size, respectively. From these figures, it can be seen that the errors were within the range of ±10% for the fraction of recrystallization and ±1 ASTM grain size number for the recrystallized grain size in all results, and the calculated values agreed well with the experimental values. The average error is 4.4% for the fraction of recrystallization and 10% for the recrystallized grain size.

Figure 4 shows the calculation results when the parameters in the post-dynamic/static recrystallization prediction model were optimized using the results of the small B, small C, 1,500 t, and 50,000 t-No. 1 forging tests. The dashed lines indicate the error range of ±20% for the fraction of recrystallization and ±2 ASTM grain size number for the recrystallized grain size. From this figure, it can be seen that most of the results were within the error range of ±20% for the fraction of recrystallization and ±2 ASTM grain size number for the recrystallized grain size. The average error was 11.0% for the fraction of recrystallization and 30.7% for the recrystallized grain size.

4.2 Prediction Accuracy

In order to verify the accuracy of the constructed recrystallization prediction model and the optimized parameters, a prediction was conducted for the 50,000 t-No. 2 forging test. Figure 5 shows the EBSD map obtained at each observation position shown in Fig. 2c after forging.

Figure 6 shows the comparison between the experimental results (blue bar) and the predicted results (red bar) using the small A, B, C, 1,500 t, and 50,000 t-No. 1 tests for parameter optimization. From these results, the average error for the four



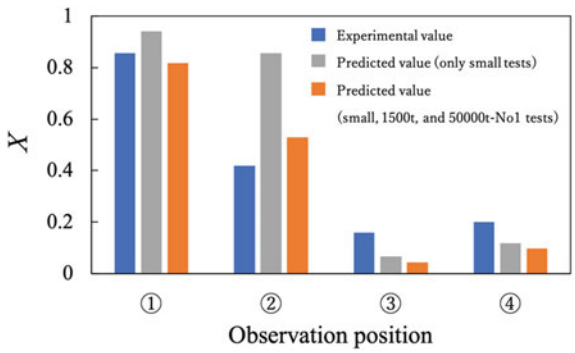


Fig. 5 EBSD map at each observation position in 50000t-No. 2 forging test. (Color figure online)

Fig. 6 Prediction results of the fraction of recrystallization in 50000 t-No. 2 forging test. (Color figure online)

observation positions was 9.2%. Predicted results using only the small tests are also shown in this figure (gray bar). In this case, the average error of the prediction results was 17.4%. The prediction accuracy was improved by optimizing the parameters using the results of the 1,500 t forging test and the 50,000 t forging test, as compared to the conventional method using only the small forging tests. In this figure, it can be seen that the error of the predicted results using small, 1,500 t, and 50,000 t-No. 1 tests are slightly larger than the result using only the small tests at positions 3 and 4. In these areas, the strain rate is very small compared to the experimental tests that are used for the parameter optimization, and it is considered that this caused the error.

The fraction of post-dynamic/static recrystallization depends on the residual strain after forging and the temperature during cooling. As a result of finite element analysis, there was almost no temperature distribution inside the small C specimens cooled at a rate of -15 °C · min^{-1}, whereas the maximum temperature difference was 92 °C inside the 1,500 t forged specimen. The maximum temperature difference inside the 50,000 t-No. 1 forged test specimen was 241 °C. By determining the parameters in the post-dynamic/static recrystallization prediction model in consideration such a temperature distribution, it is thought that the prediction accuracy for 50,000 t-No. 2 forged test, which also has a large temperature difference (maximum temperature difference 179 °C), was improved.

Figure 7 shows the prediction results for the recrystallized grain size. Comparing the experimental values with the predicted values using optimized the parameters

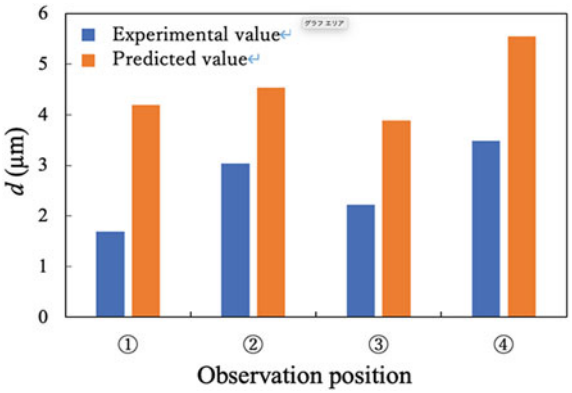

Fig. 7 Prediction results of the recrystallized grain size in 50000 t-No. 2 forging test. (Color figure online)

by the results of the 1,500 t forging test and the 50,000 t-No. 1 forging test for each position, the error was within ±2 ASTM grain size number, but the predicted values exceeded the experimental values.

The reason why the predicted value of the recrystallized grain size exceeded the experimental value may be that the calculation during the 50,000 t – No. 2 forging was in the extrapolated range. The dynamic recrystallization nucleation grain size is a function of the residual strain, the strain rate, and the temperature, as shown in Eqs. (1) and (2). In this study, the strain rate during 50,000 t-No. 2 forging obtained by finite element analysis was less than one-tenth of the strain rate in the small A test used for parameter determination. As a result, the prediction for the 50,000 t-No. 2 forging test was in the extrapolated range, and the difference between the experimental value and the predicted value may have increased. Furthermore, the post-dynamic/static recrystallization behavior is calculated using these values, and it is considered that the error from the experimental value was widened in the calculation of grain growth.

5 Conclusion

In this study, 1,500 t forging test and 50,000 t-No. 1 forging test were performed in addition to small forging tests, and a recrystallization prediction system was developed using the results. The results are shown below.

1. As a result of post-prediction in a forging test assuming a turbine disk, the average error in the fraction of recrystallization was about half that in the case of prediction using a model constructed using only small tests.
2. In the prediction result of the recrystallized grain size, although the error was within ±2 ASTM grain size number, the calculated value was larger than the experimental value. This is thought to be because post-prediction is in the extrapolated range. In the future work, it is necessary to determine the parameters using the results of forging performed under low strain rate conditions.

Simulated Microstructure Effects on Macroscopic Mechanical Properties Based on Multiscale Crystal Plasticity

Yoshiteru Aoyagi, Ryota Kobayashi, and David L. McDowell

Abstract In this study, we investigated the influence of microscopic structures of highly cold-rolled pure aluminum A1050 on macroscopic mechanical properties based on the crystal plasticity finite element (FE) analysis. Uniaxial tensile tests and biaxial tensile tests were performed, and the contours of plastic work were plotted. The comparison of experimental results and results obtained by the crystal plasticity FE simulation with a small number of grains indicates that the yield strength for the rolling direction was higher than that for the transverse direction of the rolled sheet; however, the experimental and numerical yield surfaces did not agree. Extreme value analysis was used to estimate the variation of mechanical properties in simulated results due to the combination of crystal orientation in the computational models employed.

Keywords Crystal plasticity · Finite elements analysis · Contour of plastic work · Extreme value analysis

1 Introduction

Sheet metals produced by severe rolling show high specific strength and anisotropy of mechanical properties depending on the strong rolling texture [1, 2]. It is difficult to predict the yield behavior precisely using standard yield functions developed for isotropic materials. In order to approximate the yield behavior of the anisotropic materials, anisotropic yield functions [3, 4] obtained by extension of theories for isotropic materials have been proposed. These methods require complex experimental procedures such as biaxial tensile tests [5] and compression–torsion tests [6] to determine the yield surface. Crystal plasticity simulations reproducing various

phenomena [7] have attracted attention because of the development of microscopic observation of metals using the electron backscattered diffraction pattern (EBSD) method [8, 9]. However, uniaxial tensile tests are commonly used to estimate hardening properties for calibration of parameters used in crystal plasticity simulations without consideration of the mechanical anisotropy.

In this study, crystal plasticity simulations are carried out for highly deformed aluminum to investigate the effects of microstructure on mechanical properties. The yield surface predicted by the crystal plasticity analyses based on the microstructure of the aluminum sheet is compared with the experimental result obtained by uniaxial and biaxial tensile tests. Moreover, the extreme value analysis for mechanical properties provides an understanding of the role of microstructure and size of the volume elements used in simulations on the variance of material responses.

2 Macroscopic Mechanical Properties of an Aluminum Sheet

2.1 Experimental Procedures

Experimental procedures are the same as in a previous work [10], whereas some experimental results are updated. A highly cold-rolled pure aluminum A1050 sheet with a reduction ratio of 93.3% was used as a sample. Microstructures of the sample were observed by the EBSD method, and uniaxial and biaxial tensile tests were performed. Test specimens for the uniaxial tensile tests were cut out from the aluminum sheets so that the loading direction is parallel to the transverse direction (TD) or the rolling direction (RD). Ten specimens were prepared for each direction to estimate the reliable difference between strength for RD and TD. The tensile tests were performed under the static condition: the strain rate is 1.0×10^{-3}. Note that two outliers were omitted. TD and RD correspond, respectively, to the x-axis direction and the y-axis direction in the stress space. The thickness of the specimen is 0.2 mm, and the shape of the specimen is the same as the half size of the ISO6892-1 type specimen. The shape of the uniaxial tensile test specimen and the cruciform specimen for the biaxial tensile test [4] are depicted in Fig. 1. The cruciform specimens were cut out so that the longitudinal directions of the cruciform were parallel to the RD and TD of the rolled sheet. The thickness of the specimen is 0.2 mm, the length is 90 mm, the length of the arm is 30 mm, and the measurement area is a square of 20 mm $\times$ 20 mm. The seven silts were provided in the arm part to reduce the in-plane shear stress. The biaxial tensile tests were performed under sufficiently static condition, and the stress ratio σ_x:σ_y was set in the nine different patterns: σ_x:σ_y = 4:1, 3:1, 2:1, 1.5:1, 1:1, 1:1.5, 1:2, 1:3, 1:4, where σ_x and σ_y correspond to the normal stress for the TD and RD, respectively. The stress was calculated by dividing the test load by the width of the measurement area and thickness of the cruciform specimen. In the case of biaxial tensile tests, since arm parts fracture in the early stage of the

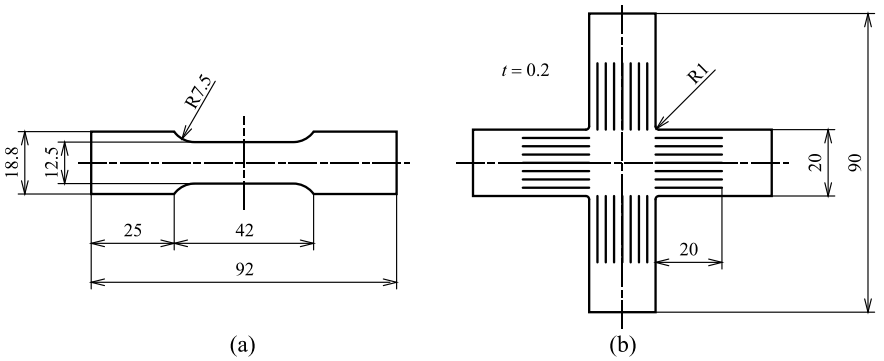

Fig. 1 Specimens for **a** uniaxial tensile test and **b** biaxial tensile test

deformation, the maximum strain is about 0.4%. Thus, the strain was measured using strain gages attached along TD and RD orientations in the measurement area. In this study, the value of the plastic work was calculated from the area under the stress–strain curves obtained by the uniaxial and biaxial tensile tests. At each stress ratio, the contours of plastic work instead of the yield surface were obtained by plotting the stress components (σ_x, σ_y) on the principal stress space when the plastic work reaches a determined value.

2.2 *Experimental Results*

The crystal orientation map and <111> pole figure obtained by the EBSD observation are shown in Fig. 2. It can be seen that the preferred orientation is Brass orientation {110} <112> and Copper orientation {112} <111> from the crystal orientation map, and S orientation is also preferred orientation from the pole figure. The average grain size is approximately 3.48 μm. The averaged 0.2% proof strength of each specimen

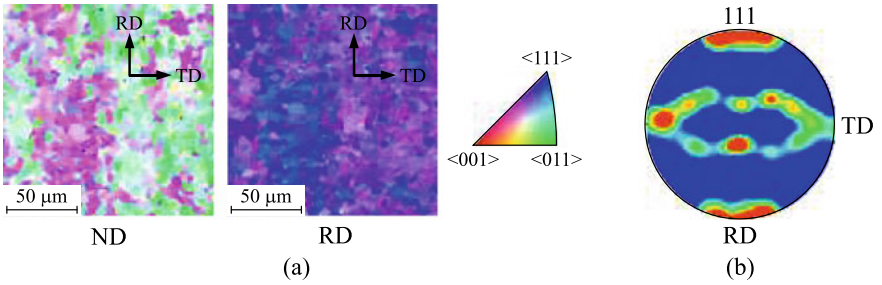

Fig. 2 **a** The crystal orientation maps and **b** the pole figure measured by EBSD observation. (Color figure online)

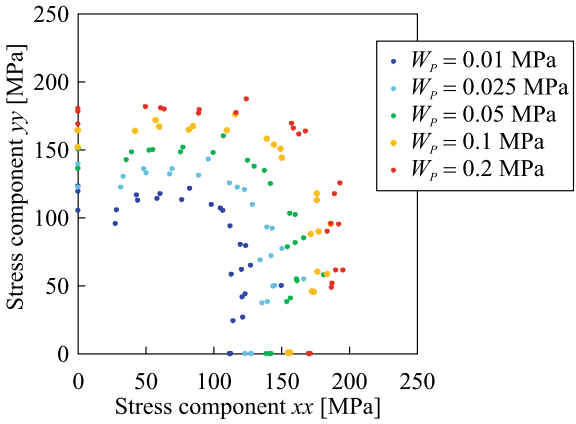

Fig. 3 Measured stress points corresponding to contours of constant plastic work. (Color figure online)

obtained by the uniaxial tensile tests are, respectively, 175.09 ± 33.65 MPa and 184.19 ± 15.02 MPa for TD and RD and averaged Young's modulus for TD and RD are, respectively, 72.90 ± 8.31 GPa and 72.59 ± 12.38 GPa. The value of 0.2% proof strength tends to be higher in RD. The contours of plastic work obtained by the uniaxial and the biaxial tensile tests are plotted in Fig. 3.

3 Crystal Plasticity Finite Element Simulations

3.1 Multiscale Crystal Plasticity Modeling

In this study, the following elasto-viscoplastic constitutive equation proposed by Pierce et al. [11] is used.

$$\overset{\nabla}{\mathbf{T}} = \mathbf{C}^e : \mathbf{D} - \mathbf{C}^e : \sum_{\alpha} (\mathbf{s}^{(\alpha)} \otimes \mathbf{m}^{(\alpha)})_S \dot{\gamma}^{(\alpha)} \tag{1}$$

where $\overset{\nabla}{\mathbf{T}}$ is the corotational rate of Cauchy stress, $\mathbf{C}^e$ is the anisotropic elastic modulus tensor, $\mathbf{D}$ is the deformation rate tensor, $\mathbf{s}^{(\alpha)}$ is the slip direction vector, $\mathbf{m}^{(\alpha)}$ is the normal direction vector to the slip plane, $(\ )_S$ means the symmetric part of second-order tensor, and $\dot{\gamma}^{(\alpha)}$ is the slip rate. In order to consider the hardening effect caused by the interaction of dislocations, following slip rate hardening law [12] is used.

$$\dot{\gamma}^{(\alpha)} = \dot{\gamma}_0^{(\alpha)} \left(\frac{\tau^{(\alpha)}}{g^{(\alpha)}} \right) \left| \frac{\tau^{(\alpha)}}{g^{(\alpha)}} \right|^{\frac{1}{m}-1} \tag{2}$$

where $\dot{\gamma}_0^{(\alpha)}$ is the reference slip rate, $\tau^{(\alpha)}$ is the resolved shear stress, $g^{(\alpha)}$ is the flow stress, and m is the strain rate sensitivity. The evolution equation of the flow stress is represented as

$$g^{(\alpha)} = \tau_0^{(\alpha)} + \sum_{\beta} \Omega^{(\alpha\beta)} a \mu \tilde{b} \sqrt{\rho_d^{(\beta)}} \tag{3}$$

where $\tau_0^{(\alpha)}$ is the reference value of $g^{(\alpha)}$, $\Omega^{(\alpha\beta)}$ is the dislocation interaction matrix, a is a numerical factor whose order is 0.1, μ is the elastic shear modulus, $\tilde{b}$ is the magnitude of the Burgers vector, and $\rho_d^{(\beta)}$ is the dislocation density. The rate of dislocation density $\dot{\rho}_d^{(\beta)}$ presented by authors [13] is given by

$$\dot{\rho}_d^{(\beta)} = \dot{\rho}_a^{(\beta)} - \dot{\rho}_r^{(\beta)} = \frac{r\rho_f}{\tilde{b}} \left| \dot{\gamma}^{(\beta)} \right| - k\rho_d^{(\beta)} \dot{\rho}_a^{(\beta)} = \left(1 - k\rho_d^{(\beta)}\right) \frac{r\rho_f}{\tilde{b}} \left| \dot{\gamma}^{(\beta)} \right| \tag{4}$$

where k is the annihilation ratio and corresponds to the inverse of the saturated density of dislocation, r is the mean length of remaining dislocation lines, and ρ_f is the density of forest dislocations.

3.2 *Uniaxial Tensile Simulation for Determination of Material Parameters*

In order to identify some material parameters, we carried out the uniaxial tensile simulation. The crystal orientation measured by the EBSD method at 27 or 216 points was randomly assigned to each grain for the computational model with an ensemble of grains, as depicted in Fig. 4. The average grain size of the computational model is 3.48 μm, and the number of grains is 27. In the analysis, periodic boundary conditions are applied. TD is parallel to the x-axis and RD is parallel to the y-axis. We carried out the numerical simulations assuming uniaxial tensile tests in this section and the biaxial tensile or compression tests in the following section by controlling the displacement at the three vortexes of the computational model.

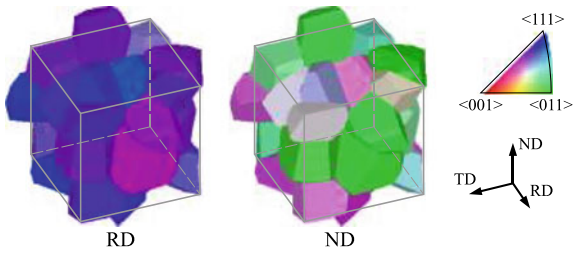

Fig. 4 Computational model with 27 grains. (Color figure online)

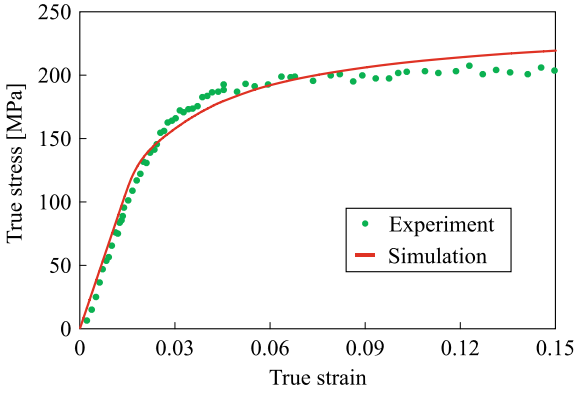

Fig. 5 Stress–strain cuves obtained by experiment and simulation for identification of material parameters. (Color figure online)

Table 1 The identified material parameters for the following simulations

Initial dislocation density	$\rho_d^{(\beta)}$	2.345×10^{12} m^{-2}
Annihilation ratio	k	7.13×10^{-14} m^{-2}
Mean length of accumulated dislocation	r	1.83 μm

The material parameters were identified by fitting the stress–true strain curves obtained by numerical analysis to that measured by the uniaxial tensile test for RD, as shown in Fig. 5. The identified initial dislocation density, annihilation rates of dislocations, and mean accumulated dislocation length are summarized in Table 1.

3.3 Biaxial Tensile and Compression Simulations for the Prediction of the Yield Surface

We performed biaxial tensile and compression simulations to predict the yield surface of cold-rolled aluminum. The computational model is the same as Fig. 4. The strain rate averaged in the analysis region $\dot{\varepsilon}_{xx}$ and $\dot{\varepsilon}_{yy}$ was varied in 28 combinations assuming biaxial stress states. The stress components σ_{xx} and σ_{yy} averaged in the analysis region when the plastic work W_p reaches the specified value are plotted in the stress space. The plastic work was calculated by integrating the plastic work at the integration points over the entire analysis region.

The contours of plastic work calculated from the results of the numerical analyses are compared to the experimental results as shown in Fig. 6. The value of plastic work $W_P = 0.01$ MPa corresponds to the macroscopic yielding estimated by the 0.2% proof strength. From the comparison between the experimental and numerical results, we find that the crystal plasticity simulation underestimates the strength for TD when the plastic work is 0.2 MPa. Anisotropic strength of metals depends strongly

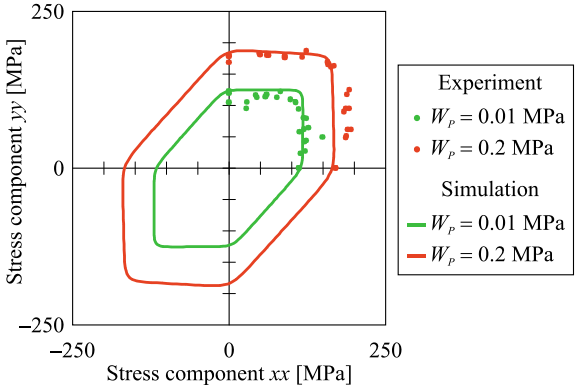

Fig. 6 Measured stress points corresponding to contours of constant plastic work obtained by experiments and simulations. (Color figure online)

on the initial crystal orientation, and 27 grains may be insufficient to represent the macroscopic mechanical behavior of severely cold-rolled aluminum.

3.4 Extreme Value Analysis of Mechanical Properties

In the crystal plasticity simulation, a large number of grains, which is enough to reproduce the effects of the microstructure is required to predict the macroscopic mechanical behavior of polycrystalline metals. In this section, we investigate the effect of the number of grains and the rolling texture of aluminum. We conducted 100 simulations with the 27 grains model and 30 simulations for the 216 grains models. Different combinations of the random crystal orientation extracted from the EBSD measurement are assigned in each simulation model.

We use the extreme value theory [14] to process mechanical properties such as the 0.2% proof strength and Young's modulus obtained by the crystal plasticity simulation using each computational model. The extreme value theory denotes that the distribution of maximum or minimum values in different assemblies selected from a set follows a specific distribution. We assume that the values of the mechanical properties calculated with each computational model show the Gumbel distribution [14] because the weakest point in materials should determine the strength of the materials. The Gumbel distribution is given by

$$P_i = 1 - \exp\left[-\exp\{\alpha(y_i - u)\}\right] \tag{5}$$

where y_i is the i-th ranked minimum value, P_i is the cumulative distribution function, i.e., the probability that minimum value in a assemble is greater than or equal to y_i, α is the inverse of parameter expressing variance, and the u is the mode value. Equation (5) can be written as

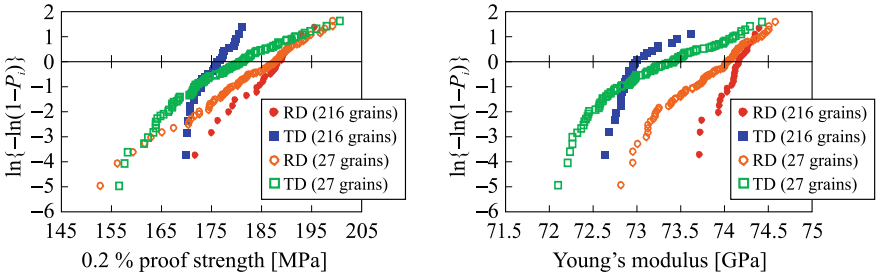

Fig. 7 The 0.2% proof strength and Young's modulus determined from the simulations. (Color figure online)

$$\ln\{-\ln(1-P_i)\} = \alpha(y_i - u) \tag{6}$$

The cumulative distribution function of each mechanical property is calculated by [15].

$$P_i(x_i) = \frac{i - 0.3}{n + 0.4} \tag{7}$$

where x_i corresponds to the values of the 0.2% proof strength σ_i and Young's modulus E_i of each computational model, i is the rank of each data, and n is the total number of models.

The 0.2% proof strength and Young's modulus values obtained by the crystal plasticity simulations are summarized in Fig. 7. It is considered that 100 simulations for the 27 grains model are reasonable because the distribution of extreme values is similar to normal distributions of extreme values. On the other hand, in the case of the computational model with 216 grains, the variance of the extreme value is smaller than that obtained using the model with 27 grains. A total of 30 simulations are enough to estimate a reliable distribution of extreme values for the 216 grains model. Note that such numbers of simulations do not indicate the necessary and sufficient number of simulations. When we apply linear approximation to the distribution of Fig. 7, the gradient of the line and the cross-section of the linear line and the horizontal axis correspond to the inverse of parameter expressing variance α and the mode value u, respectively. The mode values of the 0.2% proof strength and Young's modulus for RD are higher than that for TD regardless of the number of grains. This trend agrees with the experimental results. The mode values are almost independent of the number of grains. This result predicts that the extreme value analysis with a small number of grains can estimate the mode value of the mechanical properties. On the other hand, when we focus on the gradient of the distribution, we find that the variance of the mechanical properties is significant when the number of grains is small. It can be said that it is difficult to estimate the macroscopic mechanical properties using only one combination of crystal orientation with a small number of grains. The influence

of the crystal orientation on the macroscopic strength increases when the number of grains is small.

4 Conclusion

In this study, the effects of the microstructure on the macroscopic mechanical properties of the severely cold-rolled pure aluminum A1050 were investigated by the uniaxial and biaxial tensile tests and the crystal plasticity simulation. In the extreme value analysis based on the crystal plasticity simulations, the mode values of the mechanical properties for the computational models with the different number of grains agree well. It is difficult to estimate the macroscopic mechanical properties using only one combination of crystal orientation with a small number of grains. However, the extreme value analysis with a small number of grains can estimate the mode value of the mechanical properties.

Experimental Study on Texture Evolution of Mg-Y Magnesium Alloy in Extrusion

Dayong Li, Weiqin Tang, Ding Tang, and Yinghong Peng

Abstract The low lattice symmetry and limit deformation modes of wrought magnesium (Mg) alloys restrain it from wide use in aerospace and automobile industries. Addition of rare earth (RE) elements has been used as the texture modifier to improve the formability of Mg alloys. Mg-1Al and Mg-4Y extruded alloys were investigated to probe the effects of the Y addition on the texture and microstructure of Mg alloys. It is demonstrated that the non-RE alloys exhibit a $\{10\bar{1}0\}$ or $\{10\bar{1}0\} - \{11\bar{2}0\}$ texture depending on the recrystallized fraction, whereas the yttrium (Y) Mg alloys develop a $\{11\bar{2}1\}$ "RE texture" component. The mechanism of "RE texture" component's formation was studied by using the electronic backscattered diffraction (EBSD) technique. The results indicate that the formation of both $\{11\bar{2}0\}$ and $\{11\bar{2}1\}$ texture components is closely related to the continuous dynamic recrystallization (CDRX) of the grains which nucleate in the mantle regions of the original grains.

Keywords Magnesium · Rare earth · Texture · Dynamic recrystallization

1 Introduction

Extrusion is an efficient process for fabricating high-performance Mg alloy components, and can significantly refine microstructure and improve mechanical properties [1, 2]. However, the strong anisotropy and limited ductility of extruded Mg alloys still pose great challenge to their applications in automotive and aerospace industries. Such limitations are mainly attributed to the strong basal or fiber-type texture originated from extrusion process. Therefore, extensive works on texture modification and ductility improvement have been performed in recent years [3, 4].

Rare earth (RE) elements, such as Ce, Gd, Y, and Nd, have been used to change texture evolution, thus reducing the anisotropy and enhancing the ductility of extruded Mg alloy. It is suggested [3, 5, 6] that the texture modification or weakening for RE-Mg alloys extrusion shifts the peak intensity from the conventional

$\{10\bar{1}0\}$ pole toward a new texture component near to $\{11\bar{2}1\}$ pole, which is called "RE texture," instead of producing an ideal randomized texture.

A significant number of researches have been devoted to explaining the formation mechanism of such kind of "RE texture" component. Some researchers [7, 8] attributed the weakened texture to the particle stimulated nucleation (PSN) of recrystallization. However, this particle-related mechanism is questionable since many conventional (non-RE) Mg alloys have stable particles but still develop a strong basal texture [9]. Precipitates, which can affect the recrystallization and the textures of Al–Mn alloy, have been proved that the critical RE content required to weaken texture is below the expected bulk solid solubility [10]. Relevant experiments showed that RE elements can strongly segregate to grain boundaries [11, 12]. Furthermore, a size misfit between RE and magnesium atoms can result in a solute drag effect [9], which is believed to be related to the "RE texture" formation. Yttrium (Y) is known to produce pronounced solute drag effect due to its strong tendency to segregate to boundaries [11, 13]. However, there is still controversy on the formation mechanism of $\{11\bar{2}1\}$ "RE texture" component, due to the differences in alloy composition and extrusion conditions for various studies. Therefore, it is still of necessity to explore the influential mechanism of RE elements additions.

2 Material and Experimental Procedure

Mg-1Al and Mg-4Y were fabricated by melting pure magnesium with pure aluminum or with a master alloy of Mg-25 wt%Y in the appropriate proportions. The as-cast billets were solution treated in a furnace for 16 h at 535 °C followed by an immediate water quench.

Round bars with the diameter of 20 mm were extruded using a vertical extrusion press. The solid solute billets were lubricated with MoS_2 paste, preheated to the temperature of 400 °C, held for 1 h, and then pushed by a ram through a die. The ram was set to move with a low speed of 2 mm/s and a high speed of 10 mm/s, respectively. The extruded bars were immediately quenched into water to preserve the microstructure in its as-deformed state.

Labotex texture analysis software was used to generate orientation distributions and full pole figures. Grain sizes, recrystallized volume fraction, twin volume, misorientation distribution, and micro-textures were examined using the Channel 5 electron backscattered diffraction (EBSD) system equipped with a Nova NanoSEM^{TM} 230 scanning electron microscope. All of the EBSD data were processed with the HKL Channel 5 software.

3 Results and Discussion

3.1 The Effect of Y Addition on the Formation and Growth of DRX Grains

Figure 1 shows the grain orientation maps and the corresponding micro-textures for longitudinal section of extrusions. According to Bohlen et al. [6] and Stanford et al. [14], the grain misorientation is employed to distinguish the unrecrystallized grains from the recrystallized grains. The grains with misorientation less than 1° are regarded as "recrystallized grains"; the grains with misorientation greater than 5° are considered to be "original grains"; and the grains with misorientation between 1° and 5° are described as "intermediate grains."

Figure 1a indicates the typical $\{10\bar{1}0\} - \{11\bar{2}0\}$ texture is formed in 2 mm/s extruded Mg-1Al. The elongated "unrecrystallized grains" are mainly responsible for the $\{10\bar{1}0\}$ component. Most "recrystallized grains" are oriented around the $\{11\bar{2}0\}$ pole to form the $\{11\bar{2}0\}$ texture component. The "intermediate grains" have a wider orientation spread along the arc between the $\{10\bar{1}0\}$ and $\{11\bar{2}0\}$ poles. For 10 mm/s extrusion speed (Fig. 1b), a fully recrystallized microstructure is developed. The elongated unrecrystallized grains and the corresponding $\{10\bar{1}0\}$ texture component disappear. Both the "intermediate grains" and the new "recrystallized grains" are oriented around the $\{11\bar{2}0\}$ pole.

Figure 1c shows that the $\{10\bar{1}0\} - \{11\bar{2}1\}$ texture and partially recrystallized microstructure can be observed in 2 mm/s extruded Mg-4Y. The "recrystallized grains" produces a new $\{11\bar{2}1\}$ "RE texture" component that lies between the $\{11\bar{2}0\}$ and the {0001} poles. Some of the "recrystallized grains" even appear in the $\{10\bar{1}1\}$ pole. The "unrecrystallized grains" and most "intermediate grains" are oriented around the $\{10\bar{1}0\}$ pole to develop a sharp $\{10\bar{1}0\}$ texture component. Interestingly, the $\{10\bar{1}0\}$ component exists in the 10 mm/s extruded Mg-4Y (Fig. 1d) in which case a fully recrystallized microstructure and a single $\{11\bar{2}1\}$ texture component is expected. This indicates that the formation of the recrystallized grains is retarded by the Y addition.

The Y addition also retarded growth and broadened orientation spreads of the recrystallized grains. In fact, these two aspects are intertwined with each other during the development of texture and microstructure. If further DRX occurs repeatedly within the recrystallized grains, a much weaker texture is expected.

3.2 *The Effect of Y Addition on "RE Texture" Component in Terms of Twin*

To evaluate the effect of twins on the texture development, the high angle grain boundaries, twin boundaries, and their misorientation axes distribution of 10 mm/s extruded Mg-4Y alloy are presented in Fig. 2.

It can be found that the main contributors to the peaks of the misorientation distribution are not the twin variants, but those grain boundaries having almost as large as the misorientation of twins. Take the $\{10\bar{1}2\}$ extension twin, for example, the twin boundaries with 86 ± 5° $11\bar{2}0$ rotation only accounts for 0.991% of all the boundaries, while the grain boundaries associated with 86 ± 5° misorientation angle have an area fraction of 12%. The misorientation axes of the grain boundaries distribute in the 81–91° section randomly, instead of developing clusters around $\bar{1}2\bar{1}0$ axis like the twin boundaries. Very similar behaviors appear for the other two twin variants, contraction twin and double twin.

Based on the above analysis, the twin variants could be the origin of the broadened orientation spread and weakened texture of the recrystallized grains in the RE containing alloys. However, the twin variants are not be responsible for the development of the $\{11\bar{2}1\}$ "RE texture" component, which is based on a special case assuming a grain with $\{10\bar{1}0\}$ or $\{11\bar{2}0\}$ planes aligned with the extrusion direction. Similarly, the possibility for the contraction twin and double twin to develop the "RE texture" component can be eliminated.

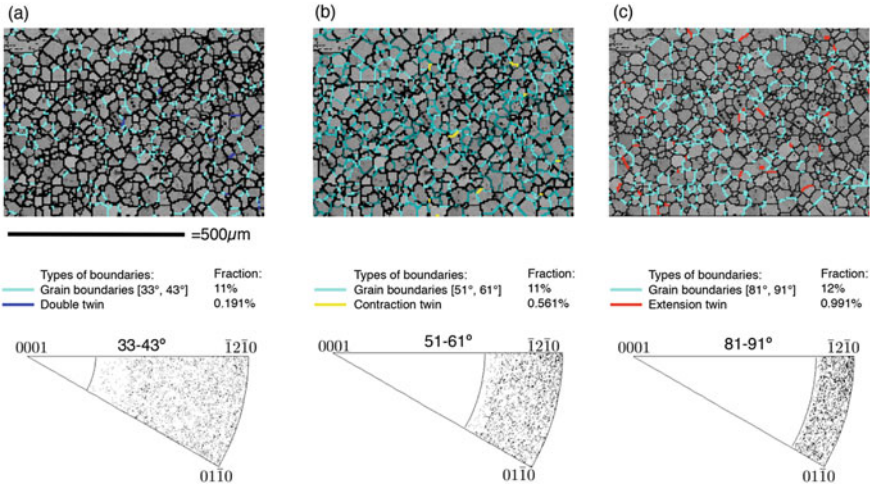

Fig. 2 **a** 38 ± 5° grain boundaries and the double twin boundaries, **b** 56 ± 5° grain boundaries and the contraction twin boundaries, and **c** 86 ± 5° grain boundaries and the extension twin boundaries of 10 mm/s extruded Mg-4Y. (Color figure online)

3.3 *The Effect of Y Addition on Texture Development in Terms of DRX Mechanisms*

Figure 3 gives a view of the continuous transition of the crystalline orientations from unrecrystallized grains to DRX grains in detail. A strong $\{10\bar{1}0\}$ texture component is retained in the subset 1 with elongated unrecrystallized grains. Subset 2 in the vicinity of subset 1 has its prismatic pole intensity along the arc between the $\{10\bar{1}0\}$ pole and the $\{11\bar{2}0\}$ pole. Subset 3 develops much smaller recrystallized grains as a consequence of DRX occurring. DRX grains are preferentially formed near the original grain boundaries where dislocations accumulate, and then grow and form new grain boundaries by absorbing the dislocations generated by further plastic deformation, thus changing the misorientations of grains. The original grain region coordinates the strain by slipping. Therefore, DRX and slip mechanisms are responsible for the misorientations between recrystallized grains and unrecrystallized grains in Mg-1Al.

The CDRX behavior of 2 mm/s extruded Mg-4Y alloy is presented in Fig. 4. Like Mg-1Al alloy with extrusion speed of 2 mm/s, subset 1 develops a strong $\{10\bar{1}0\}$ texture and subset 2 inclines to $\{11\bar{2}0\}$ pole. However, the grains in set 3 tend to form {0002} pole instead of $\{11\bar{2}0\}$ pole in Mg-1Al alloy. As a result, the recrystallized grains in the mantle regions of the original grains create a new $\{11\bar{2}1\}$ "RE texture" component. It turns out that Mg-Y alloy develops the recrystallization texture different from Mg–Al alloy during the extrusion process. The grains in the interiors of the original grains, however, develop textures similar to the non-RE Mg-1Al alloy.

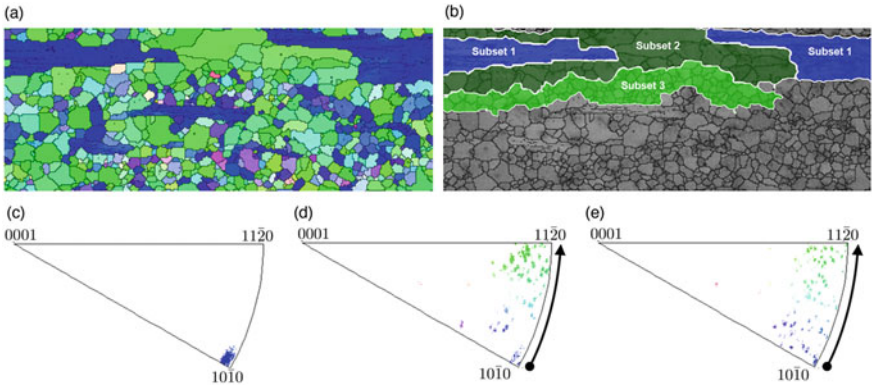

Fig. 3 EBSD maps of 2 mm/s extruded Mg-1Al alloy: **a** orientation map, **b** boundary map, **c** inverse pole figure of subset 1, **d** inverse pole figure of subset 2, and **e** inverse pole figure of subset 3. (Color figure online)

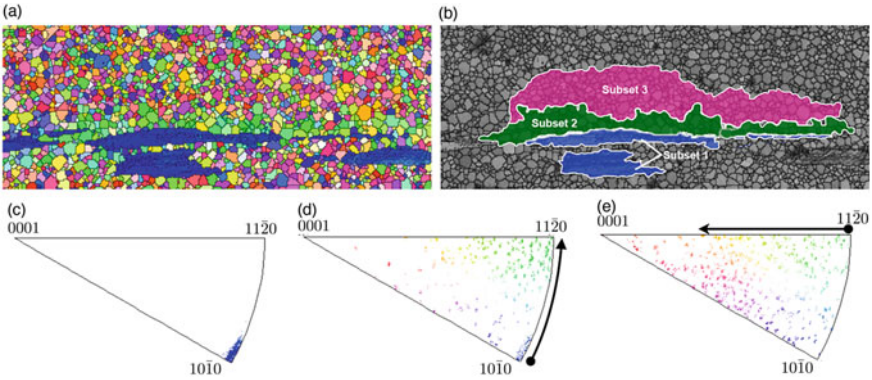

Fig. 4 EBSD maps of 2 mm/s extruded Mg-4Y alloy: **a** orientation map, **b** boundary map, **c** inverse pole figure of subset 1, **d** inverse pole figure of subset 2, and **e** inverse pole figure of subset 3. (Color figure online)

4 Conclusions

The microstructure and texture evolution of Mg-1Al and Mg-4Y were experimentally investigated during the extrusion. The effect of Y addition on microstructure and texture developments is concluded as follows:

(1) The Y addition suppresses the DRX of Y containing alloys during the extrusion.
(2) The Y addition leads to a greater propensity for extension and contraction twins. However, the twin variants are irrelevant with the $\{11\bar{2}1\}$ "RE texture" component.
(3) The $\{11\bar{2}1\}$ "RE texture" component in RE containing alloy is attributed to the DRX grains in the mantle regions of the original grains.

Advancing the Accuracy of Computational Models for Double-Sided Incremental Forming

Newell Moser, Dohyun Leem, Shuheng Liao, Kornel Ehmann, and Jian Cao

Abstract Double-Sided Incremental Forming (DSIF) is a rapid-prototyping manufacturing process for metal forming that, for low-volume production, is competitively energy-efficient. However, controlling the DSIF process in terms of accuracy and formability is an ongoing challenge. These control challenges arise due to a lack of understanding of the underlying deformation mechanisms in DSIF, which finite element simulations can help to unravel. However, DSIF pushes the limits of modern finite element formulations due to true strains that approach one, finite rotations, nonlinear contact, and triaxial stress states that range across multiple length scales. To confidently develop a finite element model of DSIF, an extensive verification process must be considered, which is the objective of this study. In this work, different finite element types and varying amounts of artificial acceleration are investigated, and recommendations based on efficiency and accuracy are summarized. A simplified, axisymmetric geometry was considered to reduce simulation time. For this geometry, accelerating the explicit finite element simulation by a mass factor of 10^5 or greater affected the stress triaxiality in the sheet by as much as 40% in some locations with respect to the quasi-static case. Additionally, the ratio of the kinetic energy to internal energy of the sheet was not a reliable indicator of whether a DSIF simulation is approximately quasi-static.

1 Introduction and Motivation

Double-Sided Incremental Forming (DSIF) is a flexible metal forming process that uses two numerically controlled tools—one above and one below the sheet—that move along a predefined toolpath [1]. In addition to flexibility, parts formed by DSIF demonstrate a marked improvement in formability relative to conventional forming processes like stamping [2]. More specifically, failure strains in DSIF surpass those observed in stamping, which are usually defined by the necking limit and are characterized by forming limit diagrams.

Although DSIF has great potential toward the rapid production of freeform sheet metal parts, the use of a secondary tool also contributes to additional challenges that can affect process control. Similar to Single-Point Incremental Forming (SPIF), the principal technical challenges in DSIF are related to process control: geometric accuracy, surface quality, process throughput, and excessive thinning or fracture [3]. In order to improve process control, there is a need to develop accurate, efficient models of DSIF in order to better understand the mechanics of the process, as well as to quantify values which cannot be easily measured (e.g., residual stresses).

There are numerous challenges associated with simulating DSIF. Even forming a simple geometry, like a funnel, involves large-strain deformations, finite rotations, cyclic loading-unloading histories, nonlinear material behavior, contact-impact interfaces, and a range of triaxial stress states. To overcome these challenging nonlinearities, state-of-the-art techniques within the finite element method are commonly used [4–7].

Without any artificial acceleration, a finite element simulation of DSIF could readily require *months* to finish [8]. One strategy to speed up a simulation is to choose a simpler geometry, like an axisymmetric part, and develop a reduced model [7]. Though, for large finite element problems, explicit (transient) integrators with artificial acceleration tend to scale better than implicit (equilibrium) integrators, particularly if strong nonlinearities are present like contact interfaces. For a more detailed discussion on explicit and implicit finite element methods, the interested reader is referred to Belytschko et al. [9] and Wriggers [10]. Since full-scale simulations of DSIF often involve a large number of finite elements (greater than 10^6 degrees of freedom), explicit methods are a popular choice to model the process [6, 11].

To artificially accelerate an explicit finite element model, either mass scaling or velocity scaling can be used. By increasing the mass in the model, the stable time step associated with explicit simulations increases, thereby necessitating fewer time steps to complete the simulation. Researchers simulating incremental sheet forming commonly use a mass scaling factor of 10^5, or more [6, 11, 12]. On the other hand, researchers must be careful not to use too much artificial acceleration. Otherwise,

the model will no longer be a fair approximation of the real process, which is usually quasi-static depending on the tool speed. However, for a given DSIF model, it is currently unclear what a safe upper limit is in terms of mass scaling.

In this study, we develop a simplified finite element model of DSIF in order to verify the relative effects of varying key parameters in the model. By changing the parameters in the model, like mass scaling, the predicted stresses and strains will be shown to significantly change relative to the baseline quasi-static simulation. As a result, recommended values and methods related to mass scaling and finite element type are given and discussed.

2 Verification Model of DSIF

In order to vary a wide range of finite element parameters within a practical time span, a simplified DSIF model was created which is still capable of capturing the predominant forming mechanics of DSIF. As shown in Fig. 1, an axisymmetric, partially preformed part was chosen, and only half of the model was meshed by using a symmetry boundary condition. In DSIF, shear distortion occurs tangential to the toolpath, so a 10 mm extension was created to distance any erroneous effects of the symmetry boundary condition from the conical region of interest. Although the symmetric boundary condition is not strictly true in DSIF, it is assumed to be a fair assumption since the region of interest is far away from the boundary and the dominant mechanics of DSIF are highly localized. To clarify, the region of interest is within the center of the toolpath's arc just as the tool crosses the X-axis.

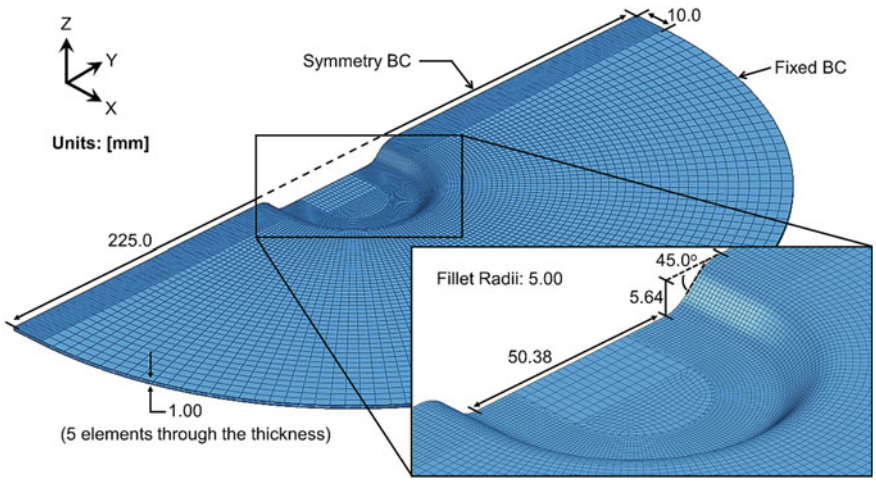

Fig. 1 Shown is the finite element mesh used for the verification DSIF model. (Color figure online)

For each revolution in the spiral toolpath, a "jump" has been added so that the tools lift-off and then regain contact while traversing along the symmetry boundary condition. By reducing the domain size and performing only five toolpath revolutions for a total length of 731 mm, this simplified model serves as an efficient testbed for comparing finite element procedures in DSIF. However, the proposed verification model is only suggested for investigating *relative* comparisons between simulations.

A total of 55,096 reduced-integration, linear brick elements with stiffness-based hourglass controls [13] were used to model the sheet in Fig. 1, while the hemispherical tools—10 mm in diameter—were modeled with rigid shell elements. Although reduced-integration elements were ultimately chosen, other element formulations were trialed, which will be discussed in the next section. In the forming region, elements were approximately 0.5 mm $\times$ 0.5 mm $\times$ 0.2 mm in size. A node-to-surface contact constraint was enforced using the penalty formulation, and friction was neglected. The material of the sheet was modeled after aluminum alloy 5754-O using J_2 flow theory, also commonly referred to as von Mises plasticity with isotropic hardening. A Voce strain hardening model was used within the material model, based on the same parameters used by Moser et al. [4].

All of the verification simulations were performed using Abaqus FEA[1] (version 2017). Since this verification model is simplified and less costly in computational resources than a full-scale model of DSIF, it was reasonable to solve this representative DSIF problem using an implicit (equilibrium) scheme. This static case was used to establish a baseline. Then, the verification model was solved using an explicit (transient) scheme with successive increases in artificial acceleration.

3 Finite Element Type

Different hexahedral element technologies were trialed using the verification model shown in Fig. 1 while assuming static conditions. Shell element formulations were not considered in this work due to the underlying assumptions in shell elements related to stresses and strains in the thickness direction, which can be inaccurate for double-sided contact [14]. A summary of the key findings is given in Table 1. Abaqus nomenclature is used as shorthand for the different types of elements: C3D20R is a 20-node, second-order serendipity element that uses reduced integration and stiffness-based hourglass controls; C3D8 is an 8-node, first-order element based on a selectively reduced integration scheme; C3D8I is an 8-node, first-order, fully integrated element that is enhanced by incompatible modes; and C3D8R is an 8-node,

[1]Certain commercial equipment, software, and/or materials are identified in this paper in order to adequately specify the experimental or simulation procedure. In no case does such identification imply recommendation or endorsement by the National Institute of Standards and Technology, nor does it imply that the equipment and/or materials used are necessarily the best available for the purpose.

Table 1 Results of trialing different solid continuum elements in the verification DSIF model. Wall time is defined as the elapsed "wall-clock" time required to complete the simulation. HG is short for hourglass, and SR for selectively reduced

Type of hexahedral solid continuum element	Shear locking	Volumetric locking	Wall time × Number of computer cores (CPU · hr)
C3D20R (w/HG Controls)	Minimal	Severe	(256.3 h) × (72 CPU) = 18,454
C3D8 (SR Integration)	Severe	None	(52.5 h) × (24 CPU) = 1,260
C3D8I (Incompatible Modes)	Severe	Moderate	(86.2 h) × (24 CPU) = 2,069
C3D8R (w/HG Controls)	None	None	(60.2 h) × (24 CPU) = 1,446

reduced-integration element that utilizes stiffness-based hourglass controls. In an effort to be comprehensive, shear locking, volumetric locking, and hourglass controls are briefly summarized next; more details are discussed by Belytschko et al. [9].

Shear locking occurs in first-order, fully integrated elements that are subjected to bending. The numerical formulation of these elements gives rise to shear strains that do not really exist—the so-called parasitic shear. Therefore, these elements are too stiff in bending. Volumetric locking (sometimes termed pressure locking) occurs in fully integrated elements when the material behavior is incompressible, such as von Mises materials. Spurious pressure stresses develop at the integration points, causing an element to behave too stiffly for deformations that should cause no volume changes (see Fig. 2). Reduced integration, or under-integrated, refers to using fewer Gaussian integration points than are necessary to integrate the element matrices exactly for an undistorted element. A linear (i.e., first-order) element with reduced integration implies that a single integration point is used, which is located at the element center.

Referring to Table 1, fully integrated hexahedral elements (C3D8I) fall victim to volumetric locking and shear locking. However, a reduced-integration (or selectively reduced integration) scheme for the element stiffness matrix not only greatly reduces running time, but these formulations can also alleviate volumetric locking and shear locking. Though, under-integrated elements can result in spurious zero-energy modes of deformation, which are commonly termed "hourglass" modes. Thus, hourglass controls must be employed to artificially stiffen the response of the element against these zero-energy deformation modes. Moreover, hexahedral elements usually provide a solution of equivalent accuracy at less cost compared to tetrahedral elements [9]. However, hexahedral elements are more sensitive to severe mesh distortions, so a structured mesh should be used wherever possible. For these reasons, the C3D8R element with a structured mesh was chosen for this simplified DSIF model.

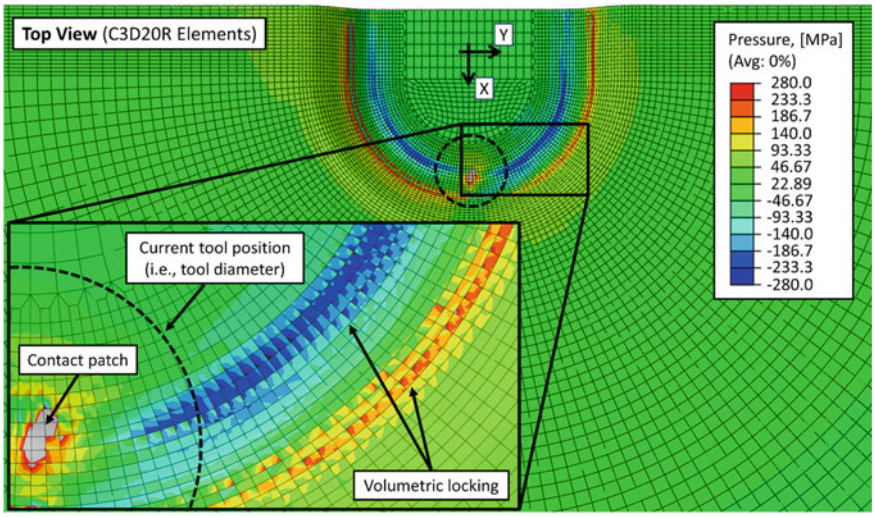

Fig. 2 An example of volumetric locking in the pressure (i.e., negative mean stress) field when using quadratic C3D20R elements. Notice the strong discontinuities across element edges. The top and bottom tools (currently hidden) are traversing counterclockwise. (Color figure online)

4 Effects of Mass Scaling

An explicit finite element simulation can be sped up by artificially increasing the mass or scaling the velocity of moving entities. More specifically, increasing the velocity by a factor of k reduces the simulation time by a factor of k, but also artificially increases the kinetic energy by k^2. Increasing the mass (or density) by a factor of k reduces the simulation time by $\sqrt{k}$, but artificially increases the kinetic energy by k. For a given artificial increase in kinetic energy, the effects of accelerating the simplified DSIF model will be similar whether it is achieved through mass or velocity scaling. So, only mass scaling is discussed here.

Referring to Table 2, four cases were considered in evaluating the effects of mass scaling: (1) the Implicit Static case based on solving the static equations using an implicit load-stepping algorithm, (2) the Quasi-static case based on no mass scaling, (3) the Mass-1 case based on a mass-scaling factor of 1.0×10^3, and (4) the Mass-2 case based on a mass-scaling factor of 1.0×10^5. The tool velocity was set to be constant for all cases involving mass scaling.

Table 2 Mass scaling factors considered in the verification DSIF model. Except for the Implicit Static model, all models utilize an explicit time-stepping algorithm

Nickname	Implicit static	Quasi-static	Mass-1	Mass-2
Mass scaling Factor	1.0	1.0	1.0×10^3	1.0×10^5
Tool velocity	~	250 mm/s	250 mm/s	250 mm/s
Wall time (72 cores)	20.1 h	256.5 h	8.7 h	0.9 h

The stress triaxiality through the thickness during the final toolpath revolution is shown in Fig. 3 for each simulation case. Note, the stress triaxiality is defined as the hydrostatic stress divided by the von Mises equivalent stress. With mass scaling, the stress triaxiality lessens in magnitude (becomes more compressive) near regions of contact. More specifically, adding mass by a factor of 10^5 changed the stress triaxiality by 41% near the tip of the top tool, and by 23% near the bottom tool. Mass-1 utilized a moderate amount of mass scaling, and the trends and magnitudes in the stress triaxiality are not significantly altered relative to the Quasi-static case. Although not shown here, increasing amounts of mass scaling had less of an effect on kinematic quantities—like the equivalent plastic strain—compared to kinetic quantities, like the stress triaxiality and the Lode angle parameter.

Another interesting observation to take note of in Fig. 3 is that the Quasi-static case, based on explicit time-stepping, predicts higher stress triaxialities compared to the Implicit Static case; ideally, they should closely match. We believe these differences are largely due to the numerical implementations of the explicit and implicit procedures, and not because of the physics of the problem at hand. The largest differences in the predictions occurred near regions of contact, which supports the assumption that these effects could be due to the difference in the implementation of the implicit and explicit contact algorithms. Both the implicit scheme (dependent on the iterative Newton's method) and the explicit scheme (based on the central

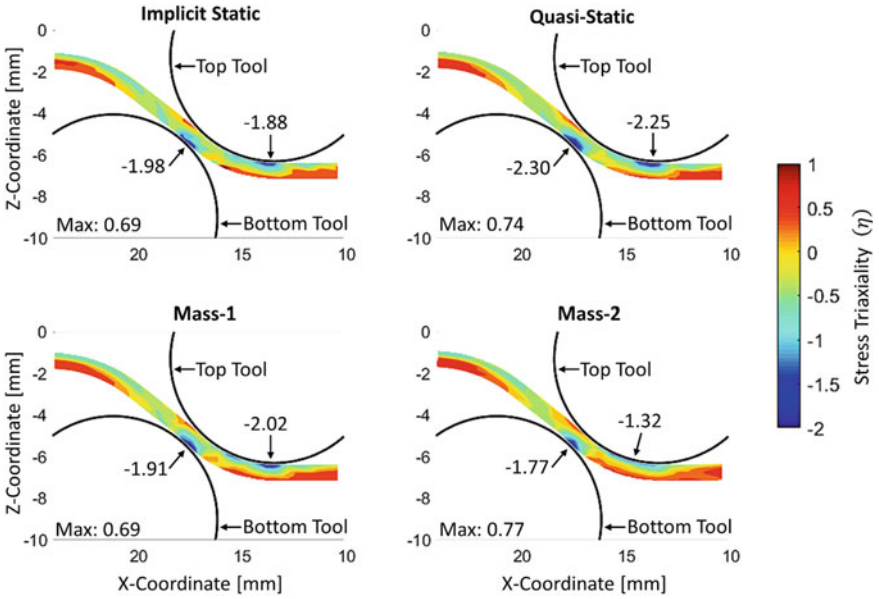

Fig. 3 The relative effects of mass scaling on the stress triaxiality. Shown in each case is the cross-sectional side view of the sheet while the tools pass over the X-axis (see Fig. 2). The black partial circles represent the perimeter of the tools at this time in the simulation. The minimum (i.e., most compressive) stress triaxialities are pointed out near the regions of contact. (Color figure online)

difference method) are second-order accurate in time regarding the truncation error [9]. However, the iterative Newton scheme inherent to implicit methods requires that the energy and displacement residual errors be within a specified tolerance in order to meet convergence requirements. Explicit methods, on the other hand, do not directly enforce the energy balance; they take a small step forward in time without the need for iterations. Furthermore, explicit methods rely on lumping (i.e., diagonalizing) the mass matrix rather than using the consistent mass matrix, and the lumping procedure is generally performed in an ad hoc fashion [15]. Although we can speculate why these differences in the stress triaxialities are appearing, we cannot be certain which is more accurate since this study is limited to relative comparisons. Still, it is interesting to note that, with everything else being equal, the implicit and explicit schemes predicted different magnitudes in the stress triaxialities; though, they do predict similar trends.

The average forming forces and their corresponding standard deviations are given in Table 3. Although the average magnitudes of the forming forces vary due to mass scaling, the results do not exhibit strong trends. This suggest that increasing the amount of artificial acceleration does not consistently change the average magnitude of the forming forces. On the other hand, increasing the amount of artificial acceleration does result in larger standard deviations of the predicted contact forces. Since the Mass-2 case is not quasi-static based on the changes in the mechanics, as shown in Fig. 3, the average forming force is not a good indicator of whether a DSIF simulation is quasi-static or not.

The likely reason that the average forming forces do not significantly differ in Table 3 is because the overall summation of the contact pressures do not significantly change with additional inertial effects. Even though the magnitude of the (compressive) stress triaxialities do change, the total compressive area also changes in such a way to make up for this. Then, when the contact stresses are integrated over the area to calculate the contact forces, the average resultant forces will not change significantly.

One way to determine if a metal forming simulation is quasi-static is to analyze the ratio between the kinetic energy and the internal energy of the deforming metal. In sheet metal forming, the internal energy is usually dominated by the accumulation of plastic strains. If the kinetic energy approaches the internal energy in magnitude, then the deforming sheet is no longer quasi-static. This rule-of-thumb is a reasonable

Table 3 The Z-forces (i.e., axial forces) in the top tool are compared between the verification simulations. The average (Avg.) and standard deviation (Std. Dev.) values are calculated from the force histories throughout the final toolpath revolution

Simulation case	Avg. Z-Force (N)	Std. Dev. Z-Force (N)
Implicit Static	471.0	± 40.9
Quasi-static	606.1	± 30.4
Mass-1	551.5	± 63.0
Mass-2	608.6	± 89.2

Table 4 The internal energy (I.E.), kinetic energy (K.E.), and standard deviation (Std. Dev.) in the kinetic energy of the deformable sheet are compared during the final toolpath revolution. All energy units are in, N·mm

Simulation case	Sheet I.E.	Sheet K.E.	Std. Dev. in K.E.
Implicit static	1.11×10^4	0.00	$\pm$ 0.00
Quasi-static	1.25×10^4	0.111	$\pm$ 0.088
Mass-1	1.36×10^4	22.4	$\pm$ 10.6
Mass-2	1.54×10^4	366	$\pm$ 118

assumption when the entire sheet is deforming, but it does not hold well for DSIF (see Table 4). In DSIF, the localized zones of the sheet will deform as the tools travel along the toolpath, and in effect, the (global) internal energy of the sheet continues to increase over time as new locations experience plastic straining. However, the kinetic energy remains approximately constant over time. Notice in Table 4 that the kinetic energy is at least an order of magnitude less than the internal energy for all cases. However, as stated before, the Mass-2 case is not quasi-static based on Fig. 3.

5 Conclusions and Recommendations

The result of this verification study is a set of finite element parameters that strike a balance between computational efficiency and (relative) accuracy. The following recommendations can be considered for new, full-scale simulations of DSIF. Though this study is not extensive, there are additional finite element parameters, like the material model, that should be validated in any new finite element model. Moreover, it is important to recall that a simplified geometry was chosen for this verification study, and consequently, we cannot guarantee that the following conclusions can be extended for all possible toolpaths in DSIF. Rather, these conclusions and recommendations should be considered as reasonable starting points, but further investigation may be necessary for specific geometries. Our conclusions and recommendations are as follows:

- As a starting point for new DSIF models, we recommend scaling the mass between a factor of 10^2 and 10^4, and in general, not above 10^5. Depending on the toolpath and mesh, adding more artificial acceleration can degrade the accuracy of the solution, specifically for kinetic terms like the stress triaxiality and Lode angle parameter.
- In choosing an element type, first-order solid continuum hexahedral elements with reduced-integration and hourglass controls are recommended. They are robust at handling the many sources of nonlinearity that arise in DSIF. However, for improved accuracy, it is important to create a structured mesh that limits element

distortion at finite strains. Also, more studies using different finite element technologies should be explored, such as B-bar formulations [16] and hexahedral thick-shell elements.

- The ratio between the global internal energy and global kinetic energy of the sheet should not be used to determine whether a simulation of DSIF is quasi-static. This energy ratio is not applicable because the nature of DSIF involves highly localized deformations. Moreover, the average contact forces are also not a good indicator of whether a DSIF simulation is quasi-static. In future work, it would be worthwhile to formulate a local energy ratio by defining a characteristic length, which could be based on the area of the contact patch between the tools and the sheet. For now, the surest method of evaluating the effects of artificial acceleration is to directly examine the changes in the mechanics, such as the stress triaxiality and Lode angle parameter.

Nonlinearity of the Crystal Yield Function in the Rate-Independent Crystal Plasticity and Its Effect on the Evolution of Anisotropy

Taejoon Park, Ji Hoon Kim, Hojun Lim, Sobhan Alah Nazari Tiji, Amir Asgharzadeh, and Farhang Pourboghrat

Abstract In typical crystal plasticity framework, the constitutive functions for the slip rate is commonly described by the rate-dependent formulation to avoid the non-uniqueness of the active slip systems due to the interdependency of the slip systems. These rate-dependent models are computationally expensive as these models impose numerically stiff, highly nonlinear equations that need to be solved at every integration point. Alternatively, the rate-independent crystal plasticity model uses the crystal yield function to describe the slip deformation and plastic spin by the active slip systems without the non-uniqueness problem. In this study, the effect of nonlinearity between resolved shear stress and slip rate on the shape of the crystal yield function in the formulation of the rate-independent crystal plasticity was rigorously investigated. In addition to the effects of the crystal plasticity model, the influence of the nonlinearity of the single crystal yield function on the evolution of anisotropy for various polycrystalline materials was evaluated.

Keywords Crystal plasticity · Anisotropy · Yield stress surface · Strain-rate potential

1 Introduction

In the crystal plasticity (CP), the plastic deformation is described by the shear deformations of the slip systems. The activation of each slip system and the resulting slip rate are determined based on the resolved shear stress for a given stress state. In typical crystal plasticity framework [1–4], a hypothetical rate-dependent formation is commonly adopted to account for the slip rate of each slip system. Since numerically

stiff, highly nonlinear equations are needed to be solved at every integration point, these rate-dependent models are computationally expensive. Alternatively, the rate-independent crystal plasticity model uses the crystal yield function to describe the slip deformation and plastic spin by the active slip systems without the non-uniqueness problem [5, 6]. When the plastic deformation determined by the crystal yield function, the slip rate that satisfies the consistency condition is iteratively obtained by the derivative of the crystal yield function based on the normality rule. Since a scalar variable is determined by the iteration rather than multiple variables, the non-uniqueness problem can be avoided.

In this study, the difference of the rate-independent formulation from the rate-dependent formulation was investigated. Specifically, the effect of nonlinear relationship between the resolved shear stress and slip rate on the shape of the yield stress and strain-rate potential surfaces as well as the crystal rotation was evaluated. For the comparison, a single face-centered cubic (FCC) crystal was considered.

2 Crystal Plasticity Models

The rate-independent crystal plasticity model uses the crystal yield function:

$$f(\sigma) = \frac{1}{\rho} \ln \left\{ \sum_{\alpha=1}^{N} \exp\left[\rho \left(\frac{|\tau^{\alpha}|}{g^{\alpha}} - 1 \right) \right] \right\} \tag{1}$$

Here, N is the number of the slip systems, g^{α} is the slip resistance, τ^{α} is the resolved shear stress, and ρ is a parameter to control the nonlinearity of the crystal yield function of the α-th slip system. If $f(\sigma) \geq 0$, plastic deformation by the slip occurs.

The slip rate, $\dot{\gamma}^{\alpha}$, of the α-th slip system is determined by the derivative of the crystal yield function:

$$\dot{\gamma}^{\alpha} = \dot{\lambda} \frac{\partial f(\sigma)}{\partial \tau^{\alpha}} \tag{2}$$

Here, $\dot{\lambda}$ is the rate of the Lagrange multiplier that satisfies the consistency condition ($f(\sigma) = 0$).

As for the typical rate-dependent crystal plasticity framework, the slip rate is commonly described by the following power-law type formulation:

$$\dot{\gamma}^{\alpha} = \dot{\gamma}_0^{\alpha} sign\left(\tau^{\alpha}\right) \left(\frac{|\tau^{\alpha}|}{g^{\alpha}} \right)^{\frac{1}{m}} \tag{3}$$

Here, $\dot{\gamma}_0^{\alpha}$ is the reference slip rate and m is the rate sensitivity parameter for the α-th slip system.

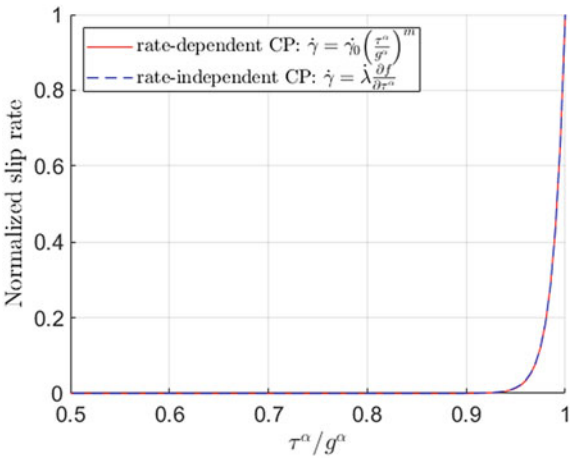

Fig. 1 Comparison of the normalized slip rate of the rate-dependent and rate-independent crystal plasticity models. (Color figure online)

The nonlinearity parameter, ρ, and the rate sensitivity parameter, m, define the nonlinear relationship between the slip rate, $\dot{\gamma}^\alpha$, and the ratio of the resolved shear stress over the slip resistance, $\frac{\tau^\alpha}{g^\alpha}$, in the rate-independent crystal plasticity and the rate-independent crystal plasticity, respectively. For comparison, the nonlinearity parameter, ρ, of the rate-independent crystal plasticity model was adjusted to match the slip rate of the rate-dependent crystal plasticity model in a quasi-static condition as shown in Fig. 1.

Both for the rate-independent and rate-dependent CP models, the slip resistance, g^α, was assumed as a function of the evolution of the dislocation density:

$$g^\alpha = A\,\mu\,b\sqrt{\sum_{\beta=1}^{n} h^{\alpha\beta}\rho^\beta} \tag{4}$$

Here, A is a material constant, μ is the shear modulus, b is the Burgers vector, and ρ^β is the dislocation density for the β-th slip system. The components of the dislocation interaction matrix, $h^{\alpha\beta}$ were calculated based on the slip plane normal of the α-th slip system and the line direction of the β-th slip system [2].

The evolution of the dislocation density for the α-th slip system was calculated based on the slip rate of the α-th slip system and the accumulated dislocation density:

$$\dot{\rho}^\alpha = \frac{1}{b}\left(\frac{\sqrt{\sum \rho^\beta}}{k_a} - k_b\rho^\alpha\right)|\dot{\gamma}^\alpha| \tag{5}$$

Here, k_a and k_b are material constants.

3 Comparison of the Crystal Plasticity Models

For the comparison of the crystal plasticity models, the yield stress and strain-rate potential surfaces were calculated for a single FCC crystal. The same plastic work increment of 0.4 MPa, which corresponds to the 0.2% offset yield stress in the uniaxial tension test, was considered to determine the equivalent yield stresses and their conjugate plastic strain increments in various deformation modes. It is worth noting that the shapes of the normalized yield stress and strain-rate potential surfaces are insensitive to the amount of the plastic work increment selected. Figures 2 and 3 show the normalized yield stress and strain-rate potential surfaces calculated based on the rate-independent and rate-dependent CP models, respectively. Both CP models showed nearly identical yield stress and strain-rate potential surfaces for the single FCC crystal.

Distributions of the numbers of activated slip systems, normalized initial yield stresses, and evolution of the tensile directions in the uniaxial tensile test were also calculated based on the rate-independent and rate-dependent CP models as shown in Figs. 4 and 5, respectively. Again, both CP models showed nearly identical results for the single FCC crystal.

In order to evaluate the effect of the heterogeneous distribution of the resolved shear stresses on the FCC slip systems, numerical simulations for the uniaxial tensile test were performed for the single FCC crystal. Based on the Newton–Raphson method, the slip rate and increment of the dislocation density for each slip system as well as the resulting increase in stress and plastic strain were iteratively calculated for each increment of the plastic work. The uniaxial tensile stress was applied to

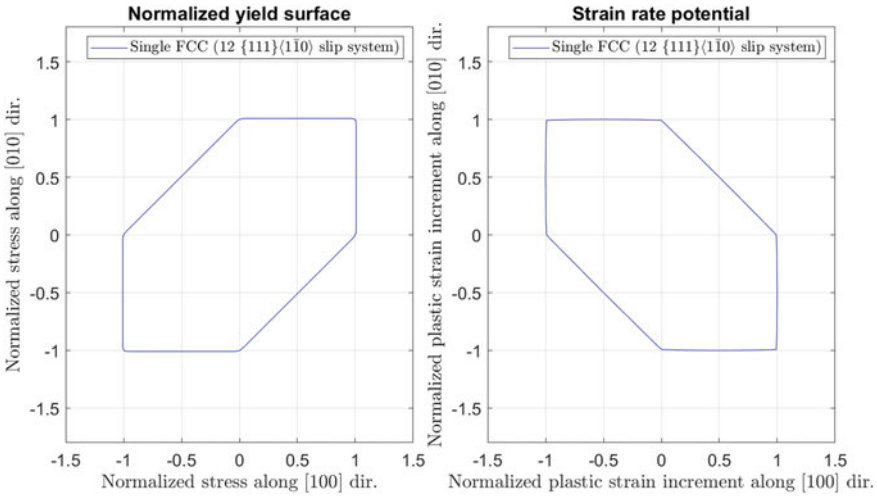

Fig. 2 Normalized yield stress and strain-rate potential surfaces of a single FCC crystal (rate-independent CP model). (Color figure online)

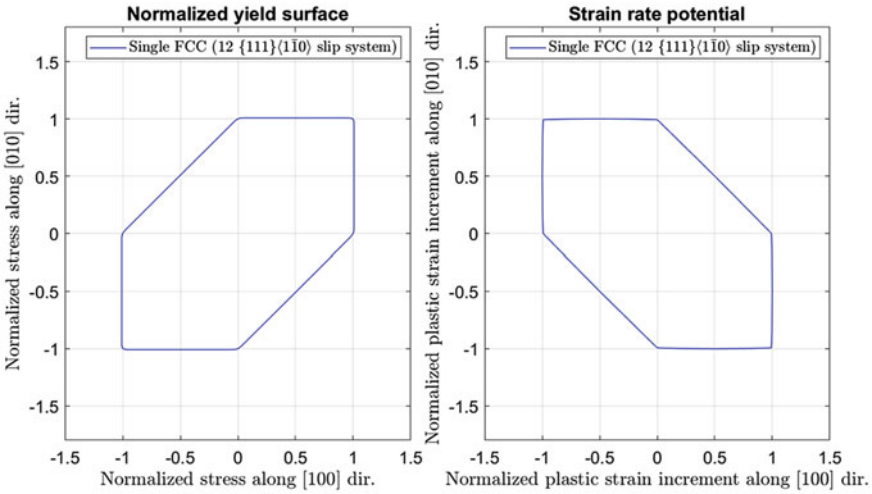

Fig. 3 Normalized yield stress and strain-rate potential surfaces of a single FCC crystal (rate-dependent CP model). (Color figure online)

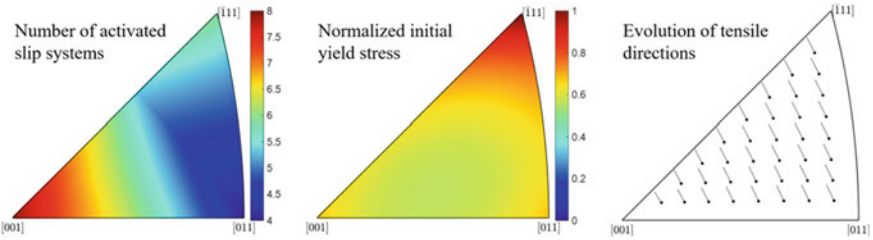

Fig. 4 Distributions of the numbers of activated slip systems, normalized initial yield stresses, and evolution of the tensile directions during the uniaxial tensile test (rate-independent CP model). (Color figure online)

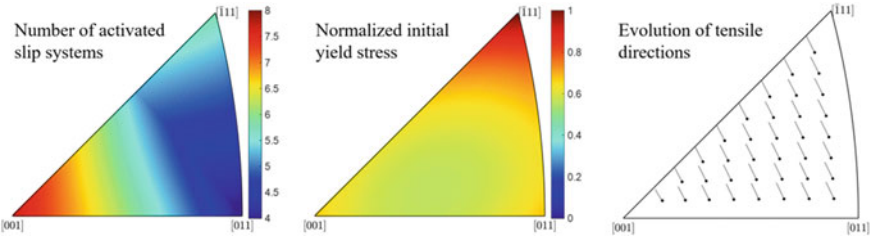

Fig. 5 Distributions of the numbers of activated slip systems, normalized initial yield stresses, and evolution of the tensile directions during the uniaxial tensile test (rate-dependent CP model). (Color figure online)

the single FCC crystal, and rotation of the crystal about the tensile direction was accounted for by the plastic spin. The [110] direction in which the lowest number of the slip systems are activated in the uniaxial tensile test, as shown in Figs. 4 and 5, was selected as the tensile direction. The tensile simulations were performed until the accumulated plastic work reached 10 MPa. Figures 6 and 7 compare the shapes of the yield stress and strain-rate potential surfaces before and after the uniaxial tension

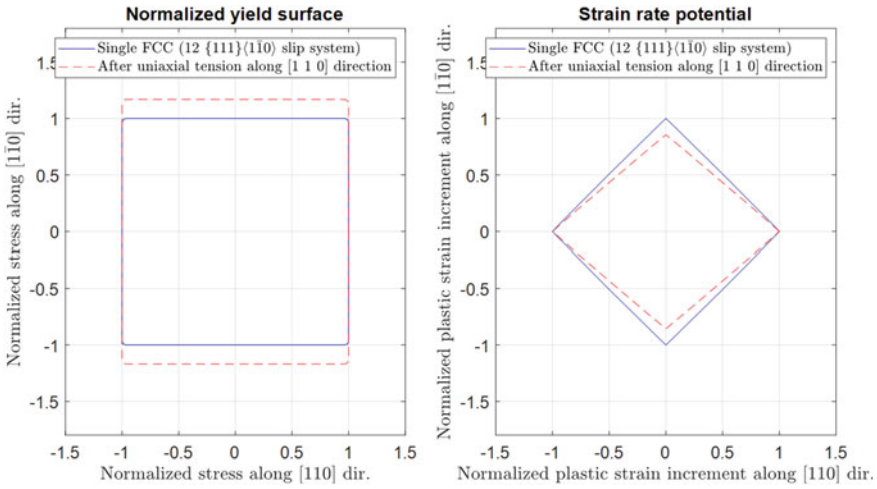

Fig. 6 Evolution of yield stress and strain-rate potential surfaces after uniaxial tension along [110] direction (rate-independent CP model). (Color figure online)

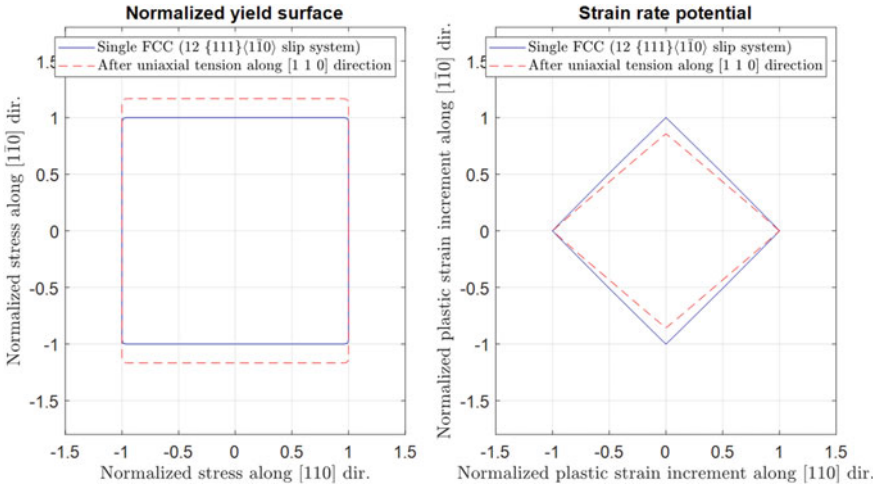

Fig. 7 Evolution of yield stress and strain-rate potential surfaces after uniaxial tension along [110] direction (rate-dependent CP model). (Color figure online)

along the [110] direction for the rate-independent and rate-dependent CP models, respectively. In spite of the heterogeneous distribution of the resolved shear stresses caused by the activated slip systems during the uniaxial tension test in the [110] direction, the yield stress and strain-rate potential surfaces of the two CP models are nearly identical.

4 Conclusions

In this study, the effect of the nonlinearity in the relationship between the resolved shear stress and slip rate was investigated. The nonlinearity parameter, ρ, of the rate-independent crystal plasticity model was adjusted to match the slip rate of the rate-dependent crystal plasticity model. For the comparison, normalized yield stress and strain-rate potential surfaces for a single FCC crystal were generated based on the rate-independent and rate-dependent formulations. Uniaxial tension simulations were also performed for the single FCC crystal to evaluate the effect of the heterogeneous distribution of the resolved shear stresses on the FCC slip systems. From the comparison of the yield stress and strain-rate potential surfaces, it could be concluded that the rate-independent and rate-dependent crystal plasticity models show nearly identical behavior when the nonlinearity in the formulation of the slip rate is about the same.

Experimental Study and Analysis on the Effects of Cyclic Bending on the Stress-Strain Curves of Aluminum Plate

Yongjun Wang and Pengyan Tong

Abstract The true stress-strain curves of 2024 aluminum alloy plate are investigated under different deformation conditions through the cyclic bending and uniaxial tensile tests. Under this condition, the equivalent strain limit is improved with the increase of the times of circle bending, which is linear accumulated along the line that is perpendicular to the neutral layer on which the bending strain is zero. Furthermore, the tensile test with the cyclic bended plate samples were carried out. The equivalent strain of layer is calculated and compared with original tensile test. It is found that the ultimate strain limit of average equivalent strain of the layers on section is extended with a significant value.

Keywords Cyclic bending · Stress-strain curve · Aluminum plate · Ultimate strain limit

1 Introduction

The localized necking and ductile fracture are two distinct failure mechanisms for sheet metal deformation processes, shows path dependent, geometry dependent, and texture dependent properties. The forming limit diagram (FLD) of sheet metal is typically gained by bulge testing, of which the strain is a monotonous increasing condition, is widely used in sheet metal forming field. In order to describe the FLD, many predictive mathematical models were built with respect to the stress-strain curve and were applied in a lot of forming process simulation.

The forming limit of sheet metal is sensitivity with stain path, different forming condition has different forming limit, especially the cyclic loading. Bambach [1] noticed this cyclic straining and the possible effect on material behavior. Emmens [2, 3] investigated the ultimate strain limit of Bending-under-tension, which means that the stress is not uniform over the thickness of the sheet with simultaneous bending and stretching, as a result that the uniform elongations of up to 430% were obtained

with mild steel. Ma et al. [4] adopted strain hardening exponent, stress triaxiality, and strain lode parameters to build a model to predict the initiation of fracture of St14 steel sheets. Li et al. [5] theoretically investigated the failure models of sheet metals under hybrid stretch-bending loadings with the system instability and local material behavior as two different failure mechanisms for forming limits and ductile fracture. Song et al. [6] investigated the characterization of forming limits at fracture of DP600 steel sheets under in-plane biaxial loadings with three ductile fracture criteria and found that the Oyane criterion with two parameters gives the best prediction. Steffen Gerke et al. [7] carried out non-proportional biaxial experiments and corresponding numerical simulations to analyze the load-history dependence on damage and fracture behavior of ductile metals with consistent anisotropic continuum damage model considering the effect of stress triaxiality and Lode parameter on damage behavior. Klingbeil [8] combined a hyperelasticity-based elasto-plastic model for non-linear isotropic as well as kinematic hardening with a modified Gurson model for ductile damage and failure during cyclic and non-proportional loading at large deformation. Harald Schmid [9] found that the forming ability reduced after a drawbead under uniaxial stress state with a conventional tensile test setup and an optical measurement system. Peng [10] found that there is a significant reduction of forming limit with the increase of grain size of copper sheet metals under different deformation paths with traditional setup of forming limit experiments. Kengo Yoshida et al. [11] investigated the effect of changing strain paths on the forming limit stresses of sheet metals using the Marciniak–Kuczynski model and a phenomenological plasticity model with non-normality effects. Jun Cao et al. [12] investigated the fracture loci containing fracture forming limit diagrams (FFLDs) in sheet metal using a modified elliptical fracture criterion based on two kinds of strain energy density to predict the ductile fracture behavior of AA2024-T351 and AA7050-T7451.

This paper focuses on the strain path on the stress-strain curves of aluminum plate with cyclic bending and tensile test, to investigate the effect of equivalent strain of cyclic bending on the tensile equivalent strain and the change of forming limit under different cyclic bending to build basement for next step research on the ductile fracture model.

2 Analytical Model

In order to build the cyclic bending analytical model, assume that the sheet metal strip is cyclically bended as shown in Fig. 1.

In Fig. 1. The radius of cylinder mold is ρ, the thickness of the sheet strip is t. After n times of bending and revers bending, the strain on the section of plate is accumulated as shown in Fig. 2.

In Fig. 2. The equivalent strain on layers is linear to the y coordinate, and it can be expressed as follows:

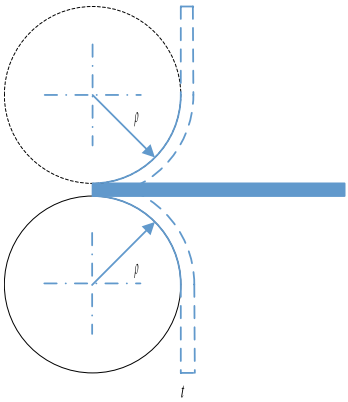

Fig. 1 Schematic of set up for cycle bending. (Color figure online)

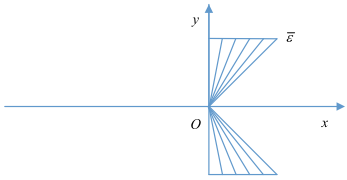

Fig. 2 Schematic of the equivalent strain after cyclic bending. (Color figure online)

$$\varepsilon_x = \frac{y}{\rho} \tag{1}$$

Assume that the width of sheet plate is not changing during bending process. Thereby it is a planar strain state, so there are the following relations.

$$\varepsilon_y = \varepsilon_x,\ \varepsilon_z = 0$$

where ε_z is the strain in the width direction.

So the equivalent strain on layer y is

$$\bar{\varepsilon}_x(y) = \frac{2}{3}\frac{y}{\rho} \tag{2}$$

After bending and revers bending times of m, the equivalent strain becomes

$$\bar{\varepsilon}_{x,n}(y) = \frac{4}{3}m\frac{y}{\rho} \tag{3}$$

When the samples were undergone uniaxial tension, the equivalent strain on layers are shown as Fig. 3.

In Fig. 3, the average equivalent strain of layer can be expressed as follows:

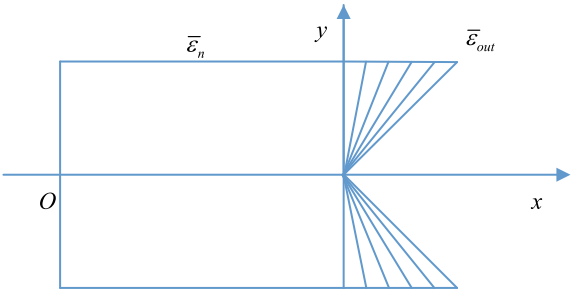

Fig. 3 Tensile after cyclic bending. (Color figure online)

$$\bar{\varepsilon} = \frac{1}{2}\bar{\varepsilon}_{out} + \bar{\varepsilon}_n = \frac{1}{3}m\frac{t}{\rho_n} + \bar{\varepsilon}_n \tag{4}$$

where the $\bar{\varepsilon}_{out}$ is the equivalent strain of outer layer, and $\bar{\varepsilon}_n$ is the equivalent strain of the neutral layer.

Assumption the material work hardening behavior obeys common power function model, so the equivalent stress is

$$\bar{\sigma} = K\bar{\varepsilon}^n \tag{5}$$

where K is the strain hardening coefficient, and n is the strain hardening exponent.

So the stress on axial can be express as follows:

$$\sigma_x = \frac{2}{b*t}K\int_0^{\frac{t}{2}}\left(\frac{4}{3}m\frac{y}{\rho} + \varepsilon_n\right)^n bdy = \frac{3}{2}\frac{K\rho}{tm(n+1)}\left(\frac{2}{3}\frac{mt}{\rho} + \varepsilon_n\right)^{n+1} \tag{6}$$

3 Experimental Work

3.1 Experiment Setup

The aluminum adopted for experiment is Al2024-O with supply state, and its thickness is 0.02 inch. The dimension of sample for uniaxial tension test is shown in Fig. 4. The capacity of the test machine is 100KN. The diameter of bending mold is 80 mm (Fig. 5).

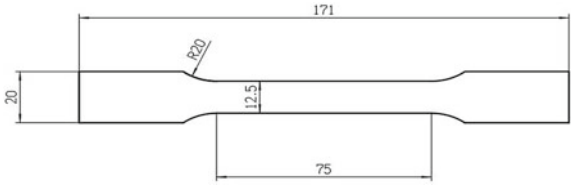

Fig. 4 Dimension of sample for uniaxial tension test

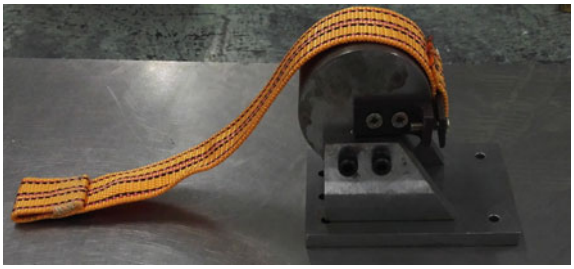

Fig. 5 Cyclic bending mold. (Color figure online)

3.2 Experiment Procedure

The experiment steps are as follows:

Firstly, machine the tensile test samples according to Fig. 4.
Secondly, number and measure the dimension of samples.
Thirdly, cyclically bend the sample according to Fig. 6.
Fourthly, uniaxial tension test.
Fifthly, test data fitting with origin software.

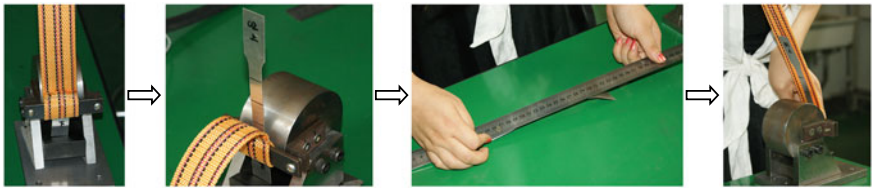

Fig. 6 Cyclic bending procedure. (Color figure online)

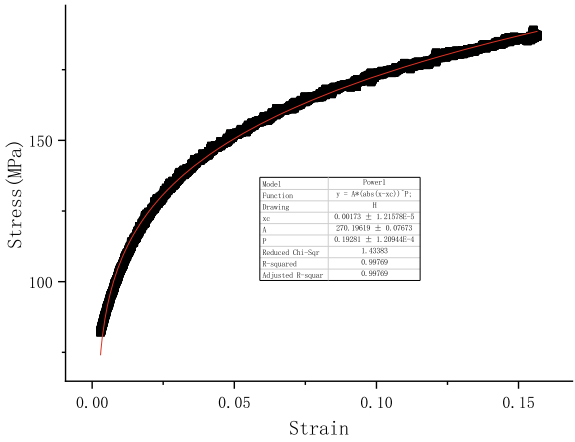

Fig. 7 Fitting for true stress-strain data of original Al2024-O. (Color figure online)

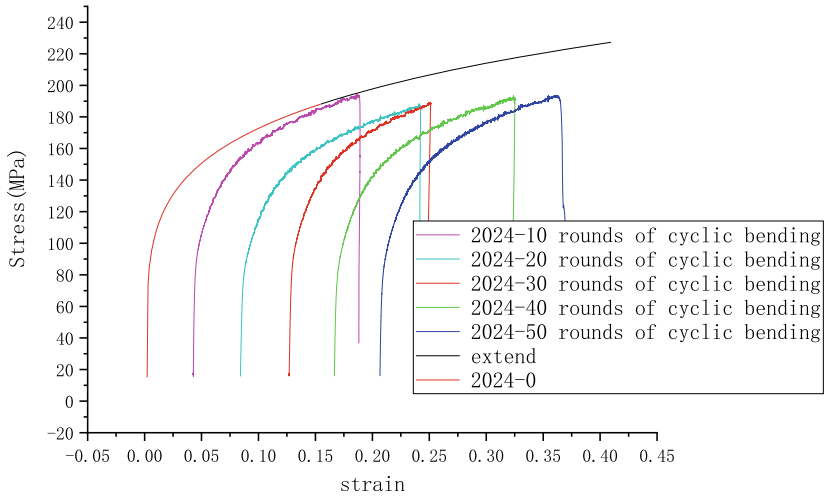
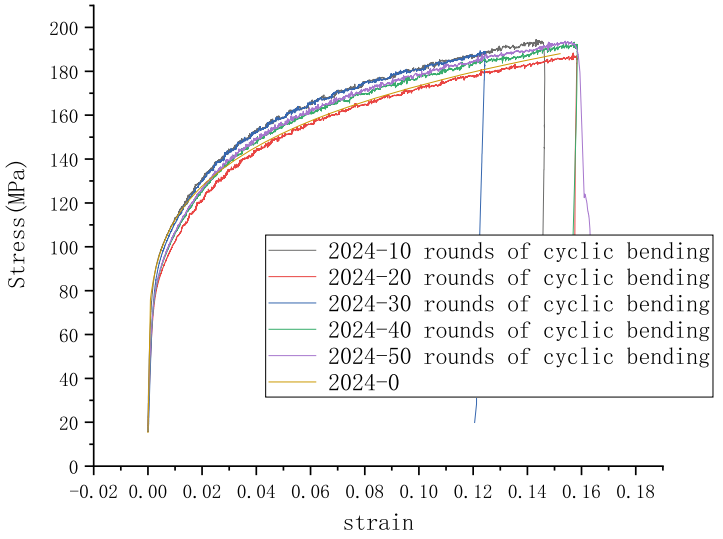
3.3 Experiment Results

The samples undergone 10, 20, 30, 40, and 50 rounds of cyclic bending,respectively, and then subjected to uniaxial tensile test. The test data of true stress–strain were fitted by origin soft ware. One set of true stress-strain data is fitted as shown in Fig. 7.



The true stress-strain curves for different rounds of cyclic bending are shown in Fig. 8. Initial material without bending is fitted by power low. The red part of original Al2024-O is the test data, and the dark part is extended according the fitted parameters, which are 0.19281 for n and 270.19619 for K. Other lines are true stress-strain curves of 10, 20, 30, 40, and 50 rounds cyclic bendingrespectively, with (for a) and without (for b) the beginning point translated to right a distant which is equal to the average equivalent strain of cyclic bending.

The material properties of curves in Fig. 8. fitted for power function are listed in Table 1.



4 Discussion

From Table 1, it can be found that the ultimate limit strain, the strength limit, and also the strain hardening exponent, as well as strength coefficient of the cyclically bended sample, is similar with original one which is not bended. However, the Young's modulus decreases significantly for cyclically bended samples, and the more rounds of cyclic bending the more notably the decrease. But the strain hardening exponent and the strength coefficient reach the biggest only when the sample undergoes 30 rounds of cyclic bending.

From Fig. 8, It can be found that the shape of the true stress-strain curves are similar with each other between bended and non-bended.

(a)

(b)

Fig. 8 True stress-strain curves for different rounds of cyclic bending. (Color figure online)

Table 1 Material properties of samples undergone cyclic bending

Cyclic number	Young's modulus/GPa	Strain hardening exponent n	Strength coefficient K	Average equivalent strain of cyclic bending	Equivalent strain limit after cyclic bending	Total ultimate equivalent strain limit
0	68.679	0.19281	270.19619	0	0.15631	0.15632
10	56.692	0.18759	279.95331	0.04283	0.14520	0.18803
20	36.456	0.19461	270.40107	0.08417	0.15797	0.24214
30	36.639	0.19694	286.64736	0.12675	0.12405	0.25080
40	24.232	0.18826	274.6957	0.16667	0.15820	0.32486
50	19.567	0.18702	276.40787	0.20667	0.15694	0.36361

The result means that the damage occurred when the sheet metal was cyclically bended, as a result Young's modulus decreases with the rounds of cyclic bending, of which the average equivalent strain is accumulated with the increase of the bending times which leads to the total average equivalent strain increase significantly.

5 Conclusions

The true stress-strain curves of Al2024-O aluminum alloy plate are investigated under different deformation conditions through the cyclic bending and uniaxial tensile tests.

The ultimate limit strain, the strength limit, and also the strain hardening exponent, as well as strength coefficient of the cyclically bended sample, is similar with original one which is not bended.

Considering the equivalent strain of cyclic bending, the total equivalent strain limit is improved with the increase of the times of circle bending.

The Young's modulus decreases significantly for cyclically bended samples, and the more rounds of cyclic bending the more notably the decrease.

Honorary Symposium: Zhongren Wang

Professor Z. R. Wang's Contributions to Metal Forming Theory, Technology, and Education

Gang Liu, Shijian Yuan, and Kaifeng Zhang

Abstract Professor Wang once served as the president of the China Society for Technology of Plasticity (CSTP). He also hosted and chaired the 4th International Conference of Technologies of Plasticity (ICTP) in Beijing, in 1993, to bring the event for the first time to China. During the 60 years' academic career life on metal forming, he has published 17 books and more than 300 academic papers, and won international and national Awards 5 times, including invention award and science & technology progress award, etc. The main contributions of Professor Wang include: developing the engineering plasticity theory and promoting its applications, inventing the dieless hydroforming method for large-scale spherical shells, solving the technological problems of several key national projects of China, leading internationalization of Chinese community of plasticity engineering, and supervising a group of talents on metal forming.

Keywords Engineering plasticity · Dieless hydro-bulging · Flexible multi-point forming · Low load precision bending

1 Introduction

Professor Z. R. Wang (1934.5.10–2019.4.25) was a full-time professor at Harbin Institute of Technology (HIT), China. Professor Wang is a famous research scientist in the field of international plasticity engineering. He received his Bachelor's degree from the Department of Metal Plastic Processing in Beijing Institute of Iron and Steel Technology, in 1955, and then obtained his Master's Degree in the Department of Metal Plastic Processing in HIT under the supervision of a former Soviet Union professor. In 1957, after his master's degree, he stayed in Harbin Institute

of technology to teach. In 1985, he was promoted to Professor and doctoral supervisor. From 1987 to 1997, he served as the director of the metal forming division. Within that decade, under his excellent leadership, the metal forming team has made a great progress in education, research, and educational discipline construction. He has carried out research into aspects of metal forming theory and technology, primarily hydroforming. Within his research career of about 60 years, Professor Wang has published 17 monographs, textbooks, manuals, and collections, as well as more than 300 academic papers. Remarkably, the monograph *Engineering Plasticity Theory and Applications in Metal Forming* was published by Wiley in 2018, when he was 84 years old.

As a representative of metal forming community in China, Professor Wang served as the president of the China Society for Technology of Plasticity (CSTP) from 1991 to 1994, and successfully hosted the 4th International Conference on Technology of Plasticity (ICTP) in Beijing, in 1993. He has successively served as the Standing Advisory Board of ICTP and made significant contributions to the conference series. Professor Wang also served as the Chairman of the International Conference on Rotary Forming in 1989 and the 1st International Conference on New Forming Technology in 2004. Furthermore, he was also the editorial board member of several well-known international journals, such as *Journal of Material Processing Technology* (JMPT). In recognition of his contribution to Chinese plasticity engineering, CSTP awarded him the *Golden Anvil Award*.

Based on deep mechanical knowledge, Professor Wang proposed the innovative forming method of spherical shells, and won the Brussels Eureka Gold Medal of World Fair Invention in 1987 and the Chinese National Technology Invention Award in 1992. Over the past 40 years, he has won National Technology Invention Awards and National Science and Technology Progress Awards four times in total, and more than 10 other science and technology awards. Meanwhile, as a successful teacher, he had supervised or co-supervised PhD candidates over 40, postgraduate and undergraduate students over hundred. Most of them has become experts or scholars in metal forming community of China, USA, UK, Japan, Canada, Germany, and Singapore (Fig. 1).

2 Research on Plasticity Theory and Its Applications

2.1 A Consistent Sequence Law of Stress-Strain Components

Through the mechanical analysis based on the classical incremental strain theory or the total strain theory, the quantitative relationship between the components of deviatoric stress and strain increments or the total strain can be directly obtained. However, the quantitative determination of stress distribution in a deforming body is difficult, and it is nearly impossible to compute the total strain using the total strain theory. Professor Wang presented the simplified consistent sequence law considering

Fig. 1 Professor Z. R. Wang and dieless hydro-bulged sphere for the 80th anniversary of HIT. (Color figure online)

the relations between the stress and strain components in line with the incremental theory and the total strain theory. It has been verified that, qualitative results from the consistent sequence law have great value to deal with complex problems in engineering practice, when quantitative data could be determined experimentally. The proposed law can be described as follows [1]:

(1) In the process of metal forming, if the associated principal strain axis directions are unchanged with the magnitude sequence of the principal stress components given as: $\sigma_1 > \sigma_2 > \sigma_3$, then, the principal strain sequence is similar, that is $\varepsilon_1 > \varepsilon_2 > \varepsilon_3$ ($\varepsilon_1 > 0$, $\varepsilon_3 < 0$).

(2) An unvaried relationship: $\sigma_2 > (\sigma_1 + \sigma_3)/2$ gives $\varepsilon_2 > 0$, $\sigma_2 = (\sigma_1 + \sigma_3)/2$ gives $\varepsilon_2 = 0$, $\sigma_2 < (\sigma_1 + \sigma_3)/2$ gives $\varepsilon_2 < 0$.

The first expression of the proposed law describes the sequential relationship between the stresses and strains, while the second expression is the unvaried relationship based on the intermediate principal stress either close to σ_1 or to σ_3. The proposed consistent sequence law supports a qualitative judgment on the basis of increment strain theory and can be used to determine the relative magnitude of strain components in various directions when the stress changes within a certain range,

though the quantitative strain components can not be calculated. Thus, the tendency of dimensional variation in the body subjected to deformation during forming can be known presumably.

For engineering applications of metal forming, the law can be elucidated in the following aspects:

(1) The greatest increase of strain occurs in the direction where acts the algebraically maximal principal stress (i.e., positive-tensile and negative-compressive) of the whole stressed body in all directions, and the greatest decrease in the direction where the minimum stress acts.
(2) The variations of dimensions are consistent with the principal stress in the direction that acts the intermediate principal stress. Then the dimensions get close to the maximum or the minimum. The dimensional variation stated above refers to the total strain.

2.2 Division of Stress and Strain on the Yield Locus

Based on the consistent sequence law between stress and strain, for specific metal forming operations, Professor Wang proposed an approach to express the relations graphically between yield criterion and the theory of plastic stress and strain relationships. Two steps are needed and given as follows:

(1) Based on the force analysis of process, identify the position corresponding to specific forming process on the yield surface, and then determine the loading locus in different areas of the deformation zone.
(2) Divide the stress state on the yield locus into different zones with various strain types according to the consistent sequence law, then determine the tendency of size variation in particular part of the workpiece [2, 3].

The stresses of some sheet and tube forming processes are able to be zoned on the yield locus in the axisymmetric plane-stress state, and the loading locus of typical plane-stress deforming processes can be determined. On this situation, the normal stress through workpiece thickness may be neglected, $\sigma_t = 0$. The projection of the Mises cylinder on the coordinate plane with $\sigma_t = 0$ is an ellipse, described by Eq. (1) involving the radial stress and the circumferential stress, where Y is the flow stress. Equation (1) is graphically represented using Fig. 2. There are three circles outside the elliptical yield locus, viz. the inner circle, the middle circle, and the outer circle. These circles separately denote the normal through-thickness strain increments, the axial (radial) strain increments, and the circumferential strain increments.

$$\sigma_\theta^2 - \sigma_\rho \sigma_\theta + \sigma_\rho^2 = Y^2 \tag{1}$$

The proposed figure is the first attempt to integrate yield locus, stress zoning, tendency of strain increment variation, and plane-stress metal forming processes

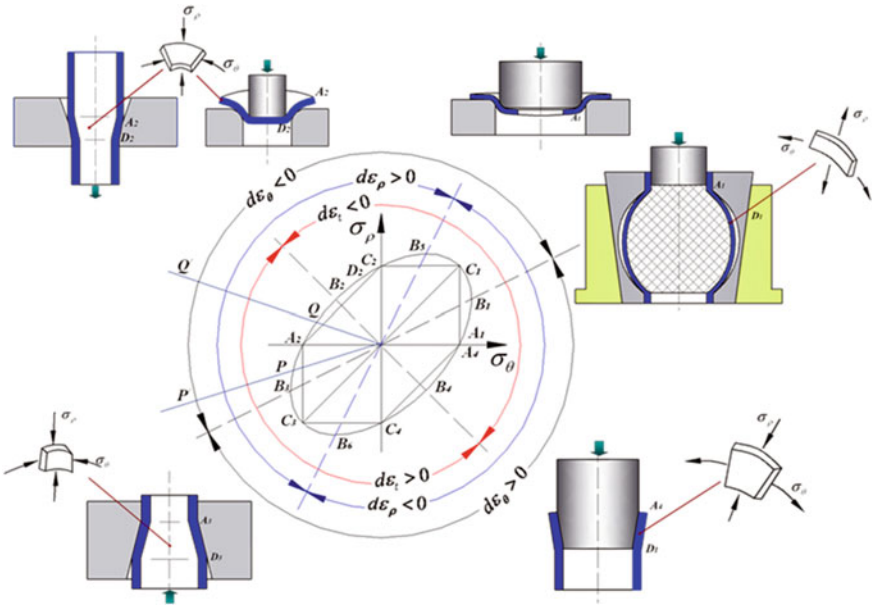

Fig. 2 Zoning of Mises yield ellipse at typical plane stress states. (Reproduced from Wang 1980 Ref [3]). (Color figure online)

using a single graph, which can be used to determine the dimensional variation tendency of a workpiece being deformed conveniently.

Using the similar approach to graphically describe the relations of plane-stress states, various metal forming operations with three-dimensional stress states are shown in Fig. 3. The figure is constructed based on the unfolded Mises yield cylinder [1, 4]. Any stress state in the deforming body dominated by the particular location on the Mises yield cylinder surface can be found in the Fig. 3. The three principal stress components of each stress state can be identified by the distance from the point to the π-plane, viz. mean stress σ_m, and a vector on the π-plane with a radius and an angle θ. In Fig. 3, the lower the position of metal forming process, the higher the compressive stress and the plasticity of the material. Again, one deformation type may correspond to different stress states. Normally, the force that tools exert on the workpiece directly related to one or two principal stresses. Because the relative positions among σ_m, σ_1, σ_2, and σ_3 can be found from Fig. 3, the force can be evaluated according to the position of the stress state [5].

Reference [6] claims Figs. 2 and 3 as important contributions to the theory of metal forming. Firstly, such graphic approach proposed a new way to integrally and simultaneously show the stress, the strain, and the yield locus. Moreover, the tendency of dimensional change in various metal forming processes is able to be presented based on a unified solution to integrate multiple indicator functions into a single diagram.

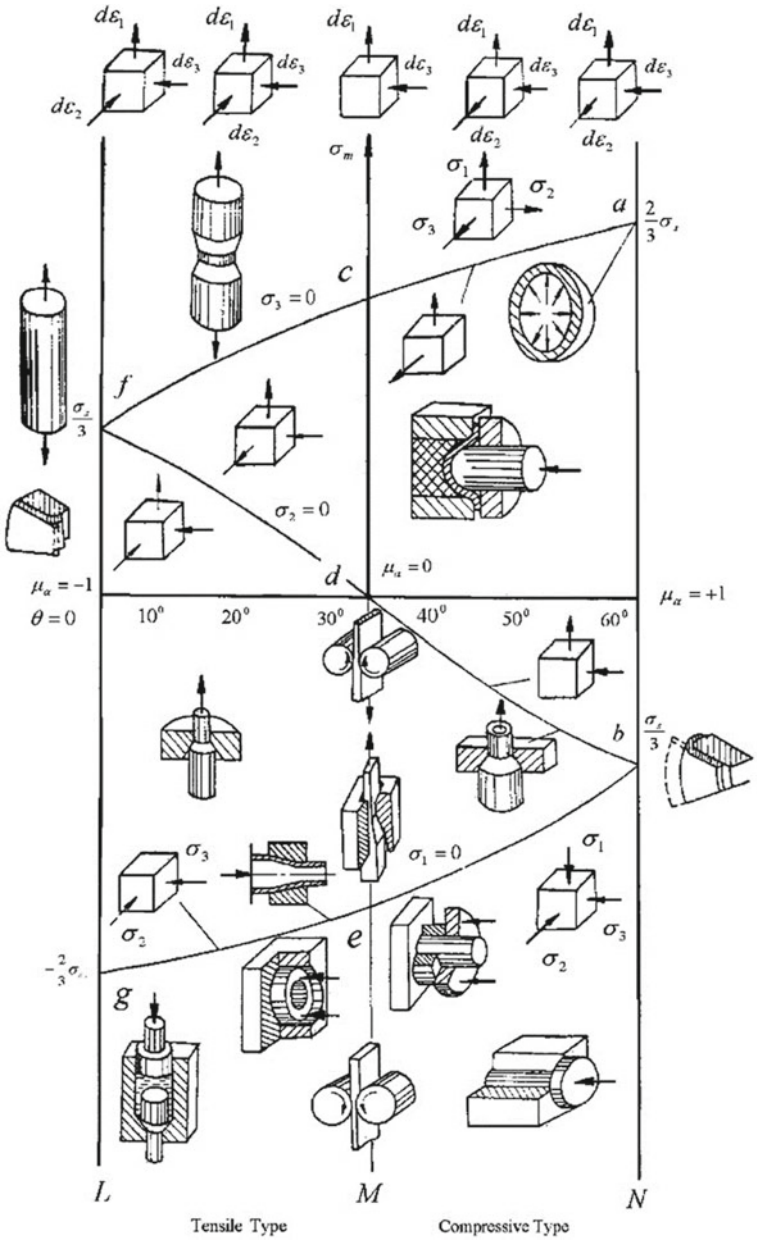

Fig. 3 Locations of metal forming processes with three-dimensional stress states on the Mises cylinder (Reproduced from Wang. 1993 Ref [4])

3 Dieless Hydro-Bulging Technology

3.1 Principle of Dieless Hydro-Bulging of Spherical Shells

Stamping using rigid dies has been the traditional technology to manufacture spherical vessels. The biggest disadvantage of conventional process is the need for presses with large-scale bed and forming dies. Moreover, the complicated stamping and trimming procedure resulted in a severely high production cost. To address above limitations, Professor Wang, for the first time, proposed the dieless hydro-bulging technology in 1985, which has gained great popularity in various industries [7, 8].

The typical dieless hydroforming process of spherical shells begins with assembling the steel plates and/or roll-bent plates with single curvature into a closed polyhedral shell followed by welding. Then the closed shell is deformed gradually into a spherical shape by filling liquid (usually pure water) to exert internal pressure [9–11]. Since the used shells are of single curvature, the preparation is consisted of blanking, bending, and/or plate rolling, assembling and welding, hydroforming is comparably simple (see Fig. 4). It excels at (1) the total manufacture cost is significantly reduced resulting from the avoidance of large-scale dies and presses; (2) the production period is shorten because of obviating the need for exchanging dies;

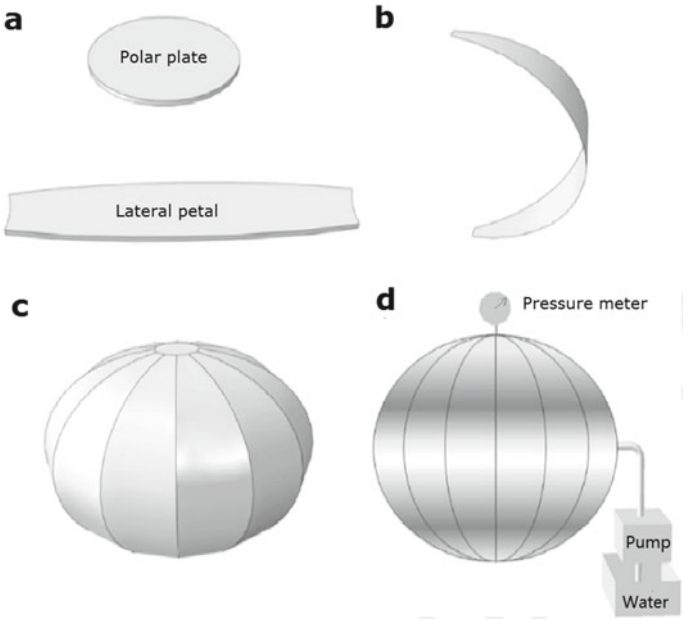

Fig. 4 Schematic of the main operations of hydro-bulging process of spherical shell: **a** blanking, **b** roll-bending of lateral petals, **c** assembling and welding, **d** hydro-bulging (Reproduced from Wang et al. 2018 Ref [12])

and (3) the welding-induced residual stresses are greatly reduced using the overload hydro-bulging.

Hydro-bulging of spherical shell is an automatic spheroidizing process under the action of the increasing internal pressure because the shape of preform is a polyhedral shell inscribed in an ideal spherical shell. Using the earth coordinate system, the principal stresses on the shell are defined as longitudinal stress σ_ρ and latitudinal stress σ_θ. Based on the Laplace equation, which describes a shell that is internally pressurized in the normal direction, the relationship between the stress, internal pressure, and radii of the shell can be written into Eq. (2).

$$\frac{p}{t} = \frac{\sigma_\theta}{R_\theta} + \frac{\sigma_\rho}{R_\rho} = \frac{p_\theta}{t} + \frac{p_\rho}{t} \tag{2}$$

where, p is the internal pressure, t is the nominal thickness of the shell, p_ρ is the forming pressure calculated with longitudinal curvature, and p_θ is the forming pressure calculated with latitudinal curvature (Fig. 5).

During the shell hydroforming, the workpiece can be regarded as a deformed object sustaining a balance force simultaneously. The force exerted on one half is balanced by the other half of the workpiece. It is understandable that the shape of the shell preform is gradually changing into a sphere neglecting the difference to the final product. Two mechanisms in forming the spherical shells are revealed as follows:

(1) Geometry Adjustment Mechanism: with the increase of internal pressure, the larger curvature radius decreases and vice versa.
(2) Physical Adjustment Mechanism: In the process of spheroidizing, strain hardening occurs in the deformed area, resulting in the stop of deformation. With the increase of pressure, the adjacent undeformed area begins to deform. This

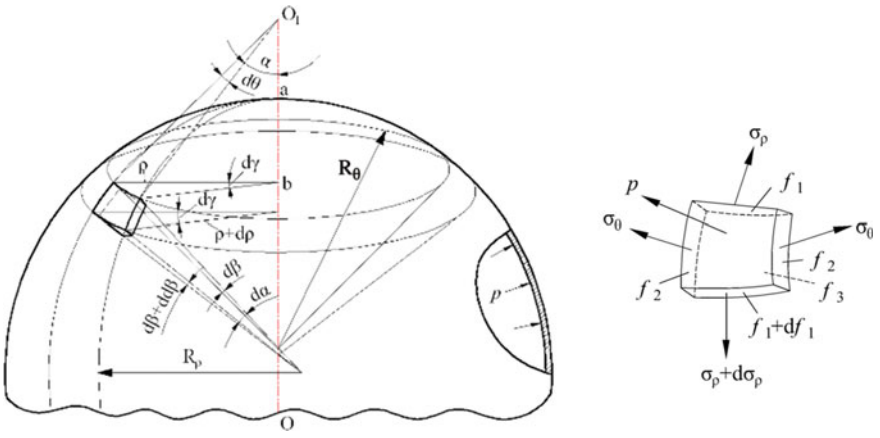

Fig. 5 Hydro-bulged shell and the element for stress analysis. (Reproduced from Wang et al. 2018 Ref [12]). (Color figure online)

mechanism contributes to avoiding the strain concentration and achieving uniform deformation.

3.2 Applications of the Dieless Hydro-Bulging Technology

Since 1985, three series of dieless hydro-bulging products have been developed: (1) spherical water tower and water supply tank; (2) pressure vessel and liquefied gas tank; (3) architectural decoration ball.

The shell made by dieless hydro-bulging technology has been successfully applied in the spherical water tower (Fig. 6a) of railway industry and urban water supply, the spherical storage tank of liquefied petroleum gas (Fig. 6b), and the spherical and ellipsoidal launch tower of communication, radio, and television; the spherical ornaments formed by this technology have also been widely used in the architecture decoration; the flight simulation ball curtain with a diameter of 7 m is also used in the field of pilot training.

Comparing to the traditional manufacturing technologies, the dieless hydro-bulging shell exhibits the following advantages:

- Flexibility. Because shells can be formed without press and dies, dieless hydro-bulging is especially suitable for small volume production.
- Shorter production cycle, lower cost, and easier manufacturing in construction site.
- Lower residual stress along the welds due to over-loading effect during bulging.

Professor Wang won the Brussels Eureka Gold Medal of World Fair Invention (1987) and the Chinese National Invention Award (1992) with the dieless hydro-bulging technology. Professor H. Sekiguchi from Tokyo University published a paper

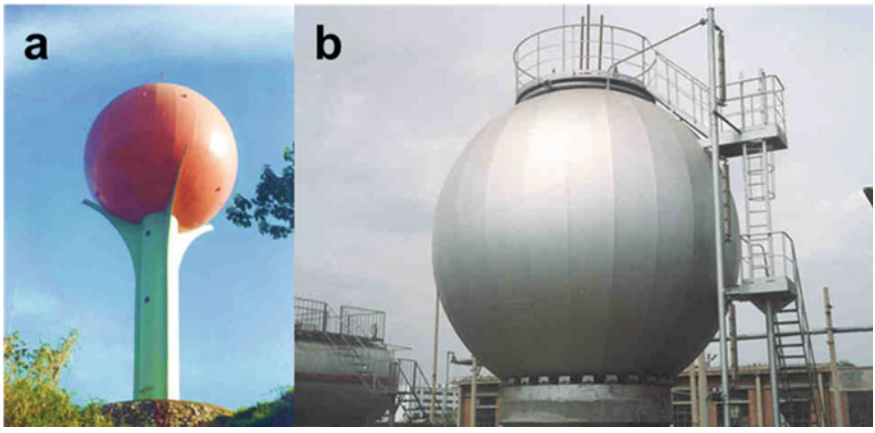

Fig. 6 **a** Spherical water tower (200 m^3), **b** Storage tank of liquefied petroleum gas (200 m^3) (Reproduced from Wang et al. 2014 Ref [13]). (Color figure online)

titled "The First Patent (?) in China" in *Journal of Japan Society for Technology of Plasticity* [14]. In 1990, the journal *American Machinist* reported new achievements selected by the 18th North American Machining Research Institute, among which the dieless hydro-bulging technology was listed as one of the top three highlights [15].

4 Contributions to Key National Projects in China

Professor Z. R. Wang exhibited great talent and skills in applying plastic theory to solve complex engineering problems. He could play the roles of scholar, engineer, and team leader. Through combining theory with engineering practice, he led the team to creatively solve a series of technical problems in national key engineering projects, such as large-scale space environment simulator and large-scale wind tunnel.

4.1 Large-Scale Space Environment Simulator

The large-scale space environment simulator of China Manned Space Engineering Program is a large-scale device for simulating the space environment and testing Shenzhou spacecraft [16]. Figure 7 shows the appearance and loading process of the spacecraft. The main vessel had a diameter of 12 m, a height of 22.4 m, and a total volume of about 3000 m^3 [17]. At that time, the device was the largest space environment simulator in Asia and the third largest in the world. The simulator was capable of simulating the space environment characteristics, such as ultra-low

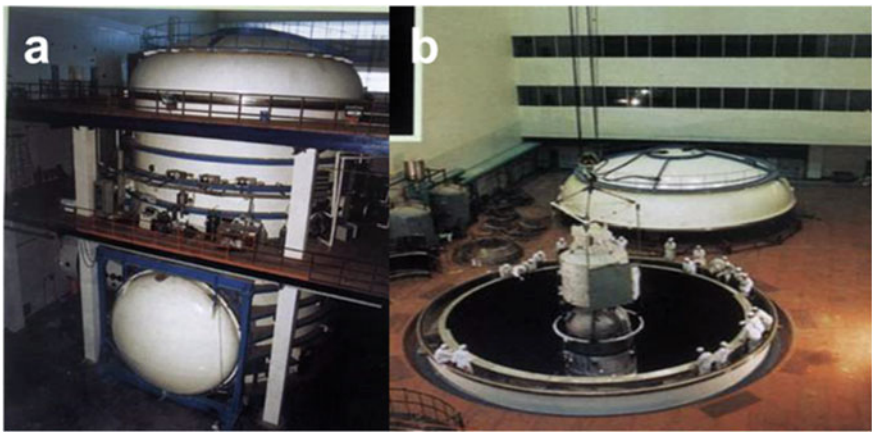

Fig. 7 **a** Appearance of vacuum vessel, **b** put into spacecraft (Reproduced from Zhi et al. 1998 Ref [16]). (Color figure online)

temperature, high vacuum and strong solar radiation, which can be regarded as to an artificially created small space.

Figure 7 shows the top cover with a diameter of 12 m on the vessel. Driven by the stringent requirement of vacuum degree of 10^{-5} Pa, a high reliability sealing needs to be realized between the cover and the vessel flange.

Therefore, the accuracy of flange forming and machining are extremely high. As the chief engineer of this project, Professor Wang led the team to accomplish a number of technology breakthroughs. A series of technical difficulties involved in the manufacture of this simulator, such as low load precision bending, machining deformation control, dynamic control of clamping mode, welding deformation control, and on-site precision machining, have been successfully solved [18]. The large-scale space environment simulator has been used in Shenzhou spaceship experiments for many times, made significant contributions to the continuous successful launches of spaceships in China.

4.2 Large-Scale Wind Tunnel

Professor Wang also served as the chief engineer of the FL-9 low speed pressurized wind tunnel construction project, which was the largest wind tunnel with low speed and high Reynolds number in Asia, in 2005 [19]. The maximum outer dimension of the wind tunnel was 86 m, the maximum diameter of the pressure-bearing shell was 14.5 m, and the volume of the tunnel was about 13000 m^3. Resulting from the characteristics of complex structure and huge size, it is very difficult to manufacture. The cross-section shapes of the large-scale shrinkage shell (Fig. 8) along the axis varies significantly, which is composed by hundreds of curved plates with different profiles. If the conventional stamping process is adopted, hundreds of dies sets are

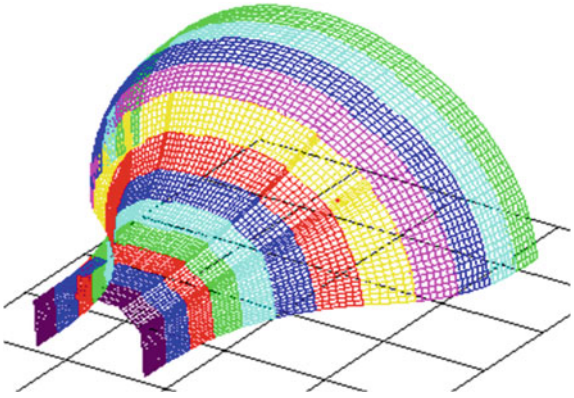

Fig. 8 Structure of the part in a wind tunnel (Reproduced from Wang et al. 2004 Ref [19]). (Color figure online)

needed resulting in a huge manufacture cost. Therefore, Professor Wang proposed the flexible multi-point forming technology enabling the low-cost and high-efficiency manufacturing of various curved plates to be achieved [20].

The die set for flexible multi-point forming consists of an elastic punch and an adjustable female die assembly. The adjustable die is composed of nearly one hundred scattered dies. By adjusting the height of each die, different shapes of die surfaces can be obtained. The elastic base plate was mounted on the mold to avoid the uneven surface of the workpiece. The flexible multi-point forming technology is used to manufacture all kinds of curved components needed for wind tunnel shrink shell, which greatly saved the use of die material and cycle time of processing, resulting in significantly reduced engineering cost. Figure 9 is a shrinkage body assembled with formed parts. In September 2006, the first test run was successful, and all aspects of quality examination obtained the expected results [21].

5 Contribution to Internationalization of Chinese Community of Plasticity Engineering

5.1 Chair of the 4th ICTP in Beijing

Professor Z. R. Wang was the representative of leading Chinese plasticity engineering scholars to the international community communication. As the president of CSTP, he introduced Chinese academic research progress and industry development of metal forming to the international plasticity engineering community, and organized the national plasticity engineering community to win the right to host the 4th ICTP for the first time in China.

In September 1993, CSTP successfully hosted the 4th ICTP in Beijing, and Professor Wang, served as the conference chair (Fig. 10). There were approximately 450 delegates from 32 countries and regions attended the conference, including about half from oversea. Famous research scientists and experts of metal forming from all the major industrial organization and research institutes attended the conference, e.g., T. Altan and B. Avitzur from the USA, H. Kudo, T. Nakagawa and M. Kiuchi from Japan, R. Kopp and K. Lange from Germany, and P. Standring from UK. Mr. G.Y. He, the Minister of the Ministry of Machinery Industry of China, attended the opening ceremony and delivered a speech. Fruitful academic exchanges were generated on the schemes of sheet metal processing, forging, extrusion, rolling, tube forming, drawing, rotary forming, powder forming, superplastic forming, and new plastic processing technologies, with 260 oral presentations and 83 posters given in this conference. As an innovation in the schedule of ICTP, two special free discussion

Fig. 10 Opening ceremony of 4th ICTP (G.Y. He, H. Kudo, Z.R. Wang, T. Altan). (Color figure online)

sessions were organized with the topics of: the development trend of metal forming and training of young talents.

5.2 *Launching International Conference on New Forming Technology (ICNFT)*

It is a precondition for the development of new technologies to understand the meaning of the elementary plastic processes. This is also of greatest interest, if processing windows have to be expanded to more complex, more precise or smaller geometries. Meanwhile, to form advanced high-performance materials, new forming technologies have been developed and promoted to practical applications. Therefore, in 2004, Professor Wang, Professor T.A. Dean, Professor F. Vollertsen, and Professor S.J. Yuan launched the new conference series called International Conference on New Forming Technology (ICNFT). The first ICNFT was successfully hold in Harbin, China, in Sep. 2004. More than 100 delegates from over 20 countries attended the conference (Fig. 11).

ICNFT has been organized in China, Germany, and UK alternatively for 6 times, and great success has been achieved. To date, the conference has become an inspiration forum for researchers and professional engineers to exchange innovative ideas and research experience and to discuss cutting-edge novel forming technologies potentially to be applied in the manufacturing industry in present and future years. The next 7th ICNFT will be held in Changsha, China.

Adding Value by Advancing Metal Forming Technology

Trevor Dean, Bo-Zhou Di, and Li-Liang Wang

Abstract The metal forming industry is responding to changing technical and commercial demands of customers and increasingly stringent legislative restrictions. In addition, on demand delivery requires lead times having to contract. Also Original Equipment Manufacturers are demanding deliveries just-in-time on changeable schedules and for many products batch quantities have become smaller than they were a few years ago. Thus, lead times must be shortened. To meet these challenges, in the metal forming industry, the rate at which new and existing process technologies and production practices are being developed is increasing. Computer-aided design and manufacturing systems have been allied to computer process simulation, to form powerful Cloud based, knowledge-based tools for producing parts right-first-time through identifying the customers' needs. The purpose of this paper is to illustrate the contribution made by the authors to enhance the added value of metal formed parts, through advancing scientific process knowledge and developing software to support computer-aided manufacture.

Keywords Metal forming · Added value

1 Automotive Industry

1.1 Weight Reduction Versus Cost Effectiveness

The main market for component manufacturers is the automotive industry and developments in this market are a gauge by which the technological requirements for mass produced parts may be assessed across the whole board of metal formed manufacture. Automotive Original Equipment Manufacturers (OEMs) are tending to become essentially designers, assemblers, and wholesalers of complete automobiles. They

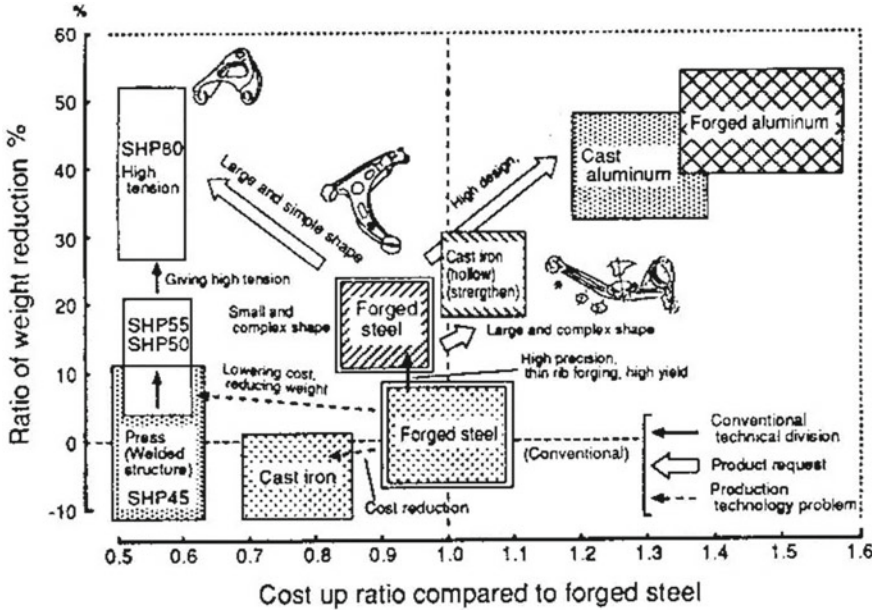

Fig. 1 Effect of processing technology and material on weight and cost of a suspension arm [1]

are reducing in-house parts manufacture and Tier 1 suppliers are being called upon to be proactive at the design stage through concurrent (simultaneous) engineering activities. Ultimately they will be responsible for component design and manufacture within and OEM's specification, which can include, material, aspect of geometry, and performance characteristics. To meet legislative and market competitive demands for improved performance, components are being made lighter in weight and with high strength/rigidity, by design and by using low-density material, and to net or near net shape to increase yield and productivity while reducing cost. The effect of reducing weight saving on component cost is illustrated for a suspension arm in Fig. 1 [1]. It is shown that, compared with a traditional forged part, lighter parts can be made by other methods some at greater and some at lower cost, the benefit of sheet metal fabrication is apparent, particularly when high strength steel is used. The sheet and tubular metal industry is engaged in forming and fabrication of a range of components for the automotive industry, with the introduction of bearings and bushes, to produce lightweight, rigid sub-assemblies such as, steering arms and linkages. The introduction of hydroforming has enabled feasible shape complication to be increased, resulting in commercial manufacture of net shape and nearer to net-shape parts. The bulk forming industry is producing nearer to net shape, often by reducing processing temperatures and engaging in finish machining and sub-assembly operations and new methods for forging products with reduced weight are being sought.

Design	Weight (kg)	Cost US$
Conventional Steel	5.8	38
Al 5xxx (5 pieces)	3.3	94
HFQ (one piece)	2.5	53

Fig. 2 Cost and weight estimation for 3 door inner panel designs

1.2 Hot Forming and Quenching Sheet Aluminium Alloy

Reducing designed weight of a part by using low-density material often results in increased cost. But Hot Form Quench (HFQ), a hot sheet metal forming process relatively recently introduced by the authors and colleagues [2], which combines forming and heat treatment, enables high strength lightweight aluminium alloy parts of complex shape to be made at acceptable cost. The car door inner panel shown in Fig. 2 is an example of an HFQ product. Aluminium door panels, usually of 5xxx series alloy, are used in some premium cars and because of the low formability of the alloy and the impossibility of forming the part in one piece, they comprise an assembly of several components and compared with the cost of a standard steel one piece product, a weight reduction of 43% increases cost by 150%. For the HFQ product, made as a single piece, a weight reduction of 57% increases cost by 40%. The latter cost although higher, is recouped by greater environmental friendliness and lower outgoing costs, in the driving cycle.

1.3 Forging Net-Shape Gears

Forming net-shape gears has been the subject of research and development for many years [3–5]. Two major process characteristics can add value to mono-alloy net-shape gears. Compared with conventional forged gear blanks, expensive post-formed machining is eliminated or much reduced and material yield is greatly increased; both facts reduce costs. In addition, it has been shown that gears with formed teeth have high dynamic mechanical properties, exemplified by toughness and fatigue strength. Small size compact gears can be forged or extruded cold and the authors have expended much work on process development for forging large spur and helical gears (too large for cold forming) on single action presses, the type most commonly found in UK forge shops. The starting point of the work was the production of traditional gear blanks, as shown in Fig. 3. When hot forged, these parts are inaccurate, have a poor surface, because of flash have a low yield and are not close to finished form.

Fig. 3 Progression toward net-shape forged gear. (Color figure online)

Therefore, they are of low added value. An advance in added value is achieved by warm forming (to improve dimensional accuracy) in completely closed tools, gear blanks with synchro dog teeth. Apart from the synchro teeth which are cold formed to size, all-over machining of the blanks is necessary. The next advance was to near net-shape to forge the gears with involute running teeth. This brought the parts nearer to net shape, but difficulty in locating gears for fine machining the running teeth to size severely undermined the added value.

To form net-shape involute gear teeth which are ready for service, a warm/cold process was envisaged in which the teeth were forged near to net shape, which is oversize with an 0.1 mm envelope in completely closed dies and subsequently, after cleaning and lubricating, cold ironed to bring them to net shape. Essentially, the tool consists of a punch with mandrel and a pre-stressed die containing a tooth form in its bore and the ironing operation consists merely of pushing the oversize warm forged gear, positioned on punch and mandrel, through the die. This is a simple process but die design is complicated as elastic distortion of the gear and the tooling has to be considered and geometry of the die teeth is not conventional involute.

Tooth form of the ironing die was obtained using FE (Finite Element) and an elastic plastic model. Tooth flank profiles within specification can be formed and utilising the changing tool/work-piece interface pressure, natural crowning of the teeth can be obtained, as is required for high performance gears.

(a) Two-part Billet (b) Section through Forged Gear

Fig. 4 Bimetallic billet and forged gear. (Color figure online)

1.4 Forging Bimetallic Gears

Figure 4 shows a gear forged in a development program the aim of which is to enable production of gears with reduced weight using two metals [6]. The gear comprises an outer band of heat treatable steel and a core of lightweight metal; aluminium, maybe magnesium, alloy, that fit loosely together.

Usually they are preheated separately to appropriate temperatures, fitted together in a tool, as shown in Fig. 4a, and forged in one operation. Bonding of the two workpiece components is achieved by mechanical locking in both vertical and horizontal planes and if the temperature at the bimetallic interface is sufficient, by metallurgical bonding. The added value of this product is that it enables lighter designs of mechanical power transmissions for vehicles.

1.5 Forging High Performance Pistons from Powder

One way to reduce the environmental impact of internal combustion engines is to increase their running efficiency and this requires increased combustion temperature and pressure. The extra loading is taxing the strength of conventional die cast pistons, so investigations into the manufacture of pistons with higher properties was undertaken at University of Birmingham. An aluminium alloy was made from powder, having a composition possessing high mechanical properties at high temperature, which was consolidated into bar using the 'Conform', continuous extrusion process. The bar was cut into billet which was heated and forged, in one operation, to form a fully dense and near net-shape piston. Added value was achieved in the higher service performance properties of the pistons and also the high yield of nearly 90%, obtained through forging. Figure 5 shows forged and machined pistons.

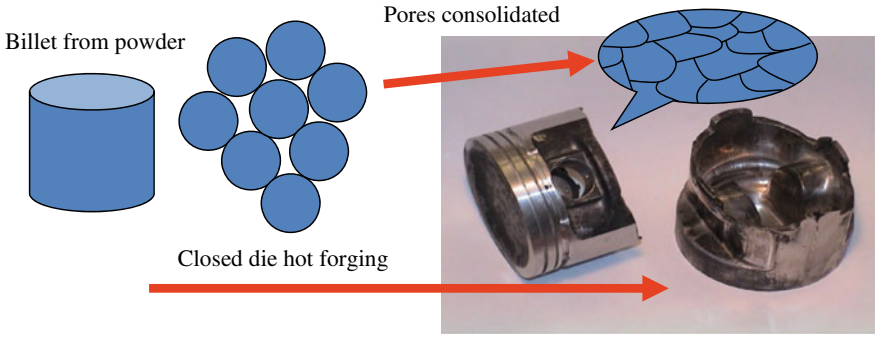

Fig. 5 Near net-shape forged high performance piston. (Color figure online)

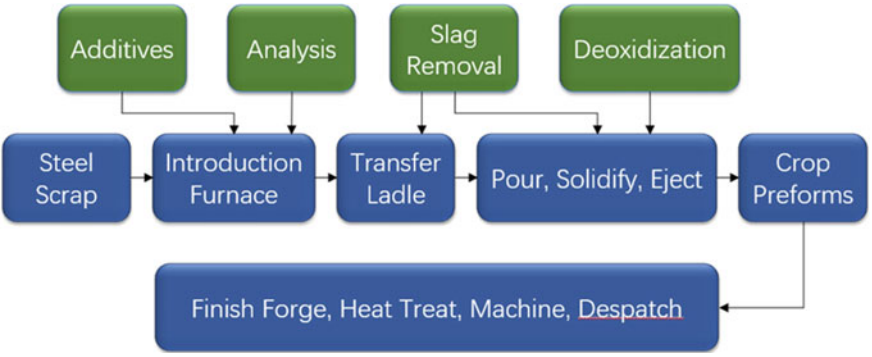
2 Mining Industry

2.1 Forging Cast Preforms

Forging of cast iron preforms, to improve mechanical properties and geometric accuracy, has been the subject of intermittent research for many years, as exemplified by the patent Schlegel [7]. In contrast, the considerable potential for added value arising if scrap metal can be cheaply recycled to prime raw material and formed into high specification components has not yet been thoroughly addressed. Such an opportunity occurred for these authors with a British company manufacturing edge tools for agricultural use. The main aim was to melt scrap alloy steel, made both in-house and bought in (at 1/10th the cost of prime metal) cast it into preforms for forging a range of components, utilising the residual casting heat. The processing route is shown in Fig. 6.



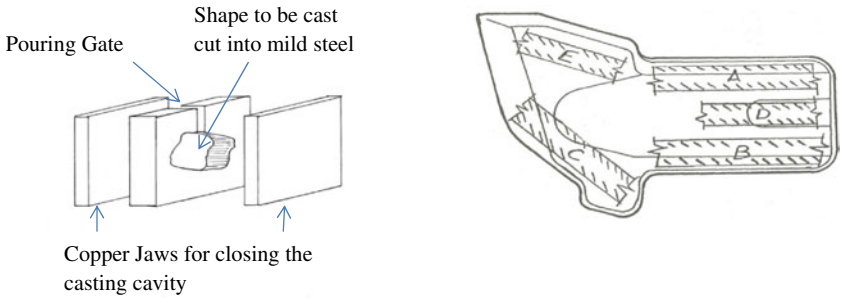


Fig. 6 Processing route for hot forging cast preforms. (Color figure online)

(a) Mould Components (b) Forged Cast Preform

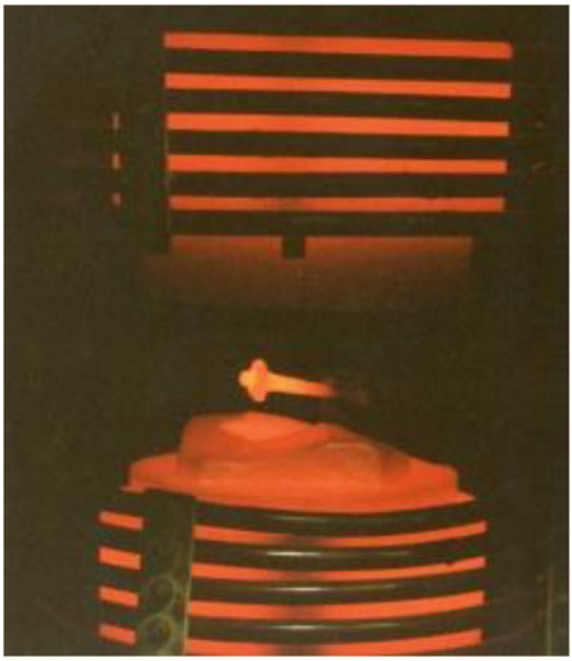
Fig. 7 Coal cutter pick forged from cast preform. (Color figure online)

A key feature of the process is that the casting moulds should be cheap, reusable, and enable rapid production. They were made by flame cutting an outline of the shape to be cast, plus pouring gate, through a mild steel slab of thickness of the casting, (or castings), to be made in it. When the slab is sandwiched between two water-cooled copper jaws, a cavity is formed into which molten metal is poured. The metal solidifies rapidly in the moulds and then the copper jaws are retracted and the mould moves to an ejector stage and is followed to the pouring stage by an empty mould. Figure 7 is a sketch of the main mould components and a forged, cast preform, with positions of test-pieces shaded. The part chosen for trials was a coal cutter pick in alloy steel BS 817 M40, weighing 1 kg. Also shown are the regions from which tensile and impact test-pieces were machined. It was discovered that for a reduction in thickness of about 60% in forging, not all casting voids were closed. Mechanical properties of cast/forged parts depended on orientation, relative to casting direction, of the cast preform in the die and on the degree of deformation. However, the toughness and tensile properties in the cast/forged parts, on average could be as high as that in conventionally forged parts. Overall, because preforms of 'ideal shape' could be cast, the amount of flash produced in the finishing die was only about 10%. In addition it was estimated that the cost of the cast preform could be from about 30 to 60% less than that formed from rolled bar stock, depending on output and steel composition.

3 Aircraft Industry

3.1 Hot Die Forging Aerofoil Blades

Nearly half the production cost of forged engine aerofoil blades can be due to shape correction after forging. A major reason for post-forging distortion is thermal gradients in the forgings due to their thin section and heat loss to dies. A means to overcome



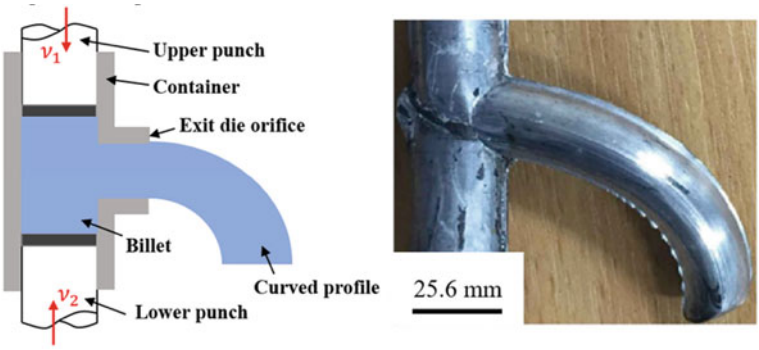


Fig. 8 Heated blade preform between heated dies. (Color figure online)

this is isothermal forging, but this process is time-consuming and reduces productivity unacceptably. The idea was conceived to undertake forging in hot dies while heating work-pieces in a conventional furnace. Figure 8 is a photograph of a preform about to be placed between dies heated by induction coils. The specification of mechanical and metallurgical properties of blades is strict and the consequence of this new technology on the properties has to be predictable through material modelling and process simulation. Added value is through shortening and cheapening of the production process.

4 Railway and Architectural Industries

4.1 Forming Curved Complex-shaped Profiles

For structural and aerodynamic reasons, curved profiles are widely used in the transport industry for manufacturing lightweight structures. Conventionally, the profiles are made from straight extruded bar, which is curved by form bending or cutting and welding. In addition to adding cost and time to manufacture, the first method degrades section geometry and the second impairs mechanical properties also. A new method introduced by the authors, differential velocity sideways extrusion, termed DVSE, in which bar is extruded using two opposing pistons, enables profiles with

(a) Deformation Kinematics (b) Extruded Curved Bar

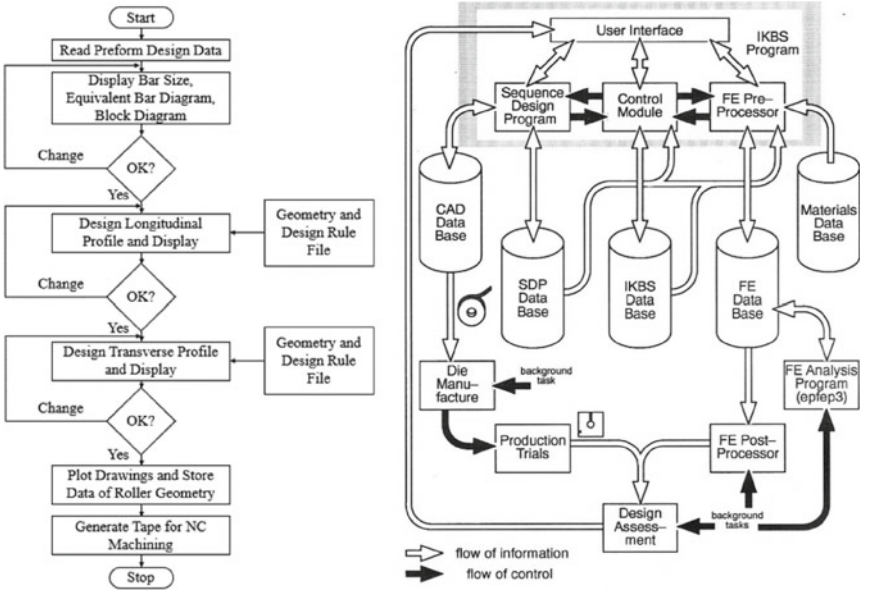

Fig. 9 Differential velocity sideways extrusion. (Color figure online)

prescribed curvature to be extruded directly [8]. The basis of the process is shown in Fig. 9. It has been demonstrated that not only can curved profiles be extruded accurately, but also, for AA1050, compared with the billet, grain refinement and increases in hardness, yield strength, and ultimate tensile strength by 134.8%, 354.0%, and 116.8%, respectively, were achieved in the formed curved bar [9]. Added value is in provision of higher strength profiles with undistorted section geometry utilising a more efficient production process.

5 Computer-Based Production Systems

Computer-based facilities can add value to formed parts; by reducing lead times, through speeding up product and process design, by reducing cost through process optimisation and by maximising product qualities through modelling and simulation.

Research and development of computer-based aids for the metal forming industry, initially undertaken at the University of Birmingham in the late 1970s, was ahead of its time in that the UK industry was only in an early stage of adopting the rudimentary computer-based modelling software being introduced commercially. Nevertheless, this software led to component design being expressed digitally instead of hand drawn graphics and paved the way for subsequent computer-based aids to process and production. Integration of the rapidly developing modelling software with empirical design rules, based on best industrial practice, enabled researchers at Birmingham to produce computer-aided design (CAD) programs usable by inexperienced workers to design acceptable tooling and processes. The structure of these 'knowledge-based' systems (KBS) is exemplified by [10–12] and an example of the linear structure of the programs can be seen in Fig. 10a, which shows that data for CNC (Computer Numerically Controlled) machining of tools could be generated also. Earlier, work was centred on the hot forging industry, which was experiencing

(a) Knowledge-based system (b) Intelligent knowledge-based system (IKBS)

Fig. 10 Program structures for computer-aided design and manufacture

shortage of experienced engineers, including the company that had adopted the net-shape gear forging process. When numerical computing methods and FE simulation software became available, by enabling tool designs to be validated and if necessary modified in a virtual environment, they allowed CAD programs to be expanded to become, intelligent knowledge-based systems, which could not only be used to rapidly design process and tools using well tried rules, but also optimise processes and deal with new types of components by using simulation only when necessary. The new information resulting from simulation is added to the database. An example of the structure of an Intelligent knowledge-based system (IKBS) for forging dies is shown in Fig. 10b [13].

The structure of the IKBS comprises 3 essential programs: (a) Sequence design program, which will deal with part families governed by the same set of design rules, (b) FE pre-processor to create data files for simulation, and (c) Control module to supervise the other two modules. An important aspect of the IKBS is that it compares a component to be designed for with previously dealt with cases in the same family. The degree of similarity for each operational stage is based on a 'success indicator', which shows how satisfactory is a particular designed stage and a 'confidence indicator', which shows how strongly information in the knowledge-base supports the evaluation of the success indicator. The reasoning is given in detail in [11].

6 Cloud Based Multi-objective FE Simulation Technology

In recent years, a Cloud based multi-objective FE simulation technology was developed at Imperial College London [14–16]. This Cloud based system is forging a gateway to financially reward academic innovations, e.g. published data and advanced models, etc. in collaboration with a renowned FE code provider, AutoForm, leading to the direct applications of frontier knowledge in industry and academia. As shown in Fig. 11, the structure of the Cloud based multi-objective FE simulation system includes three essential layers: (a) Resource layer, which will collect resources contributed by researchers from academia and industry, (b) Cloud platform layer, which will host functional modules and portfolios and execute these numerical models online, and (c) Application layer. Users from industry and academia will visualise the FE simulation results via user interface to enable process optimisation.

Added value of the Cloud based multi-objective FEA (Finite Element Analysis) system is in provision of interoperable functional modules (advanced models and testing data) and portfolios (bundles of FE models and functional modules), to avoid repeated lab-scale research. The reuse of knowledge could lead to a 50 to 85% cost reduction in research and development, depending on the forming technologies. Moreover, added value can be realised via the Internet of Things of supply chains

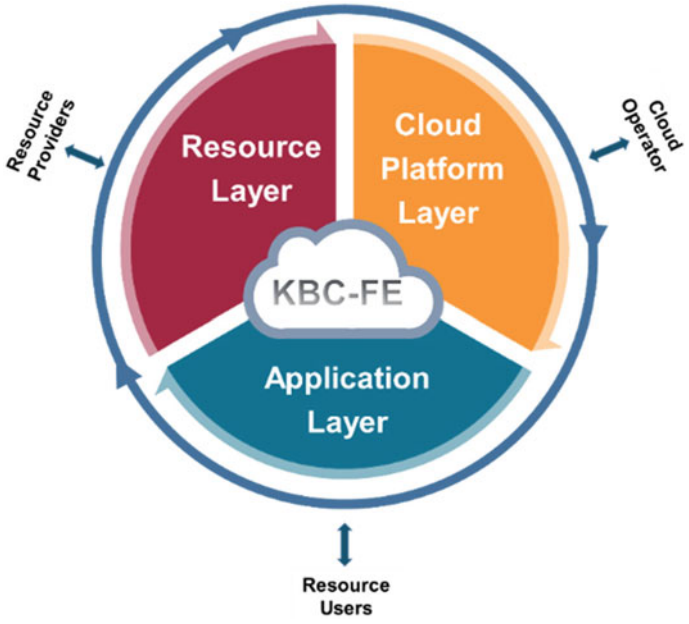

Fig. 11 The framework of cloud based multi-objective fe simulation system. (Color figure online)

for future metal forming industry, i.e. the Cloud based FEA system will enable data exchange and the data-guided production right-first-time through identifying the customers' needs.

7 Concluding Remarks

In this paper, the authors presented a review of research conducted in the past forty years within the research group to enhancing the added value of metal formed parts. Development of advanced manufacturing technologies has reduced the efforts for post-form fabrications, enhanced post-form strength of the metal formed parts, and enabled recycled materials to be used in manufacture, adding value to metal formed parts. In addition, digital technologies can add value to formed parts by reducing lead times, by reducing cost through process optimisation, and by maximising product qualities through modelling and simulation. In the future, added value of metal formed parts can be further enhanced through the identification of customers' needs and the production of mass-customised products.

Acknowledgments This paper was written in fond memory of Professor Z.R. Wang, a sound scientist, excellent engineer, and warm friend.

A Study of the Forming Quality of Magnesium Alloy Cylindrical Parts with Inner Ribs by Induction-Heating-Assisted Spinning

Qinxiang Xia, Jinchuan Long, Gaozhu Huang, Shuai Yuan, and Yi Qin

Abstract Magnesium alloy cylindrical parts with inner ribs (MACPIR) are attractive as lightweight components for improving the performance of high-end equipment in various industrial sectors. Induction-heating-assisted spinning (IHAS), an effective way to manufacture cylindrical parts made of difficult-to-deform materials, was used to form the MACPIR. However, when using this process for MACPIR, nonuniform deformation and other forming defects can easily occur between the cylindrical wall and inner ribs. A FEM model of MACPIR during IHAS was developed via ABAQUS, and experimental verification was conducted. Forming defects that occurred during the spinning process of MACPIR were analyzed, and evaluation indexes of forming quality were proposed. The results show that the concavity of rib back, and nonuniform distribution of rib height along tangential and axial directions are the main forming defects. Additionally, the influence of process parameters on the forming quality was discussed. The results indicate that the forming quality of MACPIR can be improved under a forming temperature of $T = 300 \sim 350$ °C, roller feed rate $f = 0.4 \sim 0.6$ mm/r, and thinning ratio of wall thickness $\Psi_t = 65 \sim 75\%$. The simulation results confirm well with experimental ones.

1 Introduction

Magnesium alloys are being widely applied in the automobile, aviation and aerospace fields due to their light weight [1]. Cylindrical parts with inner ribs can also be used to reduce weight and enhance overall product performance [2, 3]. Thus, magnesium alloy cylindrical parts with inner ribs (MACPIR) become one of the most promising lightweight components. The formability of magnesium alloys is limited at room temperature due to their hexagonal close packed (HCP) crystal structure, but it can be greatly enhanced at an elevated temperature [4]. As an effective method of forming cylindrical parts made of difficult-to-deform metals, induction-heating-assisted spinning (IHAS) was used for manufacturing the MACPIR. However, differences in the required amount of deformation between the inner ribs and the cylindrical wall can result in nonuniform deformation during the spinning process. Also forming defects such as cracks and bulges occur easily because of unwise selection of process parameters [5]. Therefore, it is of significance to study the forming quality of MACPIR formed by IHAS and explore the optimal process parameters to decrease the forming defects.

Investigations on power spinning of cylindrical parts with inner ribs (CPIR) have been reported in recent years. Jiang et al. [6] simulated the backward ball spinning of 5A02 aluminum alloy CPIR via DEFORM-3D and conducted a verification experiment. The results show that increasing the size of the balls can contribute to the formability of inner ribs. Xia et al. [7] simulated the power spinning of a Q235 cup-shaped thin-walled inner gear via MSC.MARC and compared this with experimental results. They found that the thinning ratio is the dominant factor which determines the filling height of gear teeth. Meanwhile, Zhang et al. [8] simulated the hot flow forming of AZ31B magnesium alloy cylindrical parts via ABAQUS and carried out an experiment. The results showed that wrinkles occur at the top edge of the spun workpiece under a large thinning ratio of wall thickness $\Psi_t = 45\%$ when the forming temperature $T = 420$ °C and roller feed rate $f = 0.1$ mm/r.

ZK61 magnesium alloy is a typical wrought magnesium alloy with good comprehensive mechanical properties [9]. In the previous work of the authors [10], the constitutive model of ZK61 alloy considering compensation of strain was developed and the predicted flow stress values of this showed good agreement with that obtained by a high-temperature axial compression test (HTACT). Furthermore, Xia et al. [5, 11] simulated the IHAS process of ZK61 MACPIR via MSC.MARC to analyze the material flow of a spun workpiece with inner ribs (SWIR) during the spinning. Corresponding experimental and metallographic tests were carried out to investigate the microstructure evolution of SWIR under different process parameters as well. The results indicate that a large thinning ratio of wall thickness Ψ_t or a high forming temperature T can facilitate the filling of inner ribs and increase the rib height; they also indicate that Ψ_t plays an important role in grain refinement of SWIR.

In this paper, the FEM model of ZK61 MACPIR during the IHAS process was developed via ABAQUS and the IHAS experiment was conducted. The forming defects that occurred during the spinning process were analyzed, and the influence of the process parameters on the forming quality of SWIR was investigated.

2 Development and Verification of FEM Model

2.1 Development of FEM Model

The geometric model was developed via ABAQUS, the geometric parameters of which are listed in Table 1. The trapezoidal-shaped inner ribs were selected to improve the stiffness of the cylindrical parts and facilitate the material flow within the ribs [12]. The number of inner ribs was designed as a multiple of 3 to ensure the stability of the adopted three-roller stagger spinning [13]. The height and width of inner ribs were designed according to the standard JB/T9177-1999 [14]. In the simulation, the bottom of the blank was fixed with a snap ring and its opening was a free end, and the inner ribs form under three rollers during the IHAS. Figure 1 shows the FEM model via ABAQUS, the cylindrical blank was defined as a deformable body meshed with a C3D8RT element which is suitable for hot deformation analysis, while the rollers and mandrel were all defined as rigid bodies. Moreover, four elements were meshed along the direction of the wall thickness to obtain the radial deformation information. The total number of elements were 90000.

The true stress and strain data of solution-treated ZK61 alloy during hot deformation were obtained via HTACT [9], which was conducted under a temperature of

Table 1 Geometric parameters of FEM model

Table 2 Thermodynamic parameters of ZK61 alloy

Temperature/(°C)	250	300	350	400
Elastic modulus E/(GPa)	24.43	23.45	22.51	20.31
Heat conduction coefficient λ/(W/m·°C)	111.8	116.7	120.7	125.3
Specific heat $c(\times 10^3)$/(J/Kg·°C)	1.277	1.284	1.303	1.325
Thermal expansion coefficient a $(\times 10^{-5})$/(°C)	2.33	2.34	2.39	2.41

250–450 and strain rate of 0.001–10/s. These data were imported into ABAQUS in the form of true stress and plastic strain. Since the blank meshed by the solid element has no rotational degrees of freedom, the coupling constraint is applied to a reference point located at the bottom of the blank, by which the rotations of both the blank and the mandrel can be realized. The isotropy Coulomb friction model was chosen in this study, and the friction coefficients between rollers and blank, and mandrel and blank are set as 0.1 and 0.15 [15], respectively. Also, the forming temperature during IHAS is influenced by not only heat conduction between blank, rollers, snap ring, and mandrel, but also heat radiation between the blank and the outer environment. The thermodynamic parameters of ZK61 alloy including elastic modulus, heat conduction coefficient, specific heat, and thermal expansion coefficient were obtained by dynamic thermomechanical analysis (DMA), a hot disk thermal conductivity instrument, differential scanning calorimetry (DSC), and thermal dilatometer (DIL402PC) under $T = 250$–450, to simulate the actual spinning forming process, as shown in Table 2.

2.2 Experimental and Simulation Conditions

Reasonable process parameters are essential to guarantee the forming quality of the spun workpiece. Ψ_t is generally selected as 40–70% during power spinning of CPIR, and large thinning ratio can be beneficial for the radial flow of material and filling of inner ribs, and Ψ_t of 60–75% is chosen in this study. Moreover, T of 250–400 °C is usually suitable for plastic deformation of magnesium alloys [16], and f is normally selected within 0.1–1.0 mm/r for IHAS [17]. Table 3 shows the process parameters for IHAS of ZK61 alloy CPIR. The experiment was carried out on a HGQX vertical spinning machine, as shown in Fig. 2.

2.3 Verification of Finite Element Model

The verification experiment was conducted under $T = 300$ °C, $f = 0.4$ mm/r, and $\Psi_t = 60\%$. As shown in Fig. 3a, the wave-shaped opening-end appears during both

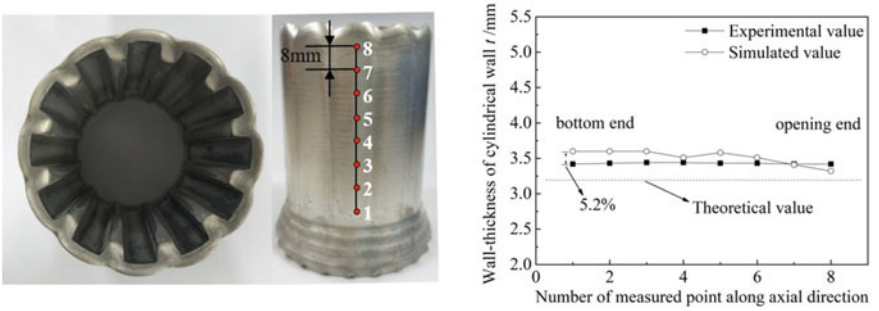

Fig. 4 Result comparison between simulated wall thickness and experimental one under $T = 300$ °C, $f = 0.4$ mm/r, and $\Psi_t = 60\%$. (Color figure online)

simulation and the experiment, where the concavity of the inner ribs occurred at the outer surface of the spun workpiece. As shown in Fig. 3b, the simulated opening-end and bottom-end of the spun workpiece are similar to that of the experiment, where the rib height near the bottom-end is higher than that near the opening-end. Therefore, the simulation results confirm well with the experimental ones. Additionally, the ultrasonic thickness gauge was adopted to obtain the wall-thickness distribution of spun workpiece. Figure 4a shows the measured points of wall thickness along the axial direction at the cylindrical wall, and Fig. 4b show the result comparison between simulated values and experimental ones, where the maximum relative error between them is only 5.2%. This indicates the developed FEM model for MACPIR during IHAS is reliable.

3 Evaluation Indexes of Forming Quality for SWIR

Figures 3 and 5 show the forming defects that occurred during IHAS of ZK61 alloy CPIR, including the concavity of the outer wall at the rib back, nonuniform distribution of rib height along the longitudinal and tangential directions. To evaluate the

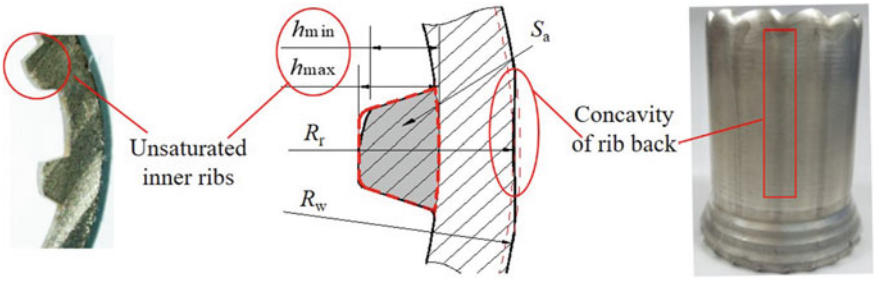

Fig. 5 Experimental result under $T = 300$ °C, $f = 0.4$ mm/r, and $\Psi_t = 60\%$. (Color figure online)

forming quality of SWIR, the indexes such as the saturation degree of inner rib S, inhomogeneity of rib height λ, and concavity ratio of rib back η were put forward, as shown in Fig. 5, and these indexes can be calculated by the following equations.

$$S = \frac{S_a}{S_t} \times 100\% \tag{1}$$

$$\lambda = \frac{h_{max} - h_{min}}{h} \times 100\% \tag{2}$$

$$\eta = \frac{R_w - R_r}{R_w} \times 100\% \tag{3}$$

where S_a and S_t are the actual and theoretical cross-section areas of inner ribs, respectively; h_{max} and h_{min} are the maximum and minimum heights of inner ribs, respectively; R_w and R_r are the outer radii at the cylindrical wall and inner rib, respectively.

4 Results and Discussion

4.1 Influence of Temperature on Forming Quality

Figure 6 shows the influence of T on forming quality of SWIR when $f = 0.4$ mm/r and $\Psi_t = 60\%$. As shown in Fig. 6a, the S increases gradually at the bottom-end as T initially increases and then decreases at the opening-end. The S_{max} occurs at the bottom-end under $T = 400$ °C, while the S_{min} occurs at its opening-end, which indicates the filling of inner ribs along the axial direction is nonuniform. Although S at the bottom-end under $T = 300 \sim 350$ °C is smaller than that under $T = 400$ °C, the differences of S between the bottom-end and opening-end under $T = 300 \sim 350$ °C is smaller, i.e., the filling of inner ribs along the axial direction within this temperature range tends to be more uniform. As shown in Fig. 6b, the λ decreases firstly and then increases with the increase of T, and λ_{min} occurs at both the opening-end and bottom-end under $T = 350$ °C, which means the filling of inner ribs can be enhanced

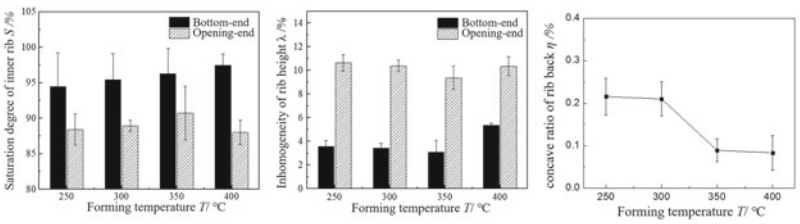

Fig. 6 Influence of T on forming quality of SWIR under $f = 0.4$ mm/r and $\Psi_t = 60\%$

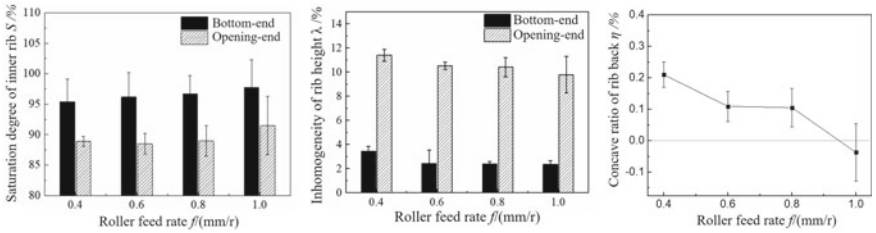

Fig. 7 Influence of f on forming quality of SWIR under $T = 300$ °C, $\Psi_t = 60\%$

effectively under $T = 350$ °C. As shown in Fig. 6c, the η decreases gradually with the increase of T, which is almost steady under $T = 350$ °C. Therefore, $T = 300 \sim 350$ °C is more beneficial for improving the forming quality of SWIR.

4.2 *Influence of Roller Feed Rate on Forming Quality*

Figure 7 shows the influence of f on forming quality of SWIR under $T = 300$ °C and $\Psi_t = 60\%$. As shown in Fig. 7a, S tends to increase as f increases. This is because the deformation degree increases by increasing the f per unit of time, material flow decreases along the axial direction and increases along the radial direction, which can facilitate the filling of inner ribs. As shown in Fig. 7b, the λ decreases gradually as f increases which indicates the filling of inner ribs tends to be uniform under a large f. However, as shown in Fig. 7c, the η decreases firstly and then increases along the negative direction as f increases. The value of η is negative when $f = 1.0$ mm/r, i.e., part of the rib back is higher than that of the cylindrical wall at both sides, and the concavity transfers into the cylindrical wall from the rib back. This is because axial flow of material at the cylindrical wall decreases and tangential flow of the material increases with the increase of f; this makes more material flow into the inner ribs and leads to the occurrence of concavity at the cylindrical wall. Meanwhile, the material flow accelerates and flow instability occurs easily under large f; this can often result in a crack defect. Therefore, a small range of f within 0.4–0.6 mm/r is more suitable for IHAS of SWIR.

4.3 *Influence of Thinning Ratio on Forming Quality*

Figure 8 shows the influence of Ψ_t on forming quality of SWIR when $T = 300$ °C and $f = 0.4$ mm/r. As shown in Fig. 8a, S increases gradually with the increase of Ψ_t, and the filling of inner ribs is more uniform along the axial direction. The S is more than 99.5% under $\Psi_t = 75\%$, i.e., the inner ribs can be filled up under this thinning ratio. As shown in Fig. 8b, the λ decreases with the increase of Ψ_t,

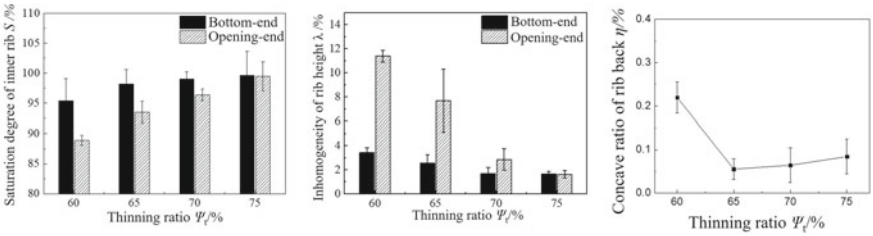

Fig. 8 Influence of Ψ_t on forming quality of SWIR under $T = 300$ °C and $f = 0.4$ mm/r

and the λ_{min} about 1.6% can be obtained under $\Psi_t = 75\%$, where the values of λ are basically consistent along the axial direction. This indicates that a large Ψ_t is beneficial for the filling of inner ribs as well as improvement of forming quality for SWIR. However, as shown in Fig. 8c, the η decreases firstly and then slightly increases with the increase of Ψ_t, and the η_{min} about 0.06% was obtained under $\Psi_t = 65\%$. This indicates that increasing Ψ_t can lead to the decreasing of η. In fact, the filling of the inner rib is insufficient under a small Ψ_t of 60%, and the concavity of the rib back is therefore severe at the inner ribs. However, the ratio of inner rib height to the cylindrical wall thickness increases when $\Psi_t \geq 65\%$, and thus springback of the material at the cylindrical wall is more obvious than that at the inner ribs; these are responsible for the slight increase of η. Therefore, a suitable thinning ratio of 65–75% is also helpful for improving the forming quality of SWIR.

5 Conclusions

The induction-heating-assisted spinning (IHAS) process of ZK61 magnesium alloy cylindrical parts with inner ribs (MACPIR) was investigated via FEM simulation and an experiment. The influence of process parameters on the forming quality of spun workpieces with inner ribs (SWIR) was studied. Some conclusions can be drawn as follows:

(1) Forming defects occurred during IHAS of ZK61 MACPIR. These mainly included concavity of the outer wall at the rib back and nonuniform distribution of rib height along longitudinal and tangential directions. These can be improved by decreasing the ratio of inner rib height to cylindrical wall thickness and increasing the filling of the inner ribs.

(2) The proposed indexes including the saturation degree of an inner rib S, inhomogeneity of rib height λ, and concavity ratio of rib back η can be used to evaluate the forming quality of SWIR. Process parameters which are beneficial for the improvement of forming quality for SWIR are forming temperature $T = 300 \sim 350$ °C, roller feed rate $f = 0.4 \sim 0.6$ mm/r, and thinning ratio of wall thickness $\Psi_t = 65\% \sim 75\%$.

A Porosity Closure Model for the Integrated Casting and Forging Process of Aluminum Alloy and Its Application

Qi Zhang, Liqun Niu, Zhenglong Liang, and Miao Cao

Abstract Integrated casting and forging process (ICFP) is a feasible manufacturing method which significantly improves the mechanical properties of casting due to forging process eliminating porosity defects. In this study, a new model that predicts the law of porosity closure during forging is proposed, which considered the variation of stress triaxiality ratio, Lode parameter and effective strain, was implemented into finite element package FORGE2.1. A356 was used as specimen materials subjected to X-ray computed tomography (CT) scanning. The comparison between the simulation results and the experimental results shows that the proposed model can accurately predict the maps of porosity closure volume in the forging process of A356 aluminum alloy. With the model, the ICFP design and optimization will be convenient.

Keywords Integrated casting and forging process · Porosity closure model · Lode stress parameter · Stress triaxiality ratio

1 Introduction

With the rapid development of the automobile manufacturing industry, higher requirements have been put forward for structure lightweight, energy saving and emission reduction, and there is a need for lightweight metal materials, especially advanced manufacturing methods for aluminum alloys. Integrated casting and forging process (ICFP) combines the advantages of casting and forging, which is a feasible method and means for eliminating porosity defects, as reported by [5]. However, the optimization of the ICFP process is determined by the conventional trial-and-error method, with a large workload and low efficiency. Mathematical model is one of the effective ways to solve this problem. Therefore, there are many researches which have concentrated on the porosity closure model and closed index in the last decades. Saby et al. [4] reviewed the various criteria or models for

predicting the void closure in industrial applications. They pointed out that the use of Lode stress parameter will be a huge improvement.

In this paper, the influence of stress triaxiality ratio and Lode stress parameter on porosity closure is quantitatively assessed and a new model (called STLB model) is defined in the following section. The new prediction model is implemented in the finite element software FORGE and is compared to the stress triaxiality based (STB) model by P. Lasne and detailed in [3]. The third section presents an evolution of the STLB model for a case of the ICFP process.

2 Prediction Model for Porosity Closure

In this section, the mesoscale approach used to perform explicit simulations is adopted, which takes into account the effect of Lode stress parameter u and stress triaxiality ratio Tx. For more details, the reader can refer to [1]. In order to study the evolution of porosity, the strain ratio of porosity radius ε_P was defined. The expression is as follows:

$$\varepsilon_P = \frac{R}{R_0} \tag{1}$$

where R_0 denotes the initial radius of the spherical porosity, and R corresponds to the radius after deformation. The $\varepsilon_{P_{max}}$ represents in the main direction of the stress, and the $\varepsilon_{P_{max}} = 0$ corresponds to a threshold value of porosity closure.

2.1 Influence of Lode Stress Parameter and Stress Triaxiality Ratios

In this section, different stress triaxiality ratios $T_X \in (0, -0.5, -1, -1.5)$ and different Lode stress parameters $u \in (0, 0.25, 0.5, 0.75, 1)$ are used to illustrate the effect of the Lode parameter on spherical porosity closure. The relationship between the strain ratio of porosity radius $\varepsilon_{P_{max}}$ and effective strain ε_e is illustrated in Fig. 1. When T_X is kept constant, different u value has an effect on porosity closure; the larger the u value is, the smaller is the critical strain value. In Fig. 1a, where $T_X = 0$, when $u = 1$ and $\varepsilon_{P_{max}} = 0$, the strain value is equal to 1.049. In Fig. 1b, where $T_X = -0.5$, when $u = 1$ and $\varepsilon_{P_{max}} = 0$, the strain value is equal to 0.747. Then, looking at Fig. 1c, where $T_X = -1$, when $u = 1$ and $\varepsilon_{P_{max}} = 0$, the strain value is equal to 0.612. The same behavior, concerning the influence of T_X on porosity closure, is noted again so that the strain value is still decreasing for the case $Tx = -1.5$ (Fig. 1d) with $\varepsilon_e = 0.529$. The data reveals that the stress triaxiality ratio T_X and Lode parameter u have

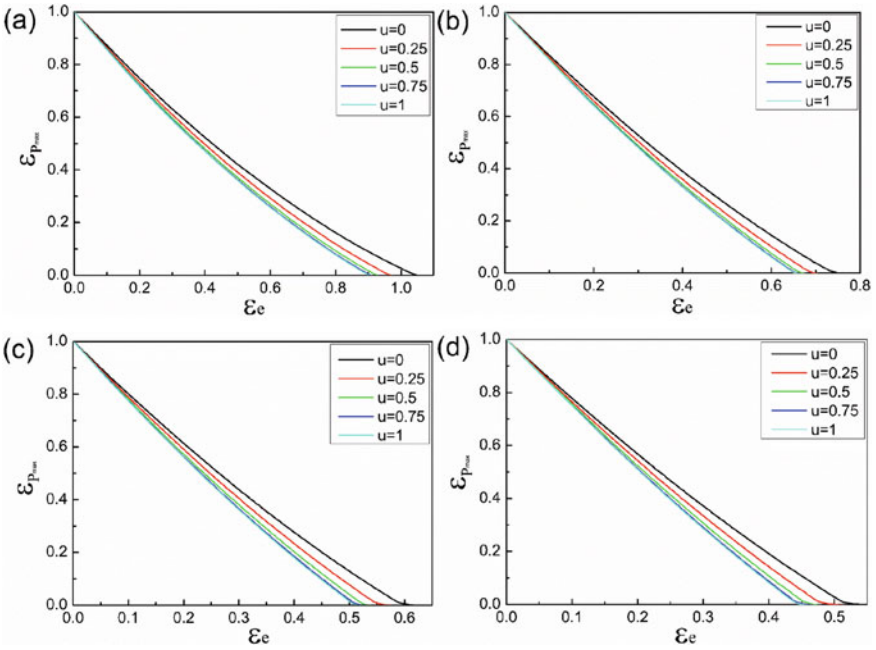

Fig. 1 Relationship between porosity ratio $\varepsilon_{P_{max}}$ and effective strain ε_e: $T_X = 0$; **a** $T_X = -0.5$; **b** $T_X = -1$; **c** $T_X = -1.5$. (Color figure online)

a significant influence on porosity closure. The effective strain value required for porosity closure decreases as the stress triaxiality level increases, as reported by [6].

2.2 A New Porosity Closure Model

A new model for predicting maps of porosity closure volume was defined, including the stress triaxiality ratio T_X and the Lode stress parameter μ. The ε_c represents the critical effective strain of the RVE surface when the porosity is completely closed. The new model can be expressed as follows:

$$\varepsilon_c = \left[D_1 + D_2 \exp(D_3 T_X)\right](1+u)^{D_4} \tag{2}$$

$$D_4 = A(T_X)^2 + BT_X + C(u)^2 + Eu + FT_X u + G \tag{3}$$

The regression coefficients can be determined by the regression method and the results are shown in Table 1. The comparison between model data and compute data is illustrated in Fig. 2, where the STLB model can accurately fit the compute data.

Table 1 The regression coefficients of the STLB model

D_1	D_2	D_3	A	B	C	E	F	G
0.448	0.599	1.341	−0.022	−0.047	−0.017	0.202	0.028	−0.389

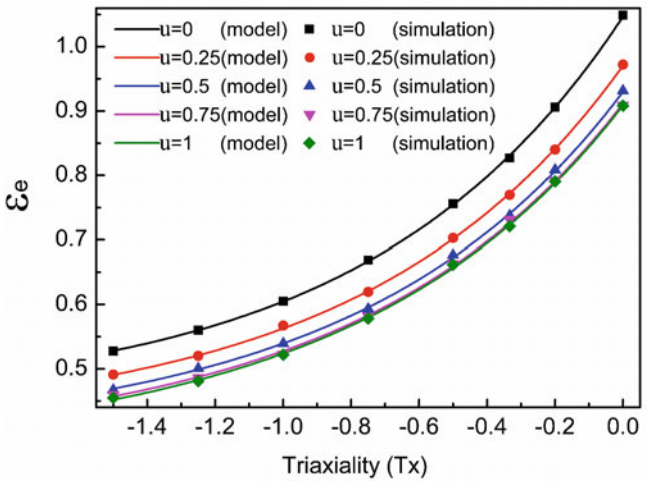

Fig. 2 Comparison between the simulation data and model data. (Color figure online)

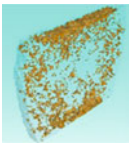
To assess the precision of the STLB model, the average error between the model calculated strain ε_m and RVE simulation obtained ε_s can be computed as follows:

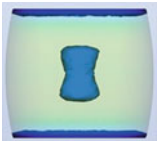
$$\text{error} = \frac{1}{\mathrm{N}} \sum_{\mathrm{i}=1}^{\mathrm{N}} |(\varepsilon_{\mathrm{m}} - \varepsilon_{\mathrm{s}})/\varepsilon_{\mathrm{s}}| \times 100\% \tag{4}$$

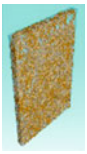
The porosity closure strain values of both model calculation results and the simulation data are extracted at different stress triaxiality ratios Tx∈ (0, −0.2, −0.333, −0.5, −0.75, −1, −1.25, −1.5) and different values of Lode stress parameters u ∈ (0, 0.25, 0.5, 0.75, 1). The error can be calculated by Eq. [4], and the error of the STLB model is 2.35%.

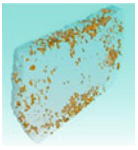
2.3 Validation of the Porosity Closure Model

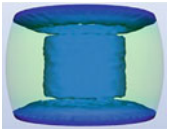
Cylindrical specimens (Ø6 mm ×H9mm) are machined from the shrinkage zone of casting parts, which is conducive to subsequent porosity measurement and analysis. The hot forging experiments were carried out on a Gleeble 3800 thermal system simulator. The experimental scheme of hot forging is shown in Table 2. A high-

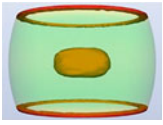












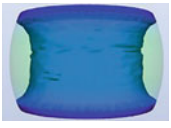


Table 2 Hot forging experimental scheme

Name	Billet size (mm)	Temperature (°C)	Strain rate (s^{-1})	Reduction (mm)	Reduction ratio (%)
Case1	Φ6.0 × H9.0	400	0.1	2.7	30
Case2				3.6	40
Case3				4.5	50

resolution and micro-focus X-ray CT system YXLON Y. Cheetah was used to reveal the porosity distribution before and after hot forging.

The 3D X-ray CT images with a thickness of 1 mm were cut along the central plane to better display its maps of micro-porosity closure. The semi-transparent display of the X-ray CT images can better reveal the distribution of internal porosities. The material is represented in virescent and the porosity is represented in yellow. The numerical and CT experimental results are shown in Table 3. When the reduction is 30%, there is no porosity closure zone in the STLB model, which is consistent with the experimental results. However, porosity closure zone exists in the STB model. When the reduction is 40%, there is a porosity closure zone in the STLB model and the STB model. The STLB model is less than the predicted porosity closure area of the STB model, which is in better agreement with the experimental results. With the amount of reduction increasing, the significant porosity closure zone exists in Case3. Evidently, the numerical results obtained from the STLB model can well predict the experimental results.

3 Applications to Integrated Casting and Forging Process (ICFP)

Process principle of ICFP mainly includes four procedures: casting, solidification, forging, and opening die, which was studied and is presented in [5]. First, casting procedure ensures that the die cavity is fully filled. Then, molten metal in the die cavity is completely solidified under a certain static pressure. Forging is the key procedure of the ICFP, which makes full use of the latent heat of solidification to further compensate the porosity and cavity of the part.

One type of automobile control arm which was made from A356 aluminum alloy is used as the research object. The thermodynamic properties of A356 alloy refers to [2]. The casting and solidification are simulated by software THERCAST. The Niyama criterion is an estimation of the risk of porosity in the THERCAST. The high risk of presence of porosity is then indicated by high values of the criterion, where 0 is the minimum value that indicates the absence of porosity. Figure 3a shows the high risk area of the presence of porosity distribution of the control arm after solidification. Typical regions are selected for microstructure observation; there are some porosities in the red region, as shown in Fig. 3b. Therefore, the result indicated by THERMCAST match the high values of the criterion at high risk for the presence of porosity.

According to the distribution results of porosities, the composite die of ICFP for automobile control arm is designed, as shown in Fig. 4. The punch is moved down to forge the parts after a certain forging waiting time. In order to design and optimize the process of ICFP, the STLB model was implemented into finite element (FE) analysis software FORGE2.1.

Figure 5 shows the evolution of Niyama distribution in the control arm during forging. It can be seen that with the increase of the reduction, Niyama value on the control arm gradually decreases, and the area of porosity distribution gradually decreases.

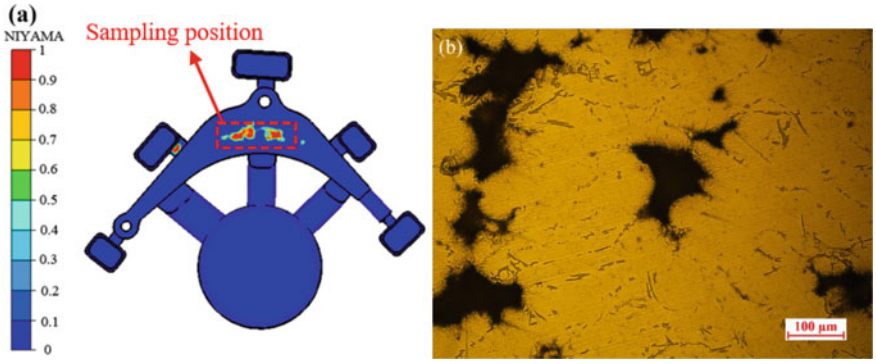

Fig. 3 **a** The sampling position of automobile control arm; **b** Microstructure of sample in **a**. (Color figure online)

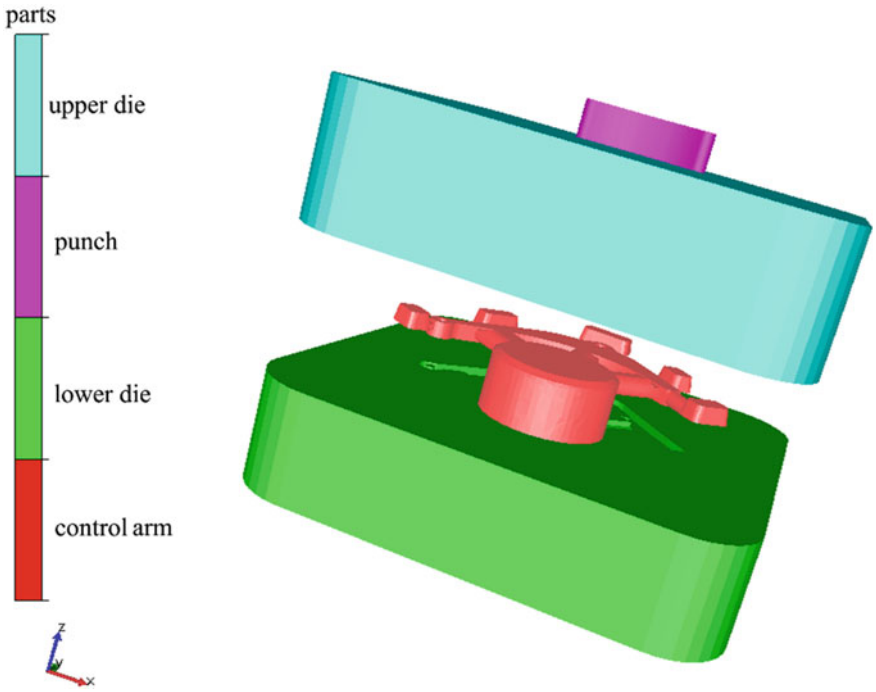

Fig. 4 The composite die of ICFP for automobile control arm. (Color figure online)

Figure 6 shows the sampling position and microstructure of ICFP for automobile control arm. Through the microstructure, it can be observed that there are no porosities in the sampling position. Obviously, the numerical results obtained from the STLB model well agree with the experimental results.

4 Conclusions

(1) The stress triaxiality ratio and Lode stress parameter-based (STLB) model is proposed. In comparison with the STB model, the new model used the Lode stress parameter that defines the stress state accurately. The average error of the STLB model is 2.35%. X-ray CT scan results show that the STLB model can predict porosity closure more accurately than the STB model.

(2) Integrated casting and forging process (ICFP) was used as validation cases. The experimental results well agree with the simulated results obtained from STLB models, which indicates that the new model for process design and optimization will be convenient.

Robust Hydroforming Technologies to Enhance the Formability of Sheet and Tube

Shi-Hong Zhang, Da-Yong Chen, Yong Xu, and Yan Ma

Abstract Pulsating hydroforming and impact hydroforming are two advanced technologies to increase the formability of material compared with other traditional forming technologies. They were systematically investigated from aspects of technical principle, forming mechanism, equipment, and applications. Pulsating hydroforming can improve the forming ability by altering the friction condition of sheet/tube parts or by utilizing the effect of transformation induced plasticity of stainless steels under the pulsating loading. As for impact hydroforming, the strain rate can reach 10^3–10^4/s and the instantaneous pressure can be GPa level, which can obviously increase the elongation of hard-to-form material by 20–60%. The effect of flexible liquid and impact impulse was investigated by both experiment and simulation, while the mechanisms were related to the compatible deformation of the second phase, strain decentralization, and defect stabilization. The technologies have been used on the manufacturing of complex, thin-walled components for the fields of aeronautics and aerospace, automobile, nuclear power, etc.

Keywords Pulsating hydroforming · Impact hydroforming · Sheet and tube · High strain rate · Formability

1 Introduction

Nowadays, complex components are needed in the fields of automobile, aeronautical and astronautical, nuclear power, etc. These components are characterized with thin-wall, large size, complex and curved surface, deep cavity. So, it is very difficult to use the conventional processes such as rigid punching, rolling, and forging to manufacture the complex parts; especially, some of them are made of low formability materials such as aluminum, magnesium, and titanium alloy. As an advanced lightweight forming process, hydroforming has been widely used in these fields to manufacture the complex and hard-to-form components during recent decades. Especially, Wang

et al. innovatively used hydroforming to manufacture spherical vessels as a polyhedral shell from polygons. The final product had a reasonable structure and need not be pressed and shaped by dies [1]. Zhang has summarized the new development of hydroforming including flat sheet hydroforming, hydro-bulging, hydromechanical deep drawing, shell forming, viscous pressure forming, etc. early in the 1990s [2]. The hydroforming presents many advantages over conventional stamping and welding processes including the reduction in the number of dies, manufacturing costs, and the increase in dimensional accuracy.

However, there are still some defects such as the wrinkling, buckling, and bursting due to the improper relationship between inner pressure and axial feed during the hydroforming process. And higher and higher standard is proposed for hydroforming especially for the hard-to-form material, such as aluminum, and magnesium alloy which is widely used in the aeronautical and astronautical field.

In recent years, a new process referred to as pulsating hydroforming of tubes had been developed based on the simulation and experiment. It is characterized by decreasing the local thinning ratio and increasing the uniform expansion, which could effectively improve the formability of the tube component [3]. It was found that both pulsating loading effect and microstructure evolution contributed to the increasement of formability based on the investigation of Mori and Xu on the mechanism of formability improvement [4, 5]. The mechanisms of formability improvement were systematically investigated, and the corresponding machine was designed and manufactured according to the study [6].

In recent decades, it was found that high speed forming could improve the formability effectively which includes the electromagnetic forming (EMF), the electrohydraulic forming (EHF), the explosive forming, and so on [7, 8]. As one of the high strain rate (HSR) forming processes, impact hydroforming (IHF) could enhance the formability of sheet metals [9]. It is proposed that the sheet is formed by high pressure and transient loading which combines the advantages of high speed forming and the flexible adaptation of liquid medium [10]. The high pressure of liquid is produced by the impact of the projectile, and the sheet is formed under this high-pressure pulse. The strain rate can reach the level of 10^3–10^4/s and the instantaneous pressure even can be more than 1 GPa in some conditions under IHF [9, 11].

In this study, both of the pulsating hydroforming and impact hydroforming are systematically investigated from the aspects of the mechanisms of the formability improvement, machine designing and manufacturing and the application of these novel technologies.

2 Pulsating Hydroforming

2.1 The Mechanism of Formability Improvement

As it was illustrated in Fig. 1, the formability of SS 304 was investigated using the loading and unloading experiment. And the experiment was done under the in situ XRD observation to study the procedure of phase transformation. It was found that the elongation and ultimate tensile strength of SS 304 was increased by 24.3% and 9.2%, respectively, by pulsating loading compared with traditional hydroforming [5].

The in situ XRD observation was conducted when the unloading strain was 0.3, 0.4, 0.5, 0.6, and near fracture, respectively. The diffraction degree (2θ) was in the range of 40–100°, and the main peaks were γ(111), γ(200), γ(220), γ(311), (110), (200), and (211), respectively, in the XRD spectra. Furthermore, it was found that the initial specimen contained only austenite (γ) from the results of X-ray diffraction as illustrated in Fig. 2. However, the diffraction of the γ phase shifted to a higher angle due to the stress of deformation. It was found that the ratio of the γ phase to the integrated intensity of phase increased gradually when the strain was enhanced, especially for γ(111) and (110). Meanwhile, it was discovered that the martensitic

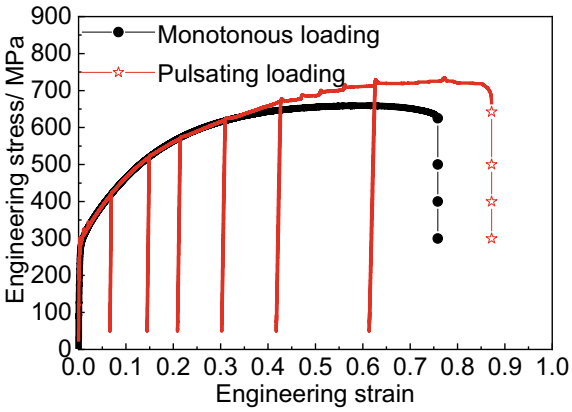

Fig. 1 Stress-strain curve and phase analysis under the pulsating loading [5]. (Color figure online)

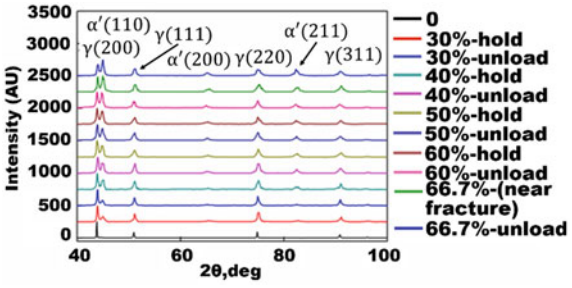

Fig. 2 The diffraction peak of each phase obtained by in situ XRD under loading and unloading tension [12]. (Color figure online)

transformation started at the first stage of deformation. The variation of martensitic fraction coincided well with previous findings before the strain of 0.4. The unloading procedure had minor influence on the kinetics of martensitic transformation at small strains (strains are not more than 0.3), while the fraction of the martensitic phase were characterized with a sudden increase at unloading points when the strain surpassed 0.4. The content of the martensitic phase increased after each procedure of unloading at large strains. By calculation, the martensitic fraction could be extremely increased by approximate 10% through single cyclic loading and unloading [12].

It was found that the plasticity of the austenitic steel was obviously improved under the pulsated loading according to the results of experimentation. The pulsated loading could increase the fraction of the martensite induced by the strain from the observation of in situ XRD. The possible explanation was that the unloading process made the dislocation density low and the austenite matrix soften, which contributed to promote the nucleation and growth of the martensite induced by strain. Consequently, the transformation induced plasticity (TRIP) effect was enhanced and the necking was delayed.

2.2 *The Design and Manufacture of the Pulsating Hydroforming Machine*

The main investigation focused on the process principle and deformation mechanism by the previous scholars. The study was rarely made on the aspect of designing and manufacturing for the pulsating hydroforming machine. In China, the first THF-300 pulsating machine was developed and manufactured by Institute of Metal Research, Chinese Academy of Sciences, in 2010. As illustrated in Fig. 3, the machine is mainly composed of three sub-systems which include the lateral feeding, the liquid filling,

Fig. 3 Novel machine of pulsating loading (THF-300): **a** Hydraulic power station; **b** Control system [13]. (Color figure online)

and the pressurization system. The exact controlling of the internal pressure was realized in the cavity of the component by using the system of closed-loop control. Several different loading modes can be achieved which include single linear, multiple-stage linear, sinusoidal, and step loading, respectively. Typically, the maximum of output pressure can be at the level of 300 MPa with the pulsating loading. The wave amplitude is in the range of 0.5–30 MPa, the frequency is not more than 0.5 Hz, and the precision is ±2 MPa, which illustrate the high precision of the machine [13].

2.3 *The Process Investigation of Pulsating Hydroforming*

Engine cradle is an important part of front axle of the chassis in automobile. It is difficult to be manufactured by the conventional hydroforming process due to the structure of hollow cross section with different dimensions. Multiple procedures are required to manufacture the complicated component (like engine cradle) including the tube bending, preforming, hydroforming, etc. But, only two steps are required to manufacture the engine cradle which include the bending and the pulsating hydroforming. It was illustrated in Fig. 4 that different amplitudes were adopted in the experiment of pulsating hydroforming compared with the monotonic loading path. It was found that the bursting would happen before internal pressure reached 120 MPa

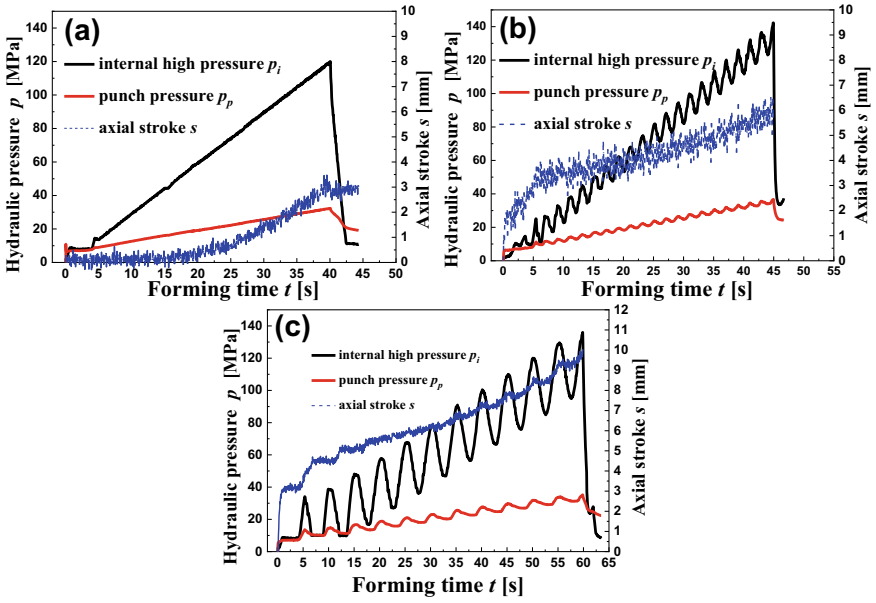

Fig. 4 Experimental data curves acquired by tube hydroforming: **a** monotonic loading path; **b** amplitude = 10 MPa; **c** amplitude = 20 MPa [5, 6]. (Color figure online)

under the monotonic loading. However, the defect could be refrained if the pulsating loading was employed by which the internal pressure could reach the pre-setting value under the condition of two different amplitudes.

The axial stroke was found only to be 3 mm from the result illustrated in Fig. 4a, which was inappreciable during the beginning stage of loading. The bursting was found to concentrate in the corner zone with 95degree angle under the situation of the monotonic loading path. Furthermore, the crack possibly occurred on the both inside and outside surfaces of the tube [5, 6].

However, more axial strokes could be obtained by using the pulsating loading compared with the common one. The loading path lead to the reduction of friction between the tube and die, which made axial strokes increase variably when the amplitudes were large. It could be found that the axial strokes displayed a stepped increase with the load pulsation during hydroforming, and the total stroke for single-side punch is nearly 10 mm when the amplitude was 20 MPa as illustrated in Fig. 4c. On the other hand, it had been proved that the TRIP effect in austenitic stainless steel could be remarkably enhanced by the process of loading and unloading resembled pulsating load according to the previous work. Therefore, the formability was drastically improved by pulsating load, and the bursting could be effectively restrained even under the homogeneous deformation [5, 6].

Consequently, the Integral engine cradle was successfully manufactured by this novel IHF using the material of 304 stainless steel without any defects, such as cracks and wrinkles. The thinning ratio was less than 30%, which could be considered safe in hydroforming. The final component was illustrated in Fig. 5 [5, 6].

Fig. 5 Integral component of engine cradle with good quality [5, 6]

3 Impact Hydroforming

3.1 The Principle of Impact Hydroforming

The process principle of IHF is illustrated in Fig. 6. The projectile is driven by the energy of source, then it shocks the liquid of the chamber; therefore, the liquid is accelerated to form the blank suddenly by means of impact wave which characterizes with high pressure and velocity; afterwards, the blank is shaped to be the final component with certain structure and size. In this procedure, the pressure can even be 500–1000 MPa and the forming time is in the range of 500 μs. As a high-speed forming means, it can increase the formability of material, especially the one which has low plasticity [9, 14].

3.2 The Design and Manufacture of High Energy-Efficiency IHF Press

Based on the research on the propagation of wave under the impact hydroforming, and also, according to the investigation on the energy source, sealing, and controlling, a novel impact hydroforming press is designed and manufactured as illustrated in Fig. 7. The composite of gas-liquid energy source was innovatively used to solve the problem of energy insufficiency. The impact energy could reach 225 kJ under the affect of the liquid which has been accelerated by the high speed projectile that drove by the energy source. Meanwhile, the energy could be controlled exactly by the method of composite energy source. Moreover, the resistance of impact forming was reduced by the design of no seal ring in the high-speed cylinder, no oil pressure under the travel route of the impact bar, and the optimization of exhaust hole. In addition,

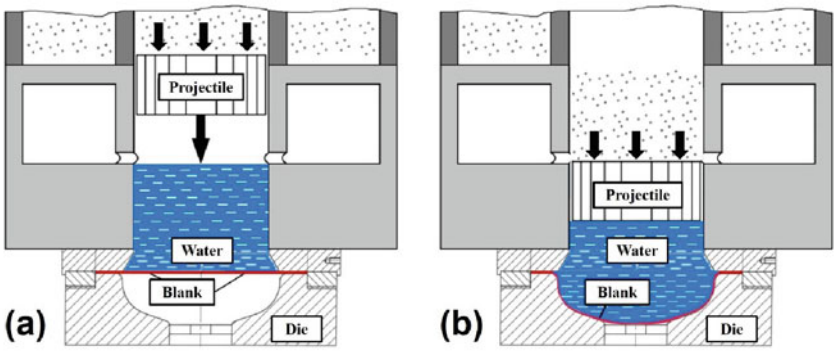

Fig. 6 Process principle of impact hydroforming: **a** Before IHF; **b** After IHF. (Color figure online)

Fig. 7 Impact hydroforming press and system [11]. (Color figure online)

the dynamic model locking was realized by employing a servo system and by the exacted control of the operating platform. The IHF machine mainly includes the energy source, accelerate zone, forming zone, and controlling system [9]. The IHF press can be used to form the tube and sheet component and evaluate the formability of metal material by providing the dynamic measure system. The basic parameters of this novel IHF press is illustrated in Table 1.

Table 1 The parameter of the novel IHF machine [9]

Parameters of IHF press	Parameter value
Impact mode	Single projectile
Principle of acceleration	Composite of gas and liquid
Max accelerate energy	18 MPa
The mass of the projectile	60, 90, 120 kg, Adjustable
Max impact speed	80 m/s
Max energy of projectile	225 kJ
Max pressure in chamber	1000 MPa
The diameter of chamber	250 mm

3.3 The Evaluation of High Strain Rate Formability

The dynamic formability of metal material is valuably investigated because the procedure of IHF finishes instantaneously. The solid-liquid coupling finite element modeling (FEM) was employed as one efficient method to evaluated the formability in the limit forming time. The Gruneisen equation of state (EOS) was used to describe the behavior of the forming liquid which could reflect the wave effect on the blank. The modified John-Cook (J-C) constitutive model was established to present the special hardening behavior of material which could offer more accurate value of elongation and strength. In addition, the Fluid-Structure-Interaction (FSI) algorithm was employed to realize the coupling between the projectile and the liquid, as well as, the liquid and the blank [11, 15, 16].

The forming ratio is defined as the ratio of initial diameter of the blank with the diameter of die cavity. And the forming height ratio is defined as the ratio of the depth of the formed part with the diameter of die cavity. The evaluation of formability should consider the influence of impact energy and forming ratio on the forming behavior of the part. Hence, the different diameters of blank were designed and adopted in both FEM and experiment, which is listed in Table 2.

The corresponding experiment was employed to verify the validity of solid-liquid coupling FEM. And the relative die was designed as illustrated in Fig. 8. The die mainly includes the upper die, fixing ring, locating ring, lower die, die set, and centering plate. The diameter of die cavity is designed as 38.5 mm, the radius of die

Table 2 The initial diameters and corresponding forming ratios for formability evaluation testing

Initial diameter of blank/mm	51.2	54.7	57.8	63.9	70.5	77.0	83.6
Forming ratio	1.42	1.51	1.60	1.77	1.95	2.13	2.31

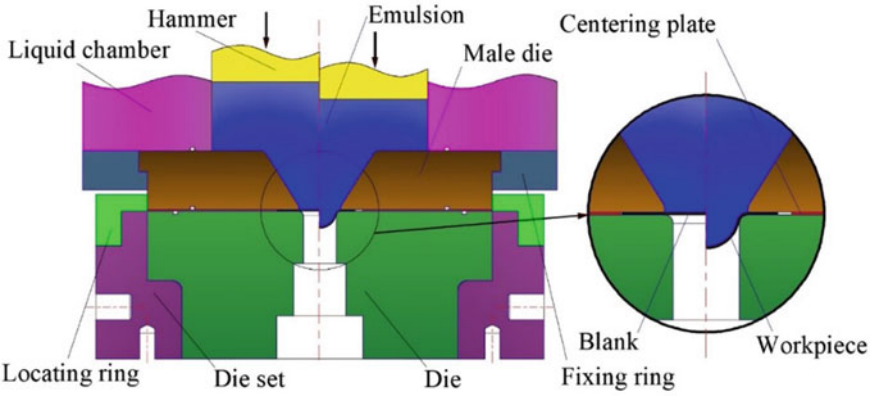

Fig. 8 The geometrical model for formability evaluation of impact hydroforming [11]. (Color figure online)

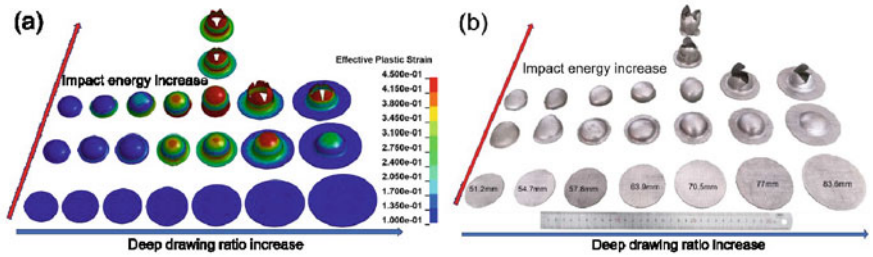

Fig. 9 The specimen of formability evaluation under impact hydroforming: **a** Solid-liquid coupling FEM; **b** Experiment of IHF [11]. (Color figure online)

corner is 5 mm, and the diameter of the chamber is 48.5 mm. As for the material, AA 2A06 is adopted considering its wide application in the aeronautic field [11].

The FEM was conducted under different impact energies and forming ratios to realize incomplete forming (with flange), complete forming (without flange), and crack. The different parts were listed as in Fig. 9a based on the solid-liquid coupling FEM. The blank can be completely drawn into the die cavity without the drawback of crack if the impact energy is large enough when the forming ratio is less than 1.77. However, the blank had the possibility to be not only completely formed if the energy was controlled reasonably but also easily cracked if the energy was little higher when the forming ratio is 1.95. The blank would crack directly if the energy was little high or incompletely deformed if the energy was not enough when the ratios were 2.13 and 2.31. The component would crack to be 3–4 parts when the forming ratio was larger than 2.02 in the same time that the energy is too high. The area of large effective plastic strain was located at the bottom and round corner of the part from the analysis of FEM. 3–5 parts were formed under each condition as used in FEM. As illustrated in Fig. 9b, the results from experiment coincide well with the one of FEM from aspects of crack features, shape, and size [11].

According to the previous FEM and experiment, the formability curve was established describing the relationship between impact engergy and forming ratio, forming height ratio, and forming ratio, which was illustrated in Fig. 10a and b. The limit forming ratios were 1.99 and 2.02 as for FEM and the experiment, respectively, which were larger than the ratio of 1.95 that is gotten from rigid punch deep drawing. Furthermore, three areas were distinguished to stand for the uncomplete forming, complete forming, and crack. At the same time, the forming height ratios were confirmed as 1.04 and 0.95 by FEM and experiment, respectively. The corresponding equations were established which stand for the relationship of impact energy, forming height ratio with forming ratio, as listed in Eqs. (1) and (2). Both of the curves and equations were very useful to quantitatively design the process of IHF [11].

$$E_{\text{impact}} = \begin{cases} -18807.21 + 38792.44 * D_{\text{ratio}} - 27104.02 * D_{\text{ratio}}^2 \\ +6488.88 * D_{\text{ratio}}^3, & \text{when} D_{\text{ratio}} \leq 1.99 \\ 800.47 + 8.35e7 * 0.00402^{D_{\text{ratio}}}, & \text{when} D_{\text{ratio}} \geq 1.99 \end{cases} \quad (1)$$

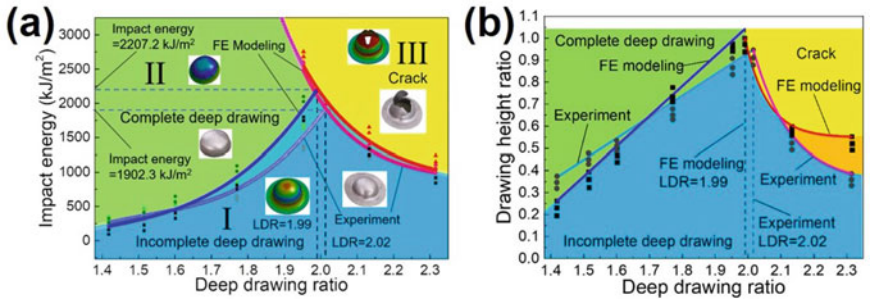

Fig. 10 The curve of formability evaluation for IHF: **a** Relationship between impact energy and forming ratio; **b** Relationship between forming height ratio and forming ratio [11]. (Color figure online)

$$D_{\text{hratio}} = \begin{cases} -1.67 + 1.36 * D_{\text{ratio}}, & \text{when} D_{\text{ratio}} \le 1.99 \\ 0.55 + 2.15E12 * (4.27E - 7)^{D_{\text{ratio}}}, & \text{when} D_{\text{ratio}} \ge 1.99 \end{cases} \quad (2)$$

3.4 The Application of IHF on the Complex Sheet Component

The complex sheet component characterizes with two chambers whose deep drawing ratio is more than 3.5, which is usually used in the aeronautic field. It is difficult to be formed by the conventional drop hammer technology because of the problems of multiple heat treatment and forming steps. The forming pressure will be more than 90 MPa and the defects of crack and wrinkle will be obvious if the common hydroforming process is employed. According to the investigation, the previous preforming and impact hydroforming are adopted as the final forming scheme of this component. The dies used for preforming and impact hydroforming are illustrated in Fig. 11a [9].

The solid-liquid coupling FEM was employed to optimize the process of IHF and the corresponding forming parameters. And the impact wave loading and the feasible liquid were applied to promote the material feeding and enhancement of the formability. Hence, the defects of crack and wrinkle were effectively avoided. The filling of the small corner of the part was especially prominent compared with the conventional forming method. And the procedure was shortened from 8 to 2 compared with the traditional drop hammer forming. The final component is illustrated in Fig. 11 [17, 18].

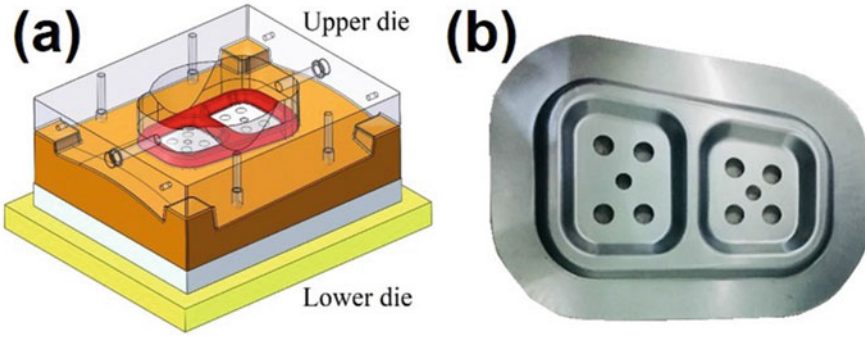

Fig. 11 The die of impact hydroforming and the deformed component: **a** Die of IHF; **b** Frame component. (Color figure online)

4 Conclusion

(1) Experimental results indicate that the fraction of strain-induced martensite increases due to the alternation of internal structure involving the internal stress and dislocation configuration when unloading occurs. It is revealed that nucleation and growth of martensite are facilitated, known as transformation induced plasticity (TRIP) under the pulsating load. Both axial feeding and TRIP effect finally contribute to the formability improvement of austenite steel.

(2) A novel high energy-efficiency IHF machine was designed and manufactured by solving the problems of energy source mode, dynamic resistance reduction, and dynamic locking of die. And a novel method was established to evaluate the dynamic formability of sheet material based on the impact hydroforming. Moreover, the complex sheet component was successfully manufactured with good surface quality and accurate size by IHF.

(3) The two novel technologies can be utilized to manufacture the components in aeronautics and astronautics, automobile, and nuclear power fields which characterize thin-wall, large size, deep cavity and complex structure.

Recent Investigations on Incremental Sheet Forming: From Fundamentals to Industrial Application Technologies

Jun Chen and Zhidong Chang

Abstract Incremental sheet forming (ISF) is a promising flexible forming process in fabricating low-batch or customized sheet metal parts, and has potentials in reduced process lead time and cost, and increased formability. In the plenary talk, recent investigations on ISF fundamentals and the technologies for ISF industrial application will be presented, which cover tool path algorithms, forming tool development, surface roughness and forming load predictions, new variants of ISF, deformation mechanism of different ISF variants, and several industrial application cases. Finally, an outlook about ISF will be made as well.

Keywords Incremental sheet forming · Tool path · Surface quality · Geometric deviation · Deformation mechanism

1 Introduction

ISF is one of the advanced flexible forming processes appropriate for small batch production of sheet metal parts. Research in the ISF field has been extended to different aspects in recent years, including forming limit, deformation mechanism, forming force, geometric accuracy, surface roughness, and tool path. Duflou et al. [1] found that the dimensional accuracy and formability for a range of materials can be improved through laser-assisted incremental forming process. Araghi et al. [2] proposed a new hybrid forming process by combining ISF and stretch forming, and indicated that noticeable reduction of cycle time and more uniform thickness distribution can be obtained. Silva et al. [3] proposed an analytical model of contact stress based on membrane analysis in the ISF process, by which the cracks were claimed to be caused by meridional tensile stress instead of in-plane shearing stress. Emmens et al. [4] presented an overview of deformation mechanisms that were suggested to explain the enhanced formability of the ISF process. Six mechanisms were suggested

as follows: contact stress, bending under tension, shearing, cyclic straining, geometrical inability to grow, and hydrostatic stress. To obtain a better understanding of the shear effect, Lu et al. [5] developed an analytical model based on the analysis of stress state in ISF deformation and proposed an explicit relationship between stress state and forming parameters. Eyckens et al. [6] investigated the straining behavior in the ISF process based on Digital Image Correlation and numerical simulation. Experimental results demonstrated that the dominant mechanism for the cone with a low wall angle is through-thickness shearing, while bending for the cone with a large wall angle. Silva et al. [7] proposed a link between plastic flow, void coalescence and growth, ductile damage, crack opening modes, and fracture toughness in ISF, and proposed an analytical framework to estimate the location of the fracture loci in the principal strain space. Duflou et al. [8] investigated the effects of tool radius, sheet thickness, wall angle, and step depth on forming load, and indicated that the slope of the force curve can be used as a failure prediction indicator. Mulay et al. [9] studied the effects of feed rate, step depth, tool diameter, and sheet thickness on surface roughness, and found that the step depth and tool diameter have significant effects on the surface roughness. Li et al. [10] investigated dimensional accuracy of straight-wall cylinders in multi-stage incremental forming based on an experiment method and mathematic analysis. Besides, some advanced materials have been applied in this field, such as titanium alloy[11], polymers [12], and composite sheets [13].

Although there have been lots of researches targeting to reveal the deformation mechanism, there is a lack of new experimental researches output in recent years. This paper attempts to present systematic investigations of the current state of the art in the ISF process over the last 2 years explored by our team, with the target of throwing light on the future development that can take place using this manufacturing process.

2 Tool Path Algorithm

Different from linear interpolation of conventional tool path, a novel quadratic spiral tool path (QSTP) generation algorithm was proposed by Chang et al. [14]. The new tool path can be generated based on the quadratic interpolation of three neighboring contour lines as shown in Fig. 1, and the points on the tool path can be obtained through the calculation of Lagrange quadratic interpolation.

For better understanding of the impact of QSTP, the thickness thinning and geometric accuracy were case-studied by forming typical parts with varied wall angles and compared with conventional spiral tool path (CSTP). Two different materials AA5052 and DC05 were used to evaluate the influences of sheet material properties. As shown in Fig. 2a, the results of two sheet materials indicate similar tendencies but with different deviations, and the part formed by QSTP has better geometric accuracy than that formed by CSTP. Thinning tendencies are similar in both parts and both materials, but better thickness distribution can be obtained in the part formed

(a)

(b)

Fig. 2 Experimental results for different sheet materials using QSTP and CSTP: (**a**) geometric deviation; (**b**) thickness thinning. (Color figure online)

by QSTP as shown in Fig. 2b. Experimental results confirm that QSTP can improve geometric accuracy, and reduce severe thickness thinning for different sheet materials compared with CSTP.

3 Analytical Prediction Model

3.1 Analytical Model of Forming Force

In order to overcome the problems of the widely used empirical models for load prediction, other than the regression method by experimental results, the new analytical models to predict the forming force were developed by Chang et al. [15] based on the analytical calculations for the contact area and the through-thickness stress. As shown in Fig. 3, the contact area is an ellipsoid crown surface, and the updated models for calculating the contact area can be developed by sliding the tool configuration along meridional and circumferential directions.

To calculate the through-thickness stress, the membrane approach was conducted as shown in Fig. 4. Along the directions of thickness, circumference, and meridian, the corresponding stress components were considered during membrane analysis. The stress components of a small element at the contact zone were analyzed for the solution of the through-thickness stress in the contact area. By multiplying the updated calculations of contact area with the through-thickness stress, the analytical force models of ISF can be represented by,=

$$F = \sigma_t S = \frac{2}{\sqrt{3}} \frac{2t}{r + 2.5t} \overline{\sigma} \frac{\pi r}{2} (h_1 + r(1 - \cos\alpha) \frac{\alpha + \arccos \frac{r - hs}{r}}{\arccos \frac{r - h_1}{r}}) \qquad (1)$$

A series of experiments of typical sheet metal parts with different geometries for different materials with varied process parameters including wall angle, step depth, tool radius, and sheet metal thickness in different typical ISF processes were used to validate the proposed analytical models. It can be seen from Fig. 5 that the predicted forces with different materials in different ISF processes are in good agreement with the measurements. It is concluded that the proposed analytical models are derived from the forming principle of ISF, have wider applicability than the empirical model,

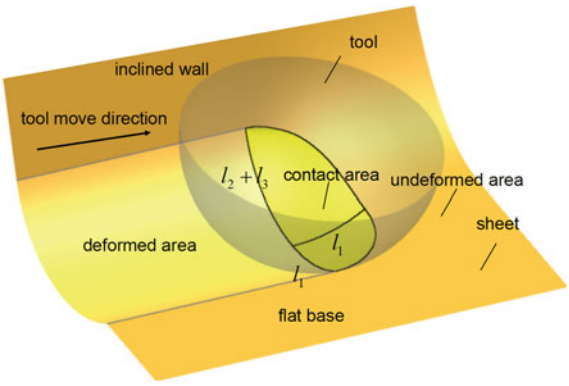

Fig. 3 Schematic illustration of contact area. (Color figure online)

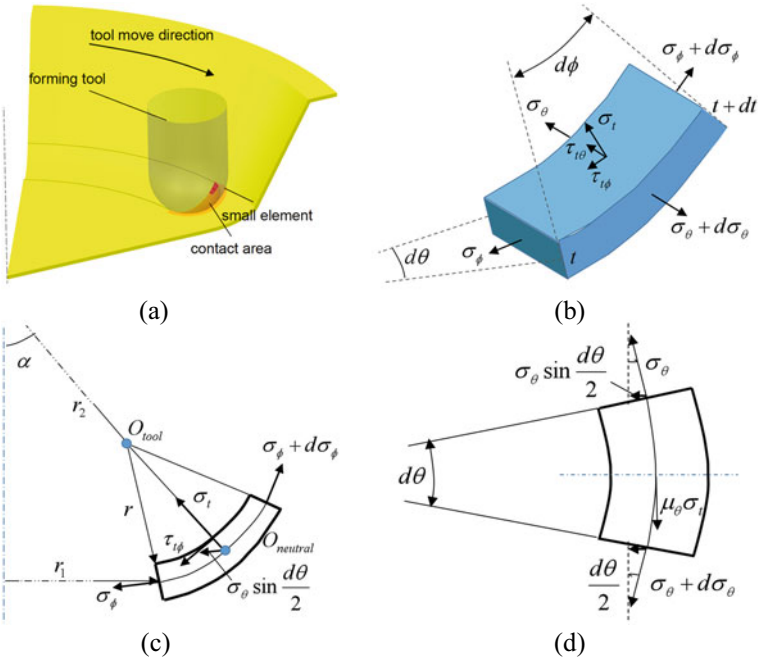

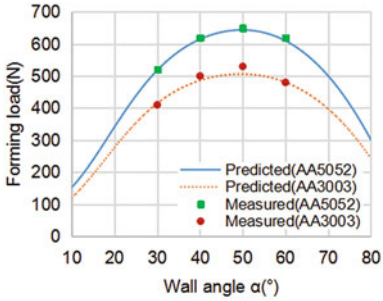

Fig. 4 Membrane approach of ISF process: (**a**) Overview; (**b**) stress components; (**c**) meridional view; (**d**) circumferential view. (Color figure online)

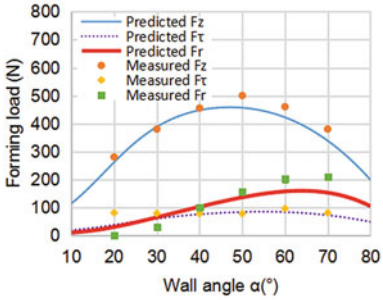
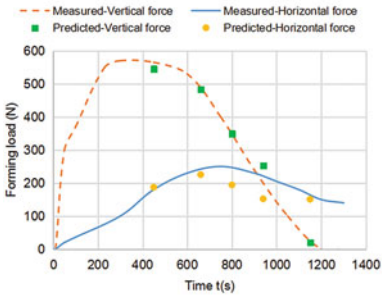
and can be used to calculate the forming force and force components along the axial, tangential, and radial directions for SPIF, MPISF, and IHF processes.



3.2 Analytical Model of Surface Roughness

In order to set up an analytical model to predict the surface roughness of the parts formed by ISF, a new mechanism about the evolution of surface roughness was assumed by Chang et al. [16] based on the forming principle of ISF as shown in Fig. 6. The "scallop" on the sheet surface is considered to be related to the uneven distribution of sheet thickness along the meridian direction, which considers elastic deflection and plastic deformation. The uneven distribution of sheet thickness under the tool head was calculated through the geometric relationship between the tool and the sheet as shown in Fig. 7. The surface roughness of the part surface can be calculated by the thickness difference of the "scallop",



$$Ra = 0.268Rz = 0.268\left(\frac{t_2}{e^{\frac{\sqrt{3}}{2}\left(\frac{1}{K}\bar{\sigma}^{B}\right)^{\frac{1}{n}}}} - t\cos\alpha\right) \qquad (2)$$

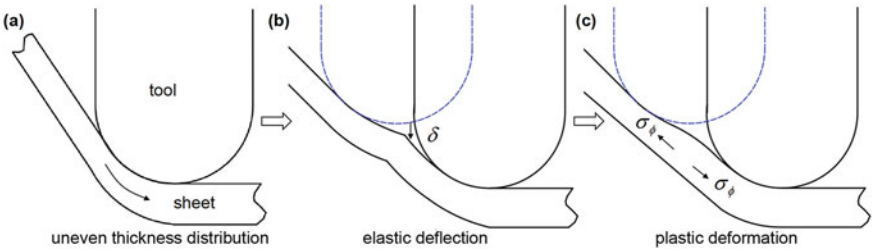

Fig. 6 Three steps of surface roughness evolution during incremental sheet forming. (Color figure online)

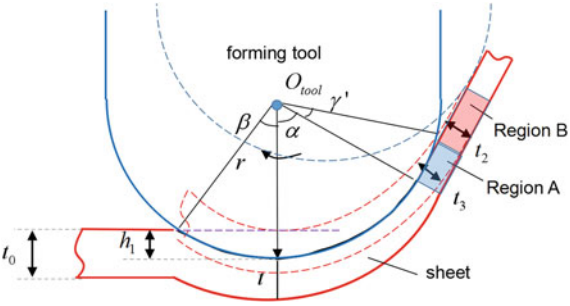

Fig. 7 Actual relationship between tool and sheet. (Color figure online)

A series of experiments for surface roughness of a conical part with varied process parameters for different materials have been conducted to validate the proposed models. As shown in Fig. 8, the predicted values of surface roughness are in good agreement with the measurements. The comparison between the calculated and measured results shows that the proposed analytical models maintain high prediction accuracy, which considered the effects of tool radius, wall angle, step depth, sheet thickness, and material properties. Besides, the new models are more accurate with wider applicability than the current geometry-based models, and can be used to calculate the surface roughness Ra and Rz under different process parameters and sheet materials.

3.3 Analytical Model of Twisting Angle

Revealing the twisting mechanism in ISF is of great importance for understanding the deformation mechanism and controlling the deformation stability. As shown in Fig. 9, the mechanism of the twisting phenomenon, proposed by Chang et al. [17], is that the uneven through-thickness stress distribution under the tool head leads to the uneven distribution of circumferential friction stress along the meridional direction, which

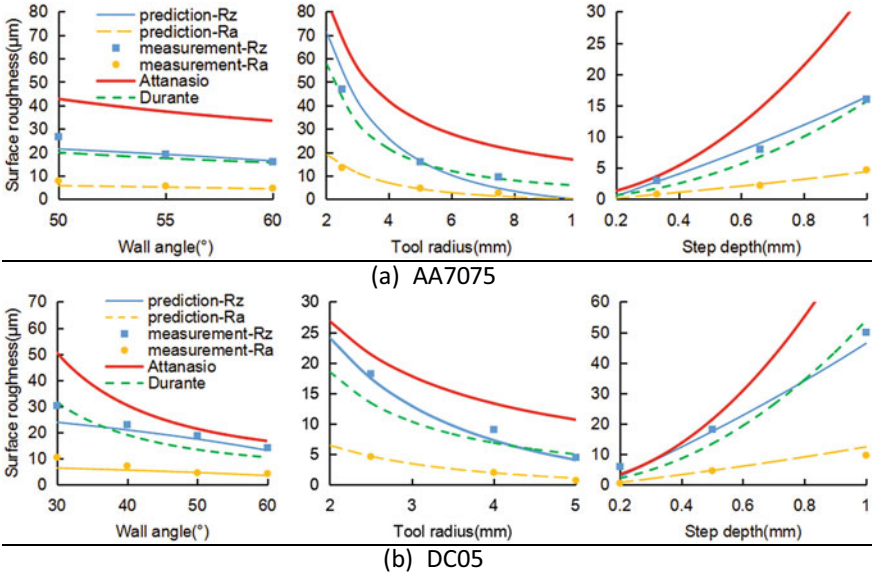

Fig. 8 Variation of surface roughness under varied process parameters for different materials. (Color figure online)

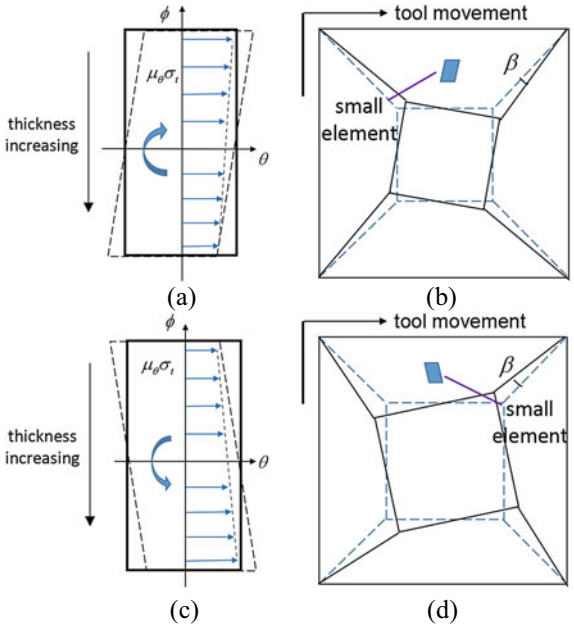

Fig. 9 Schematic view of twisting phenomena: (**a**) 40° wall angle; (**b**) forward twisting; (**c**) 65° wall angle; (**d**) reverse twisting. (Color figure online)

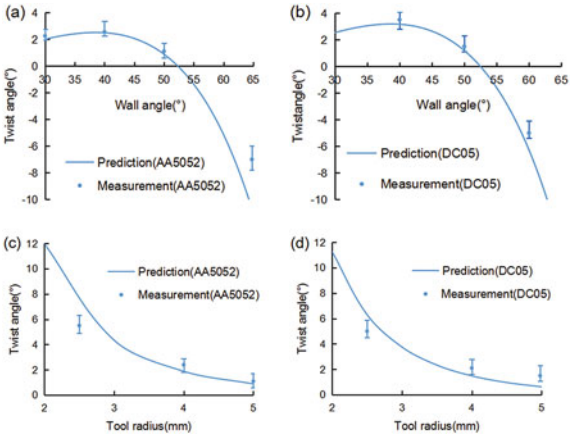

Fig. 10 Variations of twisting angle for different process parameters and materials: (**a**) varied wall angles (AA5052); (**b**) varied wall angles (DC05); (**c**) varied tool radius (AA5052); (**d**) varied tool radius (DC05). (Color figure online)

generates a torque that causes the twisting of the elements on the sheet metal. The value of dσt/dα determines the direction of the torque and the direction of twisting.

An analytical model in predicting twisting angle was developed based on membrane analysis, which can be represented as

$$\beta = \frac{\sqrt{3}\mu_\theta \ln\cos\alpha}{2}\frac{d\sigma_t}{d\alpha}$$

$$= \frac{2r_t t_o \mu_\theta \sin\alpha(\ln\cos\alpha + n) + 2.5nt_0^2\mu_\theta \sin(2\alpha)}{(r_t + 2.5t_0\cos\alpha)^2} K\left(\frac{2}{\sqrt{3}}\ln\frac{1}{\cos\alpha}\right)^n \quad (3)$$

A series of experiments on the twisting angle of truncated pyramid parts with varied process parameters and different materials have been conducted to validate the analytical model. As shown in Fig. 10, for a specified part, a small wall angle causes positive twisting angle, while a large wall angle causes negative twisting angle. It is also found that the analytical value is in good agreement with the measured values for varied process parameters and different materials, with the average numerical measurement error of 15.6%.

4 New Variants of ISF

To improve the surface quality and formability of low-ductility metallic sheets, a novel three-sheet incremental forming (TSIF) process was proposed. As shown in Fig. 11, the idea of the TSIF process is to put a target sheet with lower ductility between the upper auxiliary (UA) sheet and lower auxiliary (LA) sheet, then the three sheets are fixed together and formed by the forming tool to a geometry. The

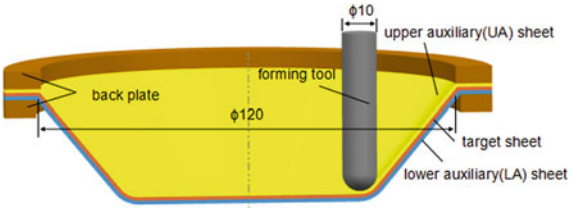

Fig. 11 Schematic of TSIF. (Color figure online)

existence of the UA sheet aims to avoid the direct contact between the tool and target sheet, and the LA sheet is prepared to provide the extra compressive stress to the target sheet and improve the stress state in the contact zone.

For better understanding forming characteristic of TSIF, the surface quality and forming limit of the target sheet were investigated by experiments for different sheet materials and compared with the conventional single point incremental sheet forming (CISF) process. As shown in Fig. 12, experimental results demonstrate that the surface roughness can be significantly reduced by an average of 80% in the TSIF process compared with that by CISF. Ra of the part formed by TSIF always keeps at a small value with the variation of step depth, indicating that the effect of step depth on Ra of TSIF is obviously less sensitive than that of CISF. Results also prove that the forming limit and fracture strains of AA2024 and AA7075 sheets can be improved dramatically with the extra compressive stress from the LA sheet, which is helpful for low-ductility sheet metal component fabrication.

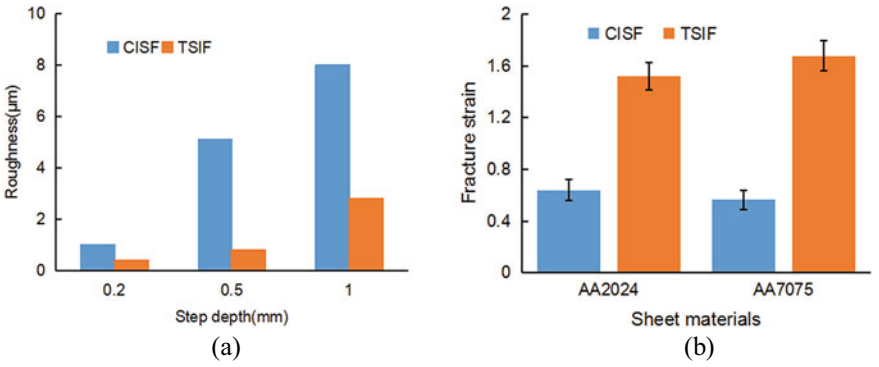

Fig. 12 Experimental results of different materials for CISF and TSIF: (**a**) surface roughness; (**b**) fracture strain. (Color figure online)

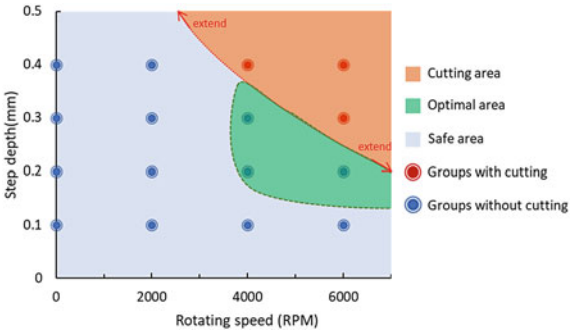

Fig. 13 Process window. (Color figure online)

5 Process Window

5.1 Formability for ISF with High-Speed Tool Rotation

ISF with high-speed tool rotation is another promising alternative for forming low-ductility sheet metals. but high-speed friction between the tool and the deforming sheet metal might cause bad surface quality, and process parameters have contradictory effects on formability and surface quality. To solve this puzzle, the effects of four factors on forming temperature and surface quality were analyzed by Wang et al. [18] through orthogonal experiments for a truncated cone with a constant wall angle of AA2024-T. A process window for ISF with high-speed tool rotation was obtained to have a higher forming temperature for better formability with reasonable surface quality. Orthogonal analysis results on forming temperature show that rotating speed has the greatest influence, followed by step depth.

By collecting the experimental results of cutting (red point) and no cutting (blue point), Fig. 13 demonstrates the safe area (blue area) and the cutting area (orange area), which shows that the ranges of rotating speed and step depth can be used to define the process window to avoid cutting. Thus, the optimal area (green area) which can guarantee high forming temperature without cutting is provided in Fig. 13. Besides, the applicability of the process window proposed was verified by another truncated cone with varied wall angles using AA2024-T and AA5052-H32. Figure 14 shows the maximum wall angle with process parameters set within the optimal area, and the formability of two aluminum alloy sheets was improved.

5.2 Geometric Deviation

One of the key challenges for ISF is geometric accuracy, especially for complex sheet metal parts. A typical non-axisymmetric part of AA5052 with the stepped feature

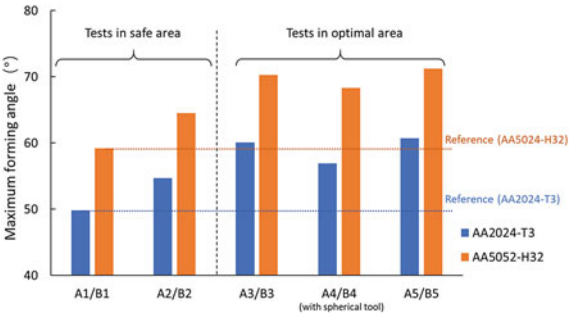

Fig. 14 Measured maximum wall angles of AA2024-T3 and AA5052-H32. (Color figure online)

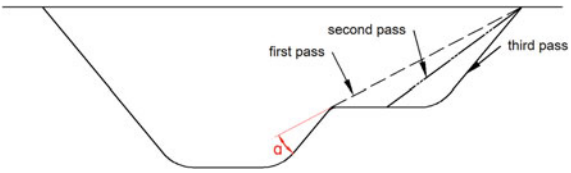

Fig. 15 Three-pass ISF of the stepped feature. (Color figure online)

was studied by Dai et al. [19] through orthogonal experiments with 4 parameters in 4 levels to determine the optimal process parameters for better geometric accuracy.

Three-pass ISF was developed to form the stepped feature as shown in Fig. 15. An attempt was made to change the forming process sequence, in which the stepped flank is formed prior to the stepped plane, and later the stepped plane is formed in several passes. Experiments demonstrate that a larger angle is helpful in subsequently forming the upper sidewall and the stepped plane, respectively.

To further improve the local geometric accuracy, the angle of the stepped flank and the height of the stepped plane need to be compensated in Multi-pass ISF. Based on the local geometric deviation and the deflection mode at the corner between the stepped plane and the stepped flank, the compensation scheme of the intermediate configuration in each pass is shown in Fig. 16. Based on the proposed methodology, the geometric accuracy of the non-axisymmetric part with the stepped feature has been obviously improved, particularly at the stepped feature as shown in Fig. 17.

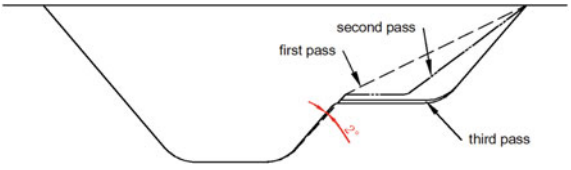

Fig. 16 Compensation scheme of the intermediate configuration for each pass. (Color figure online)

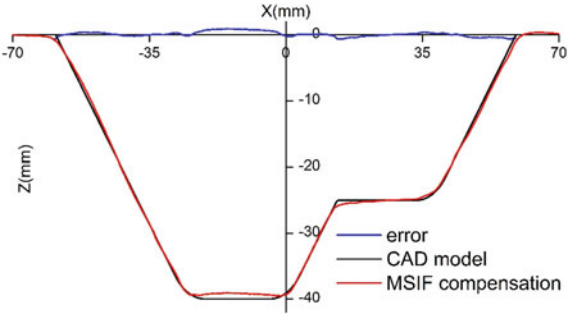

Fig. 17 Sectional profile and the error of new multi-pass ISF with toolpath compensation. (Color figure online)

6 Outlook

A systematic review of the latest developments of the ISF process was conducted, and this provides a feasible direction for future research. The process fundamentals in terms of process window, analytical models, tool paths and new variants of ISF were systematically introduced. The new tool path and variants of ISF have the capability of extending the process window for industrial application and obtaining parts with some specific requirements. Analytical models developed based on membrane analysis have the ability to accurately predict the forming force, surface roughness, and twisting angle, and provide feasible solutions to better control the forming quality of parts formed by ISF. The investigations on the process window are significant for improving the formability and geometric accuracy of sheet metal for further industrial application. The application of ISF has increased significantly, which will provide directions for the development of flexible industrial systems based on ISF.

The Effect of Ultrasonic Vibration on Material Movement in Incremental Sheet Forming

Randy Cheng, Ankush Bansal, Jiarui Kang, Xun Liu, and Alan Taub

Abstract Applied mechanical vibration in various manufacturing processes, usually at ultrasonic frequencies of 20 kHz, has been shown to influence the forming and friction forces. The material softening behavior under superimposed ultrasonic vibrations is known as acoustoplasticity. This paper investigates the effect of acoustoplastic softening phenomenon on material movement in incremental forming of AA7075 sheets. A 45° cone is formed using a two-point incremental forming strategy (TPIF). Added ultrasonic vibration shows higher amount of material movement, which is supported through quantitative measurements including greater bulge height, surface profilometry, and thickness distribution around the tool contact area. Surface roughness measurements, relative to the depth of the geometry, increase with progressive forming. This coincides with the notion of greater material movement, accumulation, and surface deformation.

1 Introduction

Incremental sheet forming (ISF) has garnered interest for its unique manufacturing advantages such as design flexibility and increased formability of sheet metal parts [1]. The process involves a hemispherical-ended tool which travels along a tool path and locally deforms a blank until the desired 3D geometry is completed. Typical

manufacturing machinery, such as CNCs, lathes, and robotic arms, can implement an ISF strategy utilizing already existing G code generating software and standard fixtures. Single-point (SPIF) and two-point (TPIF) incremental forming are covered in this work [1, 2]. SPIF does not require a die which aids in its flexibility. TPIF uses partial or half-dies to aid in supporting the sheet; this prevents additional plastic deformation away from the local contact area. The tool can also push the sheet against the die, referred to as squeeze, effectively changing the through thickness strain.

With all deformation processes, adjustments are usually required depending on the material and the design to satisfy product outcomes. The agile attribute in ISF arises from its ease of modifying the tool path which leads to quick turnaround times compared to stamping or hydroforming [3]. Higher formability in ISF can be achieved as instability and necking are suppressed from the localized nature of the deformation [1]. Although ISF offers these advantages, the process also has some compromises. Local deformations on the sheet surface leads to added tribological wear and higher roughness compared to conventionally formed parts [4]. Furthermore, unlike stamping where springback predictive models are available, ISF still requires tool path adjustments to obtain comparable dimensional accuracy [1, 2, 5].

A multitude of assistive methods have been proposed to address these process constraints [5–7]. Ultrasonic vibration assistance is a new method which takes advantage of acoustoplasticity. Langenecker and Blaha [8] first experimentally demonstrated the acoustoplastic effect (APE) during tensile deformation of aluminum and zinc crystals and noted large reduction in force. Langenecker [9] proposed an acoustic energy interaction with pinned dislocations leading to a reduction in flow stress. This phenomenon was later coined as acoustoplasticity. Various reports have illustrated a compelling argument for this softening phenomenon. Siu et al. [10] conducted hardness tests with ultrasonic excitation perpendicular to the loading axis and showed an increased plastic zone and subsequent increase in low angle grain boundary formation. Kang and Liu [11] conducted tensile experiments on pure copper with an ultrasonic excitation parallel to the loading axis. The deformed microstructure displayed a reduction in stored dislocations in grain interiors and greater geometrically necessary dislocations located near grain boundaries. Zhou et el. observed similar stress reduction effects correlated with ultrasonic vibration amplitude and frequency [12]. After a period of ultrasonic activation, the material, loaded quasi-statically in compression, may exhibit residual softening or hardening. Based on the reported work, there is substantial evidence to support the notion that ultrasonic vibration impacts the resulting microstructure and therefore, the deformation behavior.

The application of acoustoplasticity in ISF has been limited. Amini et al. [13] performed ultrasonic-assisted incremental forming (UA-ISF) on AA1050 with a straight groove geometry and noted improvements in formability, reduction in forming forces, and improved springback. Cheng et al. [14] performed ultrasonic-assisted SPIF and TPIF on AA 7075. In those experiments, the effectiveness in SPIF operations was minimal which was attributed to a loss in transmission of acoustic

energy to elastic vibration of the sheet. The UA-TPIF process showed force reductions of 11–18% accompanied by thickness reductions in the formed parts. The literature has yet to address the acoustoplastic effect on material movement, geometric accuracy, and roughness.

We examined three ISF variants: SPIF, TPIF, and TPIF + UA. The effect of ultrasonic vibration on the in-plane forces and on material movement was quantified through measurements of the bulge height, approximated from surface profilometry, and from the thickness distribution around the tool contact area at the end of the forming process.

2 Experimental Setup

Incremental forming experiments were performed on a Cincinnati HMC 400-EP CNC milling machine. A truncated cone die, with a wall angle of 45°, was selected for two-point incremental forming (TPIF) experiments. A hemispherical-ended tool with 8 mm diameter was employed to deform 1.63 mm thick AA 7075 sheets. The sheets were cut out into 200 × 200 mm blanks and held at the edges using a binder plate as shown in Fig. 1. An internal piezoelectric ceramic generates the ultrasonic frequency in the device, and an operating frequency of 20,200 Hz is maintained by a Dukane iQ-LS series wave form generator. Additional information regarding ISF parameters are listed in Table 1.

A multi-squeeze tool path strategy illustrated Fig. 2a was employed to investigate the effect of squeeze factor *SF* on part fabrication. The sine law, shown in Eq. 1, is typically used to estimate the final thickness, t_f, of the sheet in ISF forming, given the forming angle, α [1]. In TPIF, the squeeze factor is defined as the extra displacement

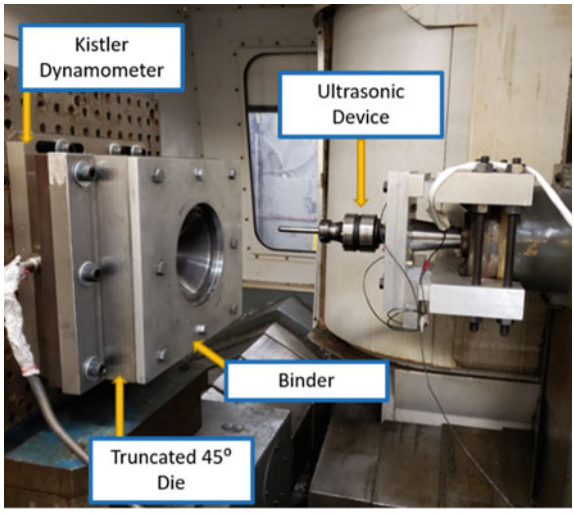

Fig. 1 Incremental forming setup. Ultrasonic input is supplied using a 20 kHz, Dukane generator. The ultrasonic device is held a custom clamp fixture. A conical 45° sits on a Kistler force dynamometer. (Color figure online)

Table 1 Incremental forming parameters

Feed rate	42.3 mm/s
Step size	0.25 mm
Spindle rotation	Locked

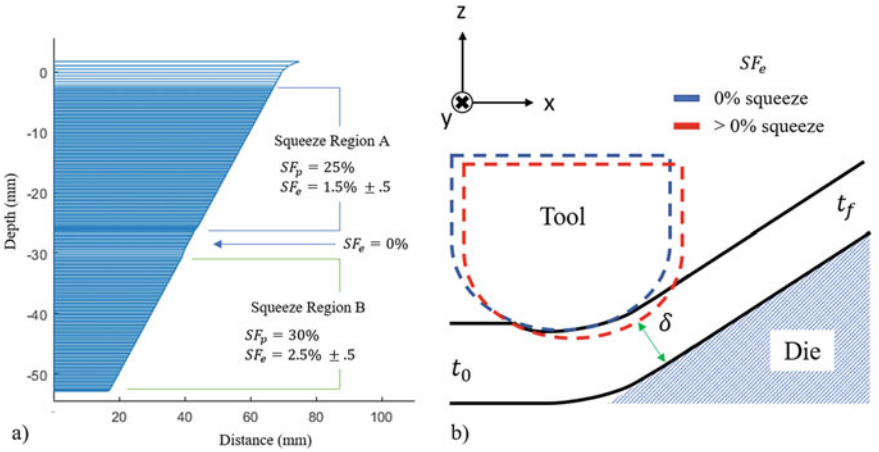

Fig. 2 Geometric illustrations for tool path strategy and programmed squeeze. **a** tool path representation showing squeeze region A, squeeze region B, and the transition in between. **b** Visual representation of effective squeeze. (Color figure online)

of the tool into the sheet, defined as the percentage of the final thickness (t_f) that is squeezed between the tool and die surfaces. A visualization of programmed squeeze is presented in Fig. 2b. The programmed squeeze factor, SF_p, is defined as in Eq. 2 [15]:

$$t_f = t_0 \cdot \sin(90 - \alpha) \tag{1}$$

$$SF_p = \left(1 - \frac{\delta}{t_f}\right) \cdot 100 \tag{2}$$

δ represents the intended distance of the tool, from die surface. A $SF_p = 100\%$ is when the tool is programmed to touch the die surface and a $SF_p = 0\%$ implies that there is no material being squeezed. The tool path strategy, Fig.2a, uses two regions of programmed squeeze factors, designated as regions A ($SF_p = 25\%$) and B ($SF_p = 30\%$). It is important to note that the programmed squeeze in the tool path

is not the same as the actual squeeze which is referred to as the effective squeeze, SF_e. Bansal et al. [15] showed that the tool deflection and machine compliance have a large impact on squeeze. The effective squeeze factor can be represented through Eq. 3. If the sum of the desired squeeze, δ, and deflection from machine compliance and tool deflection, Δ, is larger than t_f, the sheet is not being squeezed. In this case, a negative SF_e can be thought of as a degenerative SPIF.

$$SF_e = \left(1 - \frac{\delta + \Delta}{t_f}\right) \cdot 100 \tag{3}$$

Δ is the compensation factor for machine compliance and tool deflection.

The effective squeeze in our TPIF experiments ranges from $SF_e = 1 - 3\%$. Squeeze region A has a squeeze factor $SF_e = 1.5 \pm .5\%$ and squeeze region B has a squeeze factor of $SF_e = 2.5 \pm .5\%$. These squeeze factors will be referred to as $SF_e = 1.5\%$ and 2.5% for brevity. The effective squeeze factors were chosen based on the previous work of Bansal et al. [15]. There are two methods of verifying a positive effective squeeze factor. First, TPIF parts formed with $SF_e = 0\%$, like in SPIF, have an orange peel surface finish on the side of the sheet facing the die [16]. With$SF_e > 0\%$, the surface finish will be similar to that of the die surface. Second, the forming force should be greater when the sheet is being squeezed. Both conditions are satisfied in the TPIF experiments in this study.

A Hexagon laser CMM, 7525SI series, was used to measure the wall angle of the incrementally formed parts. The cross-sectional data was extracted using Polywork's inspection software. Surface roughness and profilometry data were measured on an Olympus DSX510 optical microscope.

3 Results and Analysis

The planar forming force is the resultant X and Y force. Figure 3 shows the planar forming force for the three conditions: SPIF, TPIF, and TPIF + UA. The initial increase in force, 100—200 s, is where the tool first contacts the filet region of the die. This is a common transient region, and the force stabilizes when the tool reaches a constant 45° wall angle which is referred to as the steady state. The average steady-state force in SPIF is roughly 300 N and the forming force for both TPIF and TPIF + UA conditions is greater, as expected. In the first squeeze region, $SF_e = 1.5\%$, the steady-state force is 550 ± 100 N. The spread in force is due to a slight eccentricity in the die. This minor deviation from a perfect 45° cone create sregions with slightly higher and lower squeeze so a range is provided. The planar force increases from $SF_e = 1.5\%$ to $SF_e = 2.5\%$ squeeze factor. The + UA planar force gradually increases in $SF_e = 1.5\%$ region and sharply increases in the higher $SF_e = 2.5\%$ region. The forming process of the + UA specimen was stopped at a lower depth to avoid damage to the tool/die. In the transition region between the two squeeze

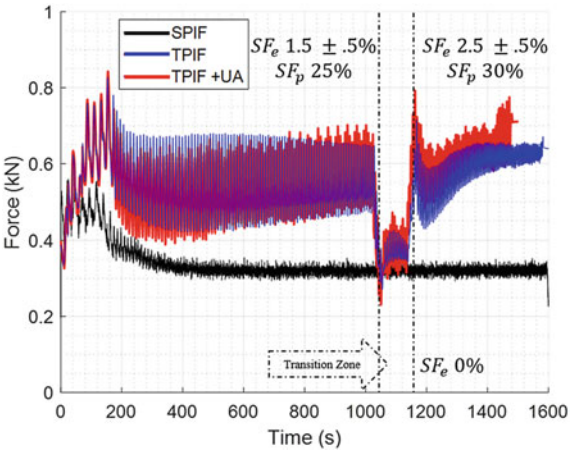

Fig. 3 Planar forming force of incrementally formed specimens in SPIF, TPIF, and TPIF + UA variants. The tool path strategy applies two regions of programmed squeeze with a gradual transition in between. (Color figure online)

conditions, the tool retracts to $SF_e = 0\%$ over several tool passes, forms the sheet at $SF_e = 0\%$, and gradually increases the squeeze to $SF_e = 2.5\%$. The forming forces during the transition region maintain a similar range of values as that during SPIF.

Geometric accuracy was measured from laser CMM profiles and EDM cut cross sections in Fig. 4. The sheet experiences some springback along the bend around −

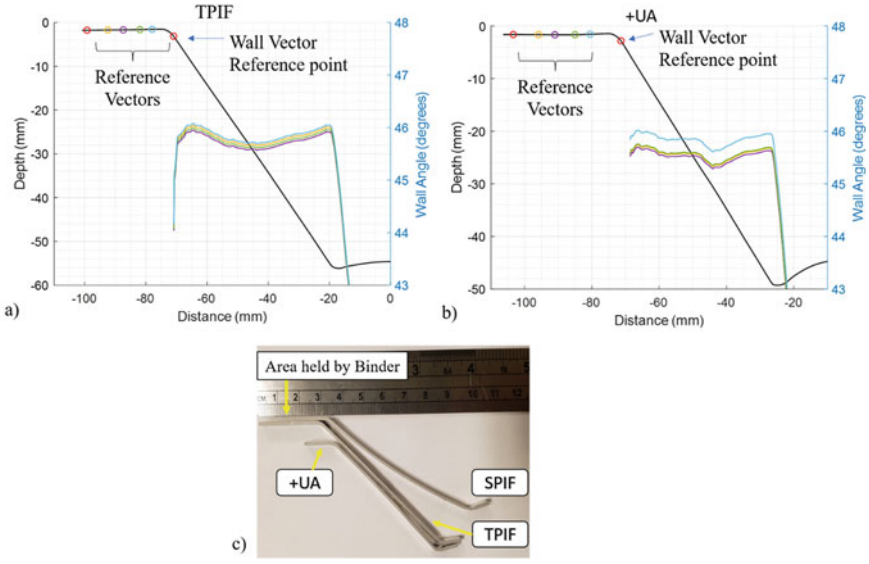

Fig. 4 Comparing wall angles of cross-sectioned ISF specimens **a** TPIF wall angle relative to the depth of the part, **b** + UA wall angle relative to the depth of the part, and **c** cut cross sections of ISF parts after forming. (Color figure online)

75 mm. Therefore, several reference vectors along the binder of the sheet were used as indicated in Fig. 4a, b. The wall vector is calculated using a point along the depth of the wall with respect to the fix point at -70 mm. The UA specimen has an average wall angle of 45.5° ± 0.2 and the TPIF specimens has a wall angle of 45.7° ± .3. The SPIF wall angle was comparable to the 45° designed tool path prior to cutting; however, after cutting, the specimen cross section curves upwards from releasing stored residual stress as shown in Fig. 4b.

In incremental forming, the sheet locally conforms to the concavity or shape of the tool due to the localized plastic deformation. This creates wavy-like surface features, which are referred to as scallops as shown in Fig. 5a. The SEM images show a higher density of flake-like features in the TPIF surface and more defined tool striation lines in the + UA specimen. Figure 5b is a cross-sectional representation of these scallop features. The spacing of the scallop feature are related to the step size (Δz) and forming angle (α) by $\Delta z/\sin(\alpha)$. This equates to a spacing of roughly 350 μm. Roughness measurements should exclude this periodic feature. A cutoff frequency of 350 μm was found to be sensitive to roughness values at the peaks, so a smaller cutoff wavelength of 80 μm was used instead. The surface roughness relative to the forming depth is plotted in Fig. 5c. The + UA specimen has a higher roughness throughout the depth of the sample. The SPIF shows relatively consistent roughness with respect to forming depth while the TPIF and + UA roughness slightly increase relative to depth.

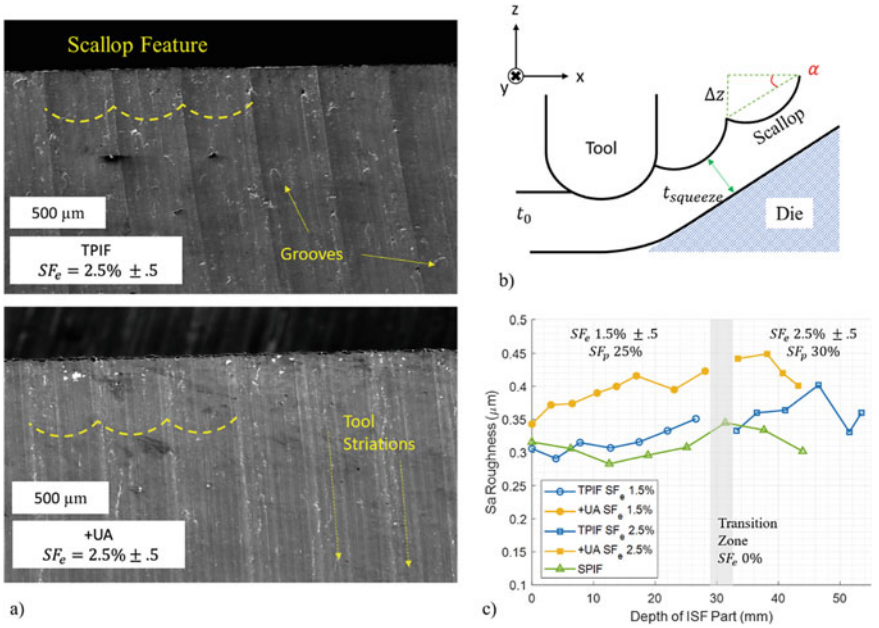

Fig. 5 Surface measurements **a** SEM images of TPIF and + UA surface indicating scallop geometry and spacing,**b** cross-section diagram of scallop feature, and **c** surface roughness, Sa, measurements relative to ISF part depth. (Color figure online)

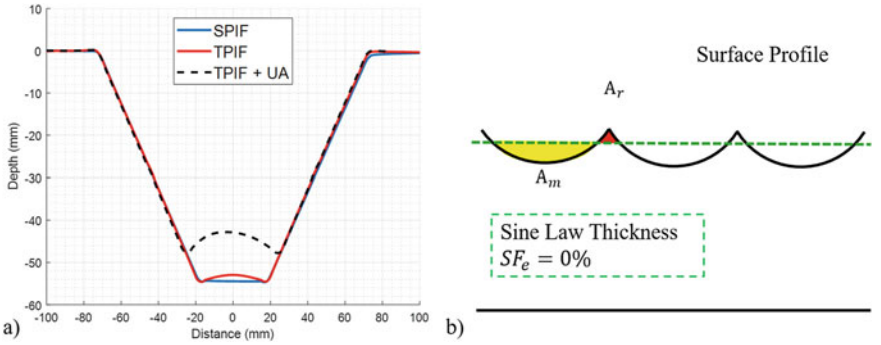

Fig. 6. **a** Cross sections extracted from laser CMM scans of pre-cut ISF parts, **b** representation of material movement in ISF given that Am > Ar. (Color figure online)

Cross-sectional scans, shown in Fig. 6a, indicate the presence of a geometric defect called a bulge at the bottom of the part. The + UA specimen has a bulge height of 4.90 mm while the TPIF bulge height is 1.61 mm. Jae et al. [17] suggested that material is moved forward in incremental forming operations under sufficient amount of squeeze, leading to a bulge. They quantified the moved material by taking the difference in thickness relative to the sine-law thickness for an individual scallop represented in Fig. 6b. If the area in the region above the line of the sine law, Ar, is equal to the material below the sine law, Am, the effective thickness coincides with the sine law. Assuming material conservation, Am > Ar indicates the material had been pushed ahead of the tool. With each Δz increment, the material is continually pushed toward the center of the part and accumulates ahead of the tool. To approximate the total amount of material moved, the area, Am-Ar, is multiplied by the number of tool passes or the number of steps in the depth direction. Using this method, material accumulation was calculated using an average Am-Ar value taken from three points in each squeeze region and plotted in Fig. 7a. As shown with the TPIF specimen, with increasing squeeze, the total volume of moved material increases. Adding ultrasonic vibrations increases the material accumulation in the $SF_e = 1.5\%$ region. Since the + UA forming was stopped at a smaller forming depth, an equivalent approximation was calculated for TPIF at $SF_e = 2.5\%$. Adding ultrasonic vibration also shows a greater amount of material accumulation in the $SF_e = 2.5\%$ region. Material accumulation can be compared using measured cross sections. The last tool contact region from the cross sections in Fig. 6a was overlayed and plotted in Fig. 7b. This cross section can be partitioned into three regions: bulge, tool contact, and wall regions. Along the wall region, both samples have a similar $t_f = 1.15\text{mm} \pm 0.02$. The thickness in the bulge or center region of the part is equal to $t_0 = 1.63\text{mm} \pm 0.01$. The thickness in the tool contact region shows a gradient between t_0 and t_f. The thickness distribution of the + UA is greater than the TPIF sample around the tool contact area suggesting greater material accumulation. A macroscopic image of each part is shown in Fig. 8. The parts in Fig. 8 are flipped upside-down and the die-side of the sheet is being shown. Both parts show evidence of squeeze as machining marks,

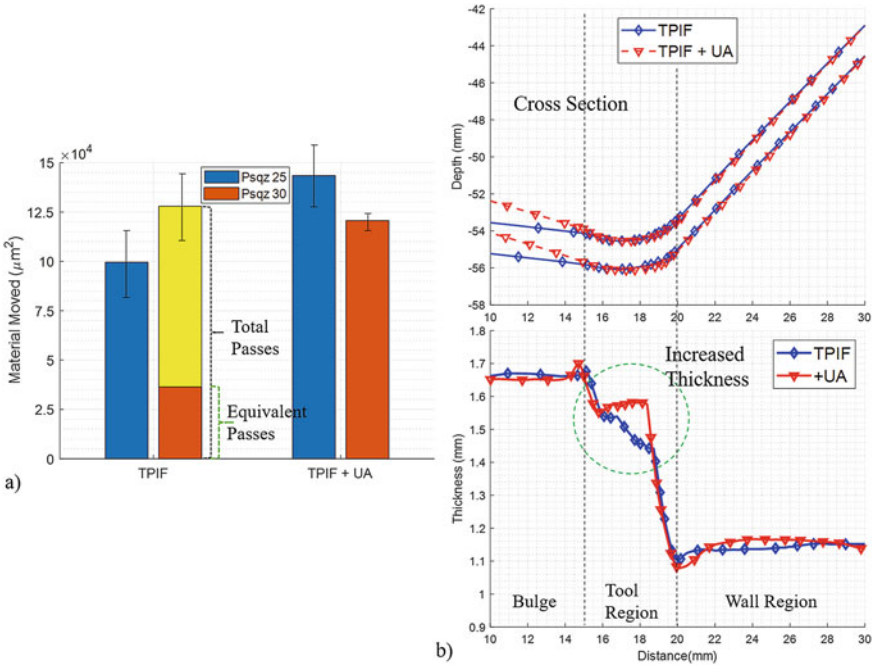

Fig. 7. **a** Material accumulated in TPIF and + UA specimens within their respective squeeze regions, **b** thickness distribution around the tool contact region of the last pass. Squeeze region $SF_e = 2.5\% \pm 0.5$. (Color figure online)

from the die, are imprinted onto the die-side of the sheet. The bulge is evident based on the depression shown in Fig. 8b.

4 Discussion

The geometric accuracy of ISF parts were measured using laser CMM scanning and post-cutting measurements. All parts achieved close to the desired 45° taper in the pre-cut measurement. Once cut, the stored residual stress is relieved, and the wall angle is measured again. TPIF and + UA specimens retain the desired wall angle while the SPIF part shows considerable springback. Springback occurs when a residual stress gradient is present in the specimen. Since TPIF and + UA utilize the back support of the die, both surfaces of the sheet can experience compressive deformation in the through thickness direction when squeezed. In single-point forming, the sheet's "die-side" experiences tensile stresses while the tool-side experiences compressive stresses underneath the tool, similar to bending. Upon cutting, the stored tensile and compressive forces cause the cross section to bend upwards.

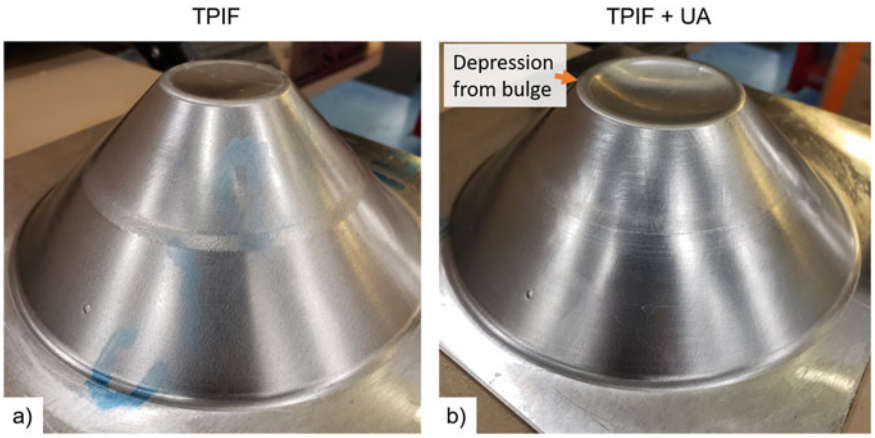

Fig. 8 Two-point incrementally formed cones **a** with effective squeeze and **b** with ultrasonic vibrations. (Color figure online)

From the planar force data, it is shown that both TPIF and + UA specimens achieved a positive effect squeeze as indicated by the greater forming force relative to SPIF. Increasing the squeeze from $SF_e = 1.5\%$ to $SF_p = 2.5\%$ increased the planar forming force as expected. The TPIF forming force was maintaining a steady mean force within their respective squeeze factor. Adding ultrasonic vibrations leads to a gradual increase in planar force in both squeeze regions. This was attributed to the formation of a macro-defect feature called a bulge. Through laser CMM scans, the + UA specimen has a larger bulge height compared to the TPIF specimen. The maximum bulge height values are 4.9 mm and 1.6 mm for + UA and TPIF samples, respectively.

The bulge formation is correlated to material movement in ISF. The sheet conforms to the geometry of the tool through the localized deformation and creates a surface feature called a scallop. In the conditions where the effective thickness of one scallop deviates from the sine law, as shown in Fig. 6b as $A_m - A_r > 0$, material must have been moved based on the material conservation law. Approximating the net material movement based on scallop geometry suggests a positive correlation with increasing squeeze. The addition of ultrasonic vibration creates deeper scallops and therefore greater material movement. Material conservation theory suggest that the displaced material should accumulate at the bottom of the part. This coincides with the gradual increase in force. With every pass, the material ahead of the tool continues to build and therefore, the force increases. The greater thickness around the last tool position in + UA sample compared to the TPIF sample supports this notion.

Coinciding with increased material movement, both TPIF and + UA samples show a slightly increasing surface roughness relative to forming depth. This is expected as greater material deformation leads to higher roughness. Maintaining same process parameters, the added ultrasonic vibration showed different outcomes of the ISF

formed parts. The results suggest that added vibrations led to greater material movement as shown by the larger bulge height and greater thickness distribution around the last tool contact area. Although the planar forming forces did not indicate acoustic softening, effects of ultrasonic vibration are reflected on the material movement. The application of ultrasonic vibrations has previously been shown to reduce forming force [14]. However, this work suggests that adding ultrasonic vibration can lead to differences in part outcomes without direct force reductions. In the same conclusion, effects of the acoustoplasticity phenomenon on ISF process closely depend on the specific forming conditions. A few key areas will be addressed in future work. Specifically, equivalent transmission of acoustic energy needs to be studied and compared to uniaxial tensile test + UA in literature. The effects of tool diameter, feed rate, and step size are all related to the total acoustic energy transmitted during incremental forming. This should further expand our understanding of how to utilize the acoustoplasticity phenomenon.

5 Conclusion

In this work, the effect ultrasonic vibration on material movement in incremental sheet metal forming was studied. Three variants of ISF were explored: single-point (SPIF), two-point (TPIF), and two-point with aided ultrasonic vibration (+UA). The + UA specimen showed a gradual increase in force with progressive forming. This greater forming force is due to an increase in material movement, resulting in the formation of a macro-defect called a bulge. The material moved is represented by the difference in thickness between the sine law thickness and measured thickness. Several quantitative measures support the increase in material movement with added vibration including the greater bulge height, approximated material movement from scallop profiles, and a greater thickness distribution from the last tool contact area. In addition, the surface roughness increased with progressive forming.

Investigation of an Integrated Process for Bending and Cross-Section Forming of Tubular Lightweight Parts Based on a Working Media Made of Materials with High Plasticity

Matthias Hermes and Viktor Holstein

Abstract Thin-walled steel profiles are the key to cost efficient lightweight structures. Structure parts and design elements in cars and trucks are often based on curved and hydroformed profiles. The possible production chains for those parts are often long and complex, and the machines and tools are expensive, and the flexibility is low. For smaller production lots, e.g., for applications in aircraft industry, these processes are not efficient. This paper shows a solution for smaller and middle-sized production lots realized by an integrated process for bending and cross section forming of tubular lightweight parts by a forming operation based on a working media made of metal alloys with high plasticity. The paper shows the process idea, fundamental mechanisms, the process analysis, and the process limits. Furthermore, a strategy is given to find a practical process windows.

Keywords Tube forming · Roll forming · Profile bending · Hydroforming · Lightweight design · High strength steel

1 Introduction

Hydroforming has been an important production technology for many years. The basics are explained in [1]. Complex thin-walled lightweight components, for example, for automotive applications, can be produced in one process step on special hydroforming presses. For smaller parts, this technology is often inefficient because of high machine costs and the relatively high process time. Moreover, the process parameters pressure axial force and positioning of the axial punch tools have to be controlled simultaneously. The preliminary process development for each work piece is difficult, and a lot of simulation and experimental work has to be done to

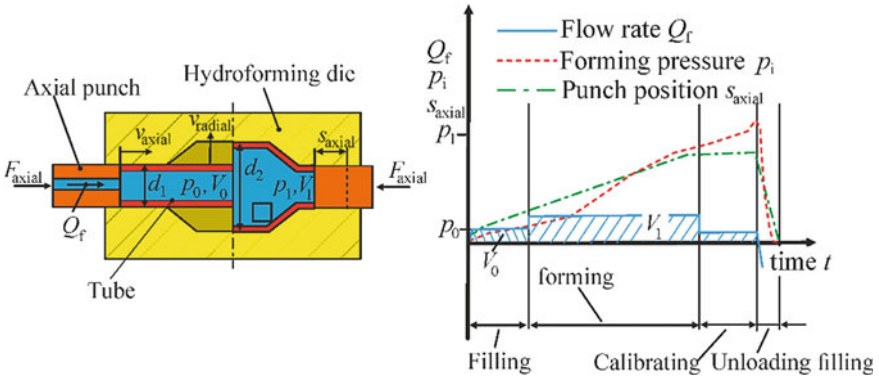

Fig. 1 Complex process parameters of a simple THF process. (Color figure online)

find a robust process window. In Fig. 1, the process parameters for a simple tube hydroforming (THF) are shown. Typical curves describe the interaction between the flow rate Q_f of the filling medium, the forming pressure p_i, and the axial position of the punch s_{axial}. Because of this complexity, it is not efficient to use THF for smaller production lots. But the trend in future production industry is to realize a flexible production down to batch size one. Another problem is hat the process chain for THF parts does not end with the THF process. Often preliminary bending or preforming steps are necessary to get the final work piece. Looking at the interesting geometries that can be manufactured with THF, a solution for smaller production lots with a simple tool design and a robust process behavior should be found. An interesting idea is shown in [2]. The work describes investigations for the use of granular medium for a hot THF process. The process idea seems to be interesting, but the granular medium has complex behavior in its inner pressure distribution. This has to be calculated to get a sufficient forming result.

Moreover, the idea explained in [3] is interesting as well. The new draw forging process couples deep drawing and cold forging in one process. It combines a sheet blank (e.g., steel) with a cylindrical core (e.g., aluminum). The sheet material defines the surface properties of the component. Inspiring is the use of two different materials and two different forming operations in one hybrid process design.

Those hybrid and flexible process designs are the vision of the modern production technology, especially metal forming technology. This paper shows a forming process for tubes that does use the combination of a THF process and a bulk metal process.

2 Process Idea and Pre-investigations

The process idea is based on different thoughts regarding problems of existing processes for common THF processes. The Idea is to use metal alloys with low melting temperatures instead of water and create a quasi-bulk metal part. This method

has been in use for bending for many years, e. g., in the field of music instruments production. The new idea is to combine the bending step with an axial tube forming process to get complex tubular lightweight parts in one production step. The plastic material works in the first step as a plastic mandrel to protect the cross section of the tube of necking in and wrinkling; at the following tube forming step, the plastic material in the tube is used as a working media. For that, it is compressed by axial punches and forms the tube into a closed die geometry. Finally, the working media is heated together with the finished work piece and is melted out of the hollow structure. Some opportunities of this process idea compared to conventional THF can be expected:

- Less sealing problems because the working media is made of solid material.
- The process should be more robust than THF. The typical effect of THF is that the thinnest or weakest area of the shape shows at first a local thinning. That should not occur with TFPW because of the solid core that should show a homogeneous forming.
- Material should behave like a bulk metal forming part, so less wrinkles should occur.
- No complex and cost intensive control system gives the opportunity to use the process as a "low budget hydroforming process", e.g., for lower production batches.

At first, a concept how such process chain of a TFPW (Tube forming with plastic working media) can be realized. So in Fig. 2, a thinkable process chain is explained in detail: The first step is coating the inner and outer tube wall to define the friction behavior and to reduce abrasive contact of the outer tube wall with the die. Different types of coatings were investigated: silicone oil, a graphite alcohol mixture, Molikote MoS_2 grease, lubricant varnish C 220, and a pure PTFE-foil.

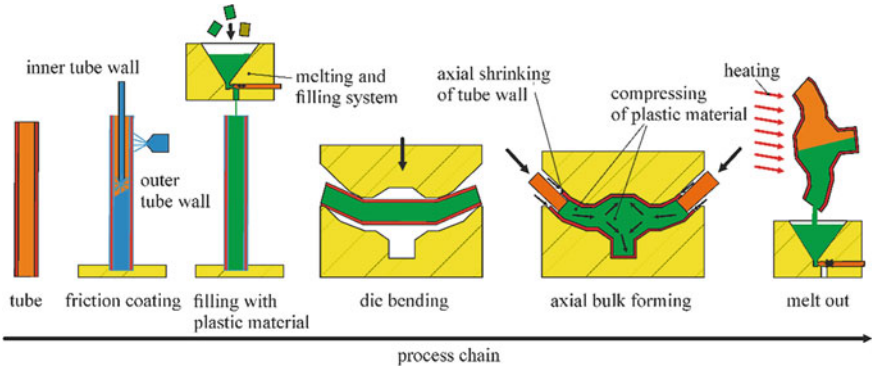

Fig. 2 Process chain for new process chain of tube forming based on a working media made of materials with high plasticity. (Color figure online)

The next step is the filling of the tube by a special melting and filling system. Because of the low temperatures, it is easily possible to use a simple valve system for that. Different alloys were investigated and the ideal for typical technical materials are:

- 75Sn25Bi (melting point at about 182 °C, for copper and aluminum alloys)
- 72Bi28In (melting point at about 115 °C, for mild steels like S 235)
- 100Bi (melting point at about 271 °C, for stronger materials like high-strength steels and stainless steels).

(It is alternatively possible to use preliminarily cast cylindrical cores made of the material that fit to the inner diameter of the tube, and mount it by sticking the core into the tube.) After that, the filled tube is cooled down to room temperature and installed into the die that has similar design like a THF die. The die can be closed without collapsing of the tube cross section because of its quasi-bulk metal behavior. The cross section can be preformed by that. The die has to be closed by a high force built up by a hydraulic press or a similar system. The next step is the axial compression of the inner material from both sides of the tube ends by hydraulic driven punches. At the same time the tube wall moves driven by friction between the tube and the core into the forming zone together with the plastic filling material that works like a working media. When the die geometry is filled with the tube wall and the inner material, the die can be opened and the work piece is heated. Because of the low melting point, the inner material runs out of the hollow shape back into the filling system and can be used for the next part.

In Fig. 3, some early results are shown. These experiments were done to realize a proof of concept. In the left picture, two double-wall tubes were bent by rotary draw bending. To reduce the cross section deformation in one tube, sand was used as filling material. For the second tube, 75Sn25Bi was used to fill the complete cross section of the double tube. This work piece was investigated for aircraft industry and shows the positive effect for bending with such filling materials very well. The sand-filled tube has wrinkles on the inner bending radius, while the second tube has

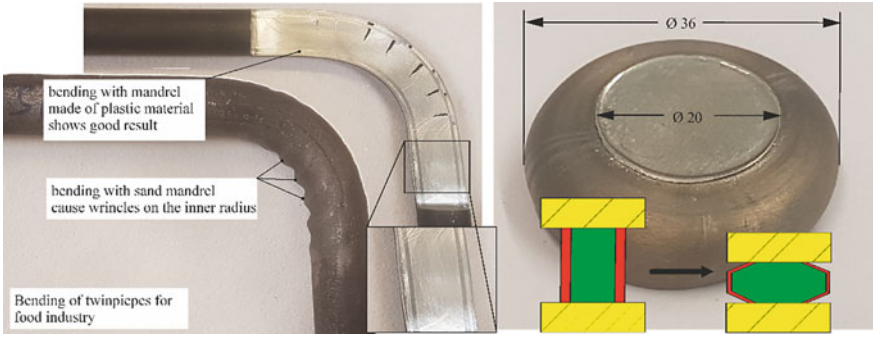

Fig. 3 Proof of concept of the filling with plastic materials. (Color figure online)

a very good bending result. At the outer radius, the filling material has some cracks that are not important for the result of the crack-free bend twin pipe.

On the right picture, a bulging test was made with a stainless steel tube 1.4571 (X6CrNiMoTi17-12–2), 20 × 1 mm filled with 75Bi25Bi. It was possible to bulge the part to an outer diameter of Ø 36 mm what means an expansion of about 80%.

These interesting results became the motivation for further work and the stepwise analyzation of the process. Filling up tubes or profiles by alloy with plastic behavior is well known in industry. So the question of how the mechanisms work in cross section forming are not clear and are explained in the following.

In Fig. 4, the main differences between THF and the TFPW are explained. In THF the fluid is pumped into the tube and expands the tube by the inner fluid pressure p_{Fluid}. At the same time, the axial force F_{axial} on the punch compresses the tube in the longitudinal direction for sealing and for pushing the material axial into the forming zone. Against this force works the friction force $F_{\text{R,die}}$ that arises by the lateral force of the forming pressure that presses the tube wall against the inner die surface and is additionally defined by the friction coefficient. On the right side, the TFPW process is analyzed. Similar to hydroforming, $F_{\text{R,die}}$ works against the movement of the tube wall into the die. Additionally, the working media made of material with high plasticity, that is filled into the tube like a core, has to move along the inner tube wall. Both forces work against the axial forming force F_{axial} of the forming punch. To get a good result, the friction circumstances of the tube, the die and the material have to be analyzed. Additionally, the forming behavior of the highly plastic working media is a strongly influencing parameter. In the following, the interdependencies of the friction coefficient influenced by the use of different coatings is shown. For the working media, the alloy 72Bi28In was used in all experiments to analyze the behavior of a seamless mild steel tube (Ø 22 × 1 mm, S235). Aim of the investigations was to learn about first interaction of the parameters to find a strategy to identify practical process windows.

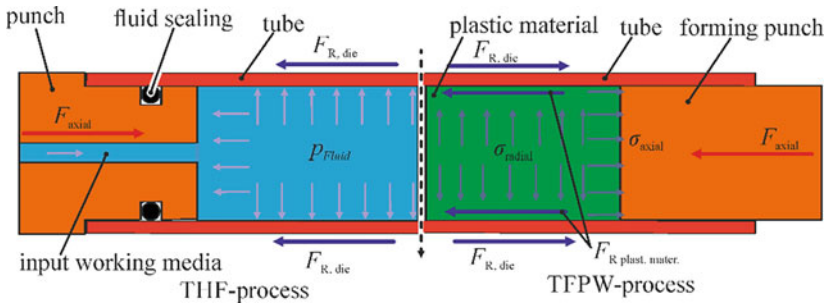

Fig. 4 Differences between a conventional THF process and the TFPM process. (Color figure online)

3 Analysis of the Influence of Coatings on Friction Parameters and Process Limits

In Fig. 5, the experimental setup and a good work piece and two failure parts are shown. The experimental setup consists of a die similar to a simple THF die. In the middle, the die has a hollow shape that makes it possible to expand a tube of Ø 22 mm to an outer diameter of Ø 35 mm. On both sides of the die, there are strong hydraulic cylinders mounted that can apply a maximum axial force of 180kN. For closing the die, a 1000kN hydraulic press was used.

The failure parts show two typical process limits: A tangential crack caused by too little axial flow into the forming die and a wrinkle caused by too much material flow in axial direction or to less radial expansion by the bulged plastic material. These parameters can be influenced by different lubrication methods on the inner and the outer tube wall.

To find a working process window for a good forming result, a variety of combinations of lubricants mentioned above were investigated. The friction coefficient that arises during the process is difficult to analyze experimentally. So, to understand the process in a better way, an axisymmetric simulation model with Abaqus FEM software with rigid bodies for the punches and the die and a 0.5 mm net for the tube and a 2 mm net for the plastic material core was built up. The forming characteristics of the tube was given by a tensile test of a sheet metal strip of the same material. For the characteristics of the 72Bi28In, a tensile specimen was made by casting and tested by tensile test. The typical process limits of wrinkles in the tube wall could be shown in FE-simulation model in principle.

In Fig. 6, two examples of the results of the numerical analysis are shown. The specimen on the right has a good forming result. The shape of the die is filled very well and the tube shows no wrinkles or cracks. The calculation was done with a friction parameter on the outer tube wall of $\mu_a = 0.01$ and on the inner tube wall with $\mu_a = 0.05$. The material flow of the tube wall into the forming zone can be

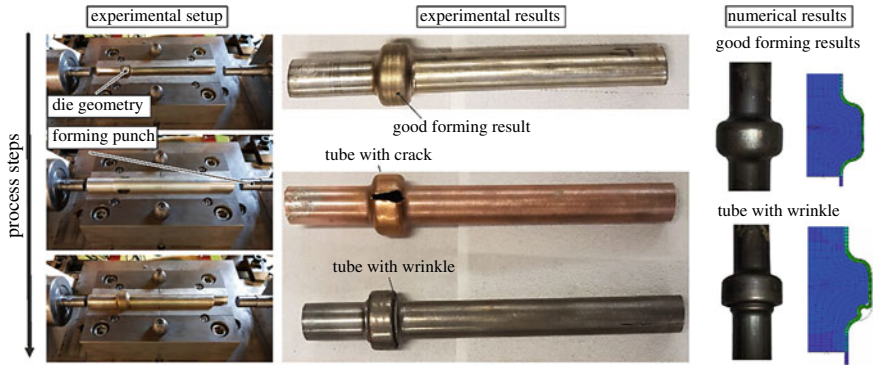

Fig. 5 Experimental setup and process limits in FEM and experiment. (Color figure online)

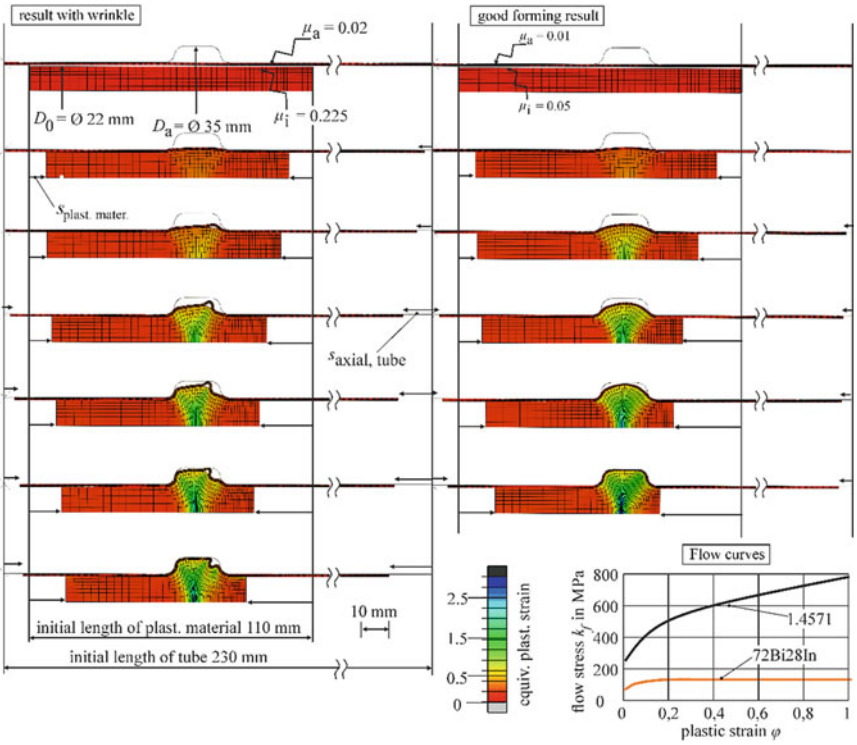

Fig. 6 Example results of the FE-model of the process with variation of the friction coefficient at the inner and the outer tube wall. (Color figure online)

detected in the diagram. The specimen on the left has a bigger difference between the friction coefficients and shows a wrinkle. The reason is less material flow of the filling material into the die shape to expand the tube. Similar significant results could be seen in experiments. To simulate the failure by localization or cracks, a FLC (Forming Limit Curve) was used. It is difficult to get FLCs from tubular materials, so an approximation according to [4] was used. With this model a range of calculations with a variation of the friction coefficients were made to find a process window.

In Fig. 7, the numerical results of these investigations are shown. To get a good forming result, the right combination of friction coefficients on the inner and the outer tube wall has to be determined. If the combination is not sufficient, a wrinkle occurs, because the tube flows too much into the die. The other failure is local thinning or a crack. This was detected by the FLC. Regarding the experimental results on the right diagram, a rough comparison can be made. The experiments show only one good combination of lubricant that lead to a good result; this combination can be found in the numerical investigations too. So, the model overestimates the process window. This shows that the model has to be developed further and other influencing parameters have to be considered in future investigations.

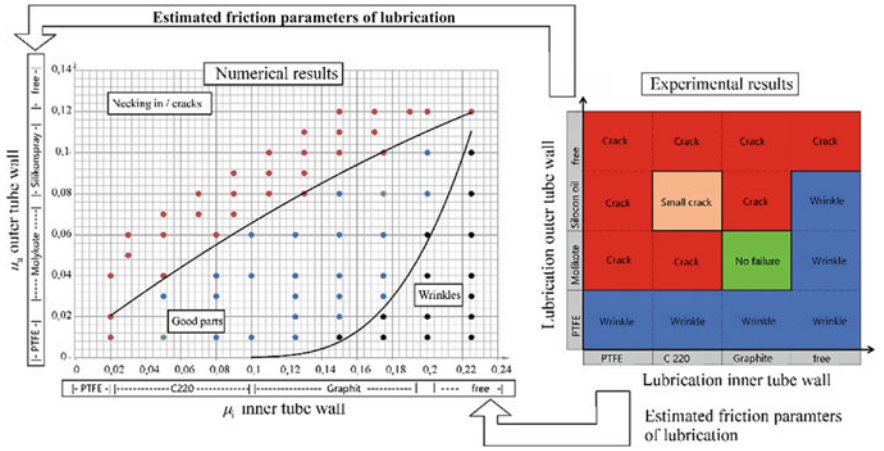

Fig. 7 Process window investigated by numerical and experimental methods. (Color figure online)

4 Summary and Outlook

The paper shows a process idea for a tube forming method for bending and cross section forming for lightweight parts using a working media made of material with high plasticity. The used materials are alloys made of Sn, Bi, and In, with low melting points. The process principle and some applications were explained. In the analysis part, the results of investigations of the influence of friction on the process limits were shown first. Following this, the process was developed further to get a better understanding of how the interaction between working media material, tube, work piece, and die works. The tool technology has to be developed and more materials and work piece geometries have to be tested.

Instability Analysis in Incremental Rotary Forming of Tube Flanges

Bhaskaran Krishnamurthy, Olga Bylya, Kyle Watt, Alastair Conway, Martin Tuffs, and Paul Blackwell

Abstract Rotary forming is an exciting route for forming flanges of different angles from seamless tubes of high-strength materials. True to its incremental nature, the process offers great flexibility, but the issues encountered are atypical and complex. One such issue observed in experimental trials is the internal buckling of tubes during specific instances of flange formation. The origin of this instability is non-trivial, and ordinarily, finite-element (FE) models fail to capture this instability. To analyse and understand the problem, systematic experimental trials were carried out using different tube thicknesses, tube materials, and tool kinematics. This paper summarises the results from a critical analysis to establish (1) a criteria for quantifying the instability and identifying the instances of its occurrence, (2) a validation methodology to fine-tune FE models for the process, and (3) use of FE models to understand the influence of tool path in the flange forming stage.

Keywords Rotary forming · Flange forming · Incremental bulk forming · Process instabilities · Tool kinematics

1 Introduction

Rotary forming is an incremental bulk forming process that affords the possibility to form a wide range of tubular components using simple sets of tools prescribing a complex tool path [5, 10]. The high degrees of freedom (DoF) and highly localised area of deformation makes it a very flexible process. For instance, the components

shown in Fig. 1a were all made from a simple conical top tool and a hollow cylindrical bottom tool (shown in Fig. 1b, c). By forming the flanges from a seamless tube, there is a significant reduction in material wastage as opposed to traditional machining operations; and by using incremental loading, it is possible to produce very high deformations (50–100%) in high-strength materials with limited ductility (12%) at room temperature using a small machine, as opposed to traditional flaring operations.

The complex tool path and the localised deformation, although advantageous when it works, poses a big challenge in understanding the mechanics and modelling of the process [3, 6]. The loading and resulting stress–strain state is non-monotonous, cyclic and significantly triaxial. This, in turn, renders the design for the processing and shaping of tool kinematics a significant challenge. Previous studies in this area are limited [1, 7, 8, 10] and stock commercial finite element software packages are not well suited to model this process, due in large part to the big uncertainty in having an appropriate material model and assumptions on boundary conditions. This problem comes to the fore when trying to shape the process for forming near-net shape components. Tubes with flanges of specific angles are a common requirement in the aerospace and automobile industry and are seen as viable components to be produced by rotary forming. With the optimal forming programme, it is possible to form these flanges in a single step without any intermediate processing or heat treatment. However, with no established industrial practise, even establishing the first framework for shaping the process is non-trivial. Choosing an appropriate starting material condition, tool kinematic parameters and tool path are complex problems which are impractical to solve by a trial and error method. This is due not only to the fact that the number of parameters are quite large for design of experiments approach, but the parameters are interdependant with no readily obvious relations with each other. This results in many process instabilities and failures which are hard to predict and plan against (as shown in Fig. 2), and some of these failures can be expensive as they have the potential to not only damage the workpiece, but the tools, as well as the machine.

(Color figure online)

Herein, the focus is on a single-step rotary forming of a 90° flange onto hollow tubular components and understanding the instability termed 'internal buckling' observed therein. As shown in Fig. 2a, the need is to form a 90° flange onto an initially straight tube with minimal defects or deviation along the fold. However, in reality, a notable internal flow of material can occur along the inner edge of the fold as shown in Fig. 2b, c. Three aerospace materials, namely JETHETE M152 steel, nickel-chromium-cobalt alloy C263, and INCONEL718 have been tested with varying parameters of tube thickness, upstand height, forming method, and forming depth. The internal buckling was observed under all conditions to varying degrees. This paper outlines the authors' attempts to quantify the instability, identify the instance of its occurrence, and develop process models to predict it.

2 Methodology

2.1 Geometry

All preforms used for the trials were of outer diameter 100 mm and length 110 mm. Two different tube thicknesses of 6 and 4 mm were used. Fillets of 1.5 mm radius were machined on both edges at the top end (forming end) of the workpiece to ensure smooth initial contact with the top tool. A 55° ($\boldsymbol{\beta}$) top tool was used as it affords possibility for nutation of 35° to the horizontal datum and thereby high flexibility without compromising on the strength of the tool [10]. A hollow bottom tool with a cylindrical cavity of a depth of 75 mm, maximum clearance of 0.1 mm with the O.D. of the workpiece and a fillet of 1 mm radius along the top edge was machined to hold the workpiece as shown in Fig. 2a.

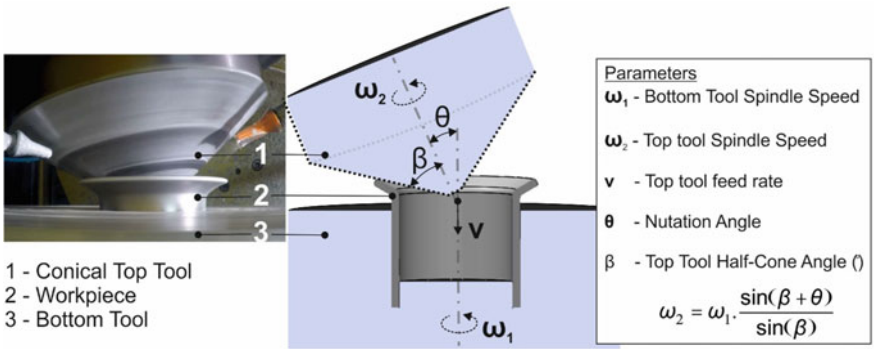

Fig. 3 Schematic representation of the rotary forming process with the key kinematic parameters highlighted. (Color figure online)

2.2 Machine

The Advanced Forming Research Centre of the University of Strathclyde, Scotland, is one of the High Value Manufacturing Catapult (HVMC) centres established to bring together academic research and industrial expertise to drive innovation in the UK. In line with this, state-of-the-art rotary incremental bulk forming machines have been installed specifically for industrial-scale research. The MJC RFN 200 T-4 machine is one such custom-designed spin-nutation type rotary forging machine. As opposed to the more common orbital type of rotary forging/forming machine, the spin-nutation-type design enables nutation angles ($\boldsymbol{\theta}$) in the range 0°–45°, with the ability to change it at any time during the process, and also apply a maximum load of 200 T at any point in this range. This is especially suited for forming flanges of different angles onto hollow tubes.

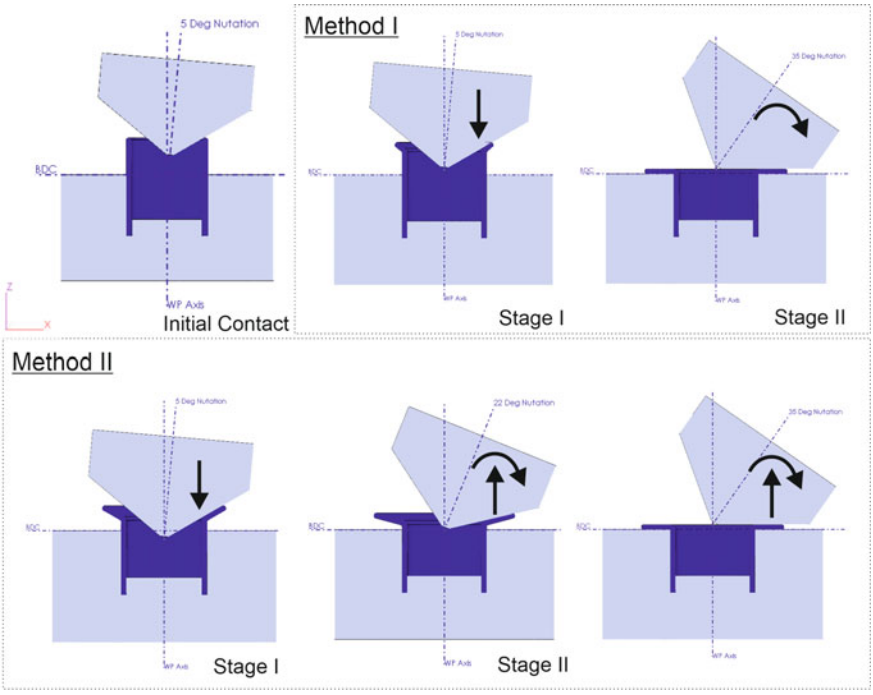
The machine has 4 DoF—the top tool can translate vertically, rotate about its own axis and also rotate along the axis perpendicular to the horizontal (termed 'nutation'), while the bottom tool can rotate about its own axis translating this rotation in turn to the workpiece. In order to maintain a rolling contact, the top tool is rotated at a higher velocity ($\boldsymbol{\omega}_2$) proportional to the rotational velocity of bottom tool ($\boldsymbol{\omega}_1$), half-angle of the cone ($\boldsymbol{\beta}$), and the nutation angle ($\boldsymbol{\theta}$) as shown in Fig. 3c.

2.3 Kinematics

The required rotation speed of the bottom tool, the Z position, X position (which gets translated to the nutation angle), rotation speed, and feed rate of the top tool were input in the form of CNC codes to the MJC RFN 200 T-4 machine. These values were chosen based on know-how and the fact that they have yielded successful results in the past.

2.4 Forming Method

One of the key aspects that needs to be decided as part of the process design is the forming method to be used. As previously mentioned, owing to the flexibility afforded by the machine, the flanges can be formed in different ways using different top tool paths. Two of the preferred methods are summarised in Fig. 4. In Method 1, during Stage I (flaring stage), the top tool is allowed to translate towards the workpiece with a small nutation angle to a depth of 14 mm. Following this in Stage II, the top tool is nutated from that depth without any change in the Z position of the top tool. Method 2 differs from 1 in that the top tool is made to translate to a larger depth in Stage I, and then prescribed a simultaneous nutation and vertical translation to achieve the final shape in Stage II as shown in Fig. 4.



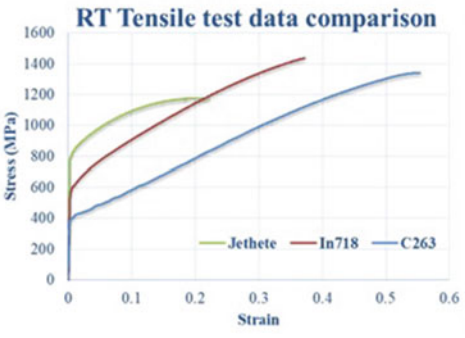


Fig. 4 Schematic representation of the different forming routes adopted. Method I involves only nutation in the second stage, while Method II involves both nutation and upwards translation. (Color figure online)

2.5 Process Modelling and Validation

Finite-element process models were developed in the commercial metal-forming software, QForm, for the project. The kinematic parameters used in the trials were input to the software, and standard friction and heat transfer parameters available in the software database were used in the setup of the model. The problem was formulated as a 3D elasto-plastic one owing to the localised complex cyclic and incremental loading observed in the process. An isotropic hardening material model was used for the three materials, which were developed using the RT tensile data shown in Fig. 5. Experimental observation of the temperatures in the component did not exceed the range 100–150 °C. It has been reported that the mechanical properties of steels and nickel alloys tended to be nearly strain-rate insensitive at such low temperatures [4], Special [9] and this was further verified in separate tensile tests. Hence, RT material data was deemed to be representative enough. The detailed modelling methodology used and the challenges faced in modelling rotary forming processes are summarised in earlier works [2, 6, 10].

To validate the model, the load, geometry, strain, and temperature data obtained from the experiments were used. The calibration procedure is summarised in Fig. 6, wherein the geometry and temperature profile generated through the trials, as observed from a high-definition video and thermal image capture, respectively, were used to validate the values obtained in the process models. Similarly, the forming load traces recorded on the machine were used for validating those obtained from the process models. The output geometry obtained from the full and interrupted trials were measured as well as scanned for analysis. To get a clear image of the region of folding, thin slices of width 20 mm were cut (as shown in Fig. 2b) from the tubes and then photographed. These were then processed and compared with those obtained from the process models (exported as .STL files) in proprietary GOM Inspect software (Fig. 6c).

Properties	Jethete	IN718	C263

(Color figure online)

In addition, an electrochemically etched rectangular dot grid system, commonly used in sheet metal forming limit identification, was used to determine the strain on the deformed surface of the tubes here. These were then used for validating the strain profile observed in the FE simulation (Fig. 6d).

3 Results and Discussion

3.1 Identification and Quantification of Instability

To identify the origin of the instability, interrupted trials were planned, i.e. the trials were stopped at the instance of starting of the instability. To determine this point, videos obtained for preliminary trials from the high-definition cameras were processed using a commercial video processing software. The videos were trimmed to the exact duration of the process, following which linear guidelines were used to identify the exact instance of the commencement of instability, as shown in Fig. 7. This was then compared with the machine data and process simulation to translate this point in time to the nutation position of the top tool. As can be observed in Fig. 7, the onset of instability is early in the nickel alloys (at 22° nutation in stage II), while it happens at a later stage in Jethete (at 26° nutation in stage II). Interrupted trials were carried out for the materials where the process was stopped at the points identified.

The interesting aspect to be noted here is the profile formed by Jethete and C263 at the onset of instability. This profile could also be observed in the completely formed geometry, as well as can be derived from Table 1, and gives clues to understanding

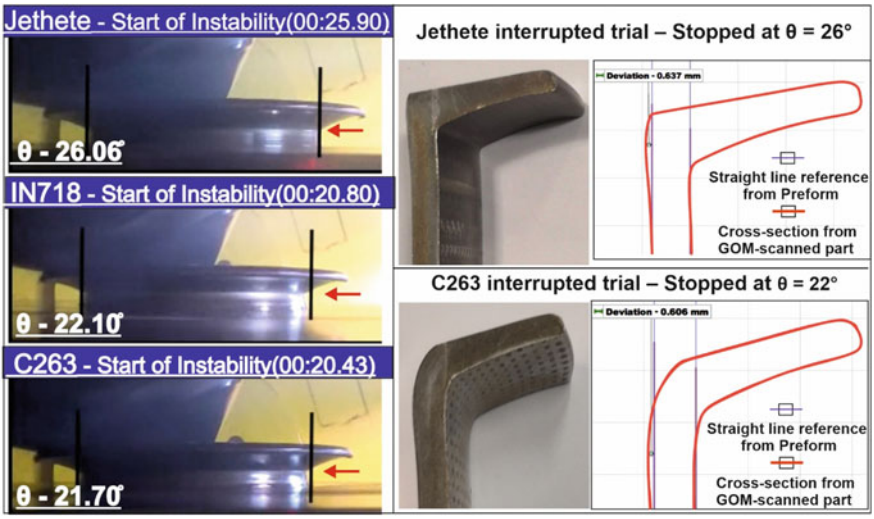

Fig. 7 Representation of the high-definition video capture analysis carried out to identify the instances of instability in the three different materials. (Color figure online)

the prevalent buckling in Nickel alloys compared to that in Jethete. More study on this aspect is needed to understand completely the origin of such a buckling effect and how to avoid it for new materials.

To quantify the instability, the key features of the formed component, outer diameter and inner diameter of the flange and the thickness at the outer and inner part of the flange, were measured using a Vernier Calliper. Three measurements were taken each time and the average of the three measurements were used for analysis. The hoop strain values were then calculated with respect to the initial circumference. These are summarised in Table 1. In addition, thin slices of 20 mm width were also

cut from the specimens and analysed with respect to the ideal expected geometry as shown in Fig. 2c.

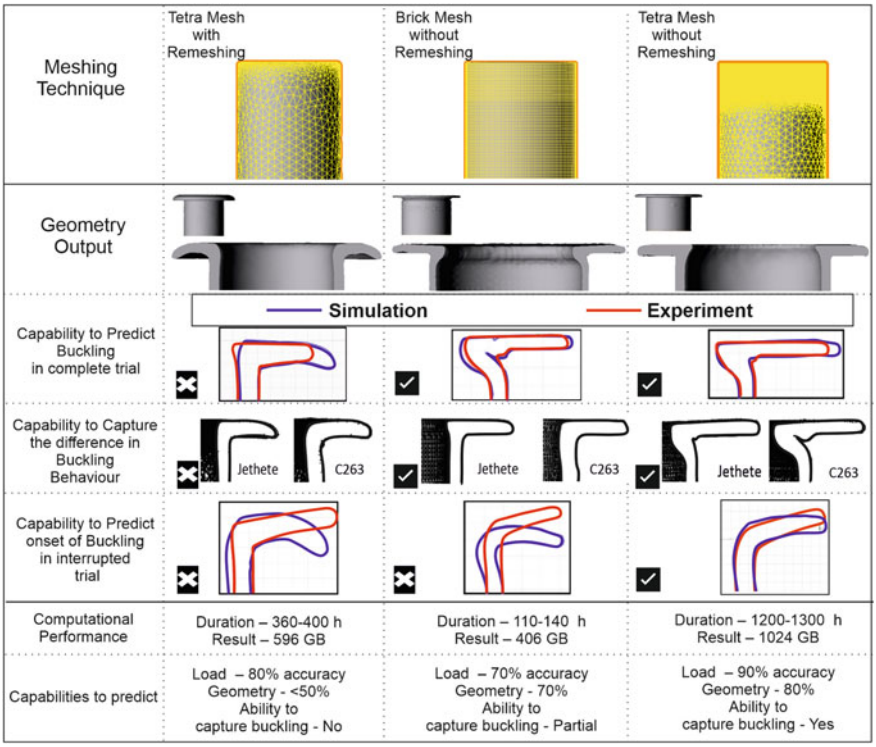
3.2 Fine-Tuning of Process Models

Validation and prediction of the output geometry was one of the most challenging aspects of developing a more robust model for the rotary forming process. More specifically, the ability to capture the buckling effect observed in the forming trials is non-trivial and required a few unconventional techniques. Using the conventional method for modelling such a finite deformation process—specifically, a strain-based remeshing technique—material flow behaviour near the fold in the flange could not be captured in the process model. Modification of the hardening behaviour in the material models did not yield positive results and the process model was still unable to capture the internal flow of material during the nutation stage. The use of a standard tetrahedral solid element mesh and remeshing technique was later identified to be the reason for this effect. Through remeshing, wherein the Finite-Element (FE) software continuously tries to realign and change the local mesh elements in the areas of high deformation, somehow rendered the material 'soft' and flow in an ideal way to help in the convergence of results.

The prevalent buckling effect observed in the trials carried out with the thinner (4 mm) tubes was very helpful in fine-tuning the process model. Figure 8 provides a summary of the stages in the fine-tuning of the model. As a first step, a brick (rectangular) shell mesh element was used without remeshing criteria. This seemed to yield better geometry prediction and was able to predict the output geometry with the buckling effect. In addition, it was also possible to capture the difference in the flow behaviour around the fold between Jethete and C263, as seen in Fig. 8. In addition, using the brick mesh without remeshing, it was possible to bring down the simulation time considerably, from 3 weeks to 3 days.

However, this method was still prone to some inaccuracy in geometry prediction, as was observed when validating the process model with interrupted trials. While the process model was able to predict the final output geometry, it still predicted the metal flow in intermediate stages of forming with error as shown in Fig. 8.

The use of a solid tetrahedral mesh, without remeshing, however, seemed to improve the geometry prediction in intermediate stages as well, and was found to provide better representation of the material flow. The use of this method did seem to increase the simulation time compared to that of the brick mesh. Therefore, the suggestion would be to run initial simulations with a brick mesh without remeshing for preliminary iterations to test hypotheses, while a solid tetra mesh without remeshing is recommended for final simulations. The lack of remeshing seemed to cause some problems while simulating Method 2 type of forming, as the tool path tends to produce a highly distorted mesh in stage II. In such a case, it was found to be useful to stop the simulation at the start of mesh distortion, remesh the



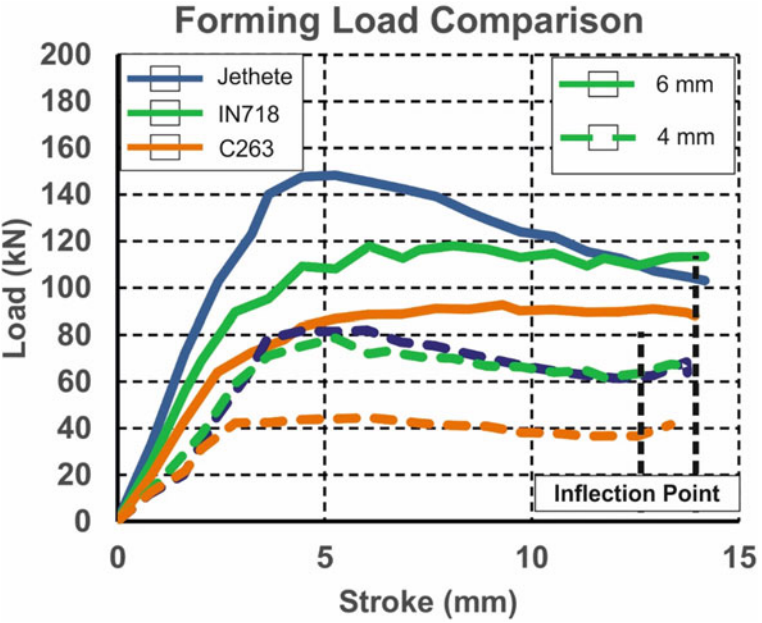


Fig. 8 Representation of the increase in maturity of geometry prediction in the process models **a** preliminary stage, **b** intermediate stage using a brick mesh without remeshing and **c** improved state using a tetra mesh without remeshing. (Color figure online)

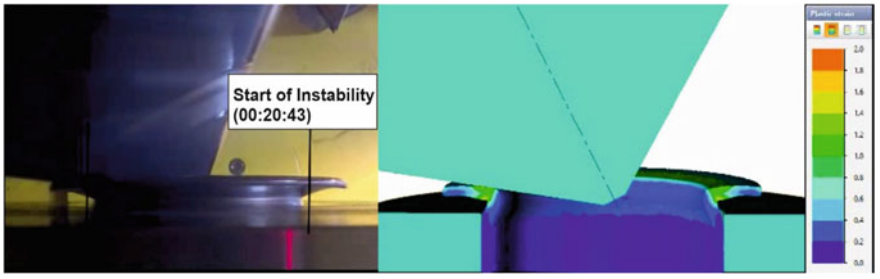
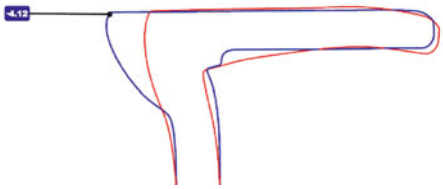


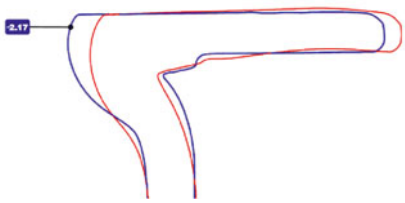
local region for a short while, and then continue the simulation without remeshing until further inacceptable distortion of the mesh.

3.3 Preliminary Improvements Through Process Models

The validated process model was used to glean some insight into the mechanics of rotary flange forming and devise some recommendations to eliminate or at least reduce the internal buckling. As shown in Fig. 9, the load trace and geometry development were analysed using the process model. The load trace in conjunction with the geometry observed in the process model provided some hints to the start of internal buckling. It is hypothesised that at the trough of the load trace, the forming mechanism changes. This critical point, termed as the 'inflection point' herein, is shown for the three materials and two different thicknesses in Fig. 9a. This was used in the shaping of our process (as shown in Fig. 9b), but further in-depth study on

(a)





(b)

Fig. 9 Preliminary results from the improved process model **b** comparison of the forming load trace for Jethete, IN718, and C263, **c** Prediction of the start of instability using the process model. (Color figure online)

the process mechanics will be useful to translate the results to new materials and geometry.

The geometry prediction capability of the process model (as shown in Fig. 9b) were used to shape the process and compare the results for the different forming methods. Table 2 shown, compares the output geometry obtained using the improved process using Method 2 with that of the initial process using Method 1. As can be seen from the measurements and GOM scan analysis shown in Table 2, the use of Method 2 seems to result in reduced buckling than that observed with Method 1.

Table 2 Comparison of the output geometries for trials carried out using Method 1 and 2. (Color figure online)

Material	Measure	Method 1	Method 2	GOM section comparison
Jethete	I.D	78.91	86.46	 Comparison – Method 1 (Blue) and 2 (Red)
	O.D	139.95	141.48	
C263	I.D	77.45	81.96	 Comparison – Method 1 (Blue) and 2 (Red)
	O.D	134.73	138.31	

Only Jethete and C263 were tested in this case, as a representative for steel and nickel alloy. In both cases, there were pronounced improvements in the output geometry. The combination of Z motion and nutation of the top tool seemed to prevent the drastic internal movement of the workpiece. Although the thickness distribution in the formed component seemed to be non-uniform in the case of Method 2, it did result in a better forming along the inner edge (part in contact with the bottom tool) of the flange. The lack of fold along the inner edge was a positive sign and the component could easily be subjected to a further machining operation to achieve the end result.

4 Conclusions

Herein, a systematic analysis of internal buckling observed in rotary forming of a 90° flange using different aerospace-grade alloys with different tube thicknesses were carried out. Methods for quantifying the instability and identifying the instances of its occurrence were identified and novel validation methodology was developed to fine-tune an FE model for the process, which were lacking hereinbefore. The main contribution from the present work were the use of validated process models to gain some basic understanding of the mechanics of rotary forming and to assist in the shaping of the rotary forming process to yield improved results.

The use of a combined nutation-translation type top tool motion (Method 2) during the flange forming stage was found to result in reduced buckling than that observed with only nutation (Method 1) for both Jethete and C263. This can be used to inform

forming strategies for the future. Furthermore, buckling was observed to be more prevalent, to happen earlier, and to occur in a different way in nickel alloys than in Jethete steel. The aspects of the material properties that leads to this effect need to be studied further to help effect successful trials using material preparation techniques such as heat treatment.

Acknowledgments The authors would like to acknowledge Rolls Royce Plc for funding this work from their Innovate UK: Aerospace Technology Institute Strategic R&D Project grant (application no. 66733-263147) titled "Manufacturing Portfolio Project 2: Manufacture of Advanced Materials". We would also like to thank the AFRC's Forging and Incremental Processes team for their excellent support, guidance, and provision of resources throughout the project. Most importantly, we greatly appreciate the time spent by key staff in both Rolls-Royce and AFRC in support of this project.

Incremental Collar Forming Process for the Manufacturing of Branched Tubes and Pipes

André Leonhardt, Peggy de Witt, Matthias Rehm, Holger Schlegel, and Verena Kräusel

Abstract Beside the manufacturing of finished parts by Incremental Sheet Metal Forming (ISF), final operations within the process chain can also be realized with this technology. The technological capabilities of performing incremental (hole-)flanging operations for sheet metal parts has been investigated in research context. The current topic focusses on the transfer of the incremental forming technology to manufacture tubular parts. An incremental collar forming process was developed where all motions are executed by the forming tool. Due to the fixed position of the workpiece, tubes, as well as pipes can be branched. Stainless steel tubes made of 1.4404 (316L) with an outer diameter of 54 mm and a wall thickness of 1.5 mm were used for experimental evidence of functional capability of the incremental collaring process. The influence of different pre-hole geometries and forming tool shapes on the properties of the collar (e. g. geometrical accuracy, wall thickness) was investigated.

Keywords Incremental forming · Collar forming · Branched tube

1 Introduction and State-Of-The-Art

Incremental forming technologies are characterized by high flexibility due to the small forming storage of the used tools enabling a fast and cost-efficient small batch production. In ISF, the sheet metal is kinematically formed by the numerical controlled motion of a simple tool causing plastic deformation of the material in a tightly limited, partial forming zone. In addition to the incremental forming of the final shape of sheet metal parts, finishing operations performed by ISF within a process chain are the context of scientific and industrial research. Taleb-Araghi et al. [1] investigated the process combination of stretch forming with a subsequent

ISF of specific part features in a single machine setup, improving the geometrical accuracy and the sheet thickness distribution as well as shortening the process time. Moreover, a lot of research effort has been spent to show the technological capabilities of incremental flanging operations being performed by ISF. The works of Voswinckel et al. [2] and López-Fernández et al. [3] involve the stretch and shrink flanging of open (cut) edges using an incremental forming approach. Investigations on the incremental hole-flanging have been carried out by Cui et al. [4], Centeno et al. [5], Cristino et al. [6], Bambach et al. [7], and Cao et al. [8]. The focus of all these studies was the so-called "forward flanging" approach in which the flanged wall is bent downward by the tool. Different tool and blank holder setups, as well as tool path strategies, are used to optimize the final flange. In contrast to these findings, Petek et al. [9] proposed an upward bending of a hole flange applying a ball headed tool—the so-called "backward flanging" method. Wen et al. [10] present a tool with tapered shoulders allowing a combination of forward and backward flanging as well as open edge and hole-flanging.

Besides the use of ISF in the flanging of flat sheet metal parts, the approach of incremental forming is already utilized for the industrial production of tubular parts, e. g. for the incremental tube end forming. These process variants are used for the thickening, closing, reducing, expanding, and profiling of the tube ends. In addition to the tube end forming with an open (cut) edge, the hole-flanging of the tube shell surface, the so-called collar forming, is applied to produce branched tubing. Branches are needed if one media flow shall be divided into different pipelines or vice versa. On the one hand, branched pipes can be produced by connecting the single tubes with T-fittings. On the other hand, the branch can be manufactured from the pipeline itself. In industry, branching is mainly produced by casting, joining or forming technologies, whereas high efforts have been undertaken to substitute casted or joined branches with formed ones [11]. The reasons for this can be summarized as follows:

- decreasing post processing of parts due to near-net-shape-forming
- increasing surface quality
- streamlined transitions between the pipelines
- decreasing part weight due to elimination of additional components
- producing of branches on long pipelines and existing pipe systems.

Collar forming can be realized by rigid or elastic tools as well as by hydroforming. In the latter case, a dome is first formed by applying internal pressure via the medium and axially pushing the pipe ends. Subsequently, the cap is cut off, so that the collar emerges. Furthermore, an elastic tool made of rubber can be applied in collar forming. At first, a pre-hole is cut in the shell surface and the elastomer is put into the tube. The elastic core is then axially compressed by two punches so that it moves into the die hole, forming the collar. Due to the long cycle times, the high investment costs for the plant and the required tools, these processes are not widely used in industry. For this reason, the collar forming with rigid tools has become established in industrial practice. Typically, this is implemented by means of a translational tool movement. A punch or a ball with an appropriate diameter is used to form the collar in one step.

A mechanical or hydraulic device, which applies the necessary forming force, is inserted laterally into the tube and positioned under the previously inserted hole. The collar is then made by pressing out the punch or the ball. With this process variant, only collar diameters smaller than the tube diameter can be formed. Alternatively, the punch can be pulled out of the tube by applying a tensile force via a tie rod. This process variant is used, especially for cold collar forming of thin-walled tubes [11].

There are only a few approaches in which the incremental flanging of sheet metal is transferred to the collar forming of tubular parts combining a translational and rotational tool movement. The T-Drill process is an industrial used incremental collar forming method needing special tooling with two forming pins. At first, a round pre-hole is drilled in which the collar forming head is inserted. After this, the forming pins are extended and the collar is formed with a superimposed rotational pull-out movement of the tool. Then the collar is trimmed to the desired height and the branch pipe is attached to the main pipe by butt welding [11]. In the craft sector, installers for heating, ventilation, and air conditioning use tools from Rothenberger with special extractor hooks for collar forming of copper pipes [11]. Further investigations and process variants of incremental collar forming were presented by Teramae et al. [12] and Yang et al. [13]. Teramae et al. used a simple bar tool with a hemispherical tip for forming the branched tube. The areas of the major and minor axis of the elliptical pre-hole are formed one after the other, whereby the forming tool is partially inclined. Thinning in particular is examined with the aim of harmonizing the thickness distribution through the special process sequence [12]. An improved bar tool with a conical pre-forming zone and a cylindrical shaping zone is presented in [13]. The collar forming of 316L tubes with a wall thickness of 0.5 mm is realized in a multi-stage forming process divided into pre-and collar forming. During the forming process, the tool moves in a sequence of translational and rotational motions which are partly superimposed. Accordingly, the objective of the current study is to present a new incremental collar forming method with simple tooling for the manufacturing of branched tubes and pipes (patented in [14]). Experimental results are presented as evidence of functional capability of the new process.

2 Description of Incremental Collar Forming Process

The basis for the new process is a tube with a defined pre-hole which is firmly clamped during the entire forming process (Fig. 1a). A simple forming mandrel is used as a tool, whose dimensions and shape can vary depending on the requirements of the collar forming task. First, the tool, which is set at a defined angle, is axially inserted into the pre-hole (Fig. 1b). Then, the forming mandrel is advanced radially to the pre-hole by a defined value (Fig. 1c). The forming of the pre-hole edge and the setting up of the collar takes place through a rotational movement of the tool around the pre-hole axis, which is superimposed with a translational outward movement along the pre-hole axis (Fig. 1d). In addition to the active rotation around the pre-hole axis, which is generated by an electric motor, a passive rolling of the active

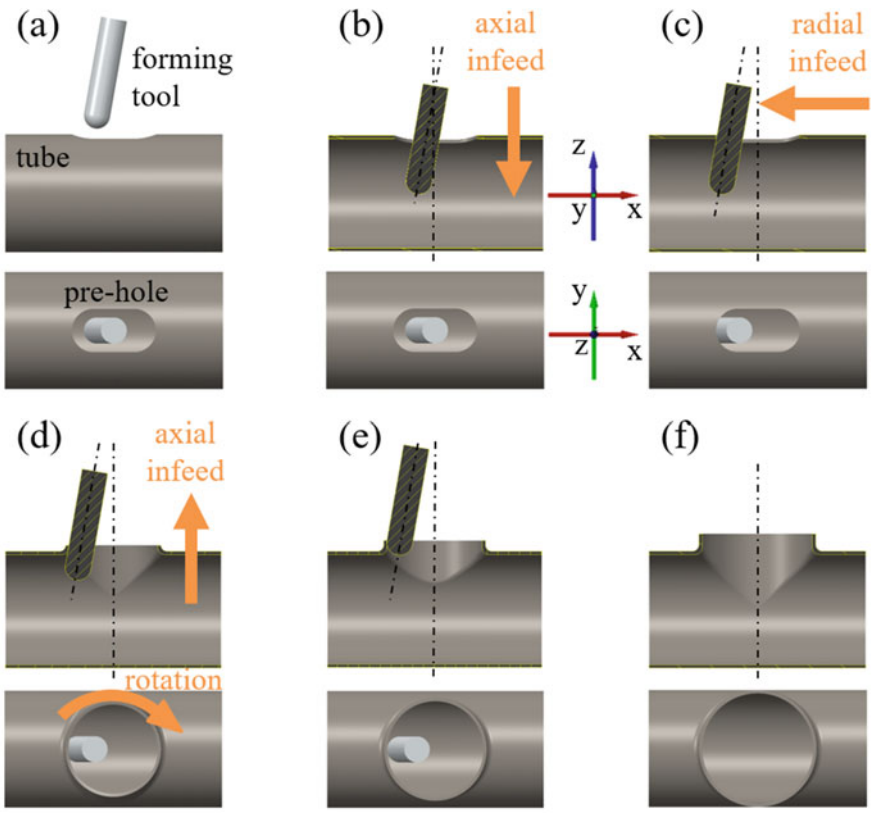

Fig. 1 Steps of tool movement for one forming cycle **a**–**e**, 1:1 collar formed after several cycles. (Color figure online)

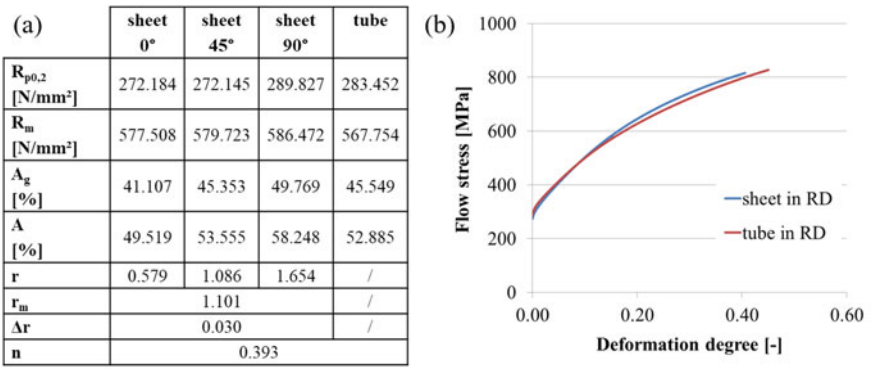
part on the pre-hole or collar contour takes place due to friction, since the forming mandrel is mounted to rotate around the tool longitudinal axis. After the mandrel has moved out of the tube (Fig. 1e), the process steps are repeated. In the first steps of the multi-stage process, the pre-hole areas of the shorter pre-hole axis are formed. The sequence of steps, consisting of axial and radial movements, is repeated until the collar has reached its target diameter (Fig. 1f).

Due to the process kinematics, a simple low-cost tool can be used to produce different collar geometries within a defined diameter range. Since all movements are performed by the tool alone, not only shorter pipe sections (T-fittings), but also larger pipes and even entire pipe systems can be formed in this way. In addition to T-fittings, cross pieces can also be produced, whereby only one-sided accessibility is necessary. In contrast to pressing with a punch, so-called 1:1 collars can also be formed, where the collar diameter corresponds to the pipe diameter. Due to this high flexibility, the process allows the forming of small lot sizes up to a quantity of 1. Furthermore, when arranged in a corresponding plant concept with several necking stages, economic production of medium to large quantities is also possible.

3 Experimentation



3.1 Investigated Tube Material

Stainless steel tubes made of 1.4404 with a wall thickness of 1.5 mm and an outer diameter of 54.0 mm were used for the experimental investigations of the incremental collar forming process. The chemical composition of the alloy X2CrNiMo17-12–2 is shown in Table 1. The tubes were manufactured from sheet metal by roll forming and subsequent longitudinal induction welding.

Tensile tests were performed according to ISO 6892–1:2016 in order to receive the mechanical properties. Samples were taken from the semi-finished sheet metal in 0°, 45°, and 90° to the rolling direction, as well as from the tube in the direction of tube axis opposite the welding seam. For the tensile specimens, the same geometry was used both for specimens from the sheet metal and for specimens from the tube with a gauge width of 12.5 mm, an original gauge length of 50 mm and a parallel length of 75 mm. At least five samples were prepared by abrasive water jet cutting. The samples taken from the tube were not straightened, but only flattened at the ends due to the clamping force. Figure 2 summarizes the results of the mechanical properties for all four testing conditions and shows the flow curves for the samples from the sheet metal in rolling direction as well as from the tube. The strain hardening exponent n was determined by the flow curve data according to SWIFT.

3.2 Experimental Setup and Testing Procedure

The forming tests were performed on a machine from ATG Automations-Technik-Gröditz GmbH & Co. KG, which was developed for the presented collar forming process. The basic structure of the machine concept is shown in [14]. All necessary movements of the forming tool are realized by various drives. Two mandrel geometries were used in the tests (Fig. 3) and the angle of the active surface was varied: a conically reducing mandrel with a negative angle of 8° and a conically enlarging mandrel with a positive angle of 4°. This results in different diameters at the spherical tooltip, which is in contact with the material at the end of every forming cycle. The additional inclination of the mandrel in the tool clamping of the machine in combination with the angle of the tool active surface create an undercut. The undercut determines the diameter increase of the collar in each forming cycle in addition to the axial infeed of the mandrel into the pre-hole and the radial infeed. An advantage of the conically enlarging tool is the possibility of a larger infeed even with smaller pre-holes. The tip of the mandrel, which has the largest dimensions, can be inserted into the tube at the centre of the pre-hole. The tool can subsequently perform a larger radial infeed, since the diameter decreases towards the tool clamping. The mandrels were manufactured from the material CPM Rex M4 by turning, hardening, and grinding.

Different pre-hole calculations were taken from the literature (Fig. 4), since circular holes cannot be used for the collar forming of tubes. However, these geometries have been calculated and designed for collar forming with punch or ball. A collar height of 4.5 mm was assumed for all pre-hole shapes. The basket arch according to NASS [15] was calculated from geometrical parameters without taking into account the tube wall thickness and the die radius of the clamping. These two geometrical parameters were included in the design for ellipse I according to HENTRICH [11], whereby the die radius was 2.0 mm. Not only the geometry, but also material parameters such as tensile strength, uniform elongation and strain hardening exponent were considered in the calculation of ellipse II according to HENTRICH [11]. The required mechanical parameters were determined from the results of the tensile tests for the sheet metal as well as the tube in rolling direction. The two axis values of the ellipse II were transferred to a slotted hole (slotted hole II according to HENTRICH) to investigate the influence of the pre-hole shape. The reason for this was that only one

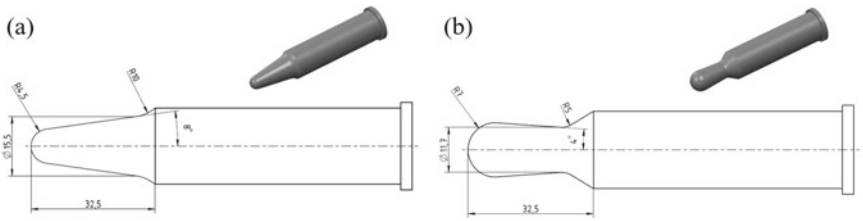

Fig. 3 Conical reducing a and conical enlarging tool for incremental collar forming process

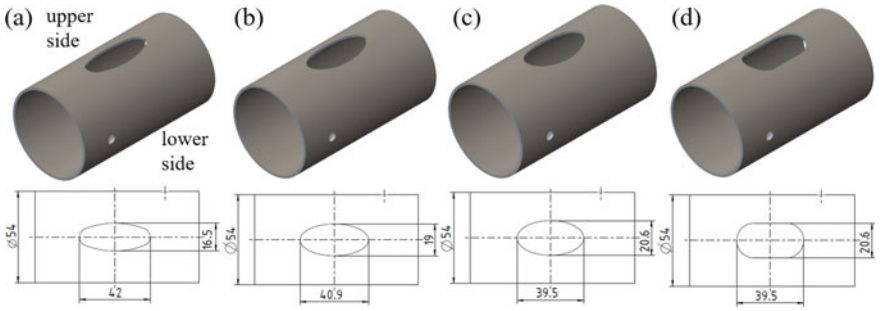

Fig. 4 Pre-hole geometries for incremental collar forming process: basket arch acc. to NASS **a**, ellipse I acc. to HENTRICH **b**, ellipse II acc. to HENTRICH **c,** and slotted hole acc. to HENTRICH **d**

axis is needed in a possible machine concept for milling a slotted hole. The pre-holes were positioned opposite the welding seam and inserted into the tube by milling. The material within the pilot hole was first removed in several roughing cycles before the final contour was produced with a finishing pass. The edge of the pre-hole had to be deburred afterwards. In addition to the pre-holes, a hole was drilled in the tube shell surface serving both to position the tube in the clamping and for subsequent referencing during evaluation. The tube was clamped between two half-shells after positioning.

A rotational speed of 86 min^{-1} and a feed rate of 3 mm/s was set for the collar forming steps (Fig. 1d, e) as well as a constant infeed of the mandrel of 1.1 mm for each cycle. All tests were performed without the use of lubricants. This avoids expensive cleaning processes after collar forming for tubes used in the food industry. The aim of the experiments was to form a 1:1 collar. The number of forming cycles had to be varied depending on the starting point for the first cycle and the projection length of the mandrels. Fifteen cycles were, therefore, required using the conically reducing mandrel and 13 cycles using the conically enlarging tool to achieve an inner diameter of 51 mm.

Besides the investigation of different pre-hole geometries, the calculation for ellipse II was used to determine the influence of the collar height and the maximum expansion ratio (Table 2). Due to the mandrel dimensions, the maximum collar height was limited to 6.5 mm. Test series were conducted for both mandrel geometries, using the same collar forming programs as before. Pre-forming cycles had to be realized for the pre-holes with collar heights between 5.0 and 6.5 mm when using the conically reducing mandrel.

Table 2 Dimensions of the ellipse axes and expansion ratio of the ellipse II according to HENTRICH for different collar heights

Collar height [mm]	Dimension of larger pre-hole axis a [mm]	Dimension of smaller pre-hole axis b [mm]	Expansion ratio (axis b to inner diameter of collar) [%]
3.0	44.0	24.1	111.62
4.5	**39.5**	**20.6**	**147.57**
5.0	38.0	19.4	162.89
5.5	36.5	18.2	180.22
6.0	35.0	17.0	200.00
6.5	33.5	15.8	222.78

3.3 Optical Measurement and Analysis of Incrementally Formed Collars

The inner and outer surfaces of the collar and the tube were scanned by the optical measurement system GOM ATOS (Fig. 5a). For this purpose, the branched tube was clamped between two cones and scanned using the optical sensor. The recorded images were referenced to each other and merged into a virtual model. For the evaluation, the tubes were first aligned using a fitting cylinder of the outer tube surface and the positioning hole. The collar height for the investigated tube diameter according to DIN 11,852, which describes tee-fittings for the food and chemical industry, is given as 3.5 mm. In industry, however, face milling is usually performed after forming in order to obtain a flat collar edge for subsequent butt welding. Therefore, the evaluation was executed at a collar height of 1.5 mm (Fig. 5b). The roundness, straightness and cylindricity of the inner and outer collar surface were determined besides the collar diameter. In addition, the collar height and wall thickness (distribution) were analyzed.

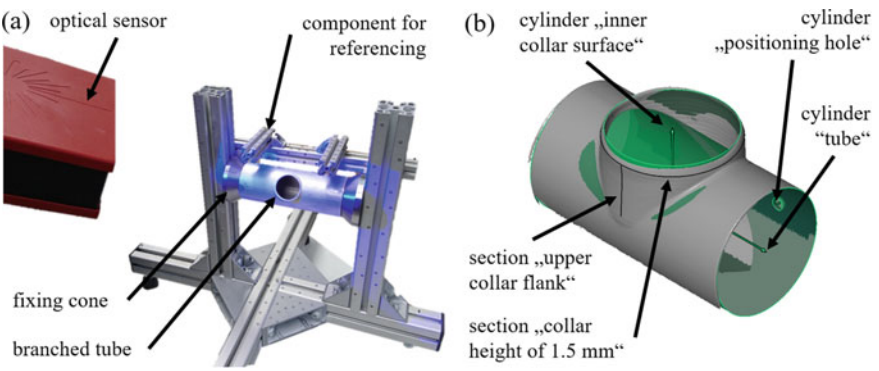

Fig. 5 Measurement setup for scanning of branched tubes **a** and scanned tube with evaluation features **b**. (Color figure online)

4 Results

4.1 Properties of an Incrementally Formed Collar

DIN 11852 provides the basis for the evaluation of the collars. In the following, the collars with pre-hole "ellipse II according to HENTRICH" will be analyzed for both mandrel geometries. The values determined from the optical measurement are summarized in Table 3. The collar height of 4.5 mm assumed for the pre-hole calculations was reached and even exceeded, taking into account the deviation of ± 1.0 mm permitted in the standard. The collar height of 3.5 mm specified in DIN 11,852 was fulfilled. The maximum and minimum height varies by more than 1.0 mm along the collar circumference. This can be improved by further optimizing the pre-hole geometry. Furthermore, a 1:1 collar was achieved as the target diameters were reached. A too large total infeed can be derived, which has to be adjusted in the machine program, due to the values for the inner diameters. Both roundness and

Table 3 Obtained heights, diameters, and shape tolerances for the collar with pre-hole ellipse II according to HENTRICH for both tool geometries

Parameter	Value for conical reducing tool	Value for conical enlarging tool
Max. collar height [mm]	5.40	5.22
Min. collar height [mm]	4.26	4.94
Difference in heights [mm]	1.14	0.28
Mean inner diameter [mm]	51.58	51.53
Mean outer diameter [mm]	54.17	53.96
Inner roundness [mm]	0.78	0.60
Outer roundness [mm]	0.57	0.40
Inner straightness [mm]	0.61	0.50
Outer straightness [mm]	0.51	0.49
Inner cylindricity [mm]	1.60	1.47
Outer cylindricity [mm]	1.14	1.08

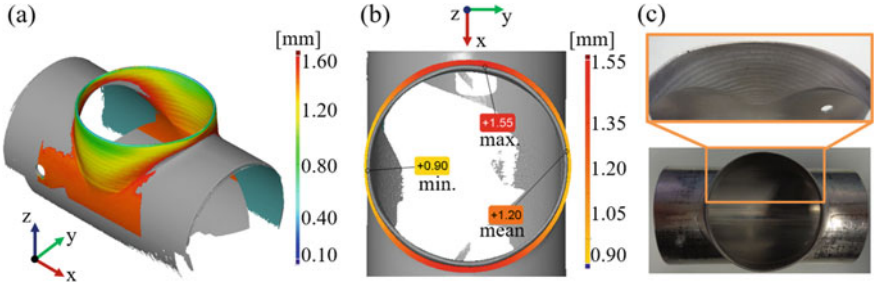

Fig. 6 Sheet thickness distribution within the collar **a** and at a collar height of 1.5 mm **b** for ellipse II formed with conically enlarging tool, inner collar surface **c** for ellipse II formed with conically reducing tool. (Color figure online)

cylindricity are lower for the outer surface, as the metal is formed against the die hole. In contrast, there is only punctual contact between the mandrel and the inner surface. The values for straightness reflect the mean value for the upper and lower flank, respectively. In some cases, the values for the upper side are twice as large as those for the lower side. The reason for this is the clamping of the tube between two half-shells. While the forming forces are transferred into the machine table at the lower side, the resiliency in the upper area leads to higher deviations. Only tolerances according to ISO 2768-c are specified in the standard with permissible deviations of ± 0.8 mm for the given tube diameter, which are maintained when transferred to the form tolerances.

The minimum sheet thickness with values between 0.8 mm and 1.0 mm is obtained along the larger pre-hole axis a, as this area is formed more severely (Fig. 6a, b). According to these values, the maximum permitted wall thickness reduction of 25% from DIN 11,852 is exceeded. An increase in thickness up to 1.6 mm occurs along the short axis b, which is caused by an initial compression of the pre-hole edge by the mandrel. The average sheet thickness is approx. 1.2 mm. Further optimization with regard to pre-hole and mandrel geometry, as well as the forming parameters such as infeed and number of cycles, will contribute to achieve a more homogeneous sheet thickness distribution.

Material abrasion occurs during collar forming, especially when using the conically reducing mandrel. This is caused by the initial compression and a subsequent chip removal of the pre-hole edge along the short axis. The larger undercut of the conically enlarging tool minimizes chip formation, since the bending ratio is increased within a cycle. Furthermore, the tool path is formed in the collar wall (Fig. 6c). The surface can be improved by a final finishing cycle with low feed rate and small infeed. In addition, the surface roughness can be enhanced through higher infeeds per cycle causing less contact cycle between material and tool. A coating of the mandrel can also optimize the tribological conditions, whereby the use of lubricants should be avoided due to targeted application in the food industry.

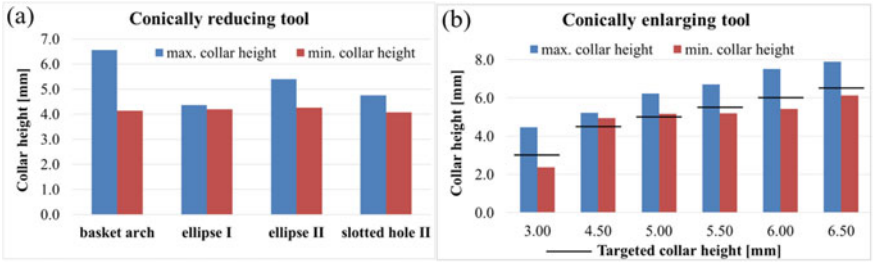

Fig. 7 Results for collar heights using various pre-hole geometries **a** and different targeted heights according to the calculation for ellipse II **b**. (Color figure online)

4.2 Influence of Pre-hole

The required collar height according to DIN 11,852 is also achieved with the other pre-hole shapes. The maximum height for the pre-hole according to NASS clearly exceeds the assumed calculation value of 4.5 mm (Fig. 7a). The range of minimum collar heights is smaller compared to the maximum values. The smallest difference between the minimum and the maximum value is obtained with ellipse I achieving a flat collar edge. The comparison between the ellipse II and the designed slotted hole II clearly indicates that the pre-hole shape also has a great influence, in addition to the dimensions of the axes. The maximum value of the collar height is reduced by adapting the shape, particularly with the conically reducing tool.

The ellipses II being calculated for different targeted collar heights were formed without continuous edge cracks. A maximum expansion ratio of over 220% was achieved. Only collars with a targeted height of 6.5 mm show necking and slight cracks visible at the neck edge. In correlation to the theoretical calculation, an increase in the values of the maximum collar height is obtained (Fig. 7b). All maximum values exceed the nominal values. With the help of the pre-hole calculation used, a range (collar height between 4.5 and 5.5 mm) with the best collar results can be determined with regard to the final minimum height as well as the flatness of the collar edge.

5 Conclusion and Outlook

A novel process for incremental collar forming of tubes made of 1.4404 was presented, with which 1:1 collars were achieved. The collars obtained were optically scanned and analyzed with regard to sheet thickness and geometrical accuracy and compared with an applicable standard for the food industry. The pre-hole calculations for collar forming with punch or ball were transferred to incremental forming variant. Four different calculation methods were examined and compared in terms of final collar height. In addition, pre-hole dimensions were determined for different targeted collar heights for a selected calculation method. A maximum collar height

of over 6.0 mm and a maximum expansion ratio of over 220% was achieved. The presented process enables the flexible production of T-pieces as well as the collar forming for large tubes and piping systems. Additional forming parameters such as infeed and feed rate will be investigated for further process optimization achieving a more homogeneous sheet thickness distribution. The number of forming cycles with regard to surface quality and cycle time should be reduced. Process simulation with numerical methods will be performed and compared with experimental results.

Deformation Analysis in Ultrasonic-Assisted Multi-stage Incremental Sheet Forming

Zinan Cheng, Yanle Li, Fangyi Li, and Jianfeng Li

Abstract The multi-stage incremental sheet forming is a promising forming strategy to fabricate complex shapes through the rational design of intermediate shapes. To further improve the formability, the ultrasonic-assisted multi-stage incremental sheet forming is proposed. The present work aims to reveal the effect of ultrasonic vibration (UV) on the thickness distribution, strain–stress state and the forming force variation. First, the finite element (FE) model is established through ABAQUS software, in which the trajectory of the forming tool with the high-frequency vibration is defined via the user subroutine VUAMP. Then, after the verification of the FE model, the thickness evolution, the stress–strain state and the forming force are comprehensively analyzed. It is found that the thickness distribution can be effective improved by introducing UV. In addition, the stress concentration in the bending area is effectively alleviated and the equivalent plastic strain is obviously increased under the UV. Final, the application of UV can lead to a notable reduction of forming force and smoother forming force curves at the latter two stages. The findings of this work provides evidences that ultrasonic assistance is an effective strategy to improve the incremental forming process.

1 Introduction

During the last two decades, great importance has been attached to incremental sheet forming (ISF) which is featured with high flexibility, great customization, small-scale production and low cost [1, 2]. In the ISF process, the three-dimensional shape is dispersed into a large amount of layers of plane shape, and the forming tool is controlled by a computer numerically controlled (CNC) machine to finish the target shape incrementally according on the prescribed trajectory. Due to the gradual accumulation of the local plastic deformation, ISF possesses a better formability compared to other traditional forming processes [3]. However, during the forming of difficult-to-form parts by ISF, the serious thickness reduction and fractures are inevitable by using traditional single-stage toolpath [4]. Therefore, the multi-stage incremental forming has been proposed. Moreover, the ultrasonic vibration (UV) was introduced to many manufacturing process (e.g. compression [5], upsetting [6] and spinning [7], etc.) due to the improvement of geometric accuracy [8] and formability [9], and the reduction of both the flow stress [10] and the surface roughness [11].

Kitazawa et al. [12] attempted to adopt the two-stage incremental forming to produce a hemi-ellipsoidal shape. Kim and Yang [13] proposed a double-pass incremental forming process and it was found that the shear-dominate deformation has an essential influence on the thickness reduction. Therefore, the final thickness strain can be predicted and the intermediate shape could restrain the serious shear deformation. Iseki and Naganawa [14] established a multi-stage incremental sheet metal bulging machine using spherical and cylindrical rollers for manufacturing shapes with vertical walls, and the final thickness distribution was calculated based on the forming limit diagram. Particularly, Skjoedt et al. [15] proposed various four-stage forming strategies including the down-up-down-down (DUDD) and down-down-down-up (DDDU) forming direction. The result showed that the strain distribution is not only depending on the toolpath geometry but also on the forming direction (upwards and downwards). Similarly, to overcome the limitation of maximum forming angle, Duflou et al. [16] implemented a five-stage incremental forming method and the maximum thickness reduction during the multi-stage is lower than that in the single-stage forming process, implying an increase of the formability. Ndip-Agbor et al. [4] relieved the stepped feature of the multi-stage forming through the prediction of the rigid body motion (RBM) and the application of the 3D contact patch toolpath. After a seven-stage forming of the developed strategies, a 15° increase of the maximum forming angle and a more evenly thickness distribution were obtained.

In terms of the application of UV in ISF process, existing studies have been focused on the single-stage incremental forming process. Amini et al. [17] found that plain strains of the parts formed by ultrasonic-assisted ISF are obviously higher than that without UV. Through a series of ultrasonic-assisted groove forming experiments, Vahdati et al. [18] found that the forming force and the surface roughness of formed parts can be reduced, and the forming depth and the geometric accuracy were enhanced. To reveal the influence mechanism of UV, Li et al. [19, 20] proposed the novel constitutive model and the material flow model to further reveal the influence

mechanisms of vibration field. The results showed that the UV can decrease the deformation flow stress and increase the equivalent plastic strain and the material flow area. Li et al. [21] found that when the vibration frequency is less than 40 kHz, the increase of the frequency can effectively reduce the vertical forming force. Through a series of experiments, Zhai et al. [22] found that the UV can effectively reduce the surface roughness and increase the surface bearing ability.

In the present work, the UV was applied to the multi-stage incremental forming process to further improve the formability. Furthermore, forming force, strain, stress and thickness evolution were analyzed through FE model to reveal the influence of UV on the deformation process. The rest of the paper is organized as follows. Section 2 describes the establishment of the FE model and the experimental platform. Section 3 interprets the simulation results and provides corresponding discussion. Final, the main conclusions of the present work are drawn in Sect. 4.

2 Methods

2.1 Finite Element Modeling

The FE model of ultrasonic-assisted incremental forming was established in ABAQUS/Explicit module based on the working principles shown in Fig. 1. In the FE model, the thickness of the sheets was defined as 1.0 mm and the material properties of AA1050-O are listed in Table1. In particular, to fully reflect the softening effect of UV, a self-developed constitutive model [19] was employed. In addition,

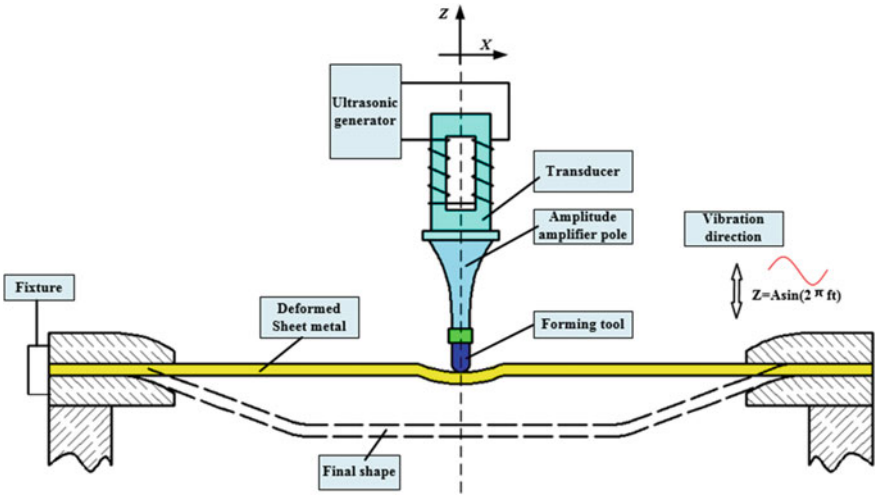

Fig. 1 Schematic diagram of the ultrasonic-assisted incremental forming. (Color figure online)

Table 1 Material properties of AA1050-O

Material property	Value (unit)
Density	2.7×10^{-9} (g/mm^3)
Yield strength	31.40 (MPa)
Ultimate tensile strength	69.68 (MPa)
Young's modulus	69.12 (GPa)
Elongation at break	52.43 (%)
Poisson's ratio	0.33

since the material of previous is different, the parameters in constitutive model were determined through the same method. The diameter of the forming tool was 5 mm. Furthermore, the sheet and the forming tool were set as the deformable shell and the discrete rigid, and the corresponding element type were determined as S4R and R3D4, respectively. The mesh strategy is shown in Fig. 2, in which the sheet was divided into the central deformed area and the surrounding fixed area. All freedoms of elements at the fixed area were constrained. The surface to surface contact condition between the forming tool and sheet was employed, and the forming tool was defined as the master surface while the sheet was set as the slave surface.

The shape of truncated cone was chosen as the forming target and the spiral toolpath was employed to avoid the stress concentration. The designed spiral toolpath and intermediate stages of the multi-stage forming are shown in Fig. 3. It is noticed that along the vertical direction, the forming tool has a continuous feed and high-frequency vibration. Therefore, the spiral toolpath needs to be analyzed as a function of the step time. The formula derivation process is shown in Fig. 4. Take an example of a single point P in the spiral toolpath, the forming depth can be determined through the following formula:

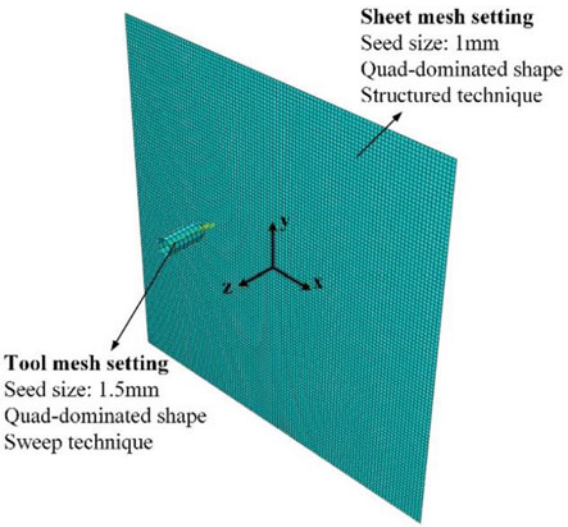

Fig. 2 The mesh setting and the mesh sketch of the sheet and forming tool. (Color figure online)

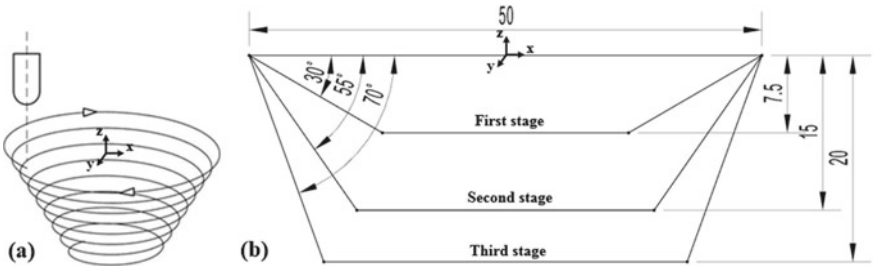

Fig. 3 **a** The spiral toolpath **b** The trajectory design of multi-stage forming

$$h = t \cdot V_h \tag{1}$$

where h is the forming depth (along the Z coordinate), t is the forming time, $V_h = H/T$ is the vertical feed speed of the forming tool. H is the total height of the truncated cone and T is the total step time. Subsequently, the radius of the spiral $R^{'}$ can be expressed as:

$$R^{'} = R - h/\tan\alpha \tag{2}$$

where R and α are the upper initial radius and the wall angle of the designed truncated cone, respectively. Then, the coordinates of a spatial point at time t can be written as follows:

$$\begin{cases} X = R^{'}\cos(\omega t) \\ Y = R^{'}\sin(\omega t) \\ Z = V_h t + A\sin(2\pi f t) \end{cases} \tag{3}$$

where $\omega = 2k\pi/T$ is the angular velocity, k is the number of spiral toolpath layers, A and f are the vibration amplitude and the frequency of UV, respectively. Then, the toolpath of the forming tool can be applied through the user subroutine VUAMP. For convenience, three forming stages were analyzed in a single FE model with three corresponding steps.

2.2 Experiments

To verify the developed FE models, corresponding experiments for ultrasonic-assisted multi-stage incremental forming were performed. As shown in Fig. 5, the experimental platform consists of an ultrasonic system, a machining center

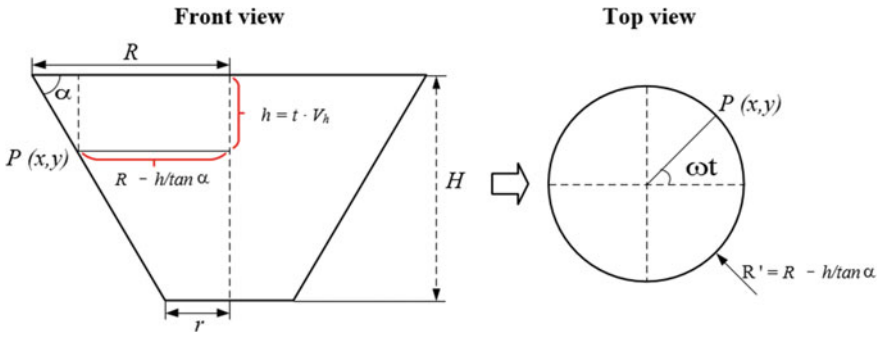

Fig. 4 The schematic diagram for the derivation process of the spiral toolpath. (Color figure online)

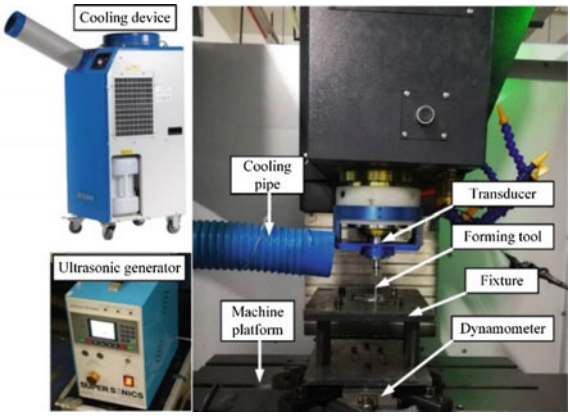

Fig. 5 Experimental platform of ultrasonic-assisted incremental forming. (Color figure online)

(DAEWOO ACE-V500), a fixture and a dynamometer (Kisler 9257B). The ultrasonic system includes an ultrasonic generator, a transducer, a forming tool, and a cooling device. Moreover, the experimental parameters are same as the simulation and the forming toolpath of three forming stages were generated in UG-NX software.

3 Results and Discussion

3.1 FE Model Verification

The comparison of forming force was shown in Fig. 6. Both force values and the evolution trend show reasonable agreement to corresponding experimental results. Without UV, the average errors in each stage are 5.8, 7.2 and 15.4%, and for UV

condition, the values are 6.9, 7.4 and 17.3%, respectively. Therefore, the developed FE model can be employed to further investigate the deformation behavior of the multi-stage forming process.

It can be noticed from Fig. 6 that the changing trend of forming force is similar under different UV condition, but the force value decreases obviously under UV

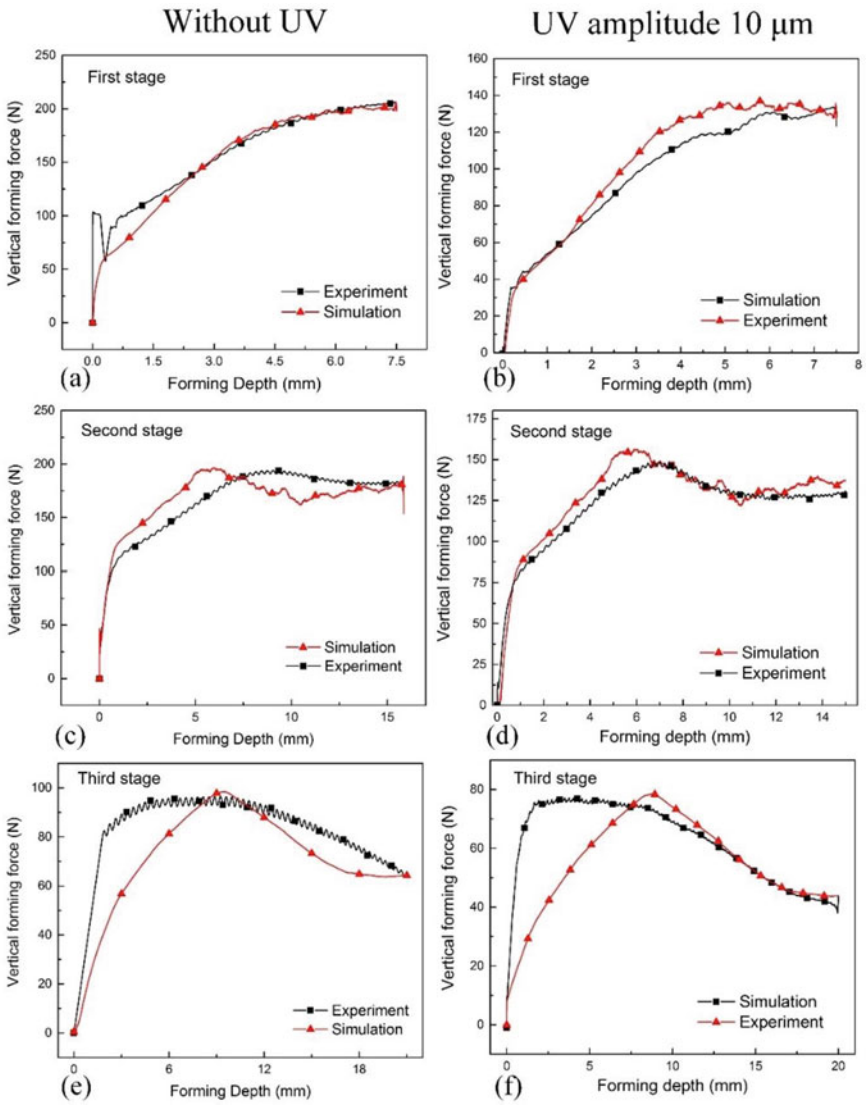

Fig. 6 Forming force comparison between simulation and experiments: Without UV: **a** First stage **c** Second stage **e** Third stage. UV amplitude 10 μm: **b** First stage **d** Second stage **f** Third stage. (Color figure online)

condition. In addition, the maximum force reduction rates caused by UV in three forming stages are 30.2, 26.1, and 20.4%. Then, due to the larger plastic deformation in the second stage, the material becomes completely yielded and then reaches the ultimate tensile strength. After that, considering the tensile property of AA1050-O material, the strength and the deformation resistance of material begins to reduce. As a result, the forming force first increases and then decreases to a relative stable value in the second stage. However, it can be observed that the force is much smaller in the third stage compared to the first two stages. There are two main factors accounting for this distinct change. First, under the serious plastic deformation condition, the thickness of the sheet metal reduces significantly. Furthermore, with the increase of the forming angle (70° in third stage), the normal contact area between the tool and the sheet gradually decreases. Consequently, the resistant force applied on the forming tool is reduced obviously.

3.2 Thickness Distribution

The thickness distribution of three forming stages under different UV condition are shown in Fig. 7. The maximum thickness reduction occurs in the side wall, while the minimum value takes place in the bottom area. Furthermore, it can be noticed that the application of UV can decrease the maximum thickness reduction in the side wall and the increase the thickness reduction in the bottom area. The maximum thickness reduction rates of three stages reduced by 2.1, 5.9 and 8.4%, respectively, and in the severe deformation condition of the third stage, the positive effect of UV becomes more obvious. Moreover, under the same volume of material, UV can make the material flow from the bottom area to the side wall so that the material distribution becomes more uniform.

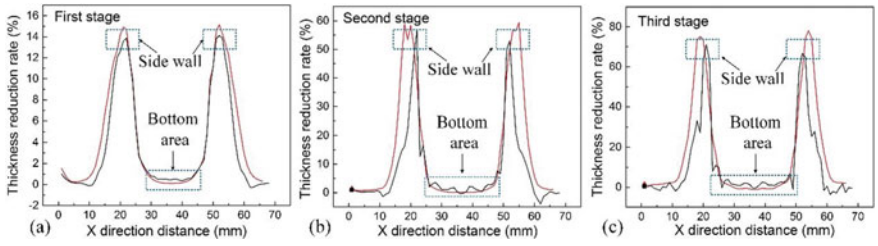

Fig. 7 Thickness evolution of cross section during the multi-stage incremental forming process: **a** First stage **b** Second stage **c** Third stage. (Color figure online)

3.3 Stress and Strain Analysis

The stress distribution of the sheet material during the multi-stage forming process is shown in Fig. 8. It can be noticed that in both UV condition, the maximum stress always occurs in the contact area of the forming tool and the sheet, and the maximum values of three stages are basically the same. However, the application of UV can effective decrease the stress during the forming process, and the maximum stress values are reduced by 47.1, 47.5, and 48% for three forming stages, respectively. Moreover, the strain evolution during the forming process is shown in Fig. 9, in which, ε_{11}, ε_{22} and ε_{33} are the strain of depth direction, circumferential and thickness direction. It can be clearly noticed that compared to ε_{11} and ε_{33}, the value of ε_{22} is

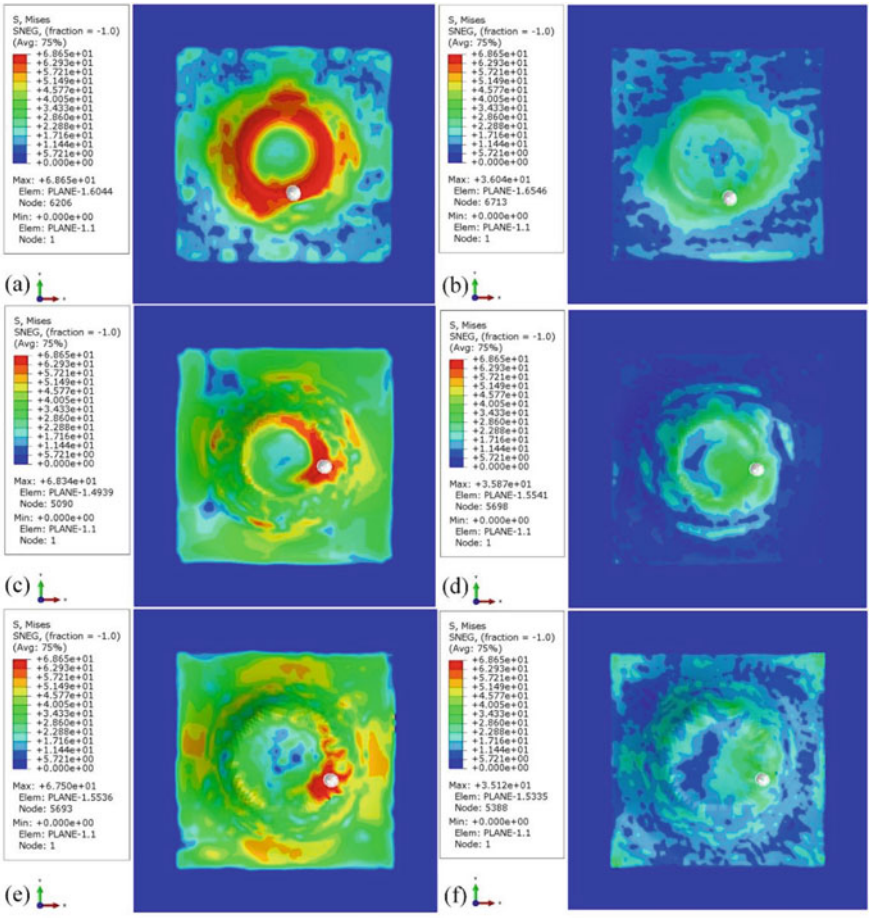

Fig. 8 Distribution of Mises stress, Without UV: **a** First stage **c** Second stage **e** Third stage. With UV: **b** First stage **d** Second stage **f** Third stage. (Color figure online)

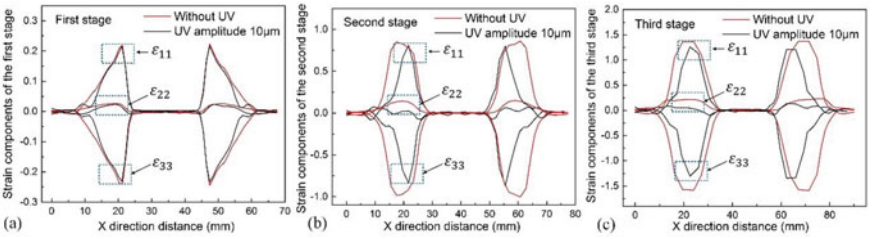

Fig. 9 Strain components of cross section: **a** First stage **b** Second stage **c** Third stage. (Color figure online)

much smaller to ignore, which indicates that the deformation in plane is the main forming mode of ISF. Moreover, in the first stage, values of strain components under different UV conditions are almost the same, while in the second and third stages, the application of UV can reduce the strain components of the formed part, especially the maximum strain value of ε_{11} and ε_{33}, which is consistent with the evolution of thickness.

4 Conclusions

In the present work, FE models for the ultrasonic-assisted multi-stage incremental forming are established and experimentally verified, in which the high-frequency vibration is loaded by the user subroutine VUAMP and a self-developed constitutive model is employed. Then, the forming force simulated thickness evolution and the stress–strain state are analyzed in detail. The main conclusions are summarized as follows:

1. The established FE model was verified through the comparison of forming force between simulation and experiment, and error between simulation and experiment is under 10%, which indicates that the FE model can be applied to further study of the forming process. Moreover, the maximum force reduction rates caused by UV in three forming stages are 30.2, 26.1, and 20.4%.
2. The thickness distribution of the cross section was analyzed through simulation results. It is noticed that the maximum thickness reduction rates of three stages reduced by 2.1, 5.9 and 8.4%, respectively. Furthermore, the maximum thickness reduction in the side wall reduce, meanwhile, the thickness reduction in the bottom area slightly increases. The results show that along the cross section, material distribution becomes more uniform under UV condition.
3. The application of UV can effective decrease the stress during the forming process, and the maximum stress values are reduced by 47.1, 47.5, and 48% for three forming stages, respectively. Furthermore, in the second and third stages, maximum values of strain components of ε_{11} and ε_{33} reduce by 12.3 and 9.1%, respectively, which is consistent with the thickness evolution.

A New Test Method for Sheet Metal Deformation Subject to Tension Under Cyclic Bending and Compression (TCBC)

H. Long, S. Ai, F. Tian, B. Lu, J. Chen, and H. Ou

Abstract A new test method for sheet metal deformation, *Tension under Cyclic Bending and Compression (TCBC)*, is developed in this study. The TCBC method is capable of testing material deformation under tension, bending, and compression with cyclic loading. The effect of each deformation mode can be independently controlled by adjusting corresponding parameters. Using the TCBC test rig developed, aluminium alloy AA5251-H22 is tested under four different testing conditions: simple tension, tension under cyclic compression, tension under cyclic bending, and tension under cyclic bending and compression. The maximum elongation of the tested specimen at fracture and the tensile force required for material plastic deformation are evaluated. The results show that the maximum elongation increases significantly under the TCBC condition due to localised plastic deformation under compression that delays the fracture. Finite element modelling of the TCBC test is developed to obtain stress distributions to explain the enhanced formability. The new TCBC method may be used for testing material formability that resembles double-side incremental forming.

1 Introduction

Incremental sheet forming (ISF) is a flexible, cost-effective, and energy-efficient process, particularly suitable for high-value manufacturing of small-batch and prototype products. In the ISF process, a simple tool with a hemispherical head moves

along predefined tool paths to deform a sheet blank incrementally into desired geometry. The ISF does not require any dedicated forming moulds or dies, thus it is flexible to manufacture small-batch products of different geometries and dimensions. The forming forces required in ISF are relatively small because the material is deformed locally and incrementally, thus there is no need to use heavy-duty forming equipment which further improves manufacturing flexibility. Furthermore, it has been widely reported that a variety of materials, when processed under ISF, has exhibited greater formability than that obtained by conventional sheet forming processes. Double-side incremental forming (DSIF), first reported by Meier et al. [1] and Smith et al. [2], has been developed to further enhance the material formability and to improve the process accuracy, compared to the conventional ISF using single-point incremental forming (SPIF). Figure 1 shows the basic concepts of single-point incremental forming (SPIF) and double-side incremental forming (DSIF). DSIF uses two simple tools at each side of the sheet blank; one tool acting as a master tool moves along predesigned tool paths to deform the material incrementally, while another tool moves synchronously acting as a support tool.

Forming limit curves (FLCs) are widely used to evaluate the material formability in conventional sheet metal forming processes. Banabic [3] reported that the dome test, hydraulic bulge test, and the Nakajima test were the commonly adopted testing methods to obtain the FLCs for various materials in the industry. An FLC defined the boundary of the stable deformation and unstable deformation of a material under various strain paths, such as uniaxial tension, plane strain, and equal biaxial tension. Materials generally exhibit much higher formability in ISF processes than that in the conventional forming processes. The FLCs obtained from SPIF experiments also show very different strain limit values and distributions upon the fracture occurrence, as illustrated in Fig. 2. The significantly enhanced formability in SPIF was demonstrated by testing various materials, including aluminium alloys used by Shim and Park [4] and Filice et al. [5], copper, steel, and aluminium alloys used by Fratini et al. [6]. For DSIF, both Malhotra et al. [7] and Lu et al. [8] reported that the material formability was further enhanced due to the compressive loading employed in DSIF in comparison with SPIF.

Emmens et al. [9] stated that FLCs could only be an effective method to predict the formability under the pre-condition that the material deformation is plane stress

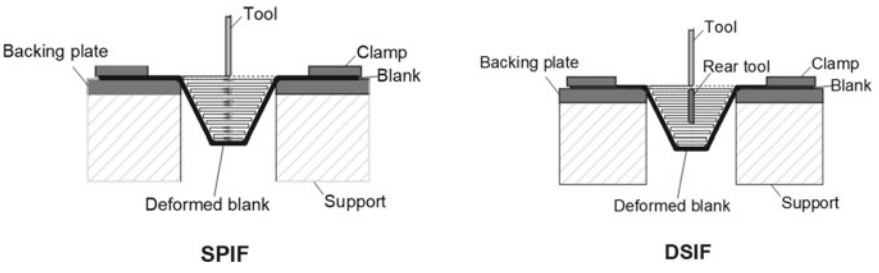

Fig. 1 Illustrations of single-point (SPIF) and double-side incremental forming (DSIF)

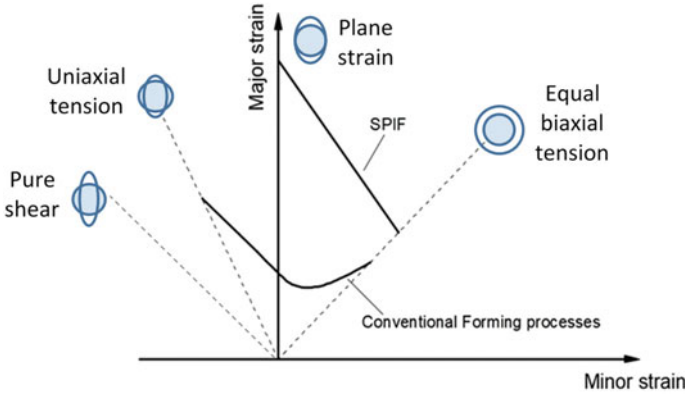

Fig. 2 Comparison of forming limit curves in conventional forming and SPIF processes. (Color figure online)

with a linear strain path, without bending and through thickness shear. In the conventional forming processes, the critical areas of the deforming part are generally under simple deformation conditions. However, the strain paths of SPIF deforming parts are generally between plane strain and equal biaxial tension [4, 10], where the material deformation is accumulated incrementally. It is widely acknowledged that the material deformation in SPIF is limited to the contact area between the tool and deforming sheet. Both experimental study and finite element (FE) simulation confirm that the material deformation in SPIF is a combination of stretching, bending, and shearing. Smith et al. [2] confirmed the effect of these deformation modes in ISF by comparing stress and strain distributions of the material elements in the thickness direction obtained from FE simulations. Eyckens et al. [11], Jackson and Allwood [12] investigated the influence of through-thickness-shear of the ISF formed parts on the material formability and identified the existence of stretching, bending, and shearing deformation modes. Furthermore, progressive toolpaths in ISF create cyclic and non-monotonic loading conditions. Consequently, the ISF formability can be affected by specific tool paths and process parameters, which makes it difficult to predict the onset of the fracture accurately. Emmens et al. [13] explained the stabilised deformation mechanisms in SPIF and concluded that the fracture could eventually occur at the weak spot of the material under continuous tensile loading. As a result, any deformation mode that suppresses the damage propagation at the weak spot improves the material formability. By applying a loading condition of cyclic bending onto the material, Emmens and von den Boogaard [14] performed the continuous bending under tension (CBT) test, in which the weakest spot in the test specimen changed constantly, leading to a significantly increased maximum elongation of 430% for material DC04.

The published studies on ISF material deformation, fracture, and formability are mostly conducted by performing the ISF test itself, as reviewed by Li et al. [15], Gatea et al. [16], and Sheng et al. [17]. However, owing to the complexity of the ISF process, including the complex loading conditions and localised contact and

cyclic deformation, it is not easy to evaluate the individual and interactive effects of different deformation modes as well as the cyclic loading condition on the material deformation and fracture by simply conducting SPIF or DSIF tests. The traditional formability evaluation methods, such as FLCs, as shown in Fig. 2, are unable to explain the experimental observation of material formability enhancement achieved in the ISF processes.

In this study, a new test method named *tension under cyclic bending and compression* (TCBC) is developed to investigate the material deformation in incremental forming processes, such as SPIF and DSIF. This test method is a further development of the CBT test method [14] owing to the introduction of compression deformation mode in addition to the deformation modes of tension and bending with cyclic loading. Using the developed TCBC test rig, four different testing conditions—simple tension (ST), tension under cyclic compression (TCC), tension under cyclic bending (TCB), and tension under cyclic bending and compression (TCBC)—are performed to investigate the bending effect, compression effect, and combined effect of bending and compression on the formability enhancement. Finite element models of TCB and TCBC tests are also developed to explain the effect of the localised material deformation and interaction of bending and compression on the formability enhancement.

2 TCBC Test Concept Development

The focus of this study is to develop a material testing method capable of applying various loading conditions such as tension, bending, and compression, with the cyclic loading effect. In the CBT test developed by Emmens and van den Boogaard [13, 14], the sheet specimen was stretched in the longitudinal direction while the cyclic bending was also applied, thus the material deformation under tension and bending with cyclic effect was investigated. To facilitate the superimposed compressive loading generated by the additional tool employed in DSIF, the new test method needs to provide a compressive force from the other side of the sheet specimen, moving synchronously with the bending tool. Figure 3 illustrates the different deformation zones at the contact between the master and slave tools because of the introduction of the compressive loading in DSIF.

Figure 4 presents the design concept of tension under cyclic bending and compression (TCBC) test. It consists of a bending roller, a compression roller, and two support rollers to enable the application of tension, bending, and compression deformation with cyclic loading effect. To develop the detailed design of the test rig, an analytical model based on the elementary plasticity theory is developed to characterise the effect of tension, bending, and compression on the initiation of material plastic deformation [18]. By considering an infinitely small element of the specimen material within the compressive deformation zone, as shown in Fig. 4, based on the force equilibrium condition and the Tresca yield criterion, the contact stress between the specimen and bending roller, σ_t, can be derived as

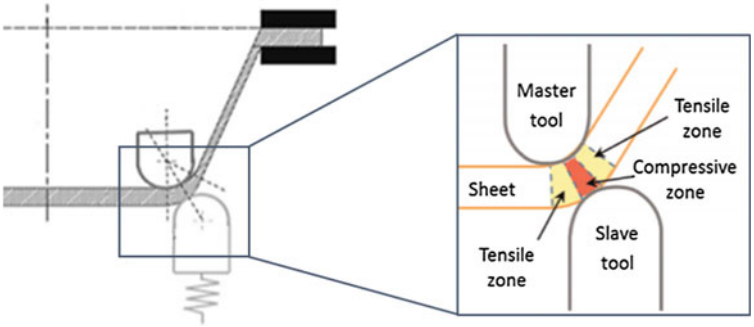

Fig. 3 Different deformation zones at the contact between master and slave tools in DSIF. (Color figure online)

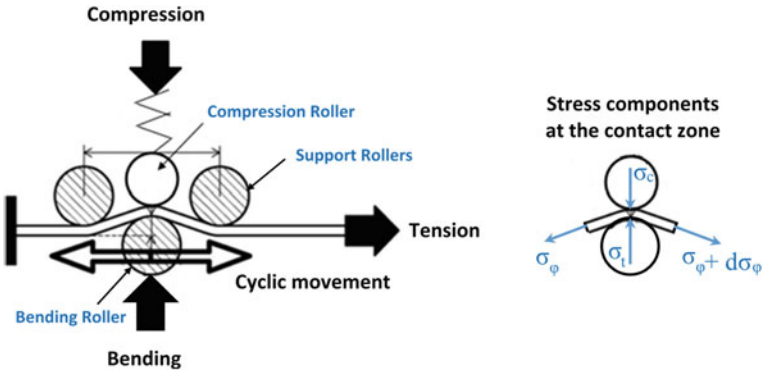

Fig. 4 Design concept of tension under cyclic bending and compression (TCBC) test. (Color figure online)

$$\sigma_t = \frac{\sigma_s + \sigma_c \frac{r_t}{t}}{1 + \frac{r_t}{t}}$$

where σ_s is the material flow stress, σ_c is the contact stress between the specimen and the compression roller, as shown in Fig. 4; r_t is the radius of the bending and compression rollers, and t is the thickness of the specimen under deformation. The tensile stress of the specimen in its longitudinal direction, σ_φ, can be derived as

$$\sigma_\varphi = \frac{(\sigma_s - \sigma_c) \frac{r_t}{t}}{1 + \frac{r_t}{t}}$$

By varying the radius of the rollers from 8 to 12 mm, using sheet thickness from 1 to 2 mm, it has been shown that the ratio of roller radius to sheet thickness only varies from 4 to 12. To illustrate the effect of compressive stress σ_c and contact stress due to bending roller σ_t on the variation of the tensile stress $\sigma_{\varphi,}$ the rollers with a

radius of 10 mm and the sheet blank thickness of 1, 1.2, 1.5, and 2 mm are tested. The ratio of the compressive stress to the flow stress, σ_c/σ_s, is varied as 0.3, 0.5, 0.7, and 0.9 to evaluate the variation of the tensile stress to the flow stress ratio, σ_φ/σ_s, as shown in Fig. 5. The analysis clearly shows that higher compressive stress will result in a much lower tensile stress required to reach the desired plastic deformation of the material, thus delaying the occurrence of fracture. Using the roller radius and sheet thickness values tested, the ratio of roller radius to sheet thickness only shows the minimal effect on the variation of the tensile stress ratio. As also shown in Fig. 5, the tensile stress ratio σ_φ/σ_s reduces proportionally while the contact stress ratio due to

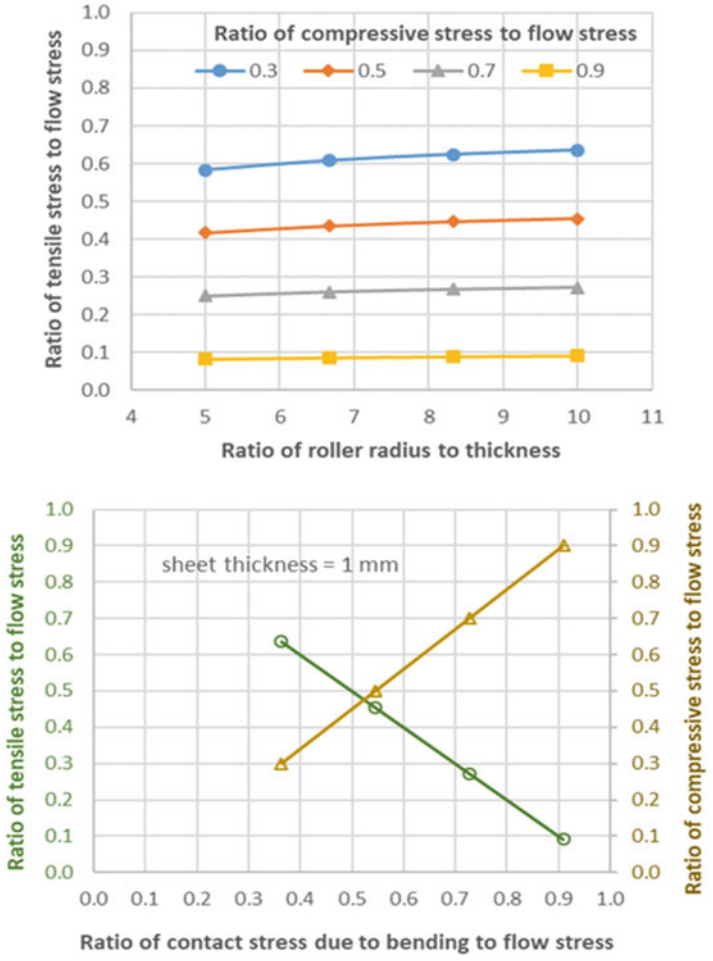

Fig. 5 Effect of compressive stress ratio (σ_c/σ_s) and bending contact stress ratio (σ_I/σ_s) on tensile stress ratio (σ_φ/σ_s). (Color figure online)

bending σ_t/σ_s increases; however, the compressive stress ratio σ_c/σ_s also increases with the increasing contact stress ratio due to bending σ_t/σ_s, which may result in high stresses in the localised areas of the specimen-tool contact, thus leading to early fracture.

3 TCBC Test Rig Design and Manufacturing

Based on the TCBC test concept developed and the analysis of the effect of the bending and compressive loading on the material plastic deformation, a test rig is designed and manufactured. The CAD model and completed TCBC test rig are shown in Fig. 6.

Various loading conditions can be applied onto the sheet specimen by using the developed loading device, mounted on a uniaxial tensile test platform as shown in Fig. 6. Both ends of the sheet specimen are clamped and the specimen is stretched from one end by the movement of the linear screw mechanism driven by a DC motor. Bending and compression loadings onto the specimen can be applied by the loading device where the specimen can be inserted through and bent from the below by the bending roller and compressed from the above by the compression roller. The compression roller is supported by two cylindrical springs to provide the required level of the compression force as well as to maintain the contact between the compression roller and the specimen. In order to ensure the bending being applied to

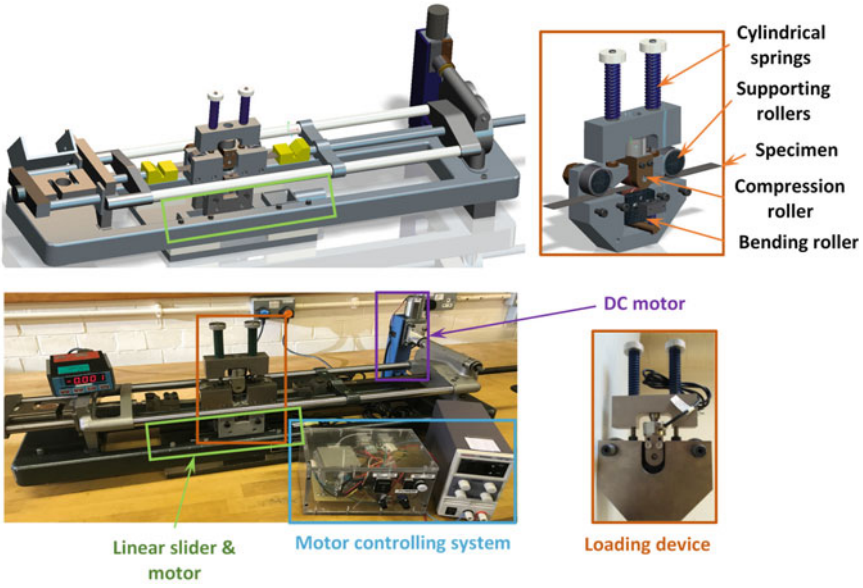

Fig. 6 Tension under cyclic bending and compression (TCBC) test rig and loading device. (Color figure online)

the target deformation zone and maintain the bending effect during cyclic loading, the specimen is kept in position by two supporting rollers positioned at a constant distance. All rollers can rotate freely around their own axis to reduce friction. The loading device can move along a slider track that is mounted on the base of the uniaxial tensile test platform and driven by another DC motor. On both ends of the slider track, a micro switch is placed; once the loading device hits the switch, the rotating direction of the DC motor will be reversed, creating a cyclic movement of the loading device. Using the motor controlling system, the stroke speed of the slider, the tensile speed, the bending depth, and the compression force can be independently controlled and varied. These correspond to the effect of each deformation mode in DSIF, including cyclic effect, tension effect, bending effect, and compression effect.

4 TCBC Experiment and Results Discussion

Using the test rig developed, four different types of experiments, representing various loading conditions, are performed. These include tests of simple tension (ST), tension under cyclic compression (TCC), tension under cyclic bending (TCB), and tension under cyclic bending and compression (TCBC). Material AA5251-H22 is used and sheet specimens with a thickness of 1, 1.2, and 1.5 mm are tested. Five test parameters are investigated where the compressive force is varied from 0 to 1700 N, bending depth from 1 to 13 mm, stroke speed from 0 to 2.5 mm/s, and stretching speed from 0 to 4 mm/min.

4.1 Effect of Various Loading Conditions on Material Deformation

Figure 7 shows the tensile force time history when the sheet thickness is 1.5 mm, the compression force 906 N, bending depth 9 mm, stroke speed 1.5 mm/s, and stretching speed 3.2 mm/min. Significant tensile force reduction is recorded under TCC, TBC, and TCBC conditions when compared to that under simple tension. The maximum tensile force under TCBC condition is only 50% of that required under simple tension. Figure 8 shows the maximum elongation ratio at fracture of the specimens tested under these conditions. The maximum elongation ratios of the specimen under TCC, TCB, and TCBC are significantly higher than that under simple tension. The specimen elongation is the greatest under TCBC while the elongation under TCB is higher than that under TCC. The fracture behaviour of the specimens is also different under different testing conditions. In the simple tension test, the crack of the specimen occurs at an approximate angle of 45° to the elongation direction of the specimen. While in other tests of TCC, TCB, and TCBC, the cracks of the specimen are all perpendicular to the elongation direction. The

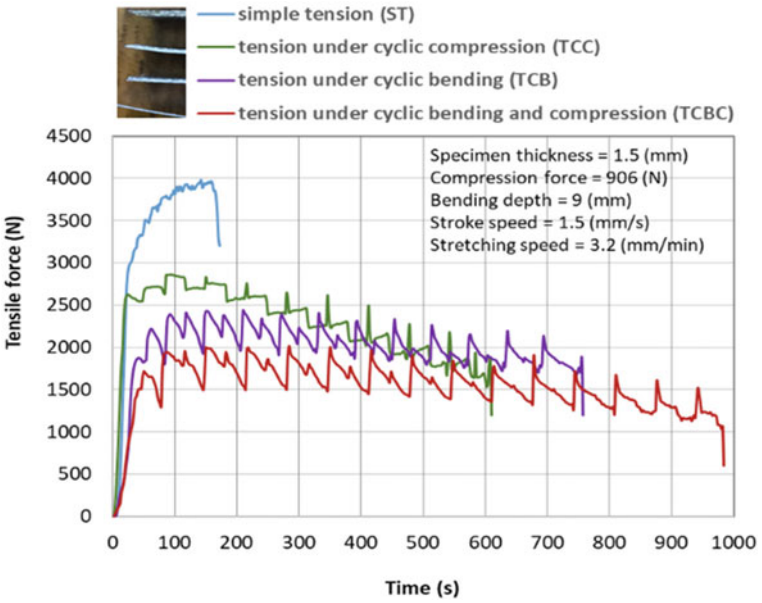

Fig. 7 Tensile force time history under four different testing conditions. (Color figure online)

difference in the cracking orientation of the specimens resulted from the difference in stress distributions due to different loading conditions, as discussed in Sect. 4.3.

4.2 Effect of Bending Depth and Compression Force on Material Deformation

To investigate the bending effect on material deformation, different values of the bending depth, varied from 1 to 13 mm, are used under the TCB testing conditions, while all other parameters remain constant. Figure 9 shows variations of the maximum elongation ratio and maximum tensile force when different values of the bending depth are applied. It shows that the maximum elongation ratio increases with the increasing bending depth; at the bending depth of 12 mm, the maximum elongation ratio achieved is 70%, i.e. equivalent to an increase of 42 mm elongation from the original gauge length of 60 mm. However, when the bending depth is further increased to 13 mm, the maximum elongation ratio starts to reduce which was explained by Emmens et al. [19] as a fracture mechanism under cyclic loading effect. Figure 9 also shows that the maximum tensile force reduces considerably when the bending depth is increased. The tensile force reduction trend levels out and remains almost constant after the bending depth reaches to and is >10 mm.

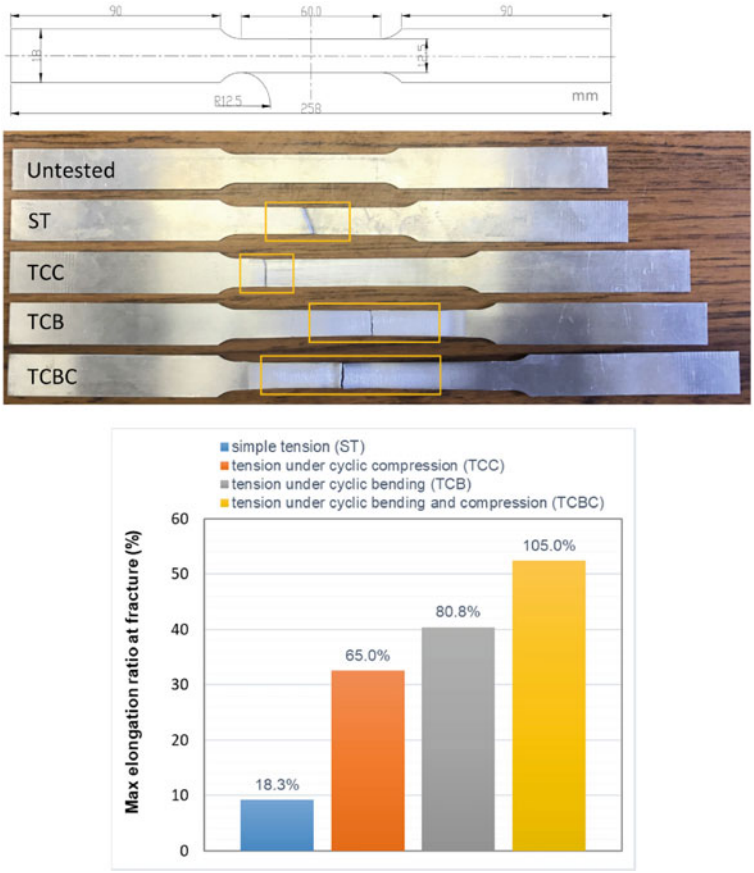

Fig. 8 Maximum elongation of tested specimens under four different testing conditions (thickness 1.5 mm, compression 906 N, bending 9 mm, stroke speed 1.5 mm/s, and stretching speed 3.2 mm/min). (Color figure online)

To investigate the compression effect on material deformation, different values of the compression force, varied from 100 to 1700 N, are applied under TCBC testing condition while all other parameters remain constant. Figure 10 shows variations of the maximum elongation ratio and maximum tensile force when different values of the compression force are used. At the compression force of 906 N the maximum elongation ratio reaches 80%; with further increases of the compression force from 906 to 1359 N the maximum elongation ratio increases significantly to peak at 142%. However, with further increase of the compression force, the maximum elongation ratio starts to decrease. When the compression force increases, Fig. 10 shows a steady decrease of the tensile force required for achieving the material plastic deformation.

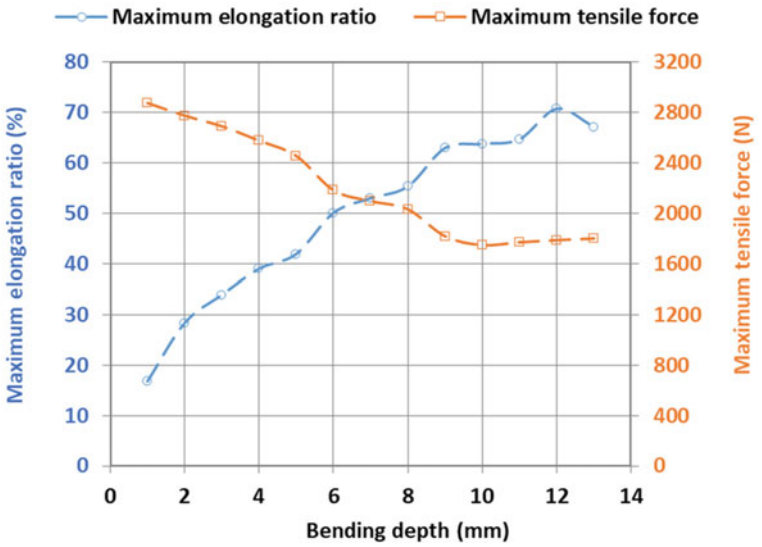

Fig. 9 TCB tests with variable bending depth (thickness 1 mm, compression force 0, stroke speed 1 mm/s, and stretching speed 2.4 mm/min). (Color figure online)

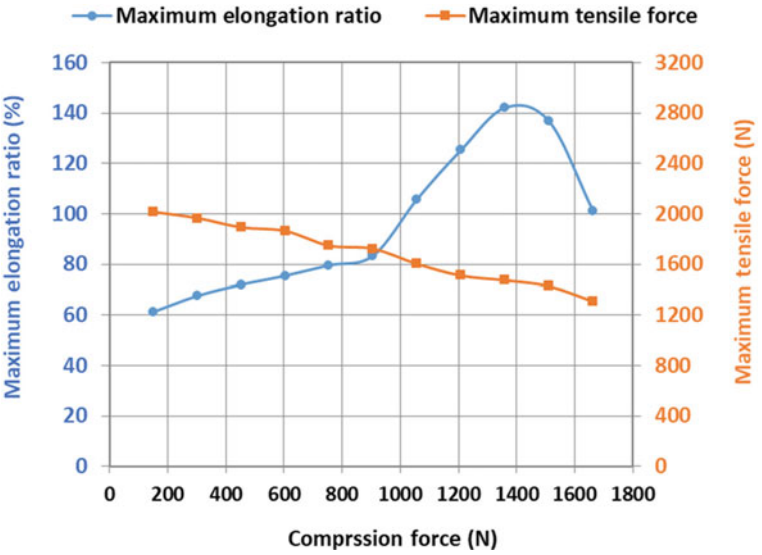

Fig. 10 TCBC tests with variable compression force (thickness 1.2 mm, bending 9 mm, stroke speed 1.5 mm/s, and stretching speed 3.2 mm/min). (Color figure online)

4.3 FE Modelling of Material Deformation Under TCB and TCBC Conditions

To understand the material deformation characteristics of the significantly increased elongation of the specimen under TCB and TCBC testing conditions, the FE models of TCB and TCBC tests are generated to simulate the experimental tests using the developed test rig. In FE modelling, a stroke speed of 1.5 mm/s and stretching speed of 2.4 mm/min are applied to the specimen thickness of 1 mm under bending depth of 9 mm. For the TCBC model, an additional compression force of 600 N is applied; while for the TCB model it is zero. The details of the FE modelling can be found in [18]. Figures 11 and 12 show the FE stress distributions on two surfaces of the specimen in the longitudinal direction at the uniform material deformation stage, under the TCB and TCBC testing conditions, respectively. Under both testing conditions, for the surface in contact with the compression roller the material is under tension and subjected to the highest plastic deformation. On the other hand, for the surface in contact with the bending roller the material is under compression.

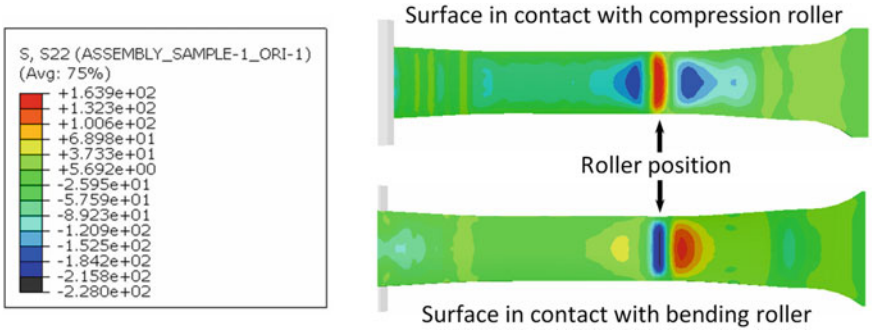

Fig. 11 TCB test—stress distributions of deformation zones around compression and bending rollers. (Color figure online)

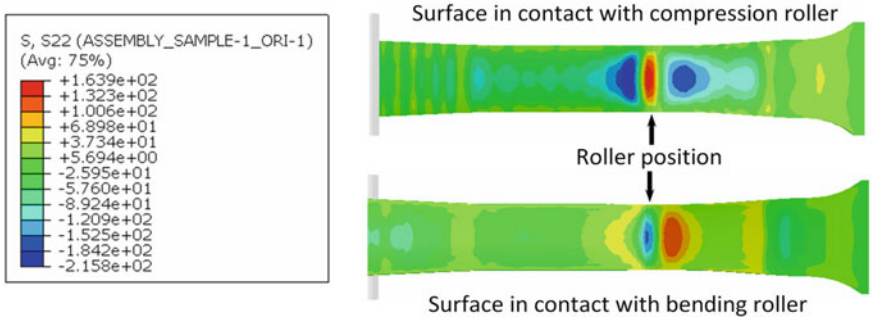

Fig. 12 TCBC test—stress distributions of deformation zones around compression and bending rollers. (Color figure online)

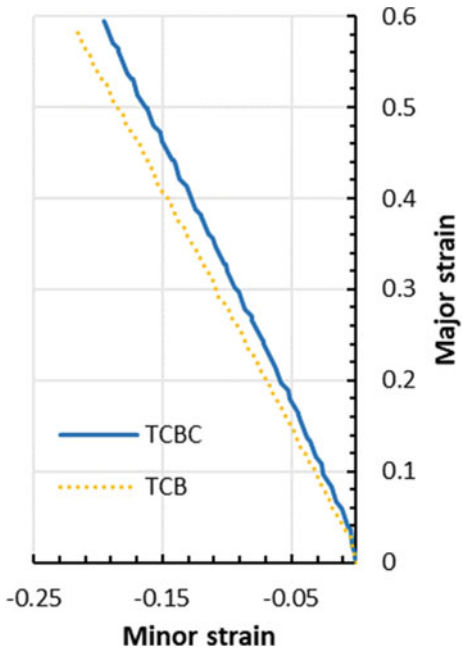

Fig. 13 Strain paths of elements in FE modelling of TCBC and TCB tests. (Color figure online)

The additional compressive force in the TCBC test reduces the difference of the stresses on these two surfaces leading to a more uniform stress gradient through the specimen thickness. The more homogeneous stress distribution in the specimen thickness allows the material to undertake a greater plastic deformation, thus delays the occurrence of fracture.

Figure 13 shows the strain paths of the elements located on the outer surface in the centre of the specimen of the TCBC and TCB FE models. The strain component in the longitudinal direction of the specimen is a major strain and the strain component in the specimen's width direction is a minor strain. The nonlinear strain paths reflect the effect of cyclic loading on the material deformation. For TCBC test, the introduction of the compressive force reduces the material deformation in the lateral direction than that in the TCB test, while elongations of the specimens in the longitudinal direction are the same. In the TCBC and TCB tests, as shown in Fig. 13, the material deformation is approximately between the plane strain and uniaxial tension, as illustrated in Fig. 2. However, in the ISF processes, the material is approximately under a strain state between the plane strain and equal biaxial tension. The difference could be caused by two factors, first due to the difference of the geometric constrains between the TCBC tests and the ISF processes, and secondly, how the tension is applied onto the specimen material. In the TCBC and TCB tests, tension is applied by continuous stretching force from the clamp. By comparison, in the ISF processes, the sheet blank is only clamped on its outer edges, once the tool(s) moves away from

the sheet-tool contact area, the tension applied on that area of the material would be partially released. As a result, the strain paths obtained from the TCBC and TCB tests are different from the ISF processes.

5 Conclusions

The new TCBC test method has successfully produced results to evaluate the material deformation under four different conditions: simple tension (ST), tension under cyclic compression (TCC), tension under cyclic bending (TCB), and tension under cyclic bending and compression (TCBC). The following conclusions may be drawn:

- The compressive force shows a significant effect on the increase of the maximum elongation of the tested specimen and a significant reduction of the tensile force required to achieve the material plastic deformation. However, high compression forces greater than a certain limit may reduce the maximum elongation, thus have a negative effect on formability.
- The bending depth displays a considerable effect on the increase of the maximum elongation even under a small value of bending depth tested. However, when the bending depth is increased above a certain limit, it may result in higher tensile stresses on the specimen surface in contact with the compression roller, thus causing early fracture of the specimen.
- The maximum elongation increases significantly under TCBC condition due to cyclic alternations of localised plastic deformation zone that delays the occurrence of fracture. The experimental testing and FE modelling results also show the effects of complex interactions between compression and bending on the material deformation and fracture.

Acknowledgments The authors would like to acknowledge the research funding support received from UK EPSRC (EP/T005254/1) and EU FP7 Marie Curie Actions (FP7-PEOPLE-2013 IIF 628055). They are also grateful to senior mechanical technician David Webster in Department of Mechanical Engineering of the University of Sheffield for his support in developing and manufacturing the TCBC test rig.

Numerical Modelling and Deformation Mechanics of the English Wheel Process

Daniel T. Bowen, Omer Music, A. Alaz Erdinc, Alborz Shokrani, and Evripides G. Loukaides

Abstract The mechanisation of traditional craft processes can serve as a starting point for novel process development in the increasingly topical field of flexible metal forming. This approach presents several challenges, including understanding the underlying mechanics, mechanisation, and providing suitable control methods for such processes. Here, we focus on the underlying mechanics of the process known as the English wheel. In this work, the process is studied through validated numerical modelling techniques. The influence of various geometrical parameters is examined and the possible patterns of plastic deformation are presented.

Keywords English wheel · Craft · Finite element · Metal forming · Stretch-bending · Tool force

1 Introduction

The environmental and economic benefits of eliminating part-specific tooling have resulted in increasing interest in developing additional flexible metal forming processes over the past few years [1]. This is defined as extending the range of attainable part geometries from a single process. The motivation for flexible forming comes from the environmental and economic benefits of eliminating part-specific tooling. The advent of Industry 4.0 signals that manufacturing is beginning to move away from traditional mass production and towards mass customisation [1, 2]. At the same time, the route to reliable new flexible processes presents many challenges.

A skilled craftsperson has the ability to form a diverse range of part geometries from a blank using just a small set of universal tooling. Such craft processes often serve as starting points for novel flexible forming process development. Some

examples include flexible asymmetric spinning [3] and more recently, the "folding-shearing" process [4]. One craft process that has not received much attention in the literature is the English wheel (EW).

The EW was first used by panel beaters in the early 1900s to create compound curves in metal sheets [5]. The process incrementally stretches sheets of metal by passing the material through two dissimilarly shaped and sized roller anvils. Wheeling (the act of using the EW) is a labour-intensive and complex process. Nevertheless, the EW remains popular with job shops and hobbyists. It is capable of producing a vast range of doubly curved surfaces with an extremely limited set of tooling, and at a very low cost, whilst delivering an excellent surface finish. For the same reasons, it is an attractive candidate for mechanisation and automation. Existing attempts of mechanisation use a data-intensive approach without considering the underlying mechanics and typically employ a robotic arm to actuate the sheet [6]. Previous work in understanding the mechanics of the English wheel is scarce. Music and Allwood [7] measured and compared the instantaneous deformation of workpieces for a number of processes, including the EW. Their focus was on the comparison between processes; hence, no in-depth information for the EW was presented.

For human operators, the ability to create sheet metal geometries with limited tooling comes from years of training and practice, which provide intuition and understanding of the craft process. However, existing craft experience is difficult to translate to a technical understanding of the process and seldom provides sufficient information for automation. The processes that require a skilled worker to initiate and continually update the manufacturing strategy are slow and costly. Deskilled processes allow for large-scale industrial adaptation, which can translate into mass customisation of parts with doubly curved surfaces.

Disappointingly, there is almost no mention of the EW process in the metal forming literature. This paper presents the first steps in comprehensively understanding the English wheel process. We employ an FEA model to examine the mechanics of the local deformation. A parametric study qualifies how different process parameters influence deformation. Our results further the understanding of the underlying mechanics; an essential step towards future attempts of mechanisation.

2 Overview of Manual Wheeling

A conventional EW is shown in Fig. 1. The frame (1) can be either fabricated from three welded bars or cast as one single piece. Cast frames are more desirable as they are stiffer and suffer less bending during the process. The upper anvil (2) has a flat radial profile and an outer radius approximately twice that of the lower anvil (3). The lower anvil is mounted on a lead screw so that the gap between the anvils can be adjusted (4). A selection of lower anvils is usually used, each with varying profiles. These profiles are defined as having various *blow radii,* as shown in Fig. 1. The blow

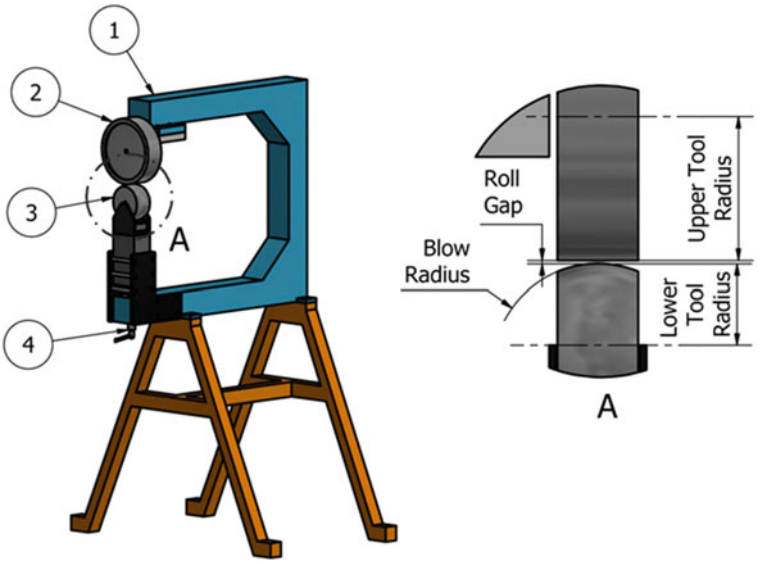

Fig. 1 Typical English wheel. (Color figure online)

radius is required to allow curved parts through the gap, but it also has a function in controlling the curvature produced, which we examine later in this paper.

During the process of manual wheeling, the sheet is not constrained around the outer edges by a supporting fixture. Instead, the sheet is held in a variety of different ways by the operator. With both roller tools free to rotate, the actuation force required to drive the sheet through the tools is provided by the worker. Between forward and backward passes, a slight yaw angle, φ, is introduced so as to work across the desirable area in a zig-zag pattern, as shown in Fig. 2. Care is usually taken not to wheel the boundaries of the sheet. The exact function and influence of this undeformed boundary on the final product is also an open question.

3 Finite Element Model

A finite element model was created in Abaqus FEA package. In this work, non-zero yaw angles were not considered, i.e., only tool paths along a single straight line were considered. This allowed a number of simplifications, including making use of symmetry to reduce computation time. A schematic of the model is shown in Fig. 3, where the relevant directions and the plane of symmetry are labelled. We also show the hold region where the boundary conditions are applied, and a central region on the sheet with a refined mesh.

The model uses an implicit time scheme solver. Upper and lower anvils are defined as analytical rigid parts. The sheet is modelled using full integration

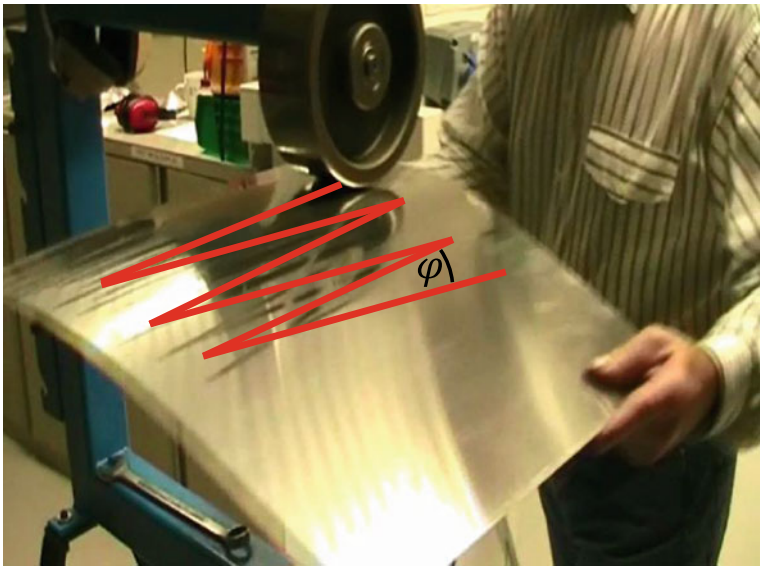

Fig. 2 Tracking pattern used during wheeling. (Color figure online)

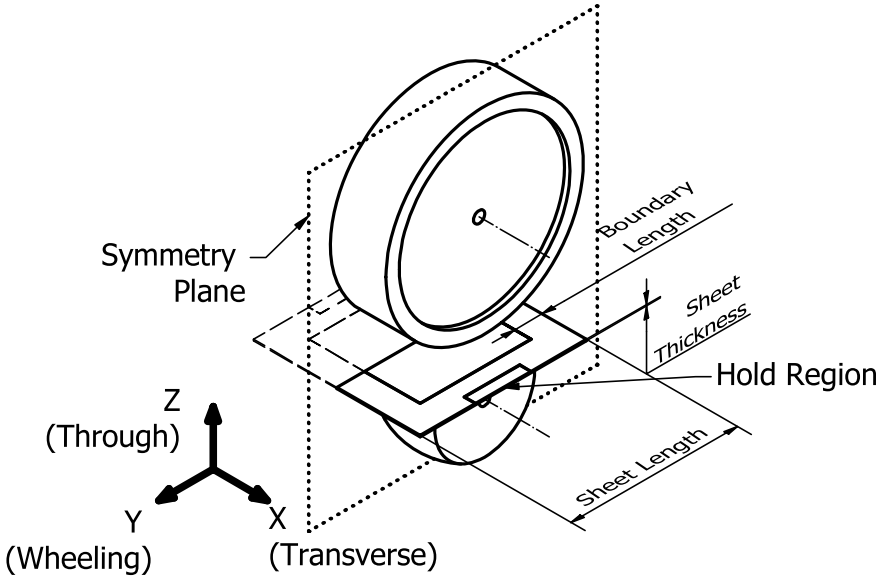

Fig. 3 Model configuration

C3D8 elements. The mesh has four through-thickness elements to capture through-thickness behaviour and the element sizes in-plane are smaller towards the plane of symmetry, with the centre elements having an in-place length of 0.5 mm. The sheet material is modelled as aluminium 5251 with Young's modulus of 70 GPa, Poisson's ratio of 0.3, and density of 2700 kg/m^3 with plastic hardening data prescribed from unidirectional experimental testing. A standard surface-to-surface contact method was specified between the anvils and sheet with a Coulomb friction coefficient of 0.2. The anvils were assigned inertia values calculated based on their shape and material (steel of density 8000 kg/m^3) and are free to rotate, similar to the real process.

Firstly, the effect of simple indentation was tested. This model was composed of two Abaqus steps, one where a vertical motion was prescribed for the tools so that the sheet was squeezed in the through-thickness direction, and one where this motion was reversed. A second model was developed to include a third step between the aforementioned two, where the sheet was actuated along the y-direction, to emulate the physical process of wheeling.

One of the major challenges in modelling the process is identifying and applying suitable boundary conditions. In practice, the worker manoeuvres and drives the sheet through the tools by grasping the outer edges. As the sheet develops curvature, they will react to this by adapting the grip based on experience. Replicating these conditions numerically requires extensive study of manual wheeling by experts to formulate the process. For this study, boundary conditions have been prescribed to have as little influence near the deformation region as possible. This was done by constraining a small region—the *hold region,* far from the deformation zone to drive the sheet through in the wheeling direction only; the remaining two directions (transverse and through) are unconstrained.

To verify the model, results from a straight line back and forth wheeling pass were compared with a physical trial on an EW. Sheet geometry was measured using a GOM ATOS optical three-dimensional coordinate measurement system. For the sheet size used in this study (150 mm × 150 mm), the measurement error is ±0.01 mm or ±3% of the maximum profile height measured. Results are displayed in Fig. 4 and show that the z-direction displacement in the numerical model is within 15% of the physical measurements.

4 Results and Discussion

4.1 English Wheel Mechanics

We first look at one base case (see Table 1), to describe the typical deformation during the process of wheeling. Initially, when the rollers first make contact with the sheet and squeeze the material, the material both thins and thickens, as shown in Fig. 5i. The thinning occurs in the region between the tool and the sheet (the contact region) as well as the region immediately surrounding it. Some of the region

Table 1 Parameters for all the simulations. Dimensions given in mm

Parameter		Base case	Variant			
			1	2	3	4
Reduction ratio, q		4%	3%	4%	5%	6%
Blow radius, R (mm)		150	50	100	150	200
Sheet thickness	1	Upper tool radius			101.6	
Sheet length	150	Lower tool radius			50.8	
Boundary length	37.5	–				

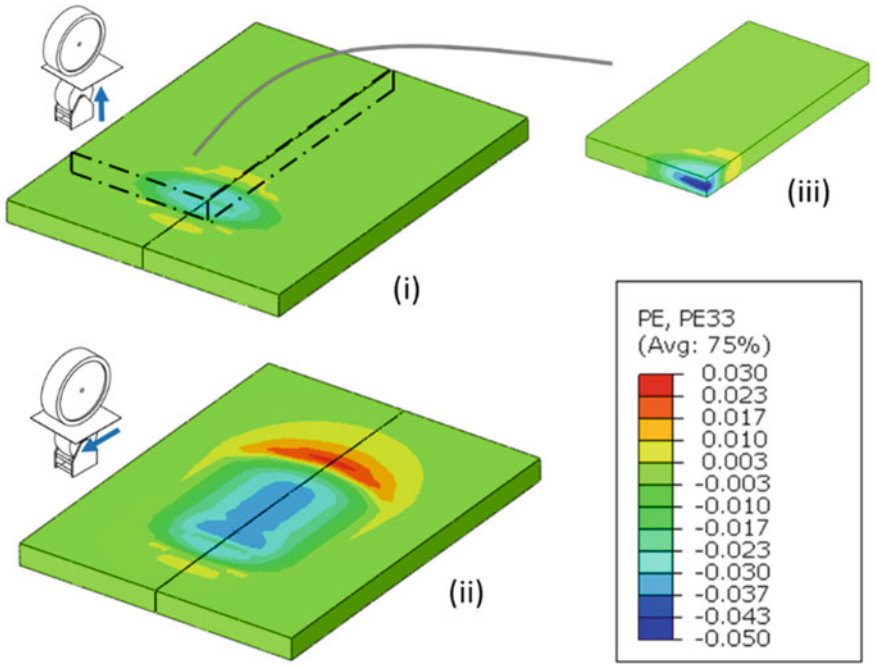

Fig. 5 Through-thickness strain mirrored along the symmetry plane during (i) initial indentation and (ii) wheeling. (iii) Cross section shown during indentation. (Color figure online)

beyond this, however, thickens. The material beyond the plastic region provides the compressive stresses that stop the material from spreading outward further and force it to thicken. This thickening of the material is not axisymmetric due to the dissimilar roller profiles.

As the sheet is driven through the rolls, material builds up in front of the anvils, in the direction of the wheelpath. The increase in thickness in this region is far greater than the thickening of material observed in the transverse direction. As shown in Fig. 5ii, this build-up can be displayed prominently at the end of the pass.

For further understanding, a section of a sheet that has been wheeled is considered far away from the initial squeeze contact area and the edge of the sheet. In this region, strains appear uniform over a short length along the wheeling path. At the locations of contact with the tools, the sheet shows both through-thickness thinning (Z) and expansion of material in the transverse direction (X). This implies that the material is being pushed outwards.

When wheeling, the curvature is developed mostly in the transverse direction. The magnitude and mechanism by which this deformation occurs can be analysed by considering the upper and lower transverse strains, ε_X. These are plotted for various points along the X direction in Fig. 6. Close to the wheeling path, high values of positive strain indicate the sheet is stretching at this point. The difference between strains (Δ) in the top and bottom surfaces shows that the sheet is also bending making for a combined mechanism of deformation.

Away from the wheelpath, these strains reduce and eventually start to compress the material. Around the region of maximum compression, the magnitude of bending also rises; the difference between upper and lower surface strains is largest here. This is the location of maximum bending in the transverse direction, and not directly under the tools. Beyond this point, plastic strains diminish. Springback was not notable, likely due to the free sheet boundaries in the process.

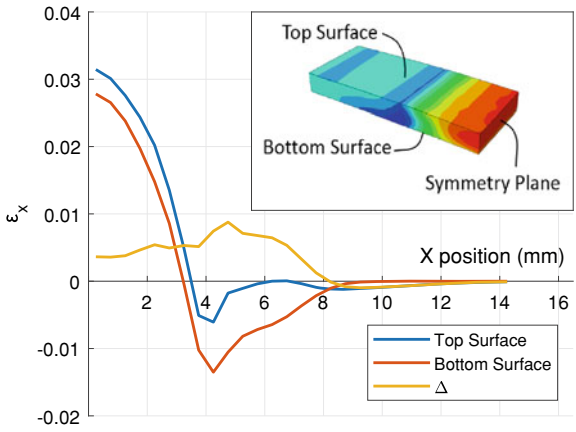

Fig. 6 Strains in X direction for wheeled section of sheet. (Color figure online)

5 Parametric Study

The base case in the previous section served to give an initial description of the process mechanics. Here, we expand our understanding with a number of trials that examine how configurable parameters affect the mechanics of the process. We define the reduction ratio, q, as the ratio of the indentation depth travelled by the tool and the original sheet thickness. Blow radius, R, is also varied with values and other default values shown in Table 1.

One set of trials focuses on the initial squeezing of the sheet. This pushes material outward and causes thickening of material around the tool contact area. In a similar process of driving, the tool is typically axisymmetric and thus the spread of material outward is the same in all directions from the bite point. In the case of the EW, the dissimilar upper and lower anvils, and their non-axisymmetric geometries cause the material to be formed in a more complex way, as seen in Fig. 5iii. The effect of the reduction ratio and the lower tool profile on the through-thickness strain, ε_z, is investigated in Fig. 7 for the indentation step. A quarter model with a refined mesh size is used for these trials; element size at the centre is reduced to 0.2 mm.

A manual on EW operation suggests that lower tools should be selected purely to adjust the contact area with the sheet, accommodating curvature in the transverse direction [5]. However, these results show that for a flat sheet, the lower tool profile can affect the thickening profile of the sheet as well. The reduction ratio also has a

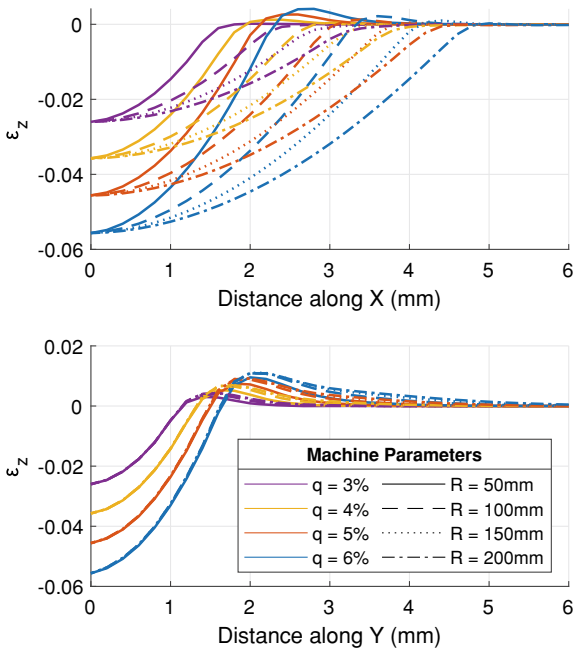

Fig. 7 Through-thickness strains after squeezing and releasing the sheet. (Color figure online)

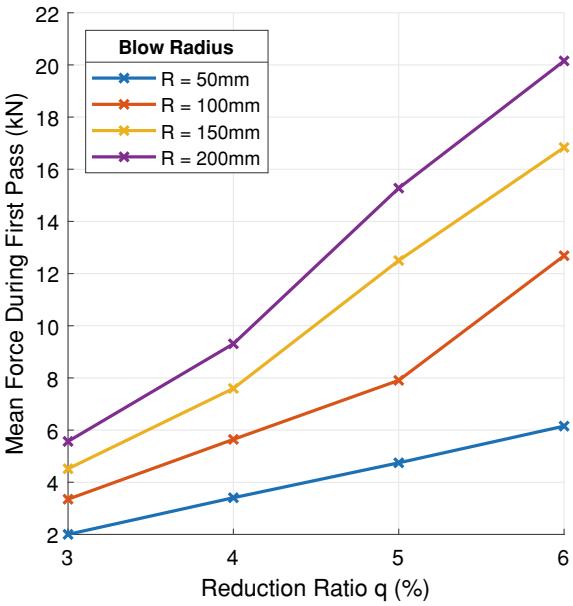

Fig. 8 Average tool reaction force in z-direction. (Color figure online)

significant effect on the magnitude of the peak strains seen in both directions. Furthermore, some threshold exists for roll gap and tool radius, whereby no thickening takes place in the transverse direction. It is acknowledged that this is not indicative of the process as a whole; it does not take into account the effect of tool rotation and sheet movement during wheeling. However, this does demonstrate that both lower tool selection and roll gap affect the through-thickness strain profile of the sheet.

The anvil reaction force in the Z-direction during wheeling was observed to change with different lower tool profiles and roll gaps. A plot of the mean force, with bars showing the standard deviation of force throughout an initial pass for different profiles, is shown in Fig. 8. When the sheet was rolled both forward and backward through the tools, the force dropped by 70%. This has implications for the accuracy of the model. For a given tool force the frame will experience some bending, causing the roll gap to increase. As the tool force is shown to be dependent on the roll gap, these coupled variables should come to an equilibrium state, resulting in a new gap and force. This change in roll gap, as previously shown, can have an effect on the characteristics of the material deformation, and not only on its magnitude.

6 Conclusions

This paper presented the first parameterised examination of the mechanisms of deformation experienced by the sheet during the wheeling process. We showed that curvature is produced locally, with the curvature in the transverse direction dominating.

We explored the influence of tool geometry and tool gap on the deformation. Other subtle effects, like the possible thickening of the workpiece immediately past the area of contact, were observed for the first time.

Future work will concentrate on identifying the best approach to accurately represent realistic boundary condition for this process in simulation. Alternative boundary conditions and actuation methods to those normally employed in traditional wheeling will be explored and their effect on the deformation mechanics will be investigated. Finally, frame deformation and the yaw angle were not accounted for in our model but will be addressed in further efforts.

The Dieless Drawing Process for the Elongation of Ultrafine Copper and Brass Wire

Andrij Milenin, Piotr Kustra, Miroslaw Wróbel, Valeriy Pidvysots'kyy, and Marek Packo

Abstract In this study, a new method of ultrafine copper and brass wires production was proposed. The proposed technology is based on the dieless drawing. The workpiece for the dieless drawing is a thin wire (100–200 μ) obtained by a conventional drawing method. The proposed technology is based on the implementation of a multi-pass incremental deformation. Moreover, in each pass, strain and strain rate sensitivity of flow stress should be positive and significant. The deformation parameters in each pass are determined based on the flow stress dependency on the strain, strain rate, and temperature. Therefore, plastometric tests of copper and CuZn37 alloy were performed. To estimate the temperature of deforming wire the FE modeling of dieless drawing was performed. The obtained data were used in the practical implementation of incremental dieless drawing technology. Roughness analysis was performed for brass samples. In the performed experiments tests, the dieless drawing will lead to an increase of roughness of the wire surface. However, this increase is relatively small. The value of R_a before the dieless drawing was 1.73 μ, and after deformation, it was 2.23 μ.

Keywords Dieless drawing · Copper · Wire · Roughness · Workability

1 Introduction

The ultrafine wire is widely used in the microelectronic industry, microrobotic, filtration, and other technical areas. The conventional manufacturing technology of fine wire is based on a cold drawing in dies with diamond cores. It was shown by Kraft [1] that using an expensive die significantly increases the cost of the process. The workability of the wire decreases due to strain hardening in the multi-pass drawing process. For some materials, this requires a process shutdown and heat treatment.

For example, as Seitz et al. have shown in their work [2], this should be done when drawing wire from magnesium alloys. In this case, additional heat treatment lasts for several hours in a vacuum or inert gas. This significantly increases the cost of the process and makes it less productive. On the other hand, the lubricants used in wire drawing and their removal by chemical treatment degrade the surface quality of the wire and further increase the cost of the process. These and other disadvantages of conventional wire drawing limit the ability to produce fine wire and increase the cost of the process.

A potential solution to the above problems could be the usage of the dieless drawing process. Generally, the process of dieless drawing is a stretching of a wire, rod, or tube with its simultaneous local heating in the deformation zone. The heat source is usually represented by an electric furnace, inductor, or laser beam. The first studies of this process were performed by Weiss and Kot [3] and devoted to the production of wire. Dieless drawing allows elongation of the wire without using a deforming die. This fact is important since in the conventional drawing process the cost of the die is very high. Additionally, dieless drawing has several other advantages. For example, Supriadi et al. [4] have shown that it is possible to vary the stretching and cross-sectional shape of the tubes along their length, which is impossible to obtain with conventional drawing or extrusion. Another advantage is the achievement of a relatively large elongation in one pass. In the process of continuous dieless drawing of carbon steel wire, Tiernan and Hillery [5] achieved uniform reductions of cross-section up to 72% in a single pass. They have shown that the drawing method is more fracture-resistant than the corresponding wire drawn conventionally with dies.

One of the promising possibilities of dieless drawing is the production of fine and ultrafine wire. Li et al. [6] have shown that by laser dieless drawing it is possible to elongate the wire with initial diameters of 125–500 μ from commercial-grade pure nickel. The maximum achieved reduction in the area was 30–40%. It was discovered that workability increases in an inert gas atmosphere.

Potentially, dieless drawing may allow obtaining a wire with a smaller diameter than the industry produces. However, the implementation of dieless drawing for the production of ultrafine wire requires a solution to two important problems that define the purpose of this paper. The first is the optimal choice of temperature and deformation parameters to achieve maximum forming limit and uniformity of diameter along the length of the wire. The concept of dieless drawing, which allows solving this problem, was proposed by Milenin [7] using the example of a magnesium alloy. The idea behind this approach is to perform multi-pass dieless drawing. Moreover, in each pass, the material must be in conditions of maximum hardening. This approach allows us to reduce the irregularity of the diameter along the length of the wire and to increase the workability of material in the technological process. However, its effectiveness depends on the sensitivity of the flow stress of the deformable material to strain and strain rate. With high sensitivity, the method becomes more efficient. By the effectiveness (E) of a multi-pass dieless drawing process, we mean the ratio of the maximum achievable elongation with multi-pass deformation to this value obtained by a single-pass process.

The second problem is the increase of roughness during dieless drawing. Furushima and Manabe [8] have shown that the surface roughness during dieless drawing increases with increasing elongation. Furthermore, the rate of increase of roughness depends on the grain size of the initial materials. Further studies by Furushima et al. [9] showed that the evolution of roughness significantly affects the workability of the material during dieless drawing. This problem has become more important for the production of the ultrafine wire because the resulting roughness can be comparable to the diameter of the wire, and significantly reduce the workability.

Thus, the solution to these problems requires both plastometric studies of the material and laboratory dieless drawing tests to predict the workability and roughness of the wire under conditions of dieless drawing.

2 Material Properties

This paper studies two materials—technically pure copper and CuZn37 alloy (brass). Plastometric studies of these materials were performed at a temperature range of 20–90 °C (copper) and 400–650 °C (CuZn37). The experiments were carried out on GLEEBLE (copper) and Zwick 250 (CuZn37) machines.

The choice of a GLEEBLE physical simulator for the study of copper was made because at high temperatures, copper has a complex dependence of flow stress on the strain. For example, this was shown by Garcia et al. [10]. Due to this fact, it is difficult to apply the inverse analysis method, which requires an accurate approximation of the dependence of stress on strain using analytical functions [11]. The GLEEBLE machine minimizes the influence of friction and controls the temperature with high accuracy, but the cost of testing is high. In experiments with the GLEEBLE, the hardware stabilization of the material temperature was carried out during the test. The accuracy of this temperature control for strain rates of 0.01 and 0.1 s^{-1} was about 1 °C. The tested samples had an initial diameter of 8 mm and a height of 10 mm. Typical flow stress–strain curves for copper are shown in Fig. 1.

In compressive tests on the Zwick 250 machine, such a correction was impossible; therefore, an inverse analysis was applied based on modeling strain-induced heating of the sample and friction. As it was shown by Chandra et al. [12], brass is characterized by monotonic dependencies of flow stress–strain. For this reason, a more simple machine (Zwick 250) was used and the subsequent processing of the results by the inverse analysis method. The used samples had an initial diameter of 5 mm and a height of 6 mm. Each experiment was repeated 2–3 times. The experiments were carried out for strain rates of 0.1, 0.5, and 1.0 s^{-1}.

The methodology of inverse analysis was adapted for the deformation conditions in the Zwick 250 machine. In the inverse analysis, the compression load (P) was calculated using an analytical model of yield strength in the form of an equation:

$$\sigma = A\exp(-m_1 t)\varepsilon^{m_2}\dot{\varepsilon}^{m_3}\exp(-m_4\varepsilon)t^{m_5} \quad (1)$$

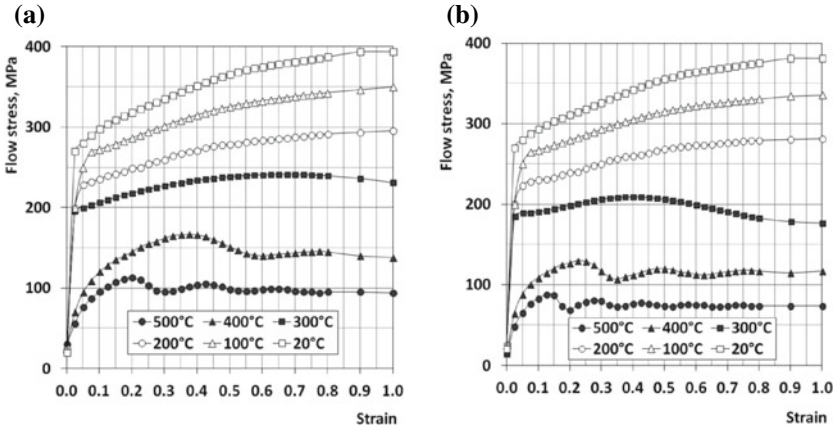

Fig. 1 Experimental dependence of flow stress on strain for commercial copper at temperatures of 20–500 °C: **a** for strain rate 0.1 1/s; **b** for strain rate 0.01 1/s

where A, m_1–m_5 = empirical coefficients, ε = strain, $\dot{\varepsilon}$ = strain rate, and t = temperature.

Equation (1) is used in the compression test model, which takes into account deformation heating, friction, and changing the shape of the sample during compression. This model, adapted for the test conditions in the machine Zwick 250, is described in the paper of Milenin et al. [13].

The squared difference of the calculated and measured compression load is taken as the objective function. The objective function was minimized by variation of empirical coefficients in Eq. (1). As a result of minimizing the objective function, the following coefficients of Eq. (1) are determined: $A = 2148.29$; $m_1 = 0.00615030$; $m_2 = 0.181711$; $m_3 = 0.155512$; $m_4 = 0.643115$; $m_5 = 0.156934$.

The average error in load approximation was 3.8%. A comparison of the calculated and experimental values of the load depending on the displacement of the tool for a strain rate of 0.5 is shown in Fig. 2. Figure 3 shows the results of the calculation of flow stress according to formula (1) using determined coefficients.

In the experiments on GLEEBLE and Zwick 250, samples of various geometries were used; however, in both cases, no signs of uneven deformation up to a strain of 0.5–0.6 were observed. Therefore, the stress state of the samples was close to linear, and the results are relevant.

3 Setup for Dieless Drawing and Experiments

For the practical implementation of the process parameters, a special experimental setup was developed (Fig. 4). The setup described here can continuously produce wire with the dieless drawing method. The setup software controls the linear rotation

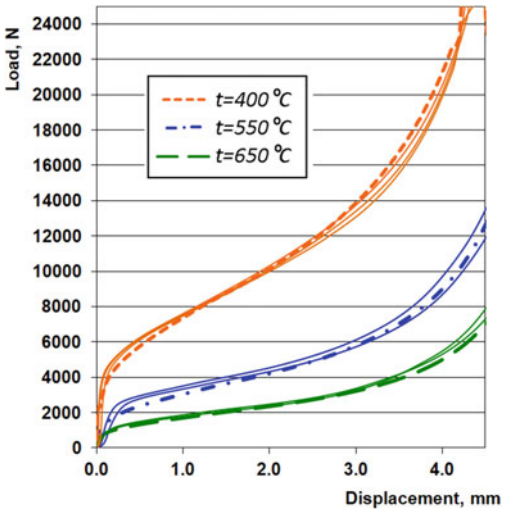

Fig. 2 Dependence of the load during plastometric compressive tests of a sample of CuZn37 alloy on the displacement of a tool: thin solid lines—experiments; thick dashed lines—calculation of load based on Eq. (1). (Color figure online)

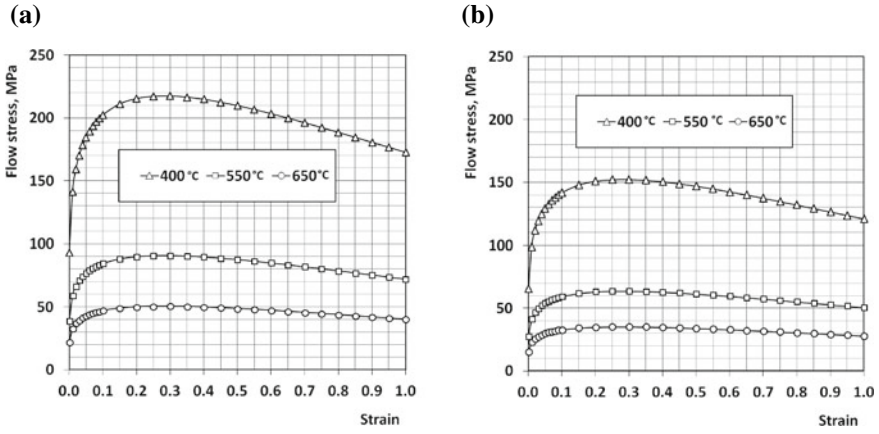

Fig. 3 The flow stress of CuZn37 alloy: **a** for strain rate 0.1 1/s; **b** for strain rate 0.01 1/s

rates of the rollers (V_1 and V_2). The designed setup allows for continuous multi-pass dieless drawing without removing the wire. In this case, after the completion of the current pass, the roller velocities V_1 and V_2 are reversed.

In the setup software the amount of strain of the wire in the heated zone during pass $\varepsilon_{\text{pass}}$ is calculated from the condition of constant volume for $V_2 > V_1$:

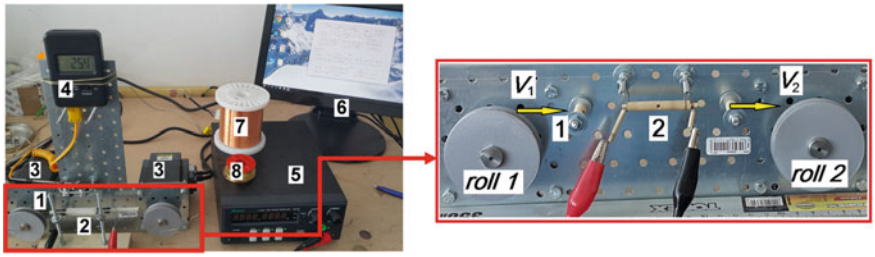

Fig. 4 Setup for dieless drawing of wire: 1—wire; 2—heating device; 3—engines; 4—module for measurement of temperature inside the heating device; 5—power supply for the heating device; 6—control computer with setup software; 7, 8—initial wire made of CuZn37 and copper. (Color figure online)

$$\varepsilon_{\text{pass}} = 1 - \frac{V_1}{V_2} \tag{2}$$

FE model of temperature in the wire is implemented in setup software. This model is based on the solution of a one-dimensional axisymmetric unsteady heat problem. Since measuring the temperature of a thin wire is extremely difficult, this software is designed to calculate the temperature in a wire.

The thermal problem in the metal was solved as non-stationary heat transport problem:

$$k\left(\frac{\partial^2 t}{\partial r^2} + \frac{1}{r}\frac{\partial t}{\partial r}\right) = c\rho\frac{dt}{d\tau} \tag{3}$$

where c is the specific heat, ρ is the alloy density, τ is the time, and k is the thermal conductivity coefficient.

Equation of non-steady-state heat exchange (3) is treated using the Galerkin method and standard FEM procedure. One-dimensional linear finite elements were used. A grid of 50 finite elements was used. Thus, the FE model of temperature is based on considering the passage of the wire cross-section through the deformation zone. This made it possible to obtain a solution in real time on the control computer of the setup (MODECOM microcomputer with processor Intel® Atom™ Z3735F was used).

As the boundary conditions, the temperature in the heating device t_d and the heat transfer coefficient α_d are used. In practical modeling α_d was taken at 300 W/m^{2}K, and t_d was measured by a thermocouple (K-type thermocouple and device TM-902C Lutron was used). When modeling, the following values of density (ρ), thermal conductivity (k), and heat capacity (c) were adopted:

$$\text{Cu: } \rho = 8650\ \text{kg}/\text{m}^3;\quad k = 250\ \text{W}/\text{mK};\quad c = 390\ \text{J}/\text{kgK};$$
$$\text{CuZn37: } \rho = 8115\ \text{kg}/\text{m}^3;\quad k = 140\ \text{W}/\text{mK};\quad c = 380\ \text{J}/\text{kgK}.$$

The conditions and results of the experiments are presented in Table 1. In Table 1, d_{wp}=initial diameter of wire; n=number of passes; ε_d=the logarithmic strain of diameter: $\varepsilon_d = ln\left(\frac{d_{\text{final}}}{d_{wp}}\right)$; E=effectiveness of a multi-pass process.

The calculated temperature of the wire for the conditions listed in Table 1 is shown in Fig. 5. The presented results show that at given wire diameters and drawing speeds, the wire temperature always reaches the temperature in a heating device with an accuracy of several degrees Celsius. Thus, the measured temperature of the heating device can be considered the deformation temperature.

For all cases listed in Table 1, the dieless drawing was carried out until the wire was broken. The final diameter of the wire was taken from the previous passage. Thus, the data presented in Table 1 characterize the conditions of a stable process. In single-pass processes ($n = 1$), the velocity V_2 increased stepwise until a wire break was reached.

The choice of strains in each pass for multi-pass processes was carried out using the dependences of flow stress on the strain, strain rate, and temperature (Figs. 1 and 3). The general rule states that the strain in one pass should correspond to the maximum strain hardening of the material. The idea of increasing workability is that high strain hardening of the material blocks the development of the neck, which increases the overall deformation of the material to failure. Since the hardening of the material decreases with the increasing strain (Figs. 1 and 3), the efficiency of the multi-pass process should increase with decreasing elongation in one pass. This was shown, for example, in [7]. However, since the maximum hardening corresponds to very small strains, there is always a trade-off between process productivity (small strains per pass increase the number of passes) and the maximum achievable strain in the process. A deeper analysis of this issue was performed in [7]. Two levels of strains in one pass are practically accepted—0.047 (positions 1, 2, 6 of the table) and 0.093 (position 5). The choice of only two strains for the study is due to the limited time and high cost of the study. Further research, however, should be carried out to establish the dependence workability on strains in each pass.

It should be noted that with these strains, brass has a much more intense hardening (Fig. 3) than copper (Fig. 1). For this reason, it can be expected that the use of multi-pass deformation for copper will be less efficient.

4 Discussion

The results obtained for copper (positions 6 and 7 of the table) allow us to formulate two conclusions. First, the total elongation of the wire is small (0.21–0.23) and significantly lesser than that of brass wire (0.31–0.63). The second conclusion is that using a multi-pass process instead of a single-pass process does not significantly increase workability. The effectiveness of the multi-pass process was 1.11. One of the reasons for this result may be the complex nature of the dependence of flow stress on strain for copper. A deeper analysis of this problem will be made in future studies.

Table 1 Conditions and results of experiments

N	Material	d_{wp} (mm)	V_1 (mm/s)	V_2 (mm/s)	ε_{pass}	n	d_{final} (mm)	t_d (°C)	Strain rate (1/s)	ε_d	ε_{final}	E
1	CuZn37	0.2	24.3	25.5	0.047	13	0.147	530	0.383	−0.308	0.616	1.97
2	CuZn37	0.2	24.3	25.5	0.047	13	0.146	590	0.392	−0.315	0.629	1.54
3	CuZn37	0.2	24.3	35.5	–	1	0.171	530	0.234	−0.157	0.313	–
4	CuZn37	0.2	24.3	41.2	–	1	0.163	590	0.335	−0.205	0.409	–
5	CuZn37	0.5	2.43	2.68	0.093	4	0.415	400	0.024	−0.186	0.373	–
6	Cu	0.1	24.3	25.5	0.047	5	0.089	300	0.145	−0.117	0.233	1.11
7	Cu	0.1	24.3	30.9	–	1	0.090	300	0.145	−0.105	0.211	–

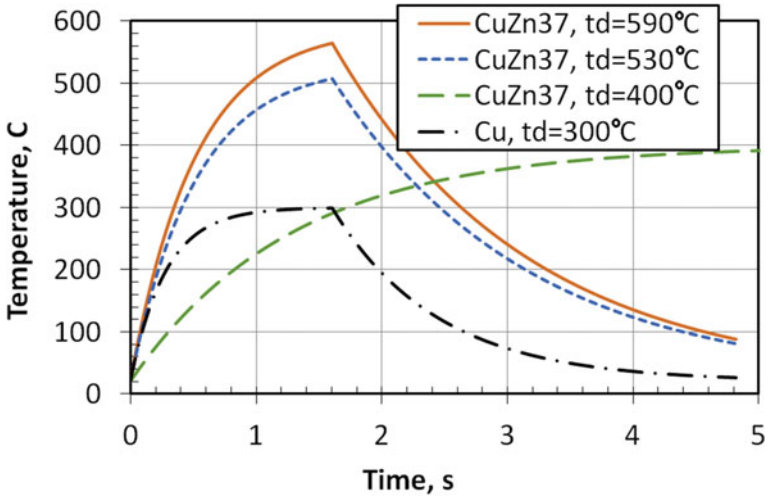

Fig. 5 The FEM calculated dependences of the temperature of the wire during the experiments (t_d is a temperature in the heating device; $t_d = 590$ °C corresponded to positions 2 and 4; $t_d = 530$ °C—to positions 1 and 2; $t_d = 400$ °C—to position 5; $t_d = 300$ °C—to positions 6 and 7 from Table 1). (Color figure online)

The surface of the wire before and after the dieless drawing is shown in Fig. 6. On the surface of the wire after deformation cracks are observed on the grain boundaries (Fig. 6c).

The results obtained for brass are more optimistic. The effectiveness of the multi-pass process at a temperature of 530 °C is 1.97 (position 1 in Table 1). At the same time, increasing the temperature to 590 °C reduces the effectiveness to 1.54 (position 2 in Table 1). This is because with increasing temperature workability in a single-pass process (positions 3 and 4 in the table) increased faster than in the multi-pass process (positions 1 and 2 in the table). The resulting wire has a defect-free surface (Fig. 7), both in the case of a single-pass (Fig. 7b) and a multi-pass process (Fig. 7c).

The result obtained at 400 °C (position 5 in Table 1) is characterized by significantly lower workability ($\varepsilon_{\text{final}} = 0.373$) and the appearance of cracks network at

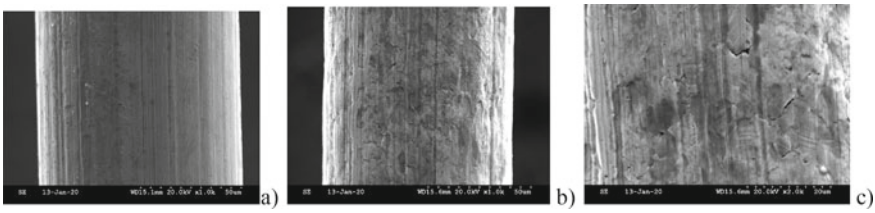

Fig. 6 SEM images of copper wire before (**a**) and after (**b**) multi-pass dieless drawing; **c** surface of wire after deformation (position 6 in Table 1)

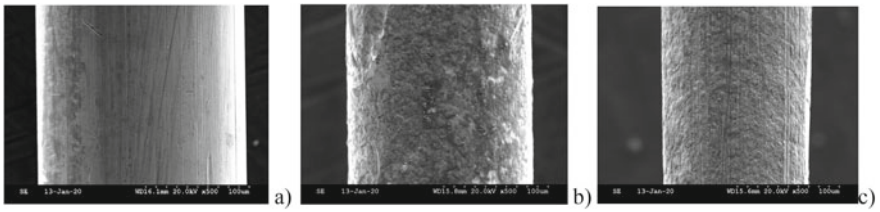

Fig. 7 SEM images of CuZn37 alloy wires before deformation (**a**), after conventional dieless drawing (**b**) (position 3 in Table 1), and after incremental multi-pass dieless drawing (**c**) (position 1 in Table 1)

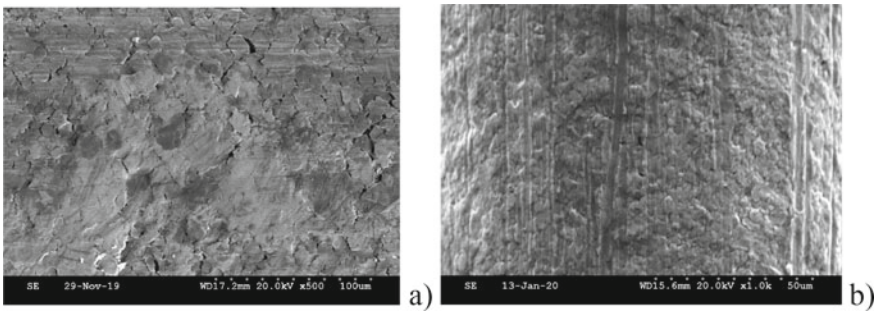

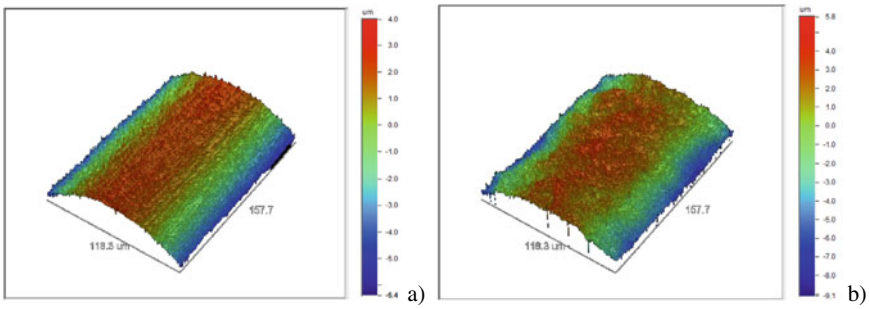

Fig. 8 SEM images of CuZn37 alloy wires after multi-pass deformation at 400 °C (**a**) and 530 °C (**b**)

the grain boundaries (Fig. 8a). For the dieless drawing at a temperature of 530 °C, no cracks are observed (Fig. 8b), although the achieved deformation is much larger ($\varepsilon_{\text{final}} = 0.616$). Figures 6, 7, and 8 have different magnifications, and the scales are shown at the bottom of each image.

Roughness analysis was performed for brass samples. In the general case, the dieless drawing will lead to an increase of roughness (Fig. 9). However, this increase is relatively small. For example, the value of R_a before the dieless drawing was 1.73 μ, and after deformation, it was 2.23 μ. In other experiments, the change in roughness was lesser. It is possible that the strain in each pass affects the roughness similar to the effect on the unevenness of the diameter of tubes, studied in [7]. It can be assumed that with a small increment of elongation in one pass, the roughness will decrease compared to a single-pass process. However, this assumption should be interpreted with caution, because at the moment we do not have theoretical and experimental evidence for this statement.

a) b)

5 Conclusions

1. An experimental setup for the multi-pass dieless drawing of an ultrafine wire was designed and commissioned to produce a reduction in the cross-sectional area of a copper and brass wire without the use of conventional wire drawing dies. A designed setup can continuously produce wire using the dieless drawing method without limitation in wire length.
2. The flow stress of technical copper and brass was studied. The results showed that brass has a more stable hardening interval on the stress-strain curve. That is why this material is more promising for multi-pass incremental dieless drawing. The dieless drawing experiments confirm the above statement. The effectiveness of the multi-pass dieless drawing process for brass wire at 530 °C was close to 2.0. Irreversible defects on the wire surface were not observed.
3. The result obtained at 400 °C is characterized by significantly lower workability of brass wire and the appearance of a cracks network at the grain boundaries.
4. The total elongation of the thin copper wire was small (0.21–0.23) and significantly lesser than that of brass wire (0.31–0.63). Using a multi-pass process instead of a single-pass process does not significantly increase workability. One of the reasons for this result may be the complex nature of the dependence of flow stress on strain for copper. A deeper analysis of this problem will be done in future studies.

Robotic Roller Forming Process and Strategies to Eliminate Geometrical Defect of Edge Waves

Yi Liu, Junying Min, and Jianping Lin

Abstract Robotic roller forming (RRF) is a new dieless and flexible forming process using a roller mounted on an industrial robot to form sheet metal products by multiple passes with predefined tool paths. In this study, DP590 (dual-phase) steel sheets are formed to bent specimens having a right angle by RRF with three passes, and edge waves are observed at the flange of DP590 specimens. Finite element analysis is utilized to reproduce the edge waves. According to finite element simulation, longitudinal plastic strains are generated at the flange edges due to excessive tensile and compressive stresses, which results in severe edge waves. Two strategies are introduced to eliminate edge waves. One has to optimize forming parameters, and the effects of forming angle increment and moving direction of the roller on longitudinal peak strains at the flange edges are evaluated. Another strategy to eliminate edge waves is to apply laser heating in RRF, where the heating spot is 25 mm in front of the roller. Experimental results demonstrate that laser heating reduces forming forces, eliminates edge waves as well as the required number of forming passes.

1 Introduction

Sheet metal bending is an important process used in the manufacturing of thin-walled components. Flanging is a typical bending process, which involves drawing or stretch forming with the assistance of die and punch. It is difficult to form ultra-high-strength steels by one step due to their small ductility. Roller forming, which progressively bends metal sheet to the desired shape by successive sets of rotating rollers [1], is applied in industry to bending some materials with high strength and low ductility for its incremental nature. Some defects, such as longitudinal bow, are prone to happen, and some research has been investigated on the optimization of process and

part shape parameters [2]. Edge waves are also typical defects in the conventional roller forming process; it is difficult to eliminate in subsequent processes. Previous studies were mainly forced on the occurrence of edge waves and the effect of forming parameters on the severity of edge waves. Farzin et al. [3] suggested that the edge waves were due to the plastic local buckling of the rim, and a buckling limit strain (BLS) of 0.9% was introduced and employed to avoid edge waves. The BLS was then used by Zeng et al. [4] to design the forming angle increment and roller radius for cold roller forming, and the desired section was produced by a minimum roller station to avoid edge waves. Tehrani et al. [5] stated that longitudinal strain in the first station should be below a critical value, and the influence of varying the fold angle in subsequent rolling stations on the occurrence of edge waves can be neglected. Roller forming can be used to fabricate various thin-walled profiles by a proper design of rollers at present; however, it is applied in some situations with mass production due to lack of flexibility and high cost of forming rollers.

In recent years, flexible sheet metal forming processes have been developed due to rapidly changing customer demands [6]. To meet the demand for small-batch and variable cross-section profiles, researchers have paid much attention to flexible bending process, especially on flanging. Wen et al. [7] utilized improved bar tools with tapered shoulders to perform forward and backward flanging of open edges and hole rims of Al 6061 sheets. Voswinckel et al. [8] analyzed the technological capabilities of conducting flanging of DC04 mild steel by incremental sheet forming. Zhang et al. [9] studied the deformation mechanics in the hole-flanging process of AA5754-O by double-sided incremental forming and found enhanced formability in shrink flanging due to meridional tensile strain and the localized deformation mode. Han et al. [10] used a rotary tool to perform the straight flanging process of AA2024-O on an incremental forming machine. The deformation process in incremental flanging is quite different from that in conventional flanging formed by press-working, and some defects such as plate warpage and buckling at flange onset might happen [7]; besides, severe thinning or even fracture could be observed in the incremental hole-flanging process of 1060 aluminum sheets [11].

Sheet metal flanging is an important finishing operation in manufacturing processes, and the surface quality of flanging has a significant impact on the subsequent joining and assembling processes. Therefore, a flexible flanging process combining the incremental nature of conventional roller forming and incremental flanging is proposed here with the aid of industrial robots and roller tools, namely robotic roller forming (RRF) process. This paper presents the details of RRF process and a typical defect, i.e. edge waves, was observed in experiments. Two strategies are proposed to eliminate edge waves in RRF: one is to optimize the forming parameters of RRF through finite element simulation, and the other is to form the parts with synchronized laser heating.

2 Robotic Roller Forming (RRF) Process

The robotic roller forming (RRF) platform has been developed at Tongji University as presented in Fig. 1. The RRF platform is composed of a roller driven by a KR600 R2830 industrial robot and a fixture frame. It can be extended to a greater RRF system collaborated by multiple industrial robots to form parts with more complex shapes. The RRF process is illustrated in Fig. 2. The sheet material used in this work is a high-strength dual-phase steel, DP590, with a thickness of 1.2 mm. The sheet specimens were firmly clamped on the fixture frame, and the roller having a diameter of 50 mm and a height of 25 mm moved along the longitudinal direction of the sheet specimen with several forming passes. The sheet specimen is incrementally formed in each pass until its final shape. Forming parameters, such as number of forming passes, forming paths, etc., can be numerically programmed into the controlling system of the industrial robot. In contrast to the flanging by stamping and conventional roller forming process, the forming roller is independent of clamping geometries, and the roller results in a small and limited deformation zone so that the required forming forces are much lower.

In the preliminary research, an L-shaped part was formed by three passes (3P); for example, the forming angle increment in each pass was 30°. The length of the specimen is 250 mm and the widths of the web and flange are 40 mm and 20 mm,

respectively. The L-shaped part after three passes is presented in Fig. 3, and the obvious edge waves were noted at the flange edges.

3 Optimization of Forming Angle Increment and Moving Direction of Roller to Eliminate Edge Waves in RRF

3.1 Finite Element Simulation

To obtain RRF specimens with higher geometrical accuracy, a finite element model of RRF is established with Ls-Dyna as presented in Fig. 4. The geometry of the simulation model was the same as the dimension mentioned above. The fixture and roller were set as rigid. Shell element was applied for the metal sheet due to a low thickness to width ratio. The element size for the clamping area (constrained for six degrees-of-freedom) was 1 mm × 1 mm, and the element sizes of the deformation zone and the flange were 1 mm × 0.25 mm and 1 mm × 0.5 mm, respectively. A material model of MAT133 was adopted for the sheet steel DP590, and the parameters of the DP590 steel were obtained by uniaxial tensile testing and biaxial tensile testing, as listed in Table 1. A contact type of forming_one_way_surface_to_surface was applied and the friction coefficient value was set to 0.27 according to experimental results. The duration of each forming pass was set to 0.01 s to accelerate the solution,

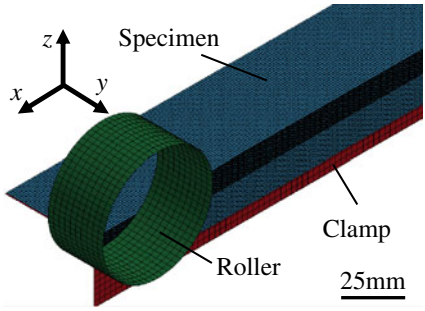

Fig. 4 Finite element model of RRF. (Color figure online)

Table 1 Material parameters of DP590 steel used in finite element simulation (MAT133 in Ls-Dyna)

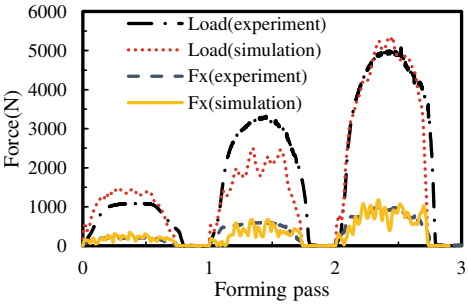

Fig. 5 Comparison of experimental and simulation results of RRF. (Color figure online)

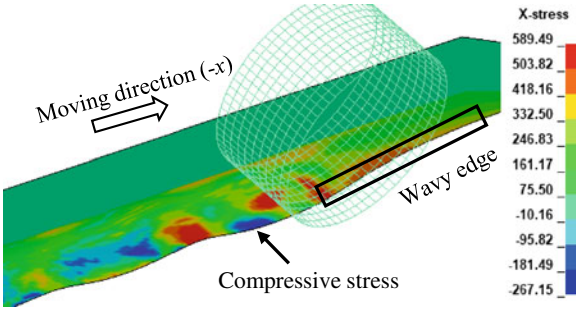

Fig. 6 Edge waves on an RRF specimen reproduced by finite element simulation. (Color figure online)

which corresponds to ~1000 times the moving speed in experiments. A normalization method is used to compare between the simulation and experimental results, and Fig. 5 indicates a good agreement between the forming load perpendicular to the contact interface as well as force along the moving direction (Fx) recorded by the load cell Omega 191 equipped on the KR600 robot and the simulation results. Edge waves are reproduced by FE simulation as shown in Fig. 6. The elements in front of the roller are elongated to a 3D curve; afterwards, the elements suffer from compressive stresses after the roller leaves to keep the edge straight. The compressive stresses increase at larger longitudinal plastic strains. The edge buckling occurs as the compressive stresses exceed a threshold value, i.e. the limit of compression instability.

3.2 Optimization of Forming Parameters

Longitudinal peak strain is closely bound up with the geometries of formed parts and forming parameters. Lindgren [12] developed a model to calculate longitudinal peak strain at the flange of a U-Channel with consideration of flange length, forming angle, yield stress, sheet thickness as well as roller radius. Abeyrathna et al. [13] proved that longitudinal peak edge strain in roller forming increases with an increase of forming angle and a decrease of flange length. Considering the specific part formed by RRF in this study, the material properties and the flange length are fixed. The roller is

a universal tool, thus the radius should be constant for each forming pass to avoid changing tools frequently, and the angle increment in each forming pass, as well as the moving direction of the roller, can be optimized by programming.

A simple method to reduce edge waves is to increase forming passes and decrease angle increment in each forming pass; therefore, two cases of forming by six passes (15° for each pass) and eight passes (12° for the first two passes and 11° for the later six passes) were studied by FE simulation. However, the longitudinal peak strain will increase in the case with a constant angle in each forming pass. By taking into account forming efficiency (i.e. minimizing the pass number), a downhill method was applied to the FE simulation to limit the accumulation of the longitudinal peak strain. In this study, the optimization target for the downhill method was to control the longitudinal peak strain in each forming pass to 0.009 [3, 4]. The longitudinal peak strain was determined by the maximum strain along the x-axis (ε_x) of elements at flange edges during this forming pass. In this simulation model, the maximum ε_x were extracted at a distance of 50 mm away from the section edge (Fig. 7) to eliminate any effect of end flare [14]. Longitudinal peak strain of forming angle increment from 12° to 19° as well as 30° for the first forming pass is obtained by simulation, as shown in Fig. 8. A linear relation between longitudinal peak strain and

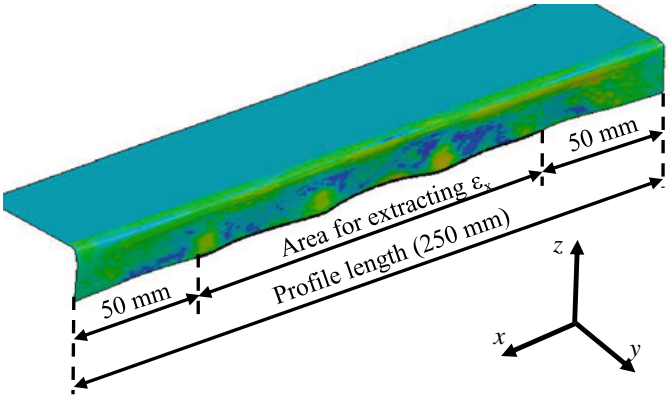

Fig. 7 Definition of area for extracting ε_x. (Color figure online)

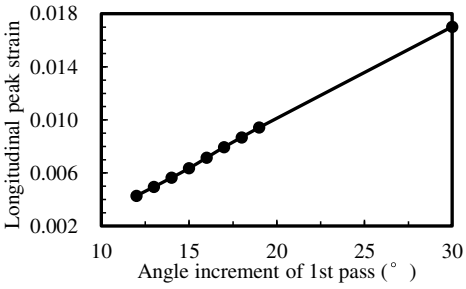

Fig. 8 Effects of forming angle increment on longitudinal peak strain at the first forming pass

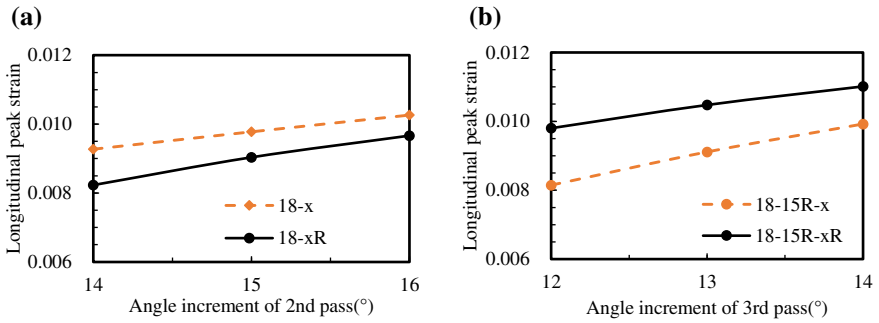

Fig. 9 Effect of angle increment on longitudinal peak strain. **a** Second forming pass; **b** Third forming pass. (Color figure online)

forming angle increment can be observed, and an angle increment of 18° is chosen to control the longitudinal peak strain to a limit of 0.009.

For the second forming pass, a factor of the moving direction of the roller is also considered. For the moving direction opposite to the first forming pass, the forming parameter is designated as forming angle plus "R". (For instance, 15R indicates an angle increment of 15°, and the moving direction reverses to that in the first forming pass.) Six forming parameters are studied by FE simulation, and the effects of forming angle increment on longitudinal peak strain are exhibited in Fig. 9a. It can be concluded that a linear relation between longitudinal peak strain and forming angle increment still exists for both moving directions, and it is depicted that the longitudinal peak strain of forming by reciprocating motion is smaller than forming by the same direction. The forming procedure for the first two passes is 18-15R. A similar phenomenon can also be observed in the simulation results for the third forming pass in Fig. 9b, and the forming procedure for the formal three passes is set as 18-15R-12. To save solution time for simulation and also increase efficiency in RRF, reciprocating motion is applied for the following analysis, and a similar operation is conducted for the following forming passes till the forming angle reaches 90°. Eventually, the forming parameter to constrain the longitudinal peak strain to a limit of 0.009 is 18-15R-12-10R-10-10R-10-5R.

3.3 Results and Discussion

In this study, five RRF processes are analyzed by FE simulation, including three passes with a constant angle increment of 30° in each forming pass (3P, 30-30-30), six passes with a constant angle increment of 15° in each forming pass (6P, 15-15-15-15-15-15), eight passes with similar angle increment in each forming passes (8P, 12-12-11-11-11-11-11-11), downhill method by one direction with variable angle increment (8P-D, 18-15-12-10-10-10-10-5) and downhill method by reciprocating

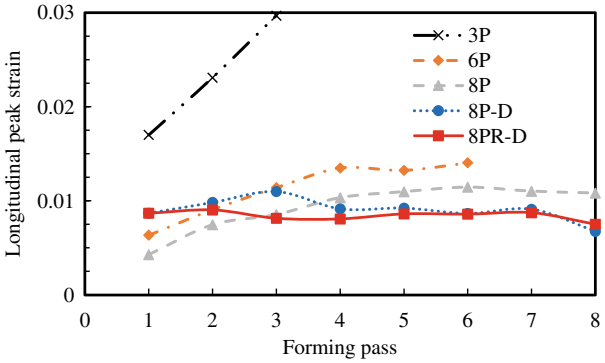

Fig. 10 Longitudinal peak strain for each forming pass of different forming processes. (Color figure online)

motion (8PR-D, 18-15R-12-10R-10-10R-10-5R). The longitudinal peak strain of each forming is presented in Fig. 10. Longitudinal peak strain increases obviously at the first three forming passes with constant angle increment of 15° or 30°, while the longitudinal peak strain is limited below ~0.01 by using the downhill method.

To evaluate the severity of edge waves, the average height of edge waves ($\bar{h}$) and the maximum height of edge waves ($h_{\max}$) are introduced and illustrated in Fig. 11. The y-coordinate of the nodes at the flange edges are extracted by each millimeter (except the nodes at a distance of 50 mm away from section edge), and a deviation between the average y-coordinate value and actual y-coordinate value is defined as the height of edge wave (h). $\bar{h}$ and $h_{\max}$ are defined as average value and maximum value of h, respectively. The edge profiles are compared in terms of $\bar{h}$ and $h_{\max}$ which are listed in Table 2, and the formed specimens of 3P, 6P, and 8PR-D are compared in Fig. 12. The optimization method to constrain the longitudinal peak strain can

be used to obtain straight edge specimens without visible edge waves compared with forming by three passes and six passes. Additionally, the average height and maximum height of edge waves of 8PR-D are decreased by 10–35% in comparison with the forming process by one direction (8P-D) and by a constant angle increment (8P).

4 Application of Laser Heating to Eliminate Edge Waves in RRF

4.1 RRF with Local Laser Heating

In RRF, the essence of edge waves is the excessive plastic deformation at flange edges resulting from bending moment generated at the bending radius. Therefore, it is feasible to eliminate edge waves by decreasing bending moment, e.g. by decreasing the angle increment of each forming pass, by softening the deformation zone through local heating.

Although the forming force of RRF is relatively low compared with stamping, the process is still constrained by the load capability of industrial robots, especially when forming ultra-high-strength sheet materials. A new concept of RRF with laser heating (LRRF) as illustrated in Fig. 13 is developed to deal with these problems. In LRRF, a laser beam is introduced 25 mm in front of the roller to locally heat the to-be-deformed area, and the roller follows the heat source synchronously and a flange is then formed by multiple forming passes. The experimental setup of LRRF illustrated in Fig. 14 was used to form DP590 steel sheets by three passes (30° in

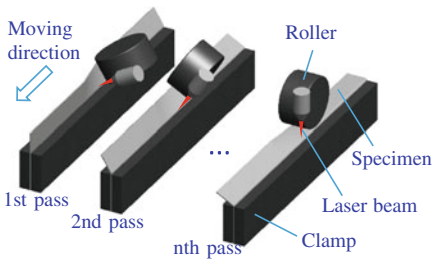

Fig. 13 An illustration of RRF with laser heating. (Color figure online)

Fig. 14 Experimental setup of RRF with laser heating. (Color figure online)

each pass) and by six passes (15° in each pass). The laser spot had a rectangle shape with a dimension of 4 mm × 2 mm, and the 4 mm edge was perpendicular to the moving direction. Laser power for LRRF was set to 1200 W and a forming velocity was 30 mm/s.

4.2 Results and Discussion

Forming forces are compared in Fig. 15 with the results from RRF experiment at room temperature. From Fig. 15, it is demonstrated that the application of laser heating reduces forming forces by 20% at the same forming parameters. The formed specimens are compared in Fig. 16, and with laser heating, edge waves are eliminated

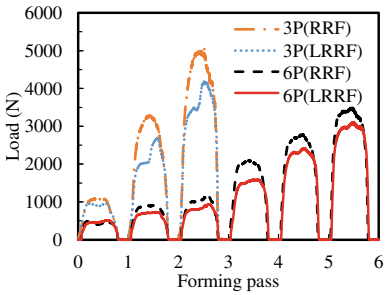

Fig. 15 Comparison of forming forces by RRF and LRRF. (Color figure online)

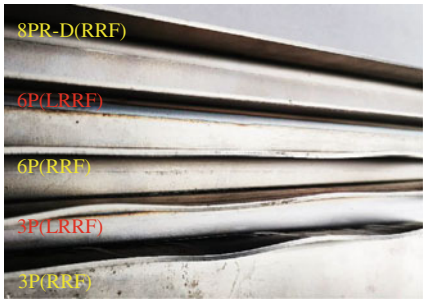

Fig. 16 Comparison of RRF and LRRF specimens. (Color figure online)

when using six forming passes with a constant angle increment of 15°. It is observed that the edge of LRRF-6P specimen is nearly identical to the specimen formed by the downhill method by reciprocating motion.

Although LRRF eliminates edge waves with fewer forming passes, the forming process parameters (e.g. moving speed of the roller, heating temperature, angle increment in each forming pass, etc.) are still required to be optimized to further minimize the number of forming passes and increase forming efficiency.

5 Conclusions

In this study, a robotic roller forming (RRF) process is proposed and developed. Experimental and numerical researches were conducted to increase the geometrical accuracy of formed specimens. Two strategies to eliminate edge waves are introduced, and the following conclusions can be drawn.

(1) The newly developed robotic roller forming process that combines advantages of the conventional roller forming process, incremental forming, and industrial robot can be used to bend high strength steel with a single roller without fracture. However, edge waves caused by excessive plastic deformation were observed on the formed specimens as geometrical defects.
(2) Edge waves can be eliminated by optimizing forming parameters. The effects of angle increment and moving direction of the roller on geometrical accuracy are investigated, and an optimal forming parameter of forming for eight passes by reciprocating motion is proposed to limit the longitudinal peak strain and consequently eliminate edge waves.
(3) It is experimentally demonstrated that edge waves can also be eliminated by applying synchronized laser heating in RRF. Results reveal that the peak forming forces are reduced by 20%, and high geometrical accuracy is achieved with fewer forming passes in comparison with RRF at room temperature.

Numerical Modelling of the Flow Forming Process: Computation Time Optimization and Accuracy Analysis

Ahmed Mehdi Roula, Katia Mocellin, and Pierre-Olivier Bouchard

Abstract Flow forming is an incremental forming process during which a roller tool deforms a rotating sheet metal by applying a force which is local and evolving during the entire process. The finite element software FORGE® is used in order to model this process. The local tool-workpiece contact conditions and the high rotation speed make the modelling of this process difficult with high computation time. It is, therefore, necessary to develop optimization strategies aiming to reduce the computation time whilst maintaining a sufficient level of results accuracy. A first configuration optimization method consists of reducing the geometry of the initial blank and using symmetry planes. The final reduced geometry obtainable is 36° wide. This method is then associated with a second one which consists of reducing the number of calculation time steps during the entire process. The calculation time steps removed are those occurring when the roller tool is not in contact with the deformable sheet metal anymore. The two combined methods give the ability to drastically reduce the computation time compared to the reference case. In addition, the global and local results of the reference case are mostly conserved when applying the configuration optimization methods.

Keywords Flow forming · Incremental forming · Numerical modelling · Computation time · Optimization

1 Introduction

Incremental sheet forming (ISF) processes refer to processes during which the plastic deformation takes place due to repeated contacts between the sheet metal and the tool. The contact zone evolves during the entire process. During these processes, high strain levels can be reached without fracture. Furthermore, the ISF processes

https://doi.org/10.1007/978-3-030-75381-8_41

make it possible to form complex 3D parts with limited machining operations so that it limits the material loss. Thus, ISF has become of great interest in the last few decades.

Flow forming (or spinning) is a specific type of ISF process. During flow forming, a metal sheet is placed over a rotating mandrel and is incrementally deformed by a roller which follows a specific trajectory to stick and compress the sheet on the mandrel. Consequently, the complex local and cyclic loading conditions allow reaching high plastic strain levels with reduced involved forces compared to the ones required in a conventional metal forming process. Despite these advantages, the ISF processes have some drawbacks. For example, strain localization (necking) can occur, leading to premature damage. This problem is misunderstood in the literature and slows down the development of new products.

Numerical modelling of ISF processes allows a better understanding of the material behaviour during the forming operation, which could improve the fracture predictions. However, the local tool-workpiece contact conditions and the high rotation speed make the modelling of these processes difficult with high computation time.

In this study, the finite element software FORGE® is used. A configuration optimization is sought in order to reduce the computation time while maintaining a sufficient level of results accuracy.

In the first section of the current work, a description of the process modelling and the principle type of results is presented. The second section describes the methods developed to reduce the calculation time. In the last section, the results obtained with this optimized model will be discussed and compared to a reference case.

2 Numerical Modelling of the Flow Forming Process

The finite element software FORGE® is used in this study. With this software, several forming processes like forging, rolling, and deep-drawing can be modelled. FORGE® uses linear tetrahedral elements with an implicit resolution using velocity–pressure mixed formulation.

The flow forming process is usually split into three main categories [1] as illustrated in Fig. 1. These categories are:

- Conventional spinning, during which the blank thickness remains nearly constant during the process;
- Shear spinning, where the thickness decreases. The final thickness depends on the angle between the part wall and the rotation axis;
- Tube spinning, during which one or more rollers deform a tubular piece to reduce the wall thickness.

The flow forming process studied in the current work differs from these processes. In fact, it could be related to conventional spinning with a reduction in the wall thickness.

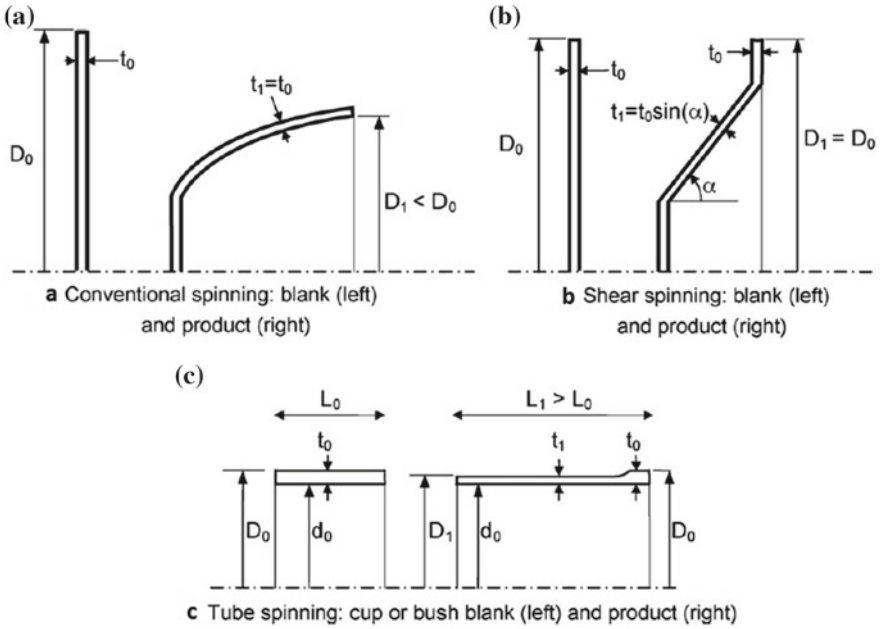

Fig. 1 Spinning configurations: **a** conventional spinning, **b** Shear spinning, **c** Tube spinning [1]

In this process, a sheet metal is maintained between a tailstock and a mandrel. All of these elements turn with a high rotation speed around a vertical axis while a roller tool, which describes a complex planar path, deforms locally the sheet metal (Fig. 2). The wall thickness is reduced during this process.

The inner shape of the metal at the end of the process is given by the outer shape of the mandrel. Meanwhile, the outer shape of the metal is given by the roller path.

As mentioned in the introduction, the high computation time is a major problem in the modelling of the flow forming process. This high computation time is due to the fine mesh size and the small-time calculation step, both required to manage the local tool-workpiece contact and the high rotation speed. An example of the mesh used is given in Fig. 3.

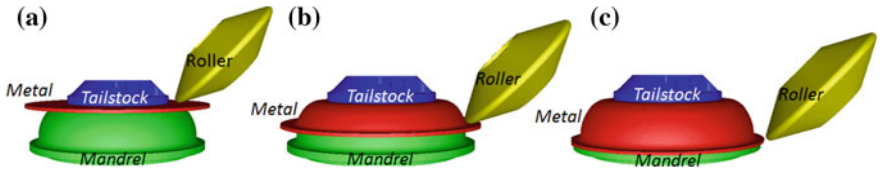

Fig. 2 Numerical modelling of flow forming process using FORGE® software: **a** initial state, **b** intermediate state, **c** final state. (Color figure online)

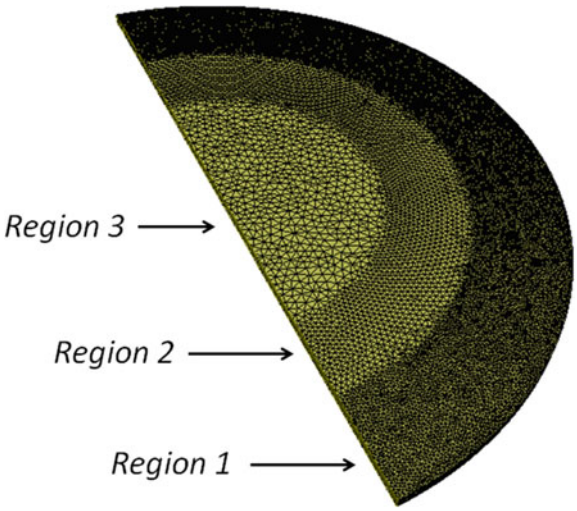

Fig. 3 Mesh used to model the flow forming of a 4.5 mm thick disc with a 280 mm diameter. The regions 1, 2 and 3 are meshed with a mean mesh size of 1, 2 and 3 mm, respectively. The disc is truncated for the illustration. (Color figure online)

Region 3, which is in contact with the tailstock, is not deformed during the process. As a consequence, it is meshed coarsely. Region 1 is the one which will be deformed; therefore, it is meshed finely. Region 2 is a transition zone between the two regions previously mentioned. A pre-study showed that for this modelling configuration, remeshing is not necessary, so it is disabled.

The material is an aluminium alloy modelled through an elastic-plastic power law given by:

$$\sigma = k\ \bar{\varepsilon}^n \tag{1}$$

where σ is the flow stress, $\bar{\varepsilon}$ the equivalent strain, and k and n material parameters whose values are 165 MPa and 0.22, respectively. The Young modulus value is 69 GPa. A tensile test, whose flow curve is shown in Fig. 4, is used to obtain these parameters.

As the strains in flow forming reach much higher values than those in tensile test, the extrapolation of the stresses at higher strain values is needed. The validity of this extrapolation has been verified for this material with the in-plane torsion test [2] (results not shown here). This test allows reaching strains as high as those met in flow forming.

Results (that will be discussed in the last section) are of two kinds: global and local results. Among the global results, can be mentioned:

– Geometrical information like the wall thickness distribution;
– Mechanical values like the roller global forces needed in the flow forming process.

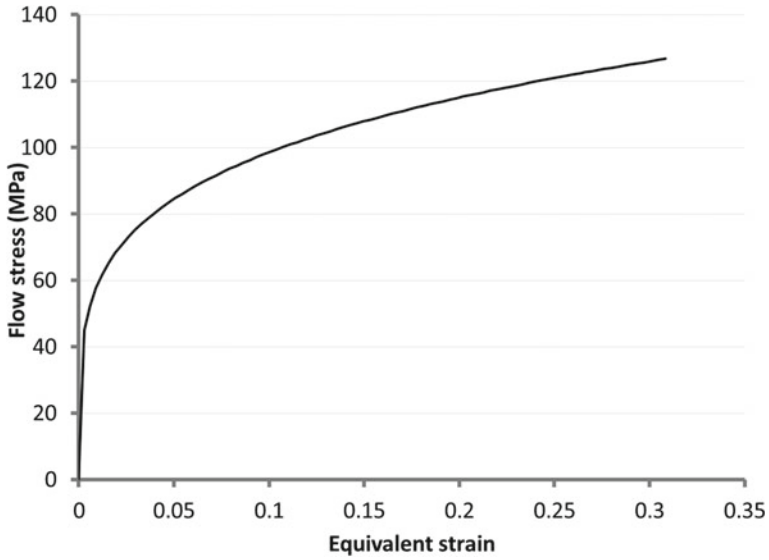

Fig. 4 Tensile flow curve of the used aluminium material

The local results concern those stored locally on sensors assumed to be linked with the material. A sensor tracks and records the local mechanical state like the equivalent strain and the Rice & Tracey damage variable. These two mechanical quantities will be defined in the last section. The evolution of the temperature on the sensors is also recorded.

3 Configuration Optimization Methods

A pre-study on the modelling of the flow forming process showed that a little CPU time can be saved if the roller is chosen to be rotating instead of the blank (which is driven by the mandrel and the tailstock). Thus, the roller adopts a helical trajectory. This change in the roller kinematics does not affect at all the accuracy of the results, the types of which are given in the end of the previous section.

Consequently, after applying this change in the roller kinematics, the modelling of the complete 3D configuration with refined mesh in the deformed zone (called hereinafter *reference case*, Fig. 3) has been launched on 30 CPUs of a calculation computer.[1] This case has a computation time of approximately 1500 h. This computation time is obviously too long and the purpose of the current section is to introduce methods to reduce it while preserving a sufficient level of results accuracy. The unique

[1]CPU: Intel(R) Xeon(R) CPU E5-2630 v3 @ 2.40 GHz.

configuration that will be studied in the following is the flow forming of a 4.5 mm thick disc having a 280 mm diameter.

3.1 Geometry Reduction

This approach (Fig. 5) consists of reducing the original complete geometry (360°). Consequently, the flow forming modelling is performed on *reduced geometries*. Nevertheless, the complete geometry of the non-deformable tools (tailstock, roller, and mandrel) is conserved as it does not impact the CPU time nor computation conditions.

An important feature of this approach is the use of two symmetry planes. These planes are placed on two lateral edges of the sheet as illustrated in Fig. 5. Obviously, applying such symmetry conditions does not correspond to the real 3D process since it adds edge effects due to the symmetry actions of the roller. For this reason, symmetry planes are not generally used in ISF modelling. However, the novelty is that due to the very small contact area between the roller and the workpiece (<4° wide), the local action of the roller on the sheet far enough from the symmetry faces could be the representative of the real process conditions.

Being equidistant from the two symmetry faces of the reduced geometry, the median plane is the most distant area from these faces. Consequently, in order to avoid edge effects, this plane is chosen to analyse geometrical and mechanical results. Actually, further research shows that the accuracy of the global and local results is conserved within a 10° wide area around the median plane.

As shown in Fig. 5c, the final geometry is the 36° one. Further geometry reduction is not possible because in such a case, the elements of the mesh are too deformed, causing non-convergence issues. The number of nodes in the reference case is approximately 191,000 while the final 36° geometry has approximately a tenth of this

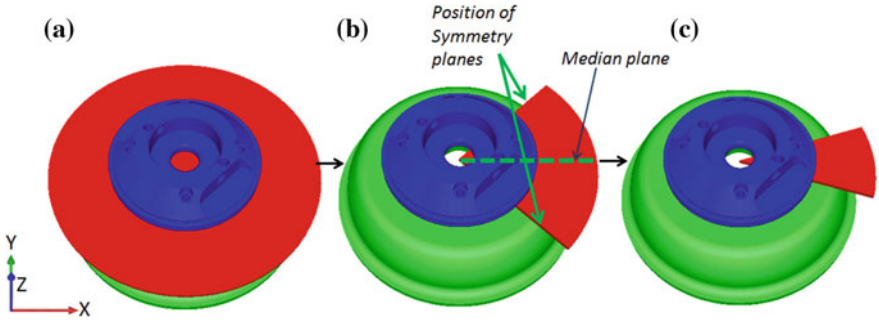

Fig. 5 Geometry reduction approach: **a** initial geometry (360°), **b** example of intermediate geometry (90°), **c** final geometry (36°). (Color figure online)

number. This final geometry will be used in the second configuration optimization method.

3.2 Calculation Time Steps Reduction

The use of the previously described approach reduces, theoretically, the calculation time by reducing the number of elements. Nevertheless, this approach involves that the roller kinematics will be unchanged so that it describes a helical path during the entire process, as explained at the beginning of the current section. This helical path of the roller is associated with a constant and fine calculation time step (10^{-4} s), used even though the roller is not in contact with the metal sheet.

The aim of the current second approach is to remove unnecessary calculation time steps when using reduced geometries. Unnecessary calculation time steps are those during which mechanical and thermal calculations are done, despite the roller is out of contact with the deformable reduced geometry.

The first step towards this configuration optimization technique is to identify and remove those unnecessary calculation time steps. For a given reduced geometry with a helical roller path during the whole process, determining those calculation time steps is equivalent to determine the times when all the forces measured on the roller are equal to zero. After that, the previously used roller kinematics is maintained (time–velocity control), so as the calculation time steps in the deformable zone (10^{-4} s).

The modelling of the flow forming process using this new optimization technique can now be performed by selecting, a priori, the calculation time steps during which the roller will be in contact with the deformable reduced geometry. This method allows avoiding approximately 18,600 unnecessary calculation time steps, which represent 79% of total calculation time steps done before applying this optimization method.

Figure 6 depicts the roller planar path after the process modelling using the reference case (without geometry and calculation time steps reductions). After applying both reduction techniques, a process modelling with a 36° reduced geometry is performed and the final roller planar path is also given in Fig. 6.

A maximum error of 0.05% between the two cases (along the X and Z axes) shows that there is an excellent match of the paths. This shows that applying the two reduction techniques does not impact the roller kinematics description. In the last section, the results obtained after implementing both configuration optimization methods will be shown and compared with a reference case.

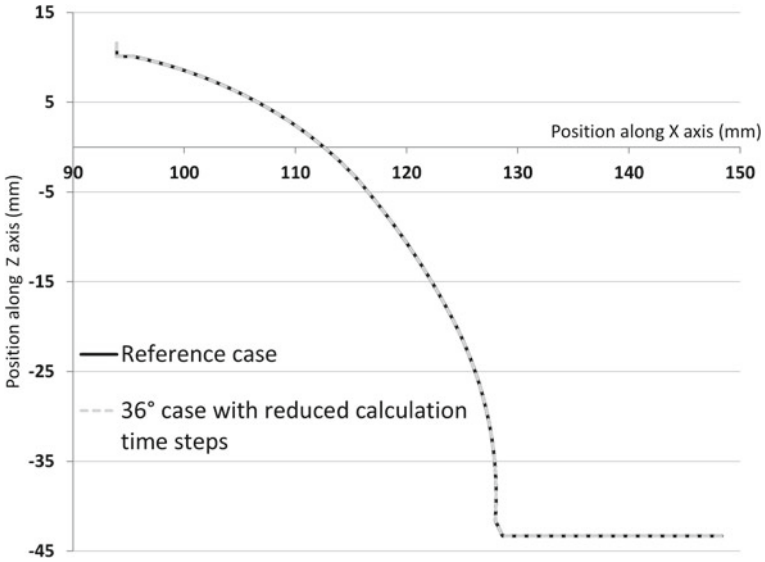

Fig. 6 Comparison of roller planar paths after the process modelling

4 Discussion

The aim of this section is to present the main results obtained after implementing the configuration optimization methods explained above. Therefore, a process modelling with a 36° reduced geometry is performed. The restriction area (area outside of which the roller will not be in contact with the sheet metal anymore) related to this reduced geometry is a little bit bigger than 36°. Therefore, it is 68° wide. This is due to the persistent contact between the blank and the roller that is not negligible. This case has been launched on 6 CPUs of a calculation computer[2] (which is different from the previous one), with a computation time of approximately 45 h.

4.1 Global Results

4.1.1 Geometrical Results

The geometrical results correspond to the wall thickness distribution after the flow forming process modelling.

Figure 7 shows the wall thickness distribution along the Z-axis (mandrel axis) in a 36° reduced geometry case (taken into the median plane) compared with the

[2]CPU: Intel(R) Xeon(R) CPU E5-2650 v3 @ 2.30 GHz.

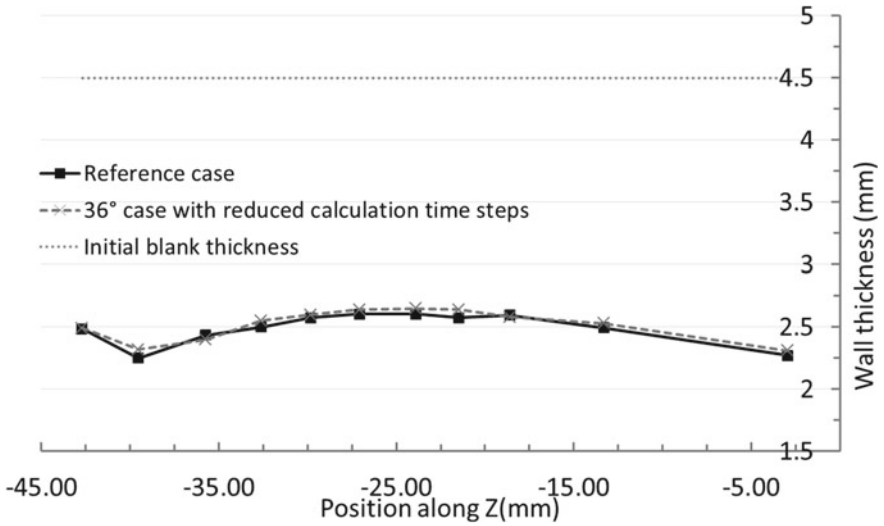

Fig. 7 Wall thickness distribution in a 36° reduced geometry compared to the reference case

reference case. The position along the Z-axis in this figure is the same as the one shown in Fig. 6.

As shown in this figure, the initial blank thickness is 4.5 mm. Therefore, even with a significant reduction ratio of approximately 45%, the use of the configuration optimization methods allows producing a wall thickness distribution very close to the one reached with the reference case (maximum error of 3%). Intermediate reduced geometries (45°, 60°, and 90°) show the same trend. Excessive thinning (necking) [3] is not expected for this configuration (4.5 mm thick disc having a 280 mm diameter).

4.1.2 Flow Forming Forces

The flow forming forces are the ones applied by the roller tool on the deformable sheet metal. These forces influence strongly the local behaviour of sheet metal, especially the stress states. Consequently, it will have a great impact on mechanical behaviour and also fracture predictions.

Figure 8 shows the norm of the flow forming force (global force in the three directions) for the 36° reduced geometry case with the calculation time steps reduction method compared to the reference case.

In this figure, it is clear that applying the two optimization methods does not influence the profile forces during the whole process. Thus, this feature could be helpful within an inverse analysis approach aiming to calibrate hardening or damage models using the experimental data.

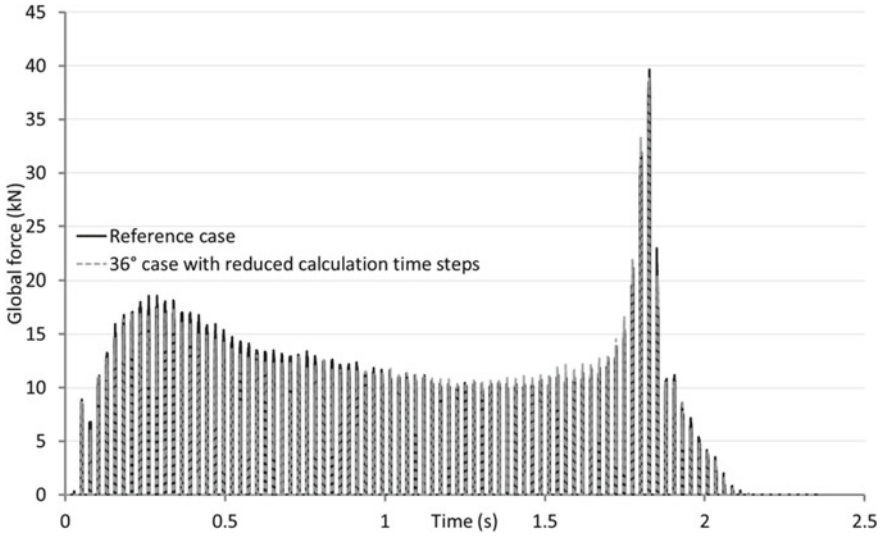

Fig. 8 Flow forming force profiles for a 36° reduced geometry compared to the reference case

4.2 Local Results

As mentioned in the first section, the local results concern information stored locally on different sensors. In this section, attention will be given to equivalent strain, Rice and Tracey damage variable [4], and temperature.

There are multiple ways of predicting ductile fracture in the ISF processes, using either coupled damage variables or uncoupled failure criteria. There is not a single damage model which is able to accurately predict the failure occurrence for all the ISF processes. As the stress triaxiality ratio is considered as one of the most important parameters with respect to ductile damage growth, it has been decided in the current work to estimate damage through the Rice and Tracey failure criteria. In addition to the stress triaxiality ratio, maximal principal stress or maximal shear stress are other important parameters regarding ductile damage. This will be addressed in a future study.

More information regarding the comparison of damage models in metal forming can be found in [3, 5].

The Rice and Tracey damage variable D, as implemented in FORGE®, is defined as

$$D = \int_0^{\bar{\varepsilon}} 0.283 e^{(1.5\eta)} d\bar{\varepsilon} \tag{2}$$

where $\bar{\varepsilon}$ is the equivalent strain and η is the stress triaxiality ratio. At any moment of the process, the value of this variable in a given element indicates the damage

occurring within this element. Thus, D reaches the critical value D_c when $\bar{\varepsilon}$ reaches $\bar{\varepsilon}_f$ (equivalent strain at fracture).

The evolution of these quantities will be studied on three sensors positioned, in the initial blank, at a radius of 105 mm and on three different positions through the thickness (Fig. 9). One sensor is located on the outer surface in contact with the roller (roller sensor). Another is located on the inner surface in contact with the mandrel (mandrel sensor). The last sensor is located at the mid-thickness (mid-sensor). These sensors are located initially in the median plane.

Figures 10 and 11 show, respectively, the final values of equivalent strain and Rice and Tracey damage variable stored on these three sensors.

It is clear from Fig. 10 that, for both cases, the highest strains are reached for the metal in contact with the roller. Strains reach, for every position through the thickness, high values (up to nearly 2). This feature is typical of ISF processes so that high final strains are reached due to progressive cumulative and localized plastic strains during the entire process [6]. These strains are far above those observed for simple tests like the tensile test. This is due to the specific stress states (negative stress triaxiality) observed in this process. Despite such strains, the progressive incremental deformation and the compressive stress state have a stabilizing effect permitting to avoid fracture [6], which is not observed experimentally during the flow forming of the current configuration (4.5 mm thick disc having a 280 mm diameter).

The higher strains are reached for the roller position. Despite that, Fig. 11 shows that the higher final value of the Rice and Tracey damage variable is the one achieved for the mandrel position. This is due to the stress state in the mandrel position, which is characterized by high positive triaxiality values when the roller passes by the sensor's position (bending visible in Fig. 9). At the same moment, the stress state near the roller position is compressive. This stress state is more stabilizing, leading to less damage, as presented in [7, 8].

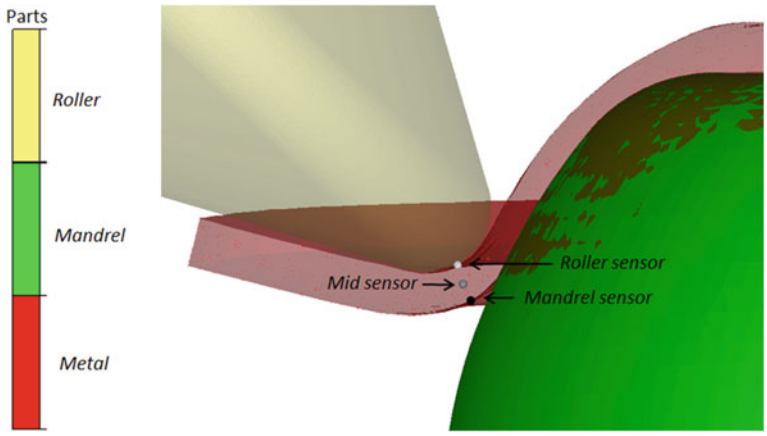

Fig. 9 Three sensors initially positioned at a radius of 105 mm. The roller is passing by the position of these sensors. (Color figure online)

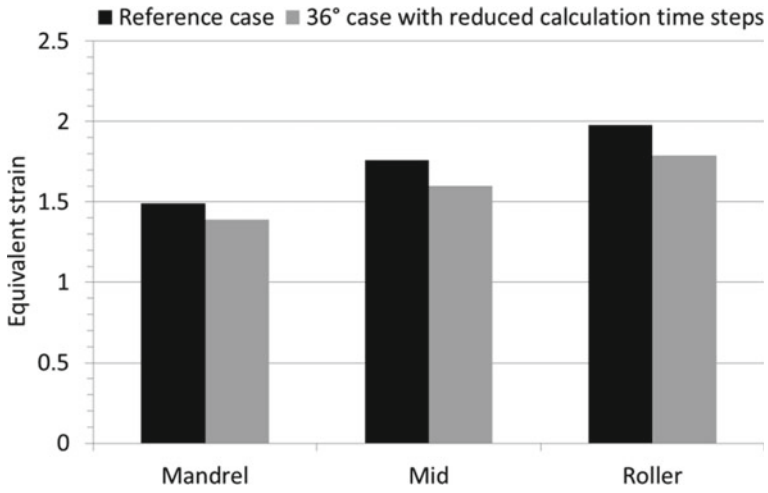

Fig. 10 Final equivalent strain values given on three sensors positioned at a radius of 105 mm

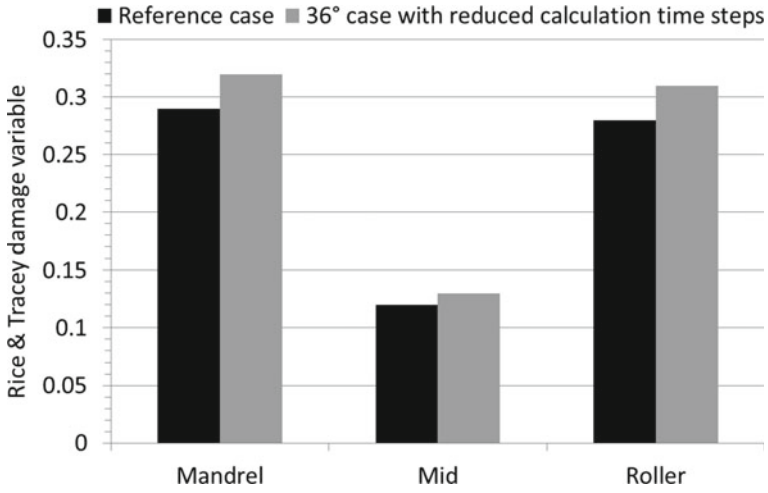

Fig. 11 Final Rice and Tracey damage variable values given on three sensors positioned at a radius of 105 mm

The mid position shows less damage than the other ones (Fig. 11). This is due to the values of stress triaxiality in this position, which are smaller than those in the other positions.

Compared to the reference case, the final equivalent strain in the case of the reduced geometry is underestimated whatever the position through the thickness (Fig. 10). Nevertheless, the difference between the two cases is <10% (9.6% for the "roller" position, 9.1% for the "Mid" position, and 6.7% for the "mandrel" position). The same observation could be done for the Rice and Tracey damage variable

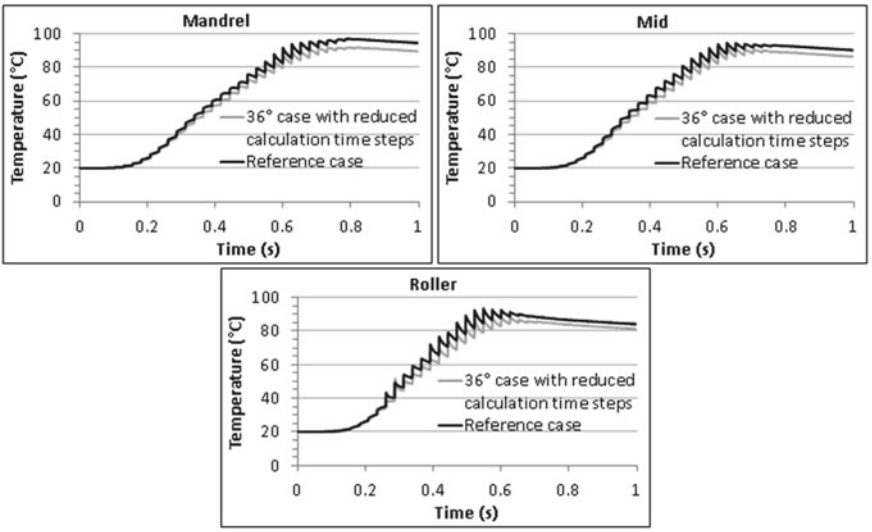

Fig. 12 Evolution of the temperature on three sensors initially positioned at a radius of 105 mm

(Fig. 11), which is this time overestimated compared to the reference case. This overestimation is due to an overestimation of the stress triaxiality in the case of the reduced geometry compared to the reference case. Nevertheless, the differences between the two configurations are 9.3% for the "roller" position, 7.7% for the "Mid" position, and 9.7% for the "mandrel" position. The same trends can be observed at other radii.

Figure 12 depicts the evolution of the temperature during the flow forming process on the sensors shown in Fig. 9.

The increase in the temperature is due to the plastic deformation caused by the cyclic action of the roller. The temperature decreases when the roller is far enough from the sensors, before increasing again, cyclically. With the evolution of the process, the roller becomes far enough from the sensors and the plastic deformation ends, leading to a progressive decrease of the temperature (this happens between 0.6 and 0.78 s depending on the considered sensor). The decrease of temperature is faster for the roller sensor compared to the two others, thanks to the heat exchange with air. Adiabatic heat transfer condition is imposed between the workpiece and the tools.

As for the equivalent strain, the temperature is underestimated for the reduced case compared to the reference case, for all of these sensors. However, the maximum difference in temperature between the two cases is less than 5%. This means that thermal properties are mostly conserved with the reduced geometry.

These results show that applying the two configuration optimization methods allows having good and representative results of the reference case (<10% error) with a huge gain in CPU time.

5 Conclusion

Process modelling has great importance in the comprehension of specific problems occurring during the ISF processes, such as premature fracture. Nevertheless, the modelling of a complete configuration (reference case) is a time-consuming task and choices have been made in order to reduce this process computation time.

In the current work, configuration optimization and time step adaptation were studied with respect to CPU time reduction and accuracy of the results. A first method, which uses reduced geometries with symmetry planes, allows reaching a minimally reduced geometry of 36° while maintaining the accuracy of the results into the median plane. Further geometry reduction causes non-convergence issues. A second approach consists of removing unnecessary calculation time steps (i.e. time steps during which mechanical and thermal calculations are done despite the roller is not in contact with the metal sheet). With the combination of the two approaches, the roller path is preserved.

Applying both approaches together enables to mostly conserve major global and local results, with a calculation time considerably reduced. This interesting outcome could make the prediction of final parts geometry or failure initiation faster. Furthermore, it could be helpful in order to determine quickly the influence of different process parameters (lubrication, rotation speed, etc.) on the final global and local results.

On the Geometrical Accuracy in Incremental Sheet Forming

Gerhard Hirt, Roman Kordtomeikel, Thomas Bremen, Marvin Laugwitz, and David Bailly

Abstract The industrial application of incremental sheet forming (ISF) still stays behind the expectations due to the low geometrical accuracy of the produced parts as well as the insufficient predictability of the forming result. This is due to the fact that some mechanisms which cause the geometrical deviations are not fully understood. Many investigations have already been carried out to determine which types of stresses induced by ISF influence the forming result. This paper tries to systematically categorize selected typical geometric deviations and to review their underlying mechanisms based on current literature as well as their own experience. The intention is to provide a structured basis for future scientific discussion and to stimulate an exchange of experience, with the goal that a better understanding may help to improve the geometrical accuracy of parts manufactured by incremental sheet forming.

Keywords Incremental sheet forming · Geometrical accuracy · Process understanding

1 Introduction

Incremental sheet forming (ISF) has been a focus of worldwide research efforts since the turn of the millennium. The aim is to develop a sheet metal forming process that can manufacture complex sheet metal parts economically, even as individual parts or in small quantities, with a minimum of component-specific tooling. Since then, several process variants have been developed, with which a large number of prototype parts, some of which are very demanding, have been produced to prove their feasibility. However, their use in industrial applications falls short of expectations,

https://doi.org/10.1007/978-3-030-75381-8_42

although economic calculations can prove profitability advantages over other prototype processes despite longer required process time. According to the authors, there are two main reasons for this:

1. The part geometries were designed for other processes and cannot be processed by ISF.
2. The required geometrical accuracy is not achieved, or at least not without time-consuming series of tests.

This paper focuses on the second topic. Geometrical inaccuracies also occur in any other sheet metal forming processes. However, based on many years of experience and using modern simulation methods, some of these can be predicted and compensated by suitable countermeasures. Such countermeasures usually require more or less complex and cost-intensive modifications of the forming tools. In the case of incremental sheet forming, compensation could largely be achieved by programming a different tool path alone, or at least the modification of tooling is less cost-intensive. However, this advantage cannot be used as long as the interaction between the tool path and the geometric deviations are not fully understood. In the end, two questions arise in each specific case:

1. Does a tool path exist that can achieve the desired target geometry from a flat sheet by incremental sheet forming keeping the required accuracy?
2. If so, how can this path be identified from the infinite number of possible tool paths?

A partial aspect of the first question, namely whether the part can be manufactured without material failure, can today be answered quite reliably with known criteria, like fracture forming limit line (FFL) and the "sine law" [1–3], or other approximate formulas relating sheet thinning to the part geometry. It is more difficult to answer the question which accuracy level can be achieved? The aim of this paper is therefore to collect, propose and describe physical mechanisms leading to selected typical geometrical deviations observed in the authors' experience or described in the literature. The intention is to provide a structured basis for future scientific discussion, with the goal that a better understanding may help to improve the geometrical accuracy of parts manufactured by incremental sheet forming. This article is therefore structured as follows: In Sect. 2, the geometric requirements for sheet metal parts are briefly described, as they represent the target definition to be fulfilled by the process. Section 3 explains the focus of the paper regarding process variants and defect types. Section 4 describes the fundamentals of the mechanics of incremental sheet forming to the extent necessary for understanding the following section. The fifth section postulates physical mechanisms for the formation of geometrical defects.

2 Geometrical Tolerances for Sheet Metal Parts

As in other areas of manufacturing technology, the geometrical tolerances that must be adhered to for sheet metal parts depend on the part size and the area of application. For example, in the automated mass production of automotive bodies with narrow gaps, much tighter tolerances must be maintained in comparison to those required for facade construction or large aerospace components. Whenever only small quantities are produced for large parts, detailed adjustments can be made individually, sometimes manually, during assembly. From the authors' experience, tolerances in the range of ±0.5 mm can be reported for OEMs in the automotive sector even for prototype production for doors, hoods or fenders. Allwood et al. [4] have surveyed the geometrical tolerances for various products by means of a questionnaire with various sheet metal component manufacturers in the UK, and here it comes to a tolerance range of ±0.15 to ±1.0 mm for the automotive sector, ±5.0 mm for shipbuilding and ±0.13 to ±5.0 mm for the aerospace sector, depending on component size and complexity. If the literature on incremental sheet forming provides information on the achieved geometrical accuracy, in many cases the above limits are not reached [5, 6]. And even when using algorithms to compensate observed or expected deviations by modifying the tool path, the tolerances often cannot be met. Thus, it is necessary to pay more attention to the topic of geometrical accuracy in ISF.

3 Focus and Objectives

Focusing with regard to the considered process variants: There are different process variants of incremental sheet forming, which are described in [7]. There are also various hybrid process variants, such as the combination of stretch forming with subsequent incremental sheet forming [8] or the superposition of a hydrostatic pressure [9, 10]. Even though it has been shown that stretch forming can improve geometrical accuracy in many cases [11–13], the subsequent incremental forming process still follows the mechanisms of the general ISF process and influences the final geometry. Thus, stretch forming is not discussed in this paper. Also, methods with two moving tools are excluded, since this significantly increases the variety of possible causes for geometrical deviations and the number of variables [14]. Nevertheless, it can be assumed that at least some of the mechanisms and defect types discussed in Sects. 4 and 5 are also valid for this process. The focus of the paper is on the process variants a) single-point incremental forming (SPIF) and b) two-point incremental forming (TPIF) shown in Fig. 1. For variant b) it has to be distinguished whether it is a full or partial die.

Focusing with regard to the considered causes for geometrical deviations: A considerable part of the literature from the field of incremental sheet forming deals with the question of how precisely the forming tool follows the given tool path. Especially when using industrial robots with limited structural stiffness, elastic deflection

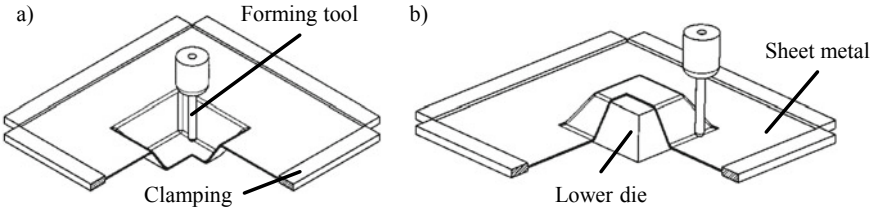

Fig. 1 Variations of the incremental sheet forming based on [15]. **a** SPIF. **b** TPIF with a full die

has to be expected due to the forming forces. The causes of this problem are at least theoretically describable and can be corrected with suitable algorithms [16–18]. In addition, when sufficiently rigid machine tools are used, the resulting geometrical tool displacements are generally significantly smaller than the geometrical inaccuracies of the product generated by the forming process [19]. Accordingly, the effects of insufficient machine accuracy are not considered in this paper; instead, it is assumed that the machine follows the given tool path exactly. Also, the geometrical deviations resulting from unsuitable tool geometry are not taken into account. This would be the case, for example, if a narrow radius in the part cannot be formed simply because the radius of the forming tool is larger. Excessive thinning, necking, and finally failure of the sheet during forming can also be seen as geometrical defects. However, there are numerous Refs. [20–22] related to the forming limits, and the existing models allow a relatively reliable prediction for many materials. Therefore, this topic is explicitly not considered further in this article. Nevertheless, it must be kept in mind that applying compensation methods to increase accuracy, such as over bending, might also increase the risk of material failure.

In this paper, the authors focus on those defects that occur despite a perfectly maintained toolpath in geometries that generally can be realized by incremental sheet forming with sufficient remaining wall thickness. The defects also include those that appear or intensify after unclamping and trimming. The aim is to derive the causes of these defects as far as possible from mechanisms that can be explained by continuum mechanics and material physics. Therefore, the next chapter provides a brief description of metal flow in ISF.

4 Deformation Modes in Incremental Sheet Forming

Various articles have discussed the "mechanics" of incremental sheet forming, mainly with the target to identify forming limits. Both, analytical considerations as well as sophisticated FE models have been used. With respect to the origins of geometrical deviations, the following considerations are to be considered.

Geometric deviations may be a consequence of generally non-adequate metal flow or a result of residual stresses, which are induced during the forming operation, or most likely both. For the following, we assume a local coordinate system in the

forming zone with the axis oriented (i) normal to the sheet surface, (ii) in the sheet plane in tool movement direction, and (iii) in the sheet plane perpendicular to the tool movement. Then generally the following deformation modes may occur: strain (compression or stretching) in all axis directions as well as shear in the direction of the tool path or perpendicular to the tool movement. The latter is usually referred to as "through thickness shear". Also bending modes occur, which basically means that "in-plane strains" vary across the thickness of the sheet.

According to Maqbool and Bambach [23] the deformation modes "membrane stretching", "bending" and "through-thickness shear" are dominant under the geometrical conditions of their numerical study. Also, Malhotra et al. [24] already postulated these three different deformation modes with the aid of FE models. Experimental investigations by Jackson and Allwood [25] also showed that stretching and shear perpendicular to the path direction and shear in the path direction are major deformation mechanisms in SPIF and TPIF. Shear in the path direction is a consequence of the friction between tool and sheet metal and is an essential strain component under the chosen experimental conditions.

As residual stresses in the material may cause elastic deformation during and after the process, it is important to understand how they develop during the process. Residual stresses are always caused when plastic deformation is spatially inhomogeneous. The most prominent example is bending, where in-plane strains vary across the thickness. Accordingly, various authors, among others Tanaka et al. [26], Maqbool and Bambach [23], study how the deformation modes can be influenced by the process parameters and especially how the bending mode can be reduced. According to Maqbool and Bambach [23], the deformation mechanism in SPIF is always a combination of the three modes mentioned in the previous paragraph. Within a numerical simulation study, shell elements (with through-thickness strain) are used to show that the relative proportion of the modes is dependent on different process parameters. According to the results, an increase in the wall angle results in an increased percentage of the "bending" mode, a decrease leads to a larger percentage of the "shear" mode. Increasing the tool radius and vertical pitch increases the global deformation and increases the portion of the bending mode accordingly. An increase in sheet thickness, friction, and a reduction in tool diameter stabilize the forming by increasing the percentage of (through-thickness) shear mode. This is in good accordance with the experimental results from Eyckens et al. [27] using digital image correlation.

These deformation modes are also helpful in discussing the origins of geometric deviations not only considering conventional springback.

5 Mechanisms of the Formation of Geometrical Defects in Incremental Sheet Forming

In the context of the geometrical accuracy of sheet metal parts, the term springback is often used. This term easily evokes the association that the geometrical defects are only caused by elastic springback, which can be well described, for example, in bending. In this case, the elastic deformation after unloading is directed against the direction of loading. In incremental sheet forming residual stresses are induced by a wide variety of reasons, leading to elastic deformation after unclamping of the sheet or trimming. The direction of these deformations is not always in the opposite direction to the intended forming. In this article, the term springback is therefore used more narrowly and refers exclusively to the fact that the elastic part of the previous deformation is completely or partially reversed when the load is removed. The paper tries to differentiate other effects than this from the general term "springback". Other effects might be for example a plastic material flow, which deviates from the theoretical assumption of pure material projection. Also, the release of elastic residual stresses of other causes, e.g. due to deformation-induced phase transformations, is not referred to as "springback" here.

Beyond the mechanisms already excluded in Sect. 3 the following sections describe five different mechanisms, which lead to typical geometrical inaccuracies. This selection makes no claim to completeness but tries to provide a substantial basis and structure, to which further mechanisms may be added.

In some cases, a simple FE model is used for illustration. It is based on the explicit solver of LS-DYNA R901 from Livermore Software Technology Corporation using four fully integrated type 2 solid elements discretized over the sheet thickness of 1 mm. The elastic-plastic material model, 24-piecewise linear plasticity, is used as material model for the sheet metal, taking into account a stored flow curve for 1.0338. The tools are assumed to be rigid and the tool path is based on time and coordinates. The ball-headed forming tool has a diameter of 20 mm. The sheet is fixed on its outer element edges and all degrees of freedom are restrained here.

5.1 Plastic Deformation Outside the Contact Zone

During an ISF process the location of the applied force (tool position) moves along the workpiece. Since the occurring forces must be large enough to form the local area, they can cause significant reaction forces or bending moments elsewhere in the part. These can lead to undesired plastic deformation at locations, which were not intended to be formed. A well-known example is the so-called draw-in, which can be seen in Fig. 2. If no contour-near support plate is used on the backside of the sheet, forming also takes place outside the contact zone of the tool. The FE model confirms plastic strain in this region, see Fig. 2a) and b). This effect, however, may occur also in any other location of a more complicated component, for example at

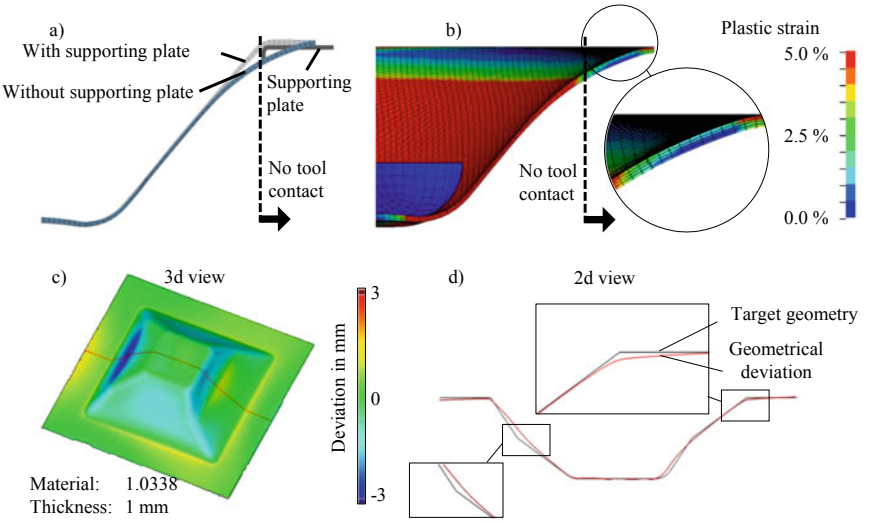

Fig. 2 **a** Comparison of FE results with and without supporting plate; **b** Strain plot (FE model) during forming shows plastic strain even in the area without tool contact; **c** Deviation plot for an experimental formed pyramid; **d** Section through the formed pyramid. (Color figure online)

previously formed locations as demonstrated by a section (Fig. 2d) cut through a formed pyramid (Fig. 2c).

5.2 Elastic Part Deflection During the Process

The entire part undergoes a continuous elastic deflection during the process as a result of the moving point of deformation force, which means that the material partially "escapes" the intended forming. Due to the often cyclic tool paths, this can also be described as tumbling. Such elastic deflection may result in the following:

- Transversely to the tool path, locally only a part of the initially intended feed per tool revolution is realized in plastic deformation.
- In the circumferential direction, this may result in the fact that the required circumferential extension is not fully achieved.

The tumbling is demonstrated by means of the forming of a hole flange. Figure 3 shows the simulation as well as experimental results of a hole-flanging process using ISF. During forming, the forming head employs a circular downward movement to realize the hole flange. The aim is a hole flange with an angle of 90° ($\alpha = \beta = 90°$). During the process it can be observed that the flange opposite to the side of the tool has a smaller angle than the side with tool contact, see Fig. 3a). This tumbling

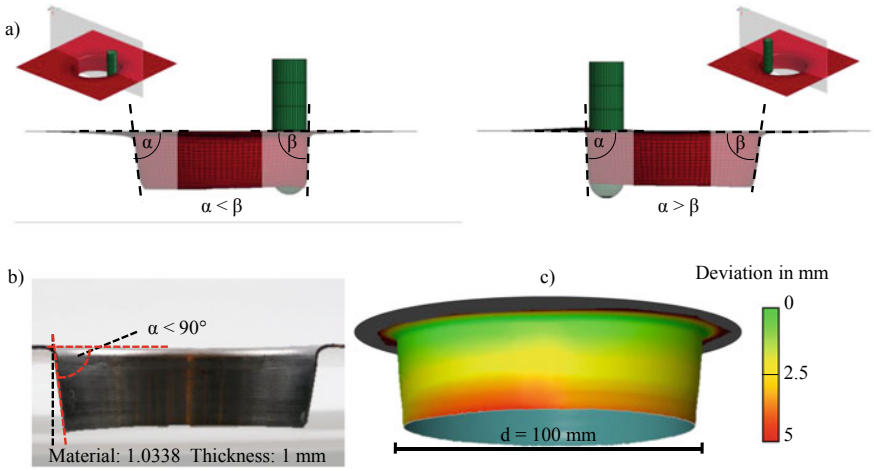

Fig. 3 **a** Illustration of the tumbling hole flange during forming (FEM simulation); **b** Trimmed conical hole flange after forming; **c** Deviation plot for the formed hole flange [28]. (Color figure online)

is noticeable throughout the entire process and ultimately results in a conical hole flange, which is well confirmed by the experimental result, see Fig. 3b) and c).

Methods to minimize this deviation are, on the one hand, a reduction of the deflection movement by additional support via dies or multiple tools [29] or, on the other hand, compensation of the previously calculated deflection movement by a modified tool path, as suggested by Cao [19].

5.3 Release of the Regular Elastic Part of the Local Deformation

"In-plane"-springback of the stretching deformations as well as springback related to homogeneous through thickness shear is usually small compared to the global deformation. Problematic, however, are changes in angle or curvature. These mainly result from a variation of residual stresses across the sheet thickness caused by a variation of strain across the sheet thickness, which was called "bending mode" in Sect. 4. With respect to the chronological occurrence of springback, it makes sense to distinguish between three cases:

1. During the process: A locally limited elastic springback occurs continuously in the follow-up of the tool tip (Fig. 4) [30, 31]. The remaining bulge c) may, however, also be caused by other reasons explained in Sect. 5.5.1.
2. After unloading and unclamping (Fig. 5): The entire component elastically springs back until it is in global mechanical equilibrium. This happens at the

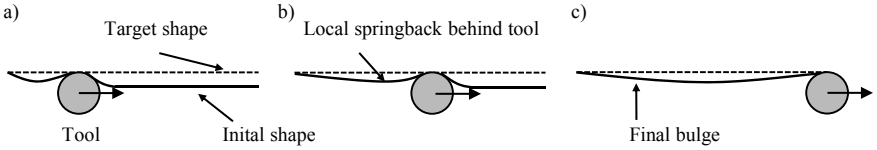

Fig. 4 Elastic springback behind the forming tool in the process according to Bambach [30]. **a** Sheet is pushed into the target position, **b** local springback behind the tool, **c** the local springback contributes to global deviations

Fig. 5 Elastic springback after ISF process for unloading, unclamping and cutting/trimming [30]

end of the process as soon as the contact between the forming tool or clamping system and the sheet metal is removed [30, 32, 33] or during the process, whenever the tool is lifted as part of the programmed tool path.

3. After trimming (Fig. 5): By trimming the component to its final contour, the (residual) stress state is changed and the part springs back elastically until it has found a new mechanical equilibrium [31–33].

However, the bending mechanism already mentioned in Sect. 4 is not the only mechanism resulting in a strain variation across the thickness. Depending on the selected feed rate, component geometry, and sheet thickness, it is also possible that such strain gradients occur like in shot peening. This can lead to residual compressive stresses in the previous contact surface. During unclamping or trimming, such residual stresses may cause changes in the curvature, which in extreme cases can result in curling of the surface. One example of curling is presented in Fig. 6. Here, curling is a result of the tool path pattern and the forming tool intruding the sheet by $i = 0.1$ mm. Intruding the sheet with the forming tool may happen during forming, for example in TPIF when thinning is considered incorrectly in the tool path design. Experiments with varying intrusion depths and tool path directions have shown that the forming result differs significantly, even for changes of the intrusion depth by a tenth of a millimeter [34]. In the presented case, a flat specimen with dimensions of 260 mm $\times$ 40 mm $\times$ 1 mm is clamped at the two short opposing sides and is formed according to a tool path pattern presented in Fig. 6b). The tool path follows the blue lines alternating parallel to the longest sheet side with a pitch of 1 mm parallel to the shorter sheet sides. The black arrows are meant to clarify the tool path strategy.

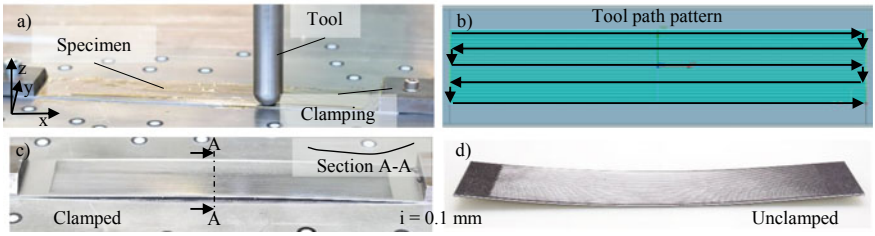

Fig. 6 **a** Experimental setup; **b** Tool path pattern for forming a flat surface; **c** Clamped sheet with surface section through part; **d** Unclamped sheet [34]. (Color figure online)

Although a flat surface is formed, it can be already seen in the clamped state that the result deviates from a flat sheet. The long edges of the sheet are clearly curved upwards, see surface section A-A in Fig. 6c). After unclamping the sheet is curling in a way that the short sides tend to upwards, as presented in Fig. 6d).

5.4 Geometry Changes Due to Transformation-Induced Residual Stresses

Further causes of residual stresses may lie in microstructural changes in the material. If materials locally change their microstructure as a result of forming (e.g. deformation-induced martensite transformation), the resulting change in the specific volume leads to considerable residual stresses, which was demonstrated by Hedström et al. on the basis of tensile tests [35]. Katajarinne and Kivivuori [36] verified the presence of a significant fraction of strain-induced martensite in ISF for different stainless steels, depending on the forming speed and steel grade. Such residual stresses may cause excessive deflections, far beyond those of usual springback, which is shown in Fig. 7 by Bambach [30] after laser cutting an incrementally formed stainless steel component.

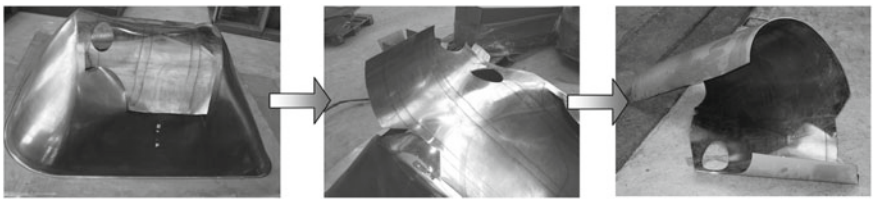

Fig. 7 Excessive elastic deflections during (left and middle) and after (right) laser cutting due to deformation-induced martensite [30]

5.5 *Geometry Inaccuracies Induced by the Local Material Flow*

Tool path planning typically follows strategies that are known from CNC-machining. However, other than in CNC-machining material is not removed but displaced. The algorithms might nevertheless work, as long as the only deformation mode would be perfectly homogeneous through-thickness shear. However, in Sect. 4, it was pointed out that among others also in-plane stretching, both, parallel or transversal to the tool path, frequently occurs. This may cause geometry deviations at least as follows.

5.5.1 Disproportional Enlargement of the Surface

An enlargement of the surface that exceeds the amount required by the geometric projection leads to compressive stresses in the sheet if this enlargement is restricted by stiffened elements (i.e. corners) of the component. If these compressive stresses are larger than the buckling stress, bulges occur, which can be directed inwards or outwards. The excessive enlargement of the surface can be a result of strains in one or two directions:

(a) If the sheet is stretched in the direction of the tool path, this necessarily results in longer "fibers" in the path direction than assumed by the pure material projection, see Fig. 4c).
(b) If the overall strain in the feed direction, i.e. transverse to the path direction, is greater than required an excessive "fiber length" in the feed direction occurs.

Even though no general quantitative relation is known describing the evolution of these excessive stretches, it can be assumed that the relevant influencing factors are the process parameters feed rate, tool radius, sheet thickness, and wall angle, as well as the component geometry and the friction between tool and sheet. Bulges that form in this way cannot be avoided simply by overcompensating the tool path, as is attempted in various publications [15, 30, 37]. Hirt et al. [15] and Junk [37] proposed a compensation, where the measured deviation of the actual geometry is mirrored to the target geometry, see Fig. 8a). Depending on the chosen "scaling factor c" a significant reduction of geometrical deviations could be realized, see Fig. 8b). However, as the compensated tool path is longer than the original one, the length of the fiber along the considered pyramid wall is not shortened but further stretched. Thus the larger bulge is replaced by smaller waves. Rather, a "shorter" tool path should have been defined for compensation, which is impossible for flat surfaces as there is no shorter path than the original straight line.

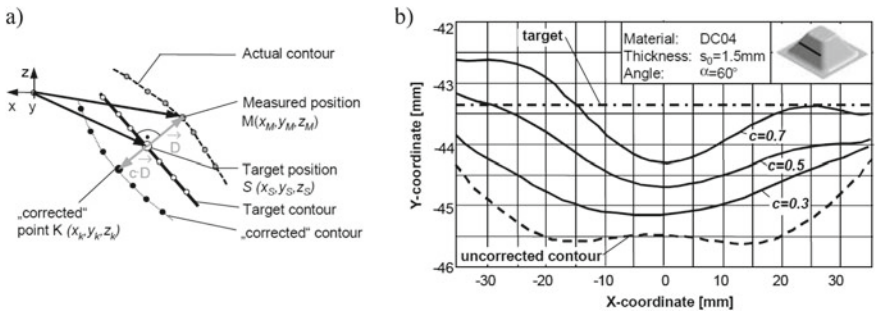

Fig. 8 **a** The correction algorithm proposed by Hirt et al. [15] and Junk [37]; **b** The resulting reduction of total deviation and the formation of waves [37]

5.5.2 Forwarding a Bulge in Front of the Tool

If a bulge is formed as a result of the mechanisms under Sect. 5.5.1, it can be pushed in front of the tool during the process. This effect is possible both in the path direction and in the feed direction. A defect often discussed in the literature [38–40] and occasionally referred to as the "pillow effect" is shown in Fig. 9a). One possible reason for this effect can be the pushing of a bulge in the feed direction. At least it is obvious that in such cases there is more material at the bottom surface of the part than theoretically foreseen by the assumption of pure material projection. Another possible reason is the geometrical stiffness of a component, which might hinder the bottom surface from simply following the circumferential forming.

Excessive pushing of material in front of the tool can lead to the formation of wrinkles and overlaps, among other things, see Fig. 9b). In general, geometrical stiffening features such as corners foster buckling, because the excessive surface cannot spread due to these constraints.

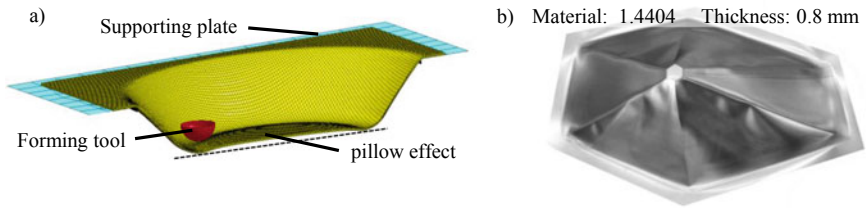

Fig. 9 **a** FE-model showing the pillow effect; **b** ISF formed pyramid made of 1.4404 showing wrinkles and overlaps [41]. (Color figure online)

6 Summary and Conclusions

Even if the forming machine perfectly follows the specified tool path, geometrical deviations may occur during incremental sheet forming. A significant part of these geometrical defects can be divided into typical categories and explained by the mechanisms summarized below:

1. The forming zone is not always limited to the local contact area (Sect. 5.1).
2. The sheet partially escapes the plastic deformation intended by the tool path, because the emerging component is elastically deflected by the moving local forming force (Sect. 5.2).
3. The release of residual stresses after unclamping and trimming leads to elastic deformations.
    a. On the one hand, these residual stresses can be a result of inhomogeneous deformation, i.e. due to the bending fraction over the sheet thickness (Sect. 5.3).
    b. Other residual stresses, such as deformation-induced microstructure transformations, can cause considerable elastic deformation in different directions during trimming (Sect. 5.4)
    c. Both types of elastic recovery (a, b) are not necessarily directed against the forming direction.
4. If the local in-plane stretches lead to an excessive increase in surface area, buckling and bulges can occur, especially in combination with geometrical constraints (Sect. 5.5).

Even if the mechanisms mentioned can at least explain the origin of the described types of defects qualitatively to some extent, a reliable quantitative description of the correlations is still lacking. With regard to efficient identification of suitable tool paths, it is also not sufficient that the numerical process simulation can correctly map these defects already in various cases. The computing times that are still far too long for complicated components do not allow a large number of process variants to be tested in simulation, especially if even the tool path should be optimized. Therefore, it will be important for future economic application of ISF to be able to decide quickly whether and with which tool path strategy a given part can be produced appropriately and precisely. Therefore, powerful process planning methods are mandatory that allow for a fast and precise accuracy prediction and must be based on a profound process understanding. For this purpose, the collection of mechanisms described above must be further sharpened and extended. It could also be helpful to create a wider experience base, e.g. a public collection of well-documented tool paths and the part geometries generated by these.

Tube Roll Forming Flower Design and Flexible Roll Adjustment with CAE Simulation

Jinn-Jong Sheu, Bao-Shan Wang, and Cheng-Hsien Yu

Abstract The roundness and the angle of the edges on the cross-sectional profile at the exit of the fin pass are crucial for the welding quality of the ERW tube. In this paper, the adjustment of the bending angles of the cage rolls was proposed to make a 9-inch tube. The proposed roll forming machine layout is capable of making tubes in a specific range of outside diameters without changing rolls. The CAE simulations were carried out to verify the proposed roll flower designs and the bending angle control strategies of the cage roll stations. The CAE simulations had verified the proposed flower design using different roll adjustments, and proper bending angle control strategies are able to make the demonstrated tube.

Keywords Cold roll forming · Tube forming · Flexible roll forming · Cage roll

1 Introduction

Roll forming is suitable for making long tubes quickly and efficiently. The process and the tool designs for tube roll forming are mostly depending on the experiences of the engineers. The try-out and tool modifications are not only time-consuming but also expensive. The application of flexible and adjustable tools is capable of dealing with the tool modification problems but the adjustment of tools is painful due to the high degree of freedom of the tools.

Naeini et al. [1] had investigated the weight of longitudinal out-of-plane bending energy for roll forming of symmetric channel sections considering different bend angles and flange widths. The decrease of the dimensionless work ratios indicates that the longitudinal out-of-plane bending energy is less significant. Woo et al. [2] had studied the defects of the flexible roll forming process via the experimental works for different materials. The double-layer material could cause problems at the interface.

Chen et al. [3] proposed a roll flower design method for ERW pipes cage roll forming with the blank edge modeling of cubic equations. The FEM software LS-DYNA was used to simulate the forming process and study the effects of the roll positions and forming angles. Wen et al. [4] had studied the phenomenon of strip edge instabilities in the downhill forming process considering the lift of the end of the strip. The roll gap should be adjusted to prevent the rotation of the strip segment and avoid the occurrence of the edge instabilities of ERW tube roll forming. Kasaei et al. [5] had compared the contour roll forming (CORF) process using BD (break down) and side rolls with the cage roll forming (CARF) process using small cage rolls. The curvature distributions of the CORF process are more uniform than the CARF process for HWF tube forming. Jiang et al. [6] had proposed a cage roll forming mill and studied the effects of the non-bending areas. The analysis of the strain distribution is likely to find the areas of buckling. In this paper, the tool adjustment method and the effect of different settings on the edge deformation of the strip were studied. The proposed roll forming machine is composed of different types of breakdown (BD) rolls,cage rolls, and fin pass as shown in Fig. 1. The tools can be adjusted flexibly to make tubes in a specific range of dimensions and thickness. There are three breakdown passes, nine cage passes, three fin passes, and one squeeze pass.

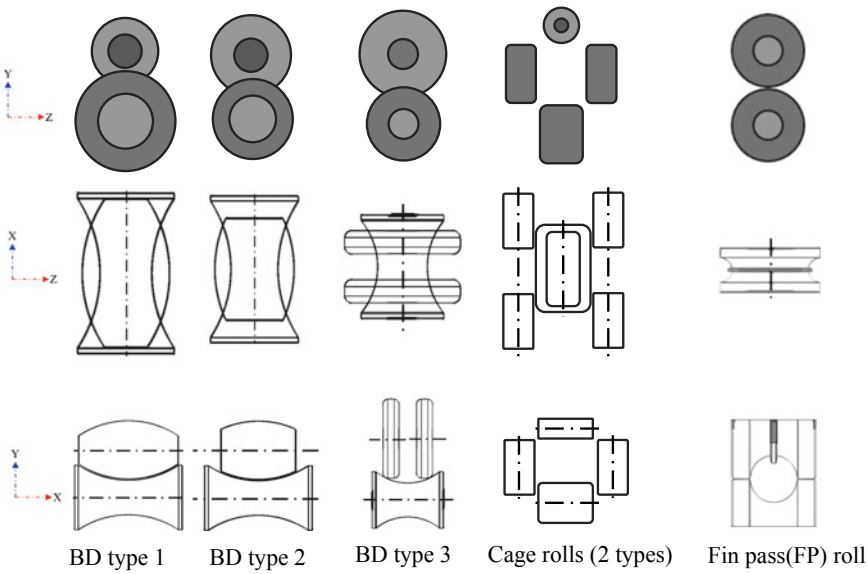

Fig. 1 Different types of tools designed to construct a tube roll forming machine. (Color figure online)

2 Design of the Tube Roll Forming Process and Tool

The roll adjustment for each pass of the roll forming machine is based on the process design or the roll flower pattern used. The forming process is generated with the virtual cross-sectional changes of the strip from the inlet break down station to the final exit of the fin pass stands. The flower pattern is the arrangement of the section profiles of the long strip according to the specific guiding line.

2.1 Roll Flower Design

The roll flower was designed to distribute the bending angle of the strip from the entrance station to the exit station (fin pass). There are three stages of flower pattern, tube bottom curvature creation by stations BD1 to BD3, edge lift, and U–O shaping by cage forming, precision control of the tube dimension, and the curvature. A roll flower designed with the assumption of the equal strip width (constant arc length of each station) was given in Fig. 2. The blank will be deformed during the forming process; as a result, the thickness, width, and the length of the strip will be changed. This virtual flower is the reference for the roll geometry design and the roll position adjustment.

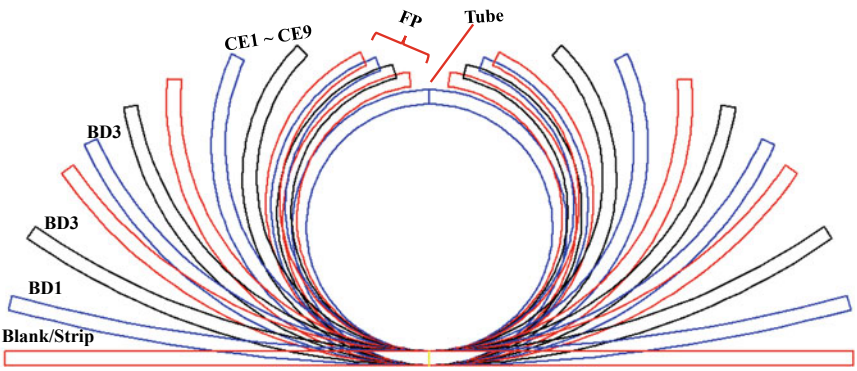

Fig. 2 Flower pattern of a tube roll forming with the assumption of constant arc length. (Color figure online)

2.2 Roll Design and Adjustment

The breakdown (BD) rolls were applied to clamp the strip and break the flat blank into a certain curvature for further roll forming pass feeding and designed according to the section profiles of the corresponding roll flower. The cage rolls were applied to lift and to press the edge of the strip to shape the curved strip into a round shape for smooth feeding of the first fin pass station. The cage roll pairs were arranged either horizontally or vertically to control the lifting angles of the strip edge and the curvature of the entire section profile. The fin pass rolls were applied to control the curvature of the final product and to grind the strip edge using the center fins for better contact of the welding station. The adjustments of the roll gap and the relative position of the roll were determined using the virtual section profile given by the roll flower. The parameters of the roll geometry design and the roll adjustment were given in the following sections.

2.3 Roll Adjustment with Respect to Roll Flower

The adjustment of the rolls for each pass of the universal roll forming machine is determined according to the roll flower pattern which presents the virtual cross section of the forming process at each pass. The vertical positions of the virtual cross sections could be aligned referring to the bottom, the gravity of the center, or any chose locations. The centers of the section profile were aligned along the roll forming direction and formed a horizontal guiding line as shown in Fig. 2. The adjustment of the breakdown rolls was adjusted to cope with the inlet strip thickness and width for feeding and curving purposes as shown in Fig. 3. Type 1 BD roll was applied in the first station for clamping and breaking the flat strip into a curved shape with

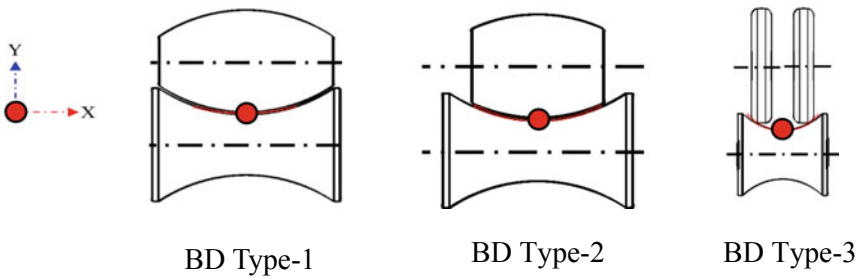

Fig. 3 The adjustment of the breakdown roll type 1, type 2, and type 3. (Color figure online)

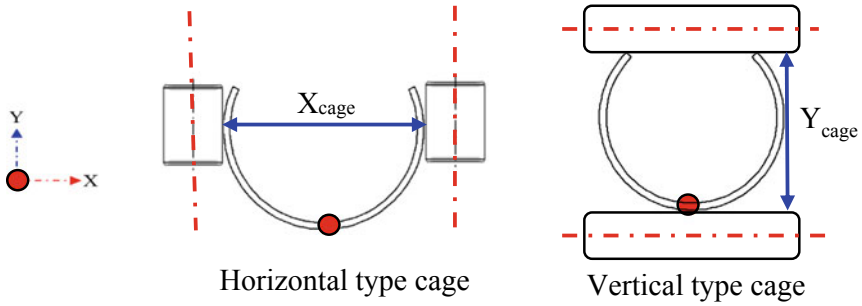

Fig. 4 The adjustment of roll distance for the horizontal cage rolls and the vertical cage rolls. (Color figure online)

small curvature. Type 2 BD roll was applied to bend the center of the strip again to increase the curvature of the blank. Type 3 BD roll was applied to bend the edge of the strip to form a better contact region for the cage rolls.

The adjustment of the vertical and the horizontal cage rolls was a sequence of the strip width and height changing to cope with the roll flower profiles. The horizontal roll distance, X_{cage}, and the vertical roll distance, Y_{cage}, as shown in Fig. 4 were adjusted to cope with the required section profiles of the roll flower. The fin pass rolls were designed to form the strip into a round tube using the shaping rolls and the center fin. The gap between the upper and lower rolls can be adjusted to cope with the extra width of the strip blank.

2.4 Roll Forming Machine Layout

The tube roll forming machine could be built by selecting different numbers of rolls with the combinations of different types of stations. The roll forming machine shown in Fig. 5 is composed of 15 stands that were arranged with a distance of 600 mm in the roll forming direction. There are two bending angle designs based on the proposed roll flower design, and the combinations of the bending angle accumulation were shown in Table 1. The cage roll forming stands were divided into three segments for different bending angle control strategies: “group” design keeps the same bending angle in the same group; “individual” design gives a higher bending angle for horizontal cage rolls in the same group to compensate the spreading out effect of the vertical cage roll.

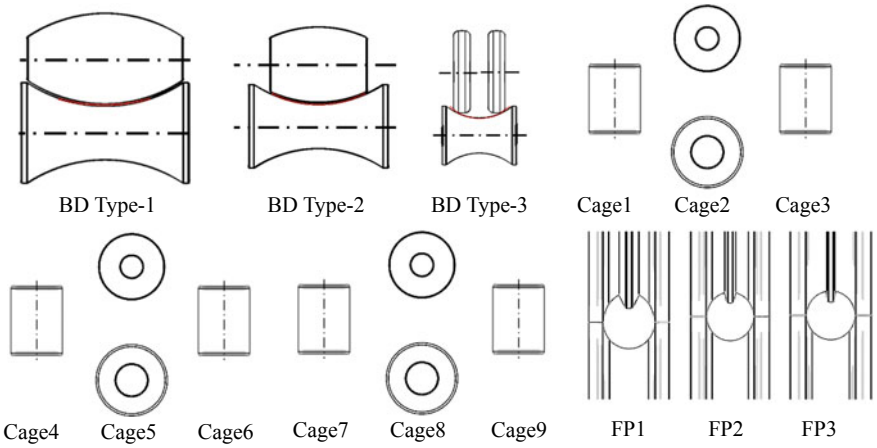

Fig. 5 Layout of the tube roll forming mill with breakdown, cage, and fin pass rolls. (Color figure online)

3 CAE Simulation of the Tube Roll Forming Process

The tube roll forming process was simulated using 3D FEM software (*simufact.forming*) to predict the forming results of the different roll adjustments. The blank material adopted is the API 5CT K55 grade sheet with 9 mm in thickness. The yield stress is 379 MPa for the K55 grade API tube. The power-law model was used for the flow stress calculation. The coefficient of the strength and the strain hardness exponent are 1004 MPa and 0.15, respectively. The outside diameter of the tube is 330 mm. The symmetry model was built to do the simulations. The width, the thickness, and the length of the blank are 520 mm, 9 mm, and 1800 mm, respectively. The three-dimensional hexagonal mesh was used to create the blank FEM model; the mesh sizes in the forming direction and the lateral direction were 20 mm and 9 mm, respectively. The number of the blank mesh is 13,680 as shown in Fig. 6. The roll forming speed is 250 mm/s. The Coulomb friction coefficient assumed is 0.14.

4 Results and Discussion

The tube roll forming process with flexible roll adjustment relies on the setup of the cage rolls to make a sound tube. The bending angle accumulations of the designed data and the simulated results were shown in Table 2. The forming process with the segment group control strategy was not able to finish the forming process due to the insufficient lifting angle to enter station 10 cage roll. The forming process with the individual cage roll control strategy was able to finish forming process successfully.

Table 1 The accumulated bending angles for the tube roll forming process design

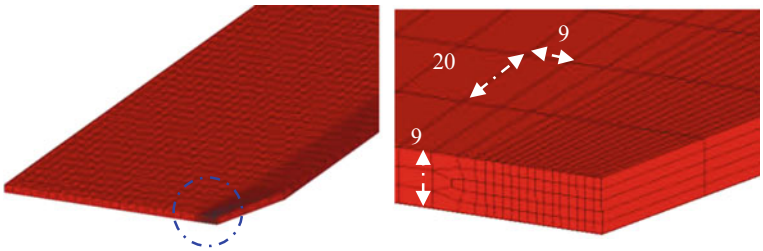

Fig. 6 The dimensions of the entire blank and the mesh refinement of the strip edge. (Color figure online)

4.1 Geometrical Control of the Cage Rolls

The main purpose of the cage rolls is to change the curvature of the strip gradually to feed into the final fin pass forming. The mean section profile curvatures of the strip from cage 1 to cage 9 were shown in Fig. 7. The final radius of the tube is 165 mm (the corresponding curvature is 0.006/mm). The average curvature of the cage roll stations was distributed in the range 0.003–0.006. The second cage roll station and the final cage roll station had shown a significant variation of curvature which indicates the roll adjustment of these two stations maybe not proper.

4.2 Strain and Stress Distributions of the Breakdown Stations

The breakdown stations should be able to form a curved blank to feed into the cage stations. The effective strain and the equivalent stress distributions of BD stations were shown in Fig. 8. The effective stress of the entire curved blank was larger than the yield stress until station 3; the spring back of the blank had decreased the bending angle and resulted in the forming difficulty of cage rolls.

4.3 Strain and Stress Distributions of the Cage Roll Stations

The cage roll stations are the width and the height control process of the blank using cylindrical rolls. The effective strain and the effective stress distributions of station 4 (cage 1) to station 12 (cage 9) were shown in Figs. 9 and 10. The effective strain is mainly distributed at the edges and the center bottom of the blank since the contacts of the rolls and the blank occurred at these areas. Stations 11 and 12 had larger strains and stresses that indicated the deformations of blank at these stations are more severe.

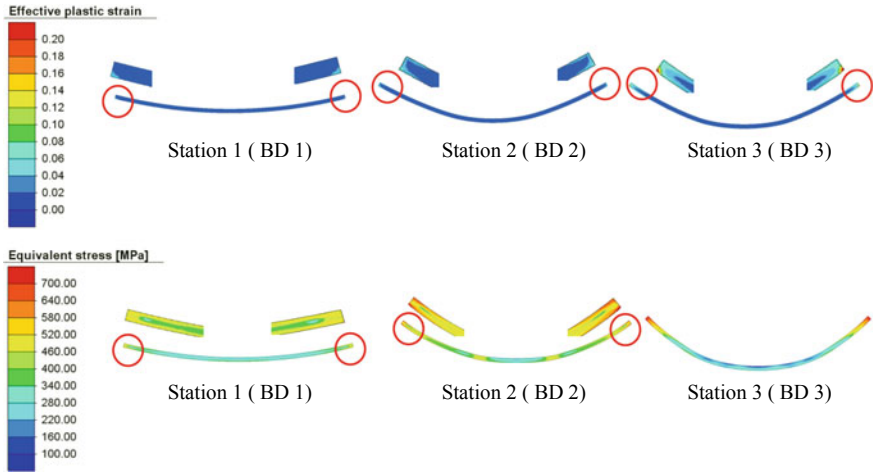

Fig. 8 The effective plastic strain (top) and the equivalent stress (bottom) distributions. (Color figure online)

4.4 Strain and Stress Distributions of the Fin Pass Stations

The fin pass (FP) stations compressed the entire blank to contact with the rolls and form the round tube. The effective plastic strain and the effective stress distributions of station 13 (FP 1) to station 15 (FP 3) were shown in Figs. 11 and 12. The effective strain distribution at the FP 1 station is similar to the previous station (cage 9) but the geometry of the blank had been changed dramatically. The equivalent stress distributions revealed that the deformations of the FP 2 and the FP 3 stations are in the vertical and the horizontal directions, respectively.

5 Conclusions

The proposed cage roll forming process was simulated using three-dimensional FEM successfully. The control strategies of the cage roll and the roll position adjustment were crucial for sound product making. The strip edge should be bent properly to avoid the spread-out phenomenon in the cage roll forming zone. The arrangement of the bending angles in the cage roll forming zone is essential and the roll adjustment should take into consideration the spring back in the previous station.

Open Die Forging of Copper Cone

A. Shirizly, G. Harpaz, and A. Shmuel

Abstract The open die forging/upsetting of bulk material to a cone shape involves high plastic deformation. The plastic strain causes major changes in the material's mechanical and metallurgical characteristics. In order to gain a better understanding of these characteristic changes, experimental, analytical, and numerical models were developed and studied. First, sample material properties and friction conditions (with several lubricants) were measured. Next, analytical models (upper bound and slab method) simulated the forging forces and the results were compared to results from a finite element (FE) model. These were then compared with the experimental findings using C101 copper. The preformed samples were surface etched with a grid pattern and the strain caused by the forming operations was measured from the grid changes. The flow pattern was inspected and compared with the outcomes using a similar material and a numerical model. A good resemblance was found between the experimental results and the theoretical models.

Keywords Open die forging · Upper bound · Lower bound · Finite element · Copper

1 Introduction

Open die forging is one of the most common processes found in the metal forming industries. The compression of a solid cylinder is well explored as a forging process. Among the early solutions for cylinder forging were the works of Kobayashi [1], Avitzur [2], Hosford [3], and a velocity for an upper bound solution was introduced. Yang and Lee [4] expanded the upper bound method to three-dimensional problems, and Dixit 2002 [5] examined the effects of barreling in a compression test. In 1989, Kobayashi et al. [6] published a finite element (FE) book with an emphasis on metal forming and presented the results for the compression of a solid cylinder. Additional work has been done to investigate compressible materials. Shirizly et al. [7, 8] investigated the open die forging of porous materials based on limit analysis and an

experimental procedure. Lichtenberger [9] described the warm forging process with temperatures below the recrystallization temperature for a cone liner material and a few forging steps than needed for the production of cold-forged cones. However, open die forging of a cone is still obscure. Engineering experience has provided some knowledge but many of the process parameters remain in obscurity. The universal models developed in this work cover a wide spectrum of cone angles (from a solid cylinder to a sharp cone), material properties, and friction conditions.

2 Analytical, Numerical, and Experimental Models

Two analytical models were developed for the open die forging of a cone: (i) the slab method that assesses the stress distribution and the applied force and (ii) the upper bound method that gives an upper limit approximation for the applied force. ABAQUS\Explicit software was used for FE modeling of the process. All models were used to analyze the process parameters (forging speed, lubrication, material hardening, etc.). The outcomes of the above models were compared with the experimental results.

2.1 Material Properties

The raw material used in this study was copper C101. To model the material's behavior, a number of uniaxial tensile tests were performed at different loading rates. The tensile samples were prepared in the longitudinal direction of an Ø50 mm extruded bar, according to the ISO-6892-1 [10]. The loading velocity of 18 [mm/min] was chosen to represent the raw material properties and matched the strain rate during the product forging process.

The Ludwik power law of strain-hardening model [11] was used to describe the plastic behavior of the raw material, according to the following expression:

$$\sigma = C\varepsilon^{n} \tag{1}$$

where σ is the true stress, C is a material constant, known as the "strength coefficient", ε is the true plastic strain, and n is the strain-hardening exponent.

The material properties derived from the tensile experiments are given in Table 1.

Table 1 Uniaxial tensile material properties (average of three samples)

Yield stress σ_y [MPa]	Ultimate tensile stress σ_{UTS} [MPa]	Elongation [%]	Reduction of area [%]	Material constant C [MPa]	Hardening coefficient n
58.5	216.7	61.5	85.2	486.9	0.5113

2.2 Slab Analysis

Slab analysis of plasticity for incompressible materials is based on balancing forces on a differential slab of material. The slab analysis relies on several assumptions:

1. The principal axes are in the directions of the applied loads,
2. The deformation is homogeneous so that the plane sections remain plane,
3. The effects of friction do not alter the directions of the principal axes or cause internal distortion,
4. The material obeys the incompressibility condition under yielding.

Figure 1 illustrates *open die forging of cone*. A force F is applied on the material via a cone punch (upper die), and the material is compressed with a constant coefficient of friction m versus the lower die.

Balancing the forces on the differential slab in the radial direction and applying the circumferential symmetry conditions gives

$$\left(\sigma_r + \frac{\partial \sigma_r}{\partial r} dr\right)(r + dr)hd\theta - \sigma_r rhd\theta + (P\cos\alpha - P\cos\alpha)rd\theta\frac{dr}{\sin\alpha} - 2\tau\sin\alpha rd\theta\frac{dr}{\sin\alpha} - 2\sigma_\theta \sin\frac{d\theta}{2}hdr = 0 \quad (2)$$

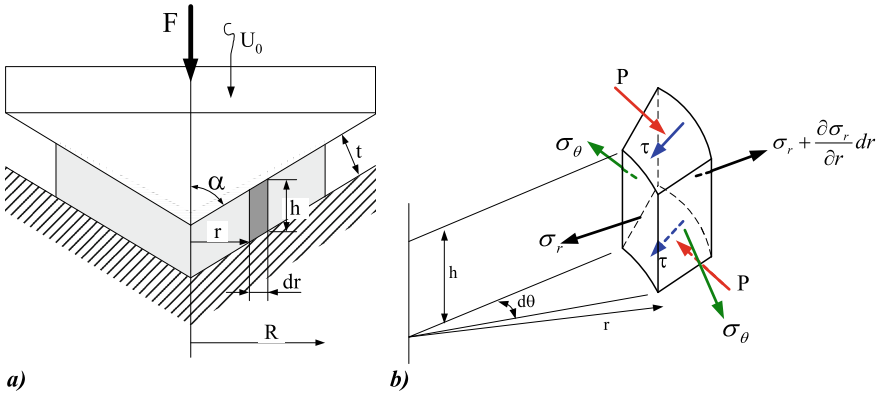

Fig. 1 Slab method model: **a** Cone model; **b** Slab used for force balancing. (Color figure online)

where $\tau = m\bar{\sigma}$ is the shear stress strength of the interface, m is the friction coefficient, and $\bar{\sigma}$ is the equivalent stress.

Simplifying by substituting $\sin\left(\frac{d\theta}{2}\right) \sim \frac{d\theta}{2}$ and neglecting second-order differentials gives

$$\frac{\partial \sigma_r}{\partial r} + \frac{\sigma_r - \sigma_\theta}{r} - \frac{2\tau}{h} = 0 \tag{3}$$

For axially symmetric flow, $\varepsilon_\theta = \varepsilon_r$; therefore, $\sigma_\theta = \sigma_r$.

Applying the von-Mises yield criteria gives

$$\bar{\sigma}^2 = \frac{1}{6}\left[(\sigma_r - \sigma_\theta)^2 + (\sigma_\theta - \sigma_z)^2 + (\sigma_z - \sigma_r)^2\right] \tag{4}$$

Solution of Eq. (3), and using yield criterion 4, as well as the axisymmetric and the radial boundary conditions $\sigma_r = 0@r = R$, leads to the stress distributions:

$$\sigma_r = \frac{2m\bar{\sigma}(R-r)}{h} = \frac{2m\bar{\sigma}(R-r)}{t}\cos\alpha;\ \sigma_\theta = \sigma_r;\ \sigma_z = \bar{\sigma} + \sigma_r \tag{5}$$

and the applied force: $F = \int\limits_A \sigma_z dA = \int\limits_0^R \sigma_z 2\pi r dr$

$$F = -2\pi R^2 C\left\{\left(1 + \frac{1}{12}\frac{\cos^2\alpha}{\sin^2\alpha}\right)^{1/2} ln\frac{h_0}{h}\right\}^n \left(1 + \frac{2m}{3}\frac{R}{h}\right) \tag{6}$$

In the case of disk upsetting ($\alpha = \pi/2$), the above solution is identical to the axially symmetric compression solution [1–3].

2.3 Upper Bound Solution

The upper bound approach is used to predict the maximum power required for deformation during a metal forming action. The upper bound solution is based on satisfying yield criteria, geometric self-consistency, kinematically admissible velocity fields, and velocity boundary conditions.

The geometry and process parameters for the upper bound solution are shown in Fig. 2a, and the relevant surfaces and velocities are shown in Fig. 2b

The admissible strain rate and velocity field for the cone are given by

$$U_r^* = \frac{U_0}{2}\frac{r}{h};\ U_\theta^* = 0;\ U_z^* = -U_0\left(\frac{z}{h} - \frac{r}{2h}\frac{\cos\alpha}{\sin\alpha}\right)$$

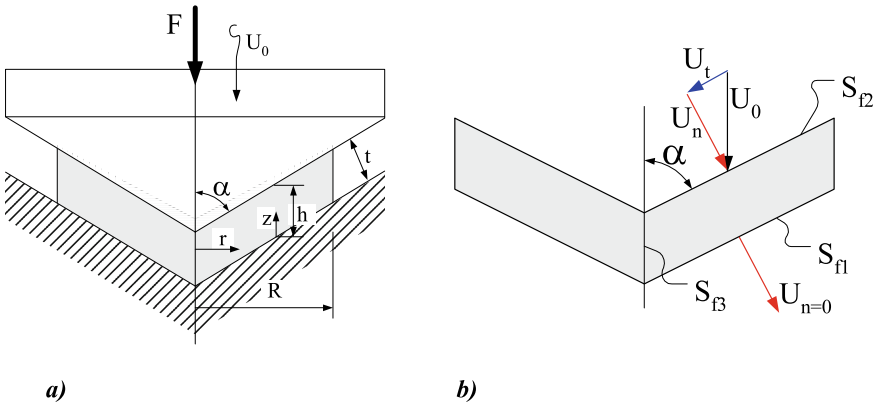

Fig. 2 Upper bound model: **a** Model parameters; **b** Contact surfaces (S_{f1}, S_{f2}, S_{f3}), applied velocity U_0 and corresponding velocities (U_n, U_t,). (Color figure online)

$$\dot{\varepsilon}_r^* = \frac{\partial U_r^*}{\partial r} = \frac{U_0}{2h}; \dot{\varepsilon}_\theta^* = \frac{U_r^*}{r} = \frac{U_0}{2h}; \dot{\varepsilon}_z^* = \frac{\partial U_z^*}{\partial z} = -\frac{U_0}{h}$$
$$\dot{\varepsilon}_{rz}^* = \frac{1}{2}\left(\frac{\partial U_r^*}{\partial z} + \frac{\partial U_z^*}{\partial r}\right) = \frac{1}{4}\frac{U_0}{h}\frac{\cos\alpha}{\sin\alpha}; \dot{\varepsilon}_{r\theta}^* = \dot{\varepsilon}_{\theta z}^* = 0 \tag{7}$$

The superscript * indicates the admissible strain rate and velocity field, and not necessarily the actual velocity field.

The upper bound of the power consumption J* is composed of:

$$J^* = \dot{W}_{def}^* + \dot{W}_f^* + \dot{W}_\Gamma^* - \dot{W}_T^* \; J^* > J \tag{8}$$

where J is the actual power and F is the actual force $F = J/U_0$.

The work rate of deformation is given by

$$\dot{W}_{def} = \int_V \sigma_{ij}\dot{\varepsilon}_{ij} dv = \int_V \bar{\sigma}\ \dot{\bar{\varepsilon}}\, dv \tag{9}$$

Applying the strain rates (7) and the Ludwik power law of strain-hardening to Eq. (1) yields the rate of deformation:

$$\dot{W}_{def}^* = \pi C R^2 U_0 \left(1 + \frac{1}{12}\frac{\cos^2\alpha}{\sin^2\alpha}\right)^{\frac{n+1}{2}} \left(ln\frac{h_0}{h}\right)^n \tag{10}$$

The work rate dissipated over the boundary between the material and the tools, S_{f1} and S_{f2} are given by

$$\dot{W}_f^* = \int_{S_f} \tau \left|\Delta U^*\right| dS_f$$

$$\dot{W}_f^* = 2\pi m C U_0 R^2 \left(1 + \frac{1}{12}\frac{\cos^2\alpha}{\sin^2\alpha}\right)^{\frac{n}{2}} \left(ln\frac{h_0}{h}\right)^n \left(\frac{R}{h}\frac{1}{3\sin^2\alpha} - \frac{1}{2} - \frac{\cos\alpha}{\sin\alpha}\right) \quad (11)$$

The work rate along the discontinuity line S_{f3} is $\dot{W}_\Gamma^* = \int_{S_\Gamma} \tau |\Delta U^*| dS_\Gamma = 0$, and on the traction surfaces $\dot{W}_T^* = \int_{S_T} T_i u_i dS_T = 0$.

Applying the upper bound force is achieved by inserting Eqs. (10) and (11) into (8) and dividing by the press velocity U_0.

2.4 Finite Element (FE) Solution

FE simulations were performed to simulate cone forging and to validate and compare with the analytical models and the experimental results. The simulations included predictions of the flow mechanism, stress and strain distributions, and the punch force throughout the forging process. The FE simulations were performed using ABAQUS\Explicit software. The preformed cone raw material was meshed using C3D8R (8-node linear brick, reduced integration with hourglass control). The upper and lower dies were meshed using R3D4\R3D3 (two-dimensional rigid elements). The typical size of all the elements in the simulation was 1 mm.

During the simulation, the kinetic and internal energies were compared to the forging process values, limiting their ratio to between 5% and 10% throughout the process. Under this constraint, the forging process was assumed to be quasi-static and the dynamic effects can be neglected relative to the plastic deformation so that the results are plausible. The preformed mesh and the setup tools in the FE simulation are presented in Fig. 3.

In all FE simulations, the lower die is fixed and the punch presses the cone against the die. The die is closed at the bottom so that toward the end of the forging process

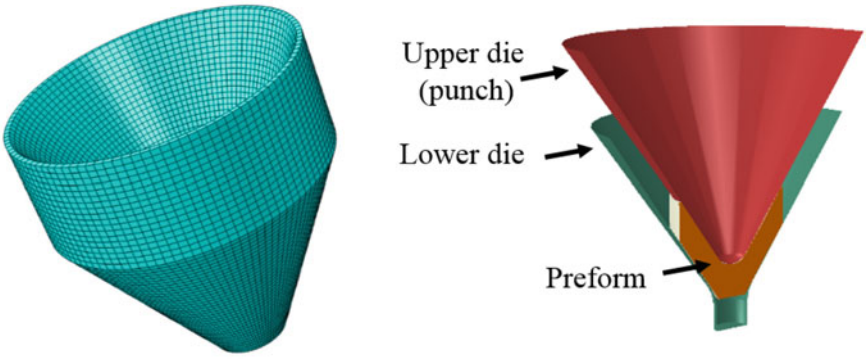

Fig. 3 Preform mesh and tools setup in the FE simulation. (Color figure online)

the material flow is inhibited to match the analytical solutions and the subsequent experiments.

2.5 *Experimental Study*

A series of experiments was conducted on copper C101 with the material properties described in Sect. 2.1. A double-action 600-ton hydraulic press was used to perform the forging tests (the major press axis was used for the forming operation and the secondary axis was used for the part release). The specimen geometry is shown in Fig. 4. Prior to the forming operation, the preform and the tolls were lubricated with a lubrication oil for "yellow" materials, such as F3118 (synthetic drawing oil) or graphite-based mineral oil. The preform samples were surface etched with a grid

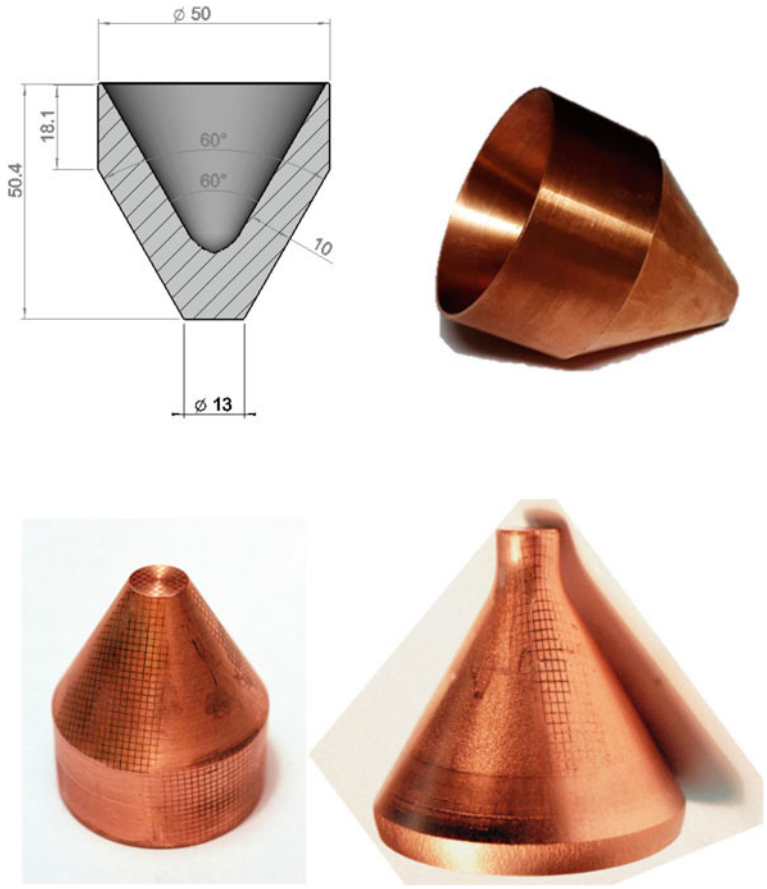

Fig. 4 The forging preform geometry prior and after surface etched with a grid pattern and grid changes due to the deformation process. (Color figure online)

pattern and the strain caused by the forming operations was measured from the grid changes. The measured strains were compared with the simulations, and the flow patterns were inspected and compared using a similar material and a numerical model.

3 Results and Discussion

The prediction of the loading paths by using a rigorous bound (slab method without friction and upper bound with the maximal friction coefficient) is given in Fig. 5, where the sample height is normalized by the initial height and the force is normalized by the force $F_0 = \pi R^2 \sigma_0$. The large difference between the bounds is due to the bound theory [2]; however, it may be more practical for the process designer to update the friction factors so that the results match the laboratory conditions. The experimental results of cone forging ($2\alpha = 60^\circ$) with two different lubricants are shown in Fig. 6. All experiments were conducted under laboratory conditions; the average results of each set of tests are scattered along the loading path and located between the bounds (with $m = 0.2$ for the upper bound approximation and $m = 0.1$ for the slab solution) and the FE simulation results (with $m = 0.1$). At the beginning of the forging process the measured force fits the FE results and was lower than the predicted bound. When the forging process progresses, the FE model and the experimental results are located between the analytical approximations.

In order to examine the influence of friction on the applied force, several coefficients of friction were used in simulations of the forging process, as shown in Fig. 7 for a cone with $2\alpha = 60^\circ$. As expected, when the friction is higher the required forging force increases and rapidly rises when the thickness becomes less than 0.6 of the initial thickness. In all the FE simulations, toward the end of the forging process

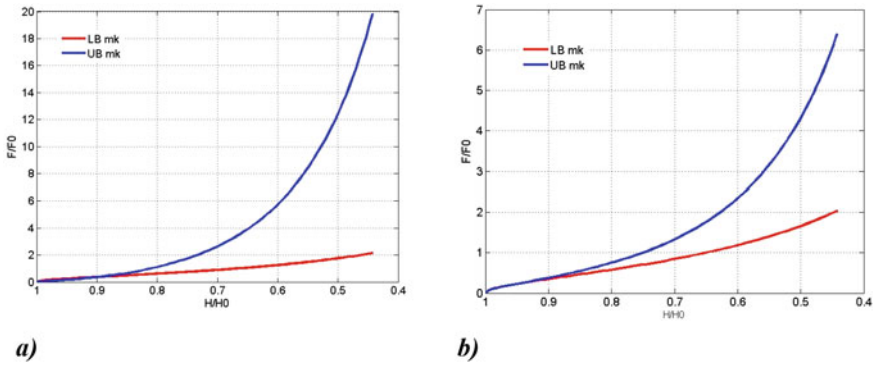

Fig. 5 The effect of the cone angle a on the predicted bounds using the slab method without friction ($m = 0$) and the upper bound with the maximal friction coefficient ($m = 1$): **a** $2\alpha = 60^\circ$—cone compression; **b** $2\alpha = 180^\circ$—compression of solid cylinder between flat dies. (Color figure online)

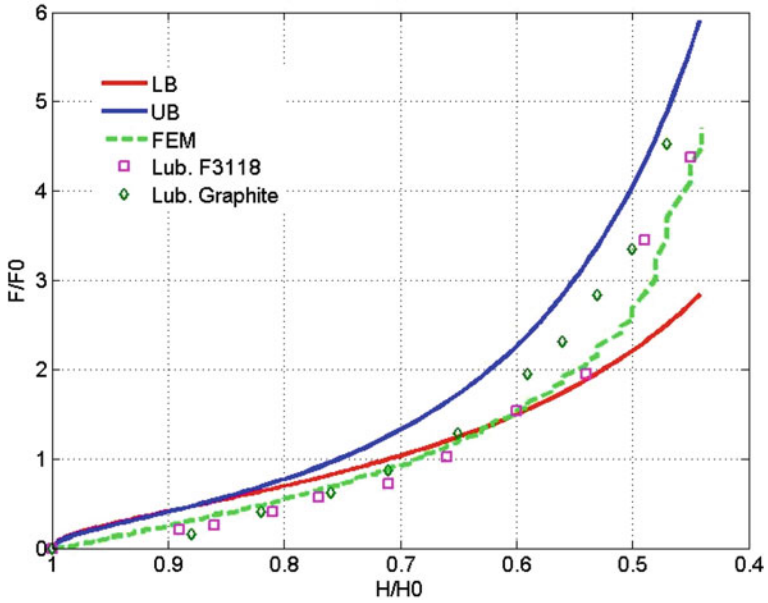

Fig. 6 Comparison between cone forging ($2\alpha = 60^{o}$) experiments (with two different lubricants), approximate limit analysis and numerical FE solution. The approximate bound solutions and the FE were obtained by different coefficients of friction for each model (0.1 for slab and FE, 0.2 for the upper bound). (Color figure online)

there is an increase in the reaction force because the flowing material is blocked at the bottom of the die, as defined in the analytical models. The radial principal stress and the displacements found in the FE simulation are presenting in Fig. 8 for $m = 0.1$ and $t/t_0 = 0.43$. It can be seen that, unlike the analytical model (purely cone), the material initially filled the cylindrical part at the bottom of the cone and then continued to deform the cone thickness. When the simulation applies to the thickness change, the simulation results are between the dual bounds (Fig. 6).

A qualitative comparison between the FE tangential strain and the results for a similar material is shown in Fig. 9. In order to present the material flow with a similar material, several layers of plasticine (with different colors and uniform thickness) were placed, layer by layer, and deformed in a Bakelite die. Then, the look-alike material was cut to represent the material flow. It can be seen that even though the Bakelite die was open at the cone edge, the material flow is very similar to the simulation.

4 Summary and Conclusions

Three simulation techniques were used to simulate the open die forging of a cone: two analytical models—upper bound and slab analyses of plasticity—and an Abacus FE simulation. The models were compared with the experimental results in the forging of a copper cone. The analytical universal models were developed for a wide range of angles of axisymmetric open die forging. The semi cone angle α was used as a parameter, and for $\alpha = \pi/2$ the solution coincides with that for disk upsetting. A good resemblance was found between the models and the subsequent experiments for the applied force and specimen deformation.

Flexible Manufacturing of Concave–Convex Parts by Incremental Sheet Forming with Active Medium

Sebastian Thiery and Noomane Ben Khalifa

Abstract Incremental sheet forming with active medium (IFAM) is a flexible manufacturing process that creates concave–convex sheet metal parts in one clamping without needing a counter tool or a die. In the first study of this new process (Ben Khalifa and Thiery in CIRP Ann 68(1):313–316, 2019, [1]), a conventional hemispherical tool has been used in interaction with pressurised air to manufacture concave–convex parts. Since the geometric accuracy was not satisfying, within the present study, a conical tool with a dedicated angle is introduced to IFAM. The idea behind this tool concept is to restrict the inclined part wall to a target angle. At first, results from the numerical investigation show an improvement of the accuracy when a conical tool is used to manufacture a truncated convex pyramid. Subsequently, experiments validate the numerical model and reveal increased process reliability. The experimental investigations of truncated convex cones and concave–convex parts close the paper and underline the feasibility of the tool concept.

1 Introduction

Nowadays, the manufacturing industry has to deal with different challenges that arise from climate change and global competition. Automotive lightweight construction is an important solution to produce safe and fuel-efficient vehicles but is subject to economic restrictions. In this context, high-strength materials are continuously developed and applied for lightweight structures. The increase in material strength comes often along with reduced formability and thus forming processes have to be

optimised simultaneously. Hydroforming has become an important technology in this field by having a great potential for processing high-strength materials.

All processes belonging to the hydroforming technology have in common that a working medium is engaged to shape metal parts [2]. Differing in the shape of workpieces, this technology can be distinguished into tube and sheet hydroforming [3]. Furthermore, there is the option either to replace the punch or die of the tool by working medium [3]. No matter which process type is selected, the forming operation by working medium happens form-based by being restricted through contact with the tool. The main advantages of hydroforming are reduction of friction, improved forming limits, and increased surface quality.

Nevertheless, one drawback of hydroforming is a more complex process design than it is required for conventional stamping tools [4]. It needs dedicated tools and is for this reason more suitable for mass production [5]. Small-batch production needs, instead, a flexible forming technology like incremental sheet forming [6].

Hydroforming and incremental sheet forming can be combined leading to a great variety of applications while saving the flexibility of incremental sheet forming. For example, pressurised oil can be used by acting as a punch to create a preform that is formed to a truncated cone in a subsequent step by incremental forming [7]. Another possible option is to use pressurised oil as a soft support during SPIF, acting as a liquid die, to produce high wall angles in a multistage forming process [8]. Being even more flexible, the highest level of interaction between pressurised medium and incremental forming is achieved by a novel process called incremental sheet forming with active medium (IFAM) [1]. By adapting the tool path to move in the horizontal plane, it allows the medium to act as counter tool [1]. This strategy extends the product range to complex concave–convex shapes without a die, a customized setup, or intermediate turning of the blank [1].

IFAM can use the same hemispherical tools as those that are applied for single-point incremental forming (SPIF) [1]. Hemispherical tool heads provide the advantages of an easy tool path generation and a uniform contact area even if a part with varying wall angle is to be formed [9]. An important parameter is the tool diameter that has a direct influence on the process capability [10]. However, a hemispherical tool shape is not a mandatory requirement for incremental forming. Tool heads can be conical with an angular profile and can affect the formability of the process [11]. Furthermore, tool heads might also have a flat end and improve profile accuracy [12]. Not only the macroscopic geometry of tools but also the surface on microscopic scale has to be considered. Textured surfaces on the tool heads enhance lubrication and change friction at the tool–workpiece interface [13].

Because the tool path is long in incremental forming processes, simulating the process by the finite element method takes a long time [14]. For simulation, either explicit or implicit time integration algorithms can be used [15]. Mass scaling and time scaling are methods to reduce the computational time for an explicit solver [16]. However, both the methods have an effect on the accuracy of the simulation [15]. Depending on the scope of simulation, one can decide to use shell elements for global modelling or solid elements for revealing local forming mechanism [17].

Using solid elements for simulating IFAM, it is shown that stress concentration and sheet thinning occur in the contact zone between the tool and the blank [1].

Because plastic deformation only happens in a small region, as it is typical for incremental forming processes, IFAM requires only very small pressures in contrast to hydroforming. Using aluminium AA1050 of thickness 1 mm for their experiments, Ben Khalifa and Thiery [1] showed that a very low-pressure level of 0.035 MPa is sufficient to cause plastic deformation due to stress concentration in the local forming zone. In comparison to IFAM, hydroforming operations require a hundred times higher pressure level, up to 5 MPa, for a homogenous plastic bulging of similar material [7].

Form-based hydroforming processes have dedicated tools, which restrict bulging of the blank and shape the blank into its target geometry. Instead, the final geometry of the blank in IFAM is the result of an interaction of the dominant process parameters pressure and tool path as well as contact conditions between tool and blank. Tool path and target shape in IFAM are not as strongly connected to each other as in SPIF. For this reason, suitable process strategies have to be developed to reach the target shape in IFAM. Approaches might be based on controlling pressure during the forming process, adapting tool path to compensate deviations, or changing contact conditions between the tool and the blank. This paper focuses on the latter strategy by introducing a tool with a dedicated angle to IFAM.

In the following section, general information for conducting IFAM experiments and simulations is provided. It includes a description of the setup and the tool geometry as well as a strategy to generate tool paths under considerations of the tool geometry. Furthermore, the material properties and the settings for the numerical model are addressed. In the third section, the numerical model is used to prove the feasibility of the conical tool shape and to determine the required pressure level for manufacturing truncated pyramids. Based on the same process parameters, the truncated pyramids are manufactured in experiments and their accuracy towards the target shape is analysed. Additionally, the accuracy of truncated cones and concave–convex parts are experimentally investigated.

2 Investigation Methods

2.1 Equipment and Tool Geometry

The experimental setup, which is placed on the machine bench of a high-speed portal milling machine, is depicted in Fig. 1a. Generally in IFAM, a blank is fixed by a blank holder on the top of a pressure chamber and a forming tool, which is attached to the spindle of the milling machine, shapes the blank either concavely or convexly into a part. The pressurised air is used as an active medium in the range 0–0.6 MPa. The pressure control valve is placed outside of the milling machine and connected by a tube to the pressure chamber. A sensor measures the actual pressure inside the

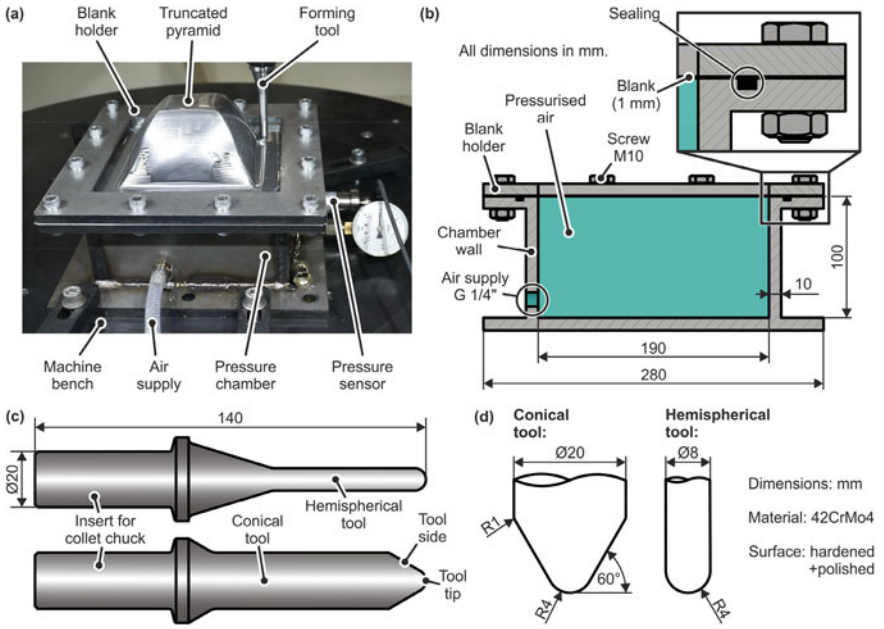

Fig. 1 **a** Experimental setup of IFAM showing the manufacturing process of a truncated pyramid, **b** half-section of the pressure chamber including a blank before forming, **c** full view of the hemispherical and the conical tool, **d** detail view and dimensions of the tooltips. (Color figure online)

chamber in relation to atmospheric pressure throughout the whole forming process. Figure 1b shows the half-section of the pressure chamber with a blank fixed by the blank holder onto the top. The pressure chamber has a depth of 100 mm and provides sufficient space to be used for SPIF if the air is released. In SPIF, the blank is shaped by the tool downwards and this progress is defined as negative or concave forming. An upward movement of the blank instead, like it is shown for the manufacturing of a truncated pyramid in Fig. 1a, is defined as positive or convex forming. The bulging is caused by the pressure acting on the bottom surface of the blank and can be controlled by tool movement to achieve a certain shape.

The full geometries of the hemispherical and the conical tool are shown in Fig. 1c; both tools have an identical length, and the shafts to connect the tools to collect the chuck of the tool holder are the same. The differences between the tools come from the changed geometry of the tooltip, whose detailed view is depicted in Fig. 1d. The tooltip of both tools has a radius of 4 mm to keep the contact conditions as comparable as possible. The radius of the shaft and the tip of the hemispherical tool are the same and the tip merges tangentially with the shaft, which is comparatively thin for this reason. At the conical tool instead, the tip is smoothly connected to a cone with an angle of 60° that is corresponding to the wall angle of the later discussed target geometry. The aim of using this conical shape is to restrict the bulging of the

blank to the target angle and to increase the geometric accuracy. Another striven side effect is an improvement of process reliability because excessive thinning is avoided and tool forces are distributed to a larger surface. To have a sufficient contact area between the cone and the blank, a large radius of the shaft is chosen. A small radius between the cone and the shaft prevents damaging the blank by a sharp edge.

2.2 Tool Path Design

The procedure for generating a tool path with its main steps is illustrated in Fig. 2a–c. A target shape has to be designed at first; the truncated pyramid that is shown in Fig. 2a with a height of 75 mm and a wall angle of 60° is the target shape for the following investigations. The origin of the coordinate system is placed at the centre of the upper surface of the blank. In the second step, the target shape is cut into horizontal layers and the contours are connected from the top to the bottom of a lengthy path, see Fig. 2b. In this step, the path resembles paths of other incremental sheet forming processes. The special feature of the IFAM tool path is created in the last step, as depicted in Fig. 2c, by projecting the three-dimensional tool path in the *XY*-plane. For simple applications, it is sufficient to move the tool to the initial position of the blank surface and afterwards only to change its position in the *XY*-plane. Only for difficult applications, it is necessary to adapt the vertical tool position during the

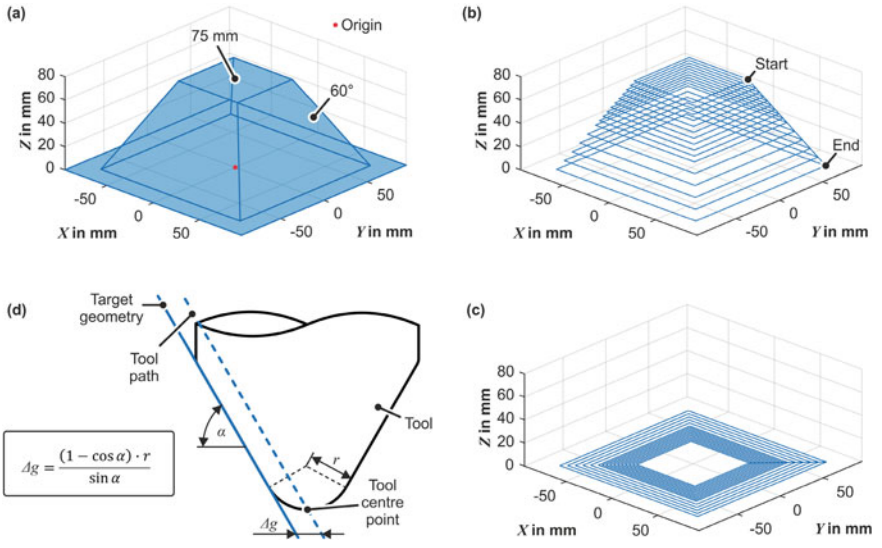

Fig. 2 **a** Creating a target shape as previous step before generating tool paths, **b** cutting target shape into layers and connecting the outer contours, **c** projecting the tool path into the *XY*-plane, **d** tool compensation. (Color figure online)

process but this can only happen inside a small range restricted by elastic bulging of the blank. The final tool path defines only the width of the truncated pyramid and does not define the height or the wall angle. By varying the pressure, it is possible to create truncated pyramids with different heights and with changing wall angles by using the same tool path.

The tool path in Fig. 2c is a reduced representation of the tool path used for the simulation and the experiments but its core message is the same. The first 41 cycles have a horizontal step size of 0.5 mm and the last 24 cycles have a larger horizontal step size of 1 mm. It would not be possible to achieve a part height of 75 mm with a large horizontal step size throughout the whole process because the convex bulging at the beginning of the process is weak. A smaller horizontal step size and a higher number of cycles increase the convex bulging [1]. Therefore, a smaller step size has been selected at the beginning of the process to enhance convex bulging and to keep it approximately constant between the first half and the second half of the forming process. This strategy allows us to use the same tool path and the same pressure level for both tools and to ensure comparability between the results. Furthermore, all the results are based on a feed rate of 1500 mm/min and a rotational speed of 60 1/min.

For generating the tool paths, a tool compensation is taken into account as shown in Fig. 2d because both conical and hemispherical tools are not perfectly sharp. The tool centre point is not located at the intersection of the conical sides but on the round tip and therefore follows the target shape with a horizontal offset Δg. Because the CNC programme is manually written, the horizontal offset Δg is calculated depending on the tool radius and the wall angle, thus resulting in $\Delta g = 2.309$ mm. This tool compensation counts for both tool shapes. Regarding the forming strategy, it can be distinguished in inner compensation for SPIF and outer compensation for IFAM.

2.3 Material Properties and Numerical Model

The experimental setup allows processing of pure aluminium blank in a range from 0.5 to 2.0 mm thickness and of deep drawing steel DC04 blank with a thickness of 1 mm. Aluminium in half-hard state, AA1050A-H24, is chosen as blank material for the following experiments. The blanks have a quadratic shape and an overall width of 280 mm; blank area inside the clamping is 190 mm $\times$ 190 mm. The rolling direction of the blank is always aligned at the X-axis of the milling machine. The surface of the blanks was lubricated during experiments. The material properties are determined by the tensile test with specimen cut in the rolling direction and the flow curve for simulation is extrapolated by Swift, see Fig. 3a. The material thickness is 0.96 mm and is accordingly considered in the numerical model.

The aim of the numerical investigation is to simulate a complete manufacturing process. The model is build up in the simulation software Abaqus 6.14-6, and an explicit solver is chosen. A rigid tool and an elastic-plastic blank are the two components of this model, which is illustrated in Fig. 3b. The blank holder and the part of the blank in direct contact with the blank holder are not included in this model,

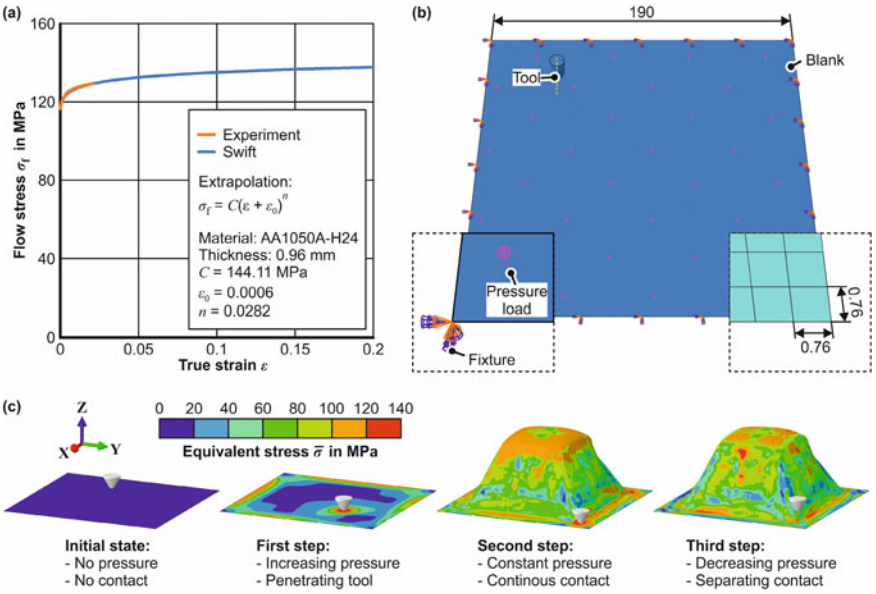

Fig. 3 **a** Extrapolation of the material's flow curve, **b** numerical model of IFAM representing the initial state, **c** equivalent stress $\bar{\sigma}$ at the end of each simulation step showing the manufacturing process of a truncated pyramid. (Color figure online)

and the blank is reduced to the area inside the clamping. Instead, the clamping of the blank is implemented as an idealised boundary condition on the edges. Because the overall shape of the final part is the focus of the investigation without analysing mechanism through the blank thickness, shell elements S4R are applied with five thickness integration points. With a constant element size of 0.76 mm, the homogenous mesh consists of 62,500 elements in total. The plastic material properties of the blank are defined with combined hardening and the number of backstresses is set to five. The contact between blank and tool is frictionless and the rotational speed of the tool is neglected. Not the entire tool but only the tooltip is considered in the model and its geometry is adapted according to Fig. 1d for the different simulation runs. The tool path of Fig. 2c is integrated as the displacement boundary condition of the tool. The last important component of the experimental setup, the pressurised air, is defined as mechanical load on the bottom surface of the blank and the pressure level is the process parameter to be optimized by simulation for later experiments.

The process simulation is divided into three steps (Fig. 3c). First, the pressure is applied and the tool penetrates the blank. The second step covers the forming process. In the last step, the tool removes from the blank and the pressure is released. When the pressure is increasing, the blank immediately reacts with upwards movement and elastic bulging. To simulate this kinematic process properly, mass scaling is deactivated in the first step as well as in the last step for a similar reason. In contrast to this, mass scaling is used moderately during the second step to ensure a time increment

of at least 2×10^{-7} s. However, the biggest amount of reducing computational time is achieved by a time scaling factor of 40 leading to a feed rate of 1000 mm/s in the simulation.

3 Results and Discussion

3.1 Influence on Geometrical Accuracy

Initially, the numerical model with the conical tool was used to determine the pressure level that is necessary to manufacture a truncated pyramid with a height not less than the height of the target shape. A pressure level of 0.425 MPa satisfies this requirement, and with this pressure level, the simulation of the manufacturing process with a hemispherical tool was repeated. The geometry of the deformed meshes of both simulations has been exported and then compared with the CAD files of the target shape. Figure 4a shows the absolute deviation between the simulation and the target geometry on the basis of the deformed mesh. In general, it can be seen that the deviations are heterogeneous within one part and that the trends of deviation are opposite between both simulations. The lateral surfaces of the part simulated with the hemispherical tool are in good agreement with the target shape but its corners do not fit well. The other way round, the part simulated with the conical tool has

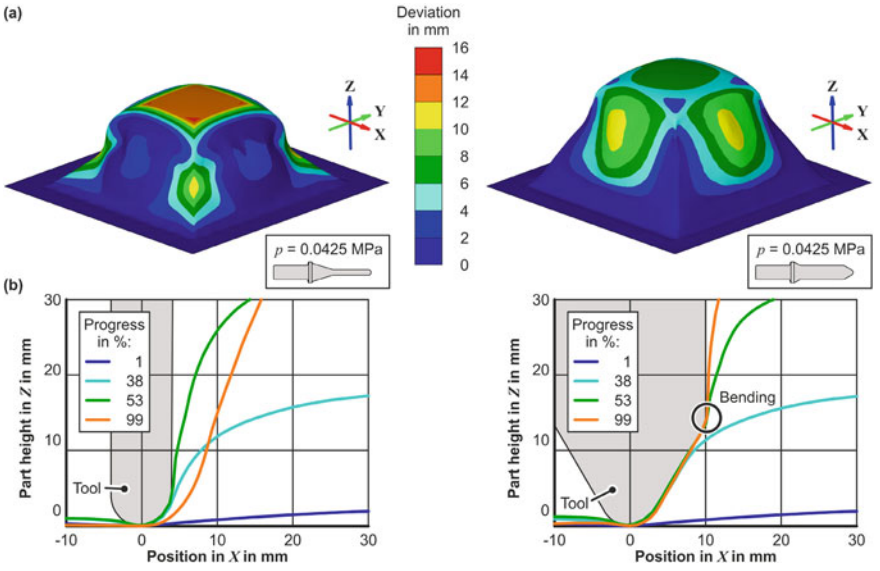

Fig. 4 **a** Absolute deviation between the simulated parts and the target shape, **b** development of the part geometry in contact region between the tool and the blank. (Color figure online)

good accuracy at the corners but not at the lateral surfaces. However, both truncated pyramids have the greatest differences towards each other on their upper face. Using the hemispherical tool, the part is with a height of 62.7 mm lower than the target shape and has a deviation of 12.3 mm. In the case of conical tool, the part grew up to a height of 82.4 mm and was 7.4 mm bigger than the target shape. The maximum deviation is smaller when using the conical tool; it can be concluded from this numerical investigation that not only the geometrical accuracy improves when a conical tool is used but also the convex bulging is facilitated under the condition of constant pressure.

This leads to the question of why the conical tool that was intended to restrict the convex bulging causes a higher part height than the tool that is not restricting the convex bulging. To answer this question, the development of the contact condition during the process has been analysed. Figure 4b shows the part geometry at different time points during the forming process by aligning the cross-sections in the *ZY*-plane in relation to the current tool position. For both simulations, a continuous change of the part wall can be observed but the tool geometries are causing different effects. In the beginning, the wall angle increases unrestricted on interaction with the hemispherical tool but after the horizontal step size changes to 1 mm, the wall angle flattens again, resulting in a smaller part. On the contrary, if it comes into full contact between the conical tool and the part wall, it remains unchanged until the end of the process. Additionally, a second bending of the part wall emerges with progress in the ongoing process and thus the target wall angle and the target height exceed.

3.2 Experimental Validation

After the general feasibility of using the conical tool was proved by simulation, experiments have been conducted with the same pressure level of 0.0425 MPa. The manufacturing of the truncated pyramid by using the conical tool directly succeeded. However, during the experiment with the hemispherical tool, a crack occurred and the experiment had to be stopped because in this case the pressure cannot be kept up and further convex forming is not possible. A new experiment with reduced pressure of 0.0405 MPa could be carried out successfully. The geometry of the manufactured parts was digitalised by a 3D scanner and the cross-sections in the *YZ*-plane, as well as the cross-section through the corners, have been analysed, see Fig. 5a and b. The part with the greatest deviation was the one with the crack manufactured by the hemispherical tool and pressure of 0.0425 MPa. The wall angle increased rapidly, and the crack occurred in the contact region between the lateral surface and the tooltip in the 38th cycle. The final height was 33.1 mm. Even when the pressure was reduced and the part could be produced completely with the hemispherical tool, the deviation remained high for both the lateral surfaces and in the corner because the convex bulging flattens out in the second part of the forming process with a horizontal step size of 1 mm. Only by using the conical tool, it was possible to create a part in the desired dimension. Especially, the accuracy in the corners

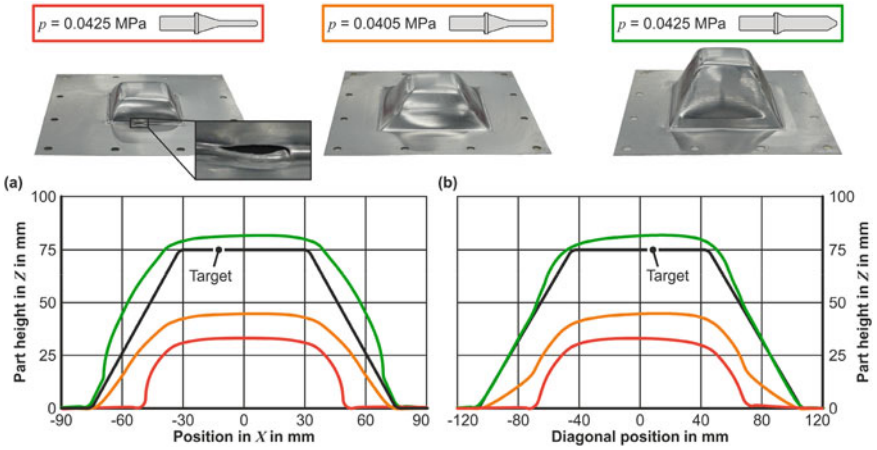

Fig. 5 **a** Cross-sections in the *XZ*-plane, **b** cross-sections of diagonal cut. (Color figure online)

was remarkable. In conclusion, the experiments not only validated the findings of the numerical investigation but also reveal that the conical tool shape increases the process reliability.

Because the manufacturing process with the hemispherical tool failed, it was only possible to compare the results between simulation and experiment concerning the conical tool. Figure 6a shows that the simulation delivered realistic results. Based on these results, the horizontal cross-sections of the truncated pyramid have been analysed at different height levels, as depicted in Fig. 6b. In the lower regions where the part is in contact with the tool, the part has a good accuracy both at the lateral surfaces and at the corners. The corners still have good accuracy in the middle region, but results in an outer bulging at the lateral surfaces. At the top region, the part deviates outwards from the target shape in all regions. The radial force of the pressure might be the reason for the deformation of the angular geometry into a round shape.

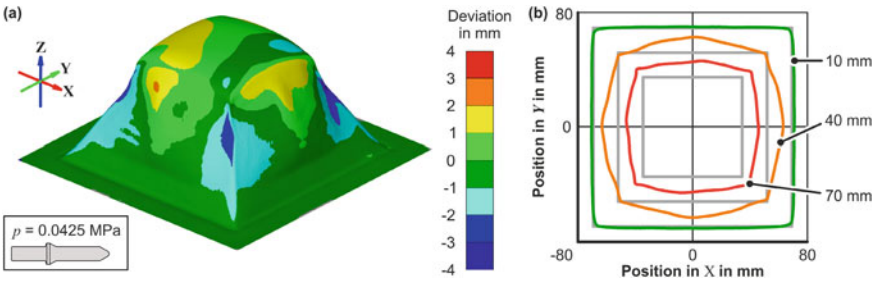

Fig. 6 **a** Comparison of the simulated part and the real experiment, **b** horizontal cross-sections at different height levels of the simulated part. (Color figure online)

3.3 Analysis of Rotationally Symmetric and Concave–Convex Geometries

To see the effect of the tool geometry in interaction with a circular tool path, truncated cones and concave–convex parts have been manufactured. Using the same strategy for these tool paths, the horizontal tool step size was 0.5 mm for the first half and 1 mm for the second half of the forming process. By analogy with the truncated pyramids, three experiments have been conducted for each geometry. The corresponding cross-sections are compared with each other in Fig. 7a and b.

At a pressure level of 0.0525 MPa, a truncated cone could be manufactured by the conical but not by the hemispherical tool. This time, the crack occurred at the transition region from one cycle to the next one shortly before the process ends. The truncated cone could be manufactured with the hemispherical tool at a pressure level of 0.0515 MPa resulting in a similar part as has been created by using the conical tool. For the latter one, the effect of the horizontal step size on the wall angle is less obvious than for the hemispherical tool. In this case, the differences between the hemispherical tool and the conical tool are not as strong as for the truncated pyramid.

The complex parts combine a concave truncated pyramid with a convex truncated cone. The truncated pyramid, which is located in the inner region, was manufactured at first by SPIF with neither pressure nor a back-plate and the vertical step size

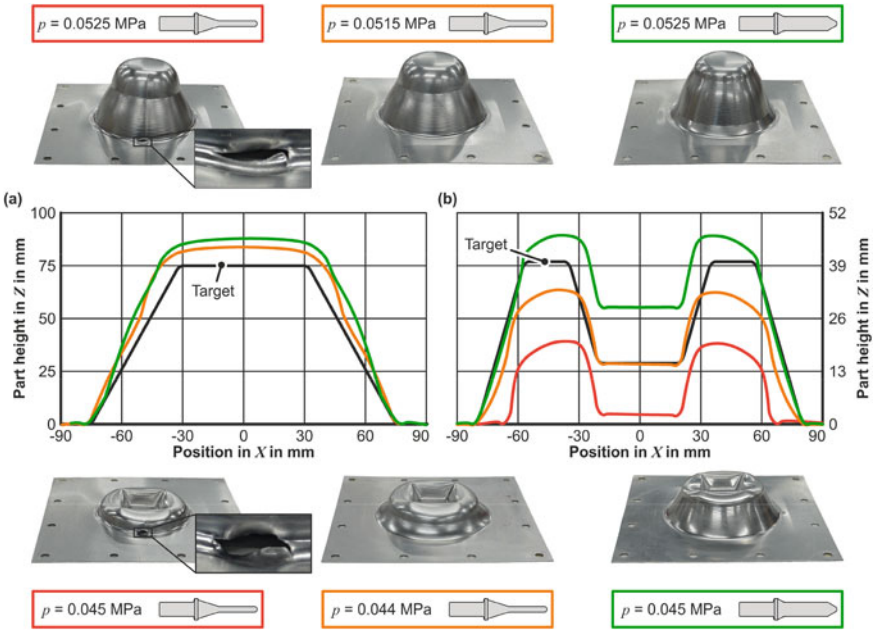

Fig. 7 **a** Cross-sections of the truncated cones, **b** cross-sections of the concave–convex parts. (Color figure online)

was 1 mm. Secondly, the pressure was applied and the outer truncated cone was manufactured. With a pressure of 0.045 MPa, the truncated cone was created with good accuracy by the conical tool. However, through unintended convex bulging of the blank in the area between the inner and the outer feature, the truncated pyramid vertically deviates from its target position. The accuracy in the outer regions of the part created by the hemispherical tool and a pressure of 0.044 MPa lags behind the accuracy of the part produced by the conical tool. When the same pressure of 0.045 MPa was used in combination with the hemispherical tool, a great wall angle emerged and the part failed during the transition from one to the next cycle like the previous truncated cone. The example of these concave–convex parts shows that the positive effects of the conical tool at least account for rotationally symmetric geometries in complex shapes.

4 Conclusions

The geometry of parts manufactured by incremental sheet forming with active medium (IFAM) is a result of interacting pressure, tool path, as well as tool geometry. All of these factors have a significant influence on the geometric accuracy. To achieve a target shape more easily, this paper pursues the approach to change the tool geometry into a conical shape, which restricts the convex bulging. The feasibility of this approach was proven by numerical investigation on the example of a truncated pyramid. The simulated processes have been repeated in experiments and the manufacturing of truncated cones and concave–convex parts completed the analysis. The following conclusions can be drawn:

1. The improvement of geometrical accuracy is dependent on the target shape. The difference is small for truncated cones, which have a rotational symmetric geometry. However, conical tools have a positive influence on the geometric accuracy for truncated pyramids and concave–convex parts.
2. Conical tools increase process reliability for any target shape. The pressure levels that can be applied in combination with the conical tools cause cracks when a hemispherical tool is used. In comparison, the manufacturing with hemispherical tools needs a reduced pressure level by at least 0.001 MPa.
3. A side effect, which is observable in simulation, is facilitated by convex bulging through conical tools. This effect is not verifiable in experiments because cracks might occur when using a hemispherical tool.
4. A second bending of the lateral part wall can emerge and cause additional bulging and exceeding of target height. However, corners of truncated pyramids have better geometrical accuracy than lateral surfaces.
5. Changing the contact conditions by adapting the tool geometry is not a stand-alone solution for overall accuracy. Investigations on pressure control and tool path design are necessary for further improvement.

Acknowledgments The authors would like to express their gratitude to the German Research Foundation (DFG) for funding the research project (grant number BE 5196/14-1) that led to the present results.

Manufacturing of Tailored Blanks with Pre-shaped Involute Gearings by Using a Flexible Rolling Process and Its Application in a Sheet–Bulk Metal Forming Process

Manfred Vogel, Robert Schulte, Onur Kaya, and Marion Merklein

Abstract Nowadays, the efficient manufacturing of functional components in short process chains is important due to the goal of a further reduction of greenhouse gases. Additionally, there are also technical demands like functional integration combined with an improvement of the component's properties. Previous investigations have shown that the application of tailored blanks with a defined thickness profile can lead to an improvement of the geometrical and mechanical properties of functional components. However, common forming processes reach their limits. A promising approach to enlarge these process limits is the application of bulk forming operations to sheet metals, the so-called sheet–bulk metal forming (SBMF). Within this process class, one possibility for manufacturing such blanks is a flexible rolling process. As a result of movement of two rolling tools in combination with a die cavity in the lower tool, a defined geometry can be manufactured perpendicular to the sheet plane. In order to raise the complexity combined with a shorter process chain and thus to fulfil the requirements defined by the subsequent forming operations, a new design that contains a preform of involute gearings is introduced. In order to acquire process knowledge, the mild deep drawing steel DC04 with an initial sheet thickness of $t_0 = 2.0$ mm is used. Furthermore, the subsequent application of the tailored blanks in a combined deep drawing and upsetting process is shown, with a characterization of the geometrical and mechanical properties.

1 Introduction

The responsibility and awareness regarding the threat of climate change led to the approval of the Paris Agreement by the international community in 2015. In order to not exceed the global average temperature rise above 1.5–2 °C, a reduction of greenhouse gas emissions is mandatory [1]. Studies have shown that the most produced global greenhouse gas (GHG) emissions take place in agriculture, energy supply, industry, and transport [2]. According to a report of Greenpeace in 2018, 9% of the total annual GHG emissions is caused by the car industry [3]. Due to a high traffic volume of more than one billion vehicles, which are currently driven mainly by internal combustion engines, this sector offers great potential for saving CO_2 [4]. Therefore, on the one hand, the automotive industry develops new alternative powertrains like battery or fuel electric driving systems [5]. On the other hand, lightweight construction is a key technology for the reduction of the vehicle's weight. Based on the requirements for functional components, e.g. synchronizer rings, the conventional bulk and sheet metal forming processes reach their limits. To satisfy the increasing demand for complex functional components and resource-efficient manufacturing, the innovative process class of sheet–bulk metal forming (SBMF) was developed. Due to a process combination, the advantages of both sheet and bulk forming operations can be used [6]. Depending on the forming process, process-adapted semi-finished parts with customized geometrical and mechanical characteristics, the so-called tailored blanks can be manufactured to increase the local material volume and thus the die filling of functional elements [7]. Previous investigations in [7] have shown that a flexible rolling process can be used for manufacturing tailored blanks with a homogeneous thickness profile. To realize a high variety of geometries, different die cavities can be mounted on the rotary table. By applying such semi-finished products in a subsequent process combination of deep drawing and upsetting, the die filling of different functional elements (e.g. gearings) can be increased. However, this process improvement reaches the limit as soon as the material is ironed due to a too large material volume and thus a too high sheet thickness. In order to extend the process limits combined with a shorter process chain, the manufacturing of tailored blanks with pre-shaped functional elements perpendicular to the sheet plane is mandatory. Thus, new challenges regarding a defined control of the material flow and strain hardening arise. Subsequently, a combined deep drawing and upsetting process is shown for applying such tailored blanks. For the investigations presented in this paper a mild deep drawing steel DC04 with an initial sheet thickness of $t_0 = 2$ mm is used.

2 Experimental Setup

This chapter gives an overview of the machine setup for the flexible rolling process as well as the target geometry. Subsequently, the manufactured tailored blanks are applied in a combination of a deep drawing and upsetting process. This experimental

setup and the geometry of the functional components are also presented in this chapter.

2.1 Flexible Rolling of Tailored Blanks and Target Geometry

The main parts of the flexible rolling machine are the two rolling tools, which are assembled on the upper construction in the x-direction as well as the rotary table in the lower construction in the z-direction. A partial view of the working area and the geometrical dimensions of the rolling tools is shown in Fig. 1. The rolls have a diameter of $d_{tool} = 80$ mm and are positioned with an offset of 180°, whereby the right roll is used as the forming roll and the left roll as the smoothing roll. Geometrically, double-tap rolls with defined forming-(α) and smoothing-angle (β) are used. The rolling tool has always a width of b = 20 mm divided into b_1 = 15 mm and b_2 = 5 mm. They are not actively driven for rotation. Only the friction between the rolling tools and the workpiece led to a rotational movement. In order to be able to induce a defined material flow, the rolling tools are driven translationally in the x-direction. During the whole forming process the blank is clamped by the blank holder with a maximum pressure of p = 100 bar. Additionally, in order to guarantee the centring of the sheet metal, it is clamped by a screw on the rotary table. A more detailed description of the flexible rolling machine regarding the construction and the kinematic process limits can be found in [6]. The rotational and vertical movement of the rotary table in addition to the horizontal movement of the rolling tools causes a radial, axial, and tangential material flow. Depending on the applied process strategy, defined tailored blank geometries with different thickness profiles can be achieved.

Due to the increasing complexity of functional components and a required reduction of the process chain length, the aim of these investigations is the manufacturing of tailored blanks with a preform of involute gearings with a subsequent deep drawing

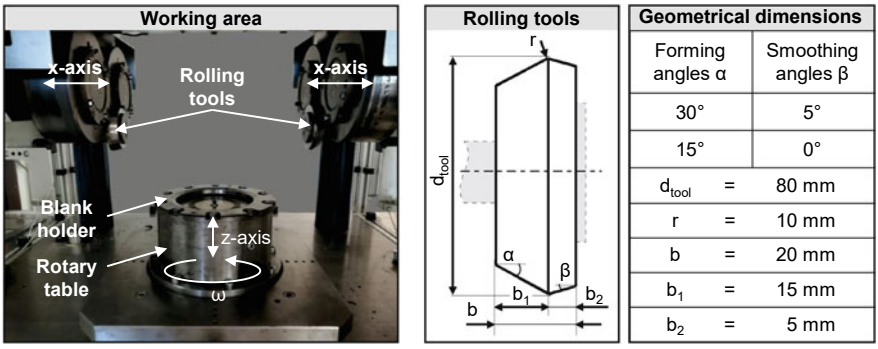

Fig. 1 Working area of the flexible rolling machine and geometrical dimensions of the tools. (Color figure online)

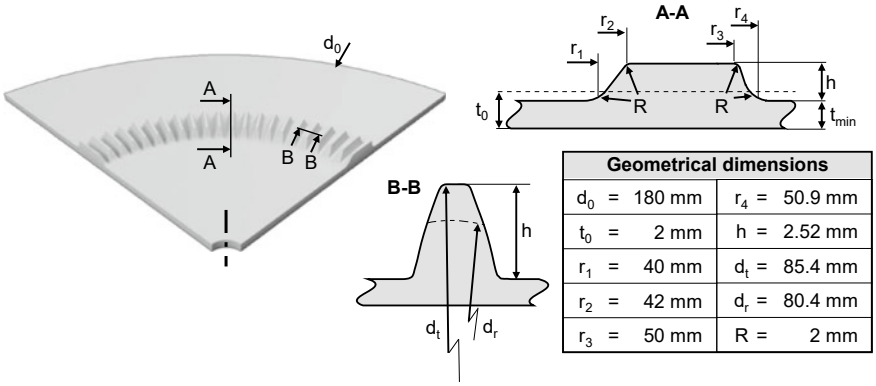

Fig. 2 Target tailored blank geometry—geometry of the die cavity

and upsetting process. In Fig. 2, the target geometry of the tailored blank is schematically shown, which also defines the die cavity as the negative form in the rotary table. Due to planned investigations regarding the application behaviour of functional components manufactured by sheet–bulk metal forming processes, the mild deep drawing steel DC04 with an initial sheet thickness of $t_0 = 2$ mm and a diameter $d_0 = 180$ mm is used. The functional elements are arranged rotational perpendicular to the sheet plane at a radial position between $r_1 = 40$ mm and $r_4 = 50.9$ mm and consist of 84 gear teeth. In order to enable a high die filling through a homogenous material flow, there is an inlet area starting at a radial position of $r_1 = 40$ mm with a horizontal width of 2 mm. In addition, the continuous transition prevents stress concentration during the manufacturing of the final geometry. In the outlet area also a transition zone has to be inserted to reduce the notch effect and thus tool loads in the die cavity. However, to inhibit the material flow out of the die cavity, the transition zone has only a width of 0.9 mm starting at $r_3 = 50$ mm. The edges themselves are rounded with a radius of $R = 2$ mm. The gearing itself is designed with a module $m = 1$, whereby a tip diameter of $d_t = 85.4$ mm and a root diameter of $d_r = 80.4$ mm are realized. Due to this geometric definition of the involute gearing, the tailored blank has a gearing height of $h = 2.52$ mm. A schematic representation of one gearing element is also shown in Fig. 2. For an application of these semi-finished products in the subsequent forming process, there is a laser cutting process at a radial position of $r_3 = 50$ mm.

2.2 Manufacturing Process and Target Geometry

To manufacture the final component, a combined deep drawing and upsetting process is applied. During the deep drawing operation the basic shape of the part is formed, whereas the functional elements of the tailored blank are formed in the subsequent

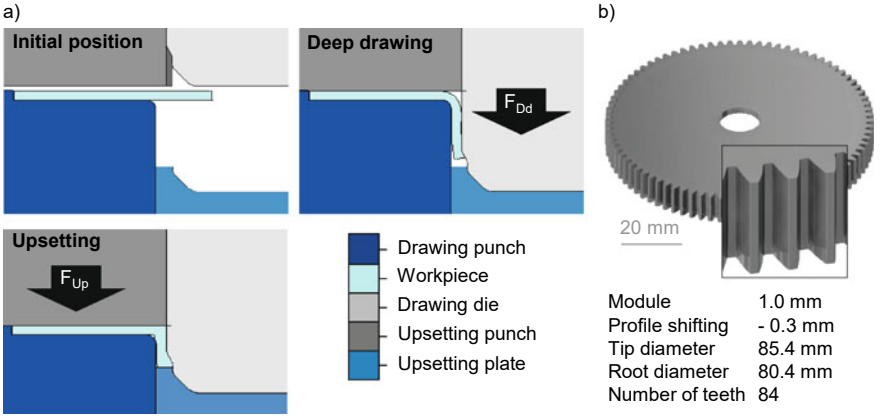

Fig. 3 **a** Process setup of the combined sheet–bulk metal forming process and **b** geometric properties of the functional component with involute gearings. (Color figure online)

upsetting stroke due to a reduction of the cup height. The process proceeds force-controlled, whereby the upsetting force exceeds the drawing force considerably. The process combination is applied in a single press stroke and therefore requires a triple-acting press. Therefore, a hydraulic press of the type TZP400-3 by Lasco with a conventional press ram and two die cushions is used. The maximum press force amounts to 4,000 kN. The tool setup developed for this sheet–bulk metal forming process consists of four active components, two in the upper and two in the lower tool. The active components in the upper tool are the drawing die and upsetting punch, whereas the drawing punch and upsetting plate are part of the lower tool. Schematic tool setup and kinematics are presented in Fig. 3a. In the initial position the semi-finished product is placed on the drawing punch and then clamped by the upper tool. Afterwards, the drawing die moves downwards to draw the cup and proceeds until it is in contact with the upsetting plate. The drawing punch radius is $r_{Dp} = 1$ mm and the external diameter amounts to $d_{Dp} = 80$ mm. As already shown in [8], the positioning of the semi-finished product in relation to the thickening direction of the tailored blank plays a decisive role for a possible component failure. Subsequently, the cup and drawing punch are displaced by the upsetting punch under the upsetting force F_{Up}. The maximum upsetting force in this investigation was set to $F_{Up} =$ 1,000 kN. For conventional blanks with an initial sheet thickness of $t_0 = 2$ mm, the upsetting force induces a radial material flow towards the gear cavity, whereas for rolled tailored blanks the upsetting force is applied to increase the die filling of the gear teeth manufactured within the flexible rolling process. The target geometry has an external involute gearing with a module of $m = 1$, corresponding to the cavity used for the manufacturing of the tailored blanks. For the final component, the tip diameter is $d_t = 85.4$ mm and the root diameter is $d_r = 80.4$ mm. The total amount of teeth is 84, as presented in Fig. 3b. As the material volume in the geared section is

different for conventional semi-finished products and tailored blanks, the resulting cup height varies under the equal upsetting force.

3 Manufacturing of Tailored Blanks

In order to analyse the benefits of manufacturing and application of tailored blanks with discrete functional elements and for increasing the process knowledge of the flexible rolling process, experimental tests were carried out. Subsequently, the semi-finished products were characterized regarding their resulting contour, sheet thicknesses, and material volumes, as well as the mechanical properties by analysing the hardness distribution.

3.1 Process Strategy and Resulting Geometry

In previous investigations in [8], a process strategy was introduced which could be used to manufacture rotational symmetric tailored blanks with a circular material thickening. The challenge was to concentrate the material flow purposefully in the thickening profile in order to achieve a homogeneous thickening. In contrast to previous investigations, the challenge regarding the manufacturing of functional elements perpendicular to the sheet plane is the die filling of local interrupted material thickening geometries. Thus, a defined control of the direction-dependent material flow is mandatory. Therefore, a new process strategy has to be developed under consideration of individual process parameters. Through process analysis for the manufacturing of tailored blanks with a rotationally symmetric thickness profile in [7], the process parameter of the vertical roll displacement (VRD) could be identified as an essential process variable for achieving a high material volume in the thickening zone. Within this paper the transferability by variation of this process parameter is analysed by taking the process limits into account. However, the geometry of the die cavities influences the direction-dependent material flow back to the centre of the blank. For this reason, in combination with investigations for manufacturing cyclic-symmetric tailored blanks in which a vertical roll displacement of VRD = 0.8 mm could be identified as appropriate [9], eight steps in the linear distribution in an interval between VRD = 0.1 mm and VRD = 0.8 mm are analysed in this paper. Additionally, an overview of all the relevant process parameters of the flexible rolling process is shown in Table 1.

In this case, the target values are both the largest possible die filling as well as a small bulging of the tailored blank, consequently resulting in the flexible rolling process. For the development of a new process strategy, the experimental tests have been geometrically measured. For a deeper analysis, the semi-finished products are digitized by a strip light projection process using the optical 3D scanner ATOS (GOM GmbH). The final results after the first stroke by using different process parameters

Table 1 Process parameters

Process parameters		Factor level
Rotary table RPM [rot/s]		0.5
Feed rate [mm/s]		0.15
Vertical roll displacement [mm]	Stroke 1	0.1/0.2/0.3/0.4/0.5/0.6/0.7/0.8
	Stroke 2	0.8/0.9/1.0

are shown in Fig. 4. In order to achieve the highest die filling, the rolling path of the forming roll starts at a radius of r = 14 mm and moves up to a radial position of r = 55 mm. The radial positions of the rolling paths are relatively referred to the transition zone between the forming and the smoothing angle of the rolling tool. The innermost position is a system-related process limit.

A radial in-feed causes a material accumulation in front of the forming roll, whereby the sheet bulges due to the tool contact in the forming roll, similar to flow forming processes [10]. In order to get this material accumulation specifically into the thickening area, there is also a rolling tool at a radial position of r = 50 mm with an offset of 180°, which points to the forming angle in the direction of the blank centre. The results of the tailored blank contours are shown in Fig. 4a as a function of different vertical roll displacements. Due to a higher reduction of the sheet thickness,

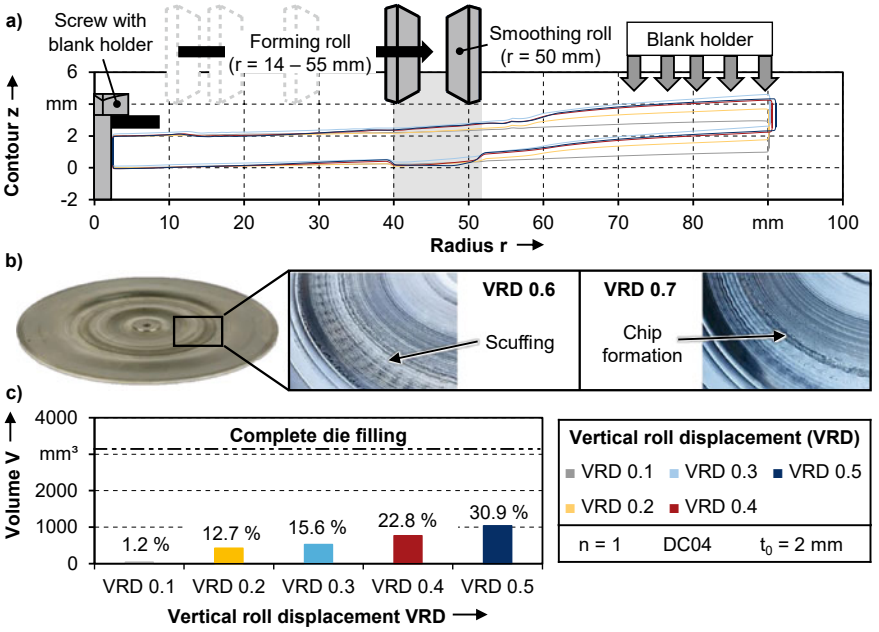

Fig. 4 Results after the first stroke: **a** contour, **b** process limits, and **c** volume in the die cavity. (Color figure online)

the material volume in the die cavities and also the bulging of the semi-finished product increase. By varying the pass reduction from VRD = 0.1 mm to VRD = 0.3 mm the bulge also rises from 1.2 to 2.3 mm in the outer diameter. However, the bulging height no longer increases with a higher vertical roll displacement. Therefore, for VRD = 0.5 mm there is also a bulging of 2.3 mm detectable. This correlation is due to the forming process and the gradient of the stress conditions in the sheet thickness direction. By increasing the vertical roll displacement, the contact pressure between the tool and the workpiece increases, which results in a more homogenous material flow and thus reduces the difference in the stress conditions between the rolling and the die side. These stresses are discharged after releasing the blank holder, which leads to the characteristic bulging of the tailored blank.

A further increase of the vertical roll displacement up to VRD = 0.7 mm leads to process failures on the surface of the tailored blank, as shown in Fig. 4b. During the flexible rolling process, the material in the primary forming zone is subjected to a three-dimensional stress and strain state due to tool contact. Consequently, the radial material flow leads to an accumulation in the secondary forming zone in front of the rolling tool, resulting in predominant compressive stress conditions. This material volume is used for the die filling of the target geometry. With a value of VRD = 0.6 mm, the accumulated material is too large in relation to the cyclic symmetric interruptions between the functional elements, so the material flow is not completely directed into the die cavities. The remaining material volume is radially displaced in front of the forming roll, which results in a material overlap. Due to further processing of the rolling path, suffering of the surface occurs. Especially for an application of the tailored blanks in subsequent processes, these defects represent damage potential through notch effects. Due to an increase of VRD = 0.7 mm, the material overlap in combination with another tool contact leads to chip formation. Depending on the flexible rolling machine, there is no significant change between VRD = 0.5 mm and VRD = 0.6 mm detectable. Thus, the vertical roll displacement of VRD = 0.5 mm represents a process limit for the first rolling stroke.

For geometric reasons, however, an increase of the vertical roll displacement also leads to a higher material volume to be achieved in the die cavities. Based on the target geometry, the complete material volume of the gearing elements is 3360 mm^3. While a vertical roll displacement of VRD = 0.1 mm leads to a material volume of only 40.3 mm^3, which is 1.2% of the target volume, VRD = 0.5 mm leads to an increase of up to 30.9%. This correlation is shown in Fig. 3c. Due to the maximum die filling at this setting and the process limit at VRD = 0.5 mm, this setting is used as the basis for a subsequent rolling stroke.

However, to shorten the process chain, a further increase of the material volume in the individual functional elements is mandatory. With the objective of a higher die filling, a second stroke is applied with an increased vertical roll displacement. In order to be able to analyse the material flow, experimental tests with adapted vertical roll displacements were carried out. Due to previous investigations in [9], the correlation between the strain hardening by the first rolling stroke and increased roll displacements in a second stroke could be clarified. For this analysis, values between VRD = 0.8 mm and VRD = 1.0 mm are considered with an interval of $\Delta =$

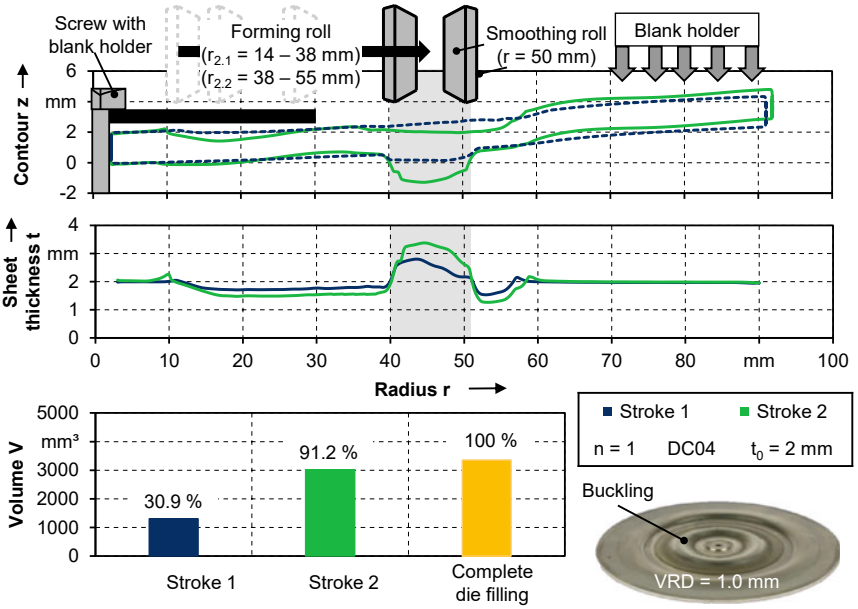

Fig. 5 Final geometric results after two rolling strokes regarding **a** contour and sheet thickness and **b** volume. (Color figure online)

0.1 mm. However, despite the previous forming stroke, buckling occurs with a rising vertical roll displacement, as seen in Fig. 5. Due to the material accumulation in front of the forming roll combined with the levelling of the smoothing roll, which is offset by 180°, material reflux occurs at the centre of the blank in addition to an increase of the outer diameter. Thus, the tailored blank buckles in the inner rolling zone between the inner blank holder and the rolling tool due to the free buckling length and the stiffness of the material. This correlates with an increase of the vertical roll displacement. As a result, in the second stroke, an enlarged blank holder is used in the tailored blank centre and the rolling path of the forming roll is divided in order to achieve an optimum ratio between a high material volume and the geometric dimensional accuracy. The forming roll moves from r = 14 mm to r = 38 mm with a vertical roll displacement of VRD = 0.8 mm. Subsequently, the inner blank holder with a heightened diameter is mounted when the outer blank holder is still clamped. Then the rolling stroke is continued with the same set of parameters until the forming roll has reached a radial position of r = 55 mm. The final geometry with regard to the semi-finished product contour and the achieved sheet thickness and material volume is shown in Fig. 5. It can be observed that the second stroke not only leads to a further thinning of the material in the inner rolling zone but also levelling of the material in the thickening area. While in the first rolling stroke a maximum sheet thickness of t = 2.8 mm is achieved, a maximum of t = 3.4 mm is possible after the second stroke. However, the volume in the die cavity increases up to 91.2%. This

new process control can thus be used for the manufacturing of functional elements with interrupted die cavities, whereby a limit of the forming behaviour of the used material must be taken into account. Furthermore, due to the orientation of the rolling strokes from inside to outside, this process strategy can be used for the manufacturing of tailored blanks with a smaller diameter and thus without a cutting operation.

3.2 *Mechanical Properties*

In order to increase the process knowledge and for evaluation of the mechanical properties for the subsequent *forming* process, the hardness distribution is a relevant parameter for the quality of the tailored blanks. Due to the high perpendicular process forces, which occur during the flexible rolling process, there is strain hardening of the material. For qualifying the final tailored blank geometry, the Vickers' hardness at the cross-sections of the functional elements and the intermediate area was measured for both strokes with a test force of F = 0.05 kp, a measuring point distance of 0.3 mm across the sheet thickness, and 0.6 mm in the radial direction. The results of the evaluation regarding hardness plots and sections of the microstructure are shown in Fig. 6.

The qualitative contour plots of the first stroke show a tendency of increase in the hardness values on the radial position of the die cavities. This can be confirmed by the grain orientation of the microstructure. During the forming stroke material

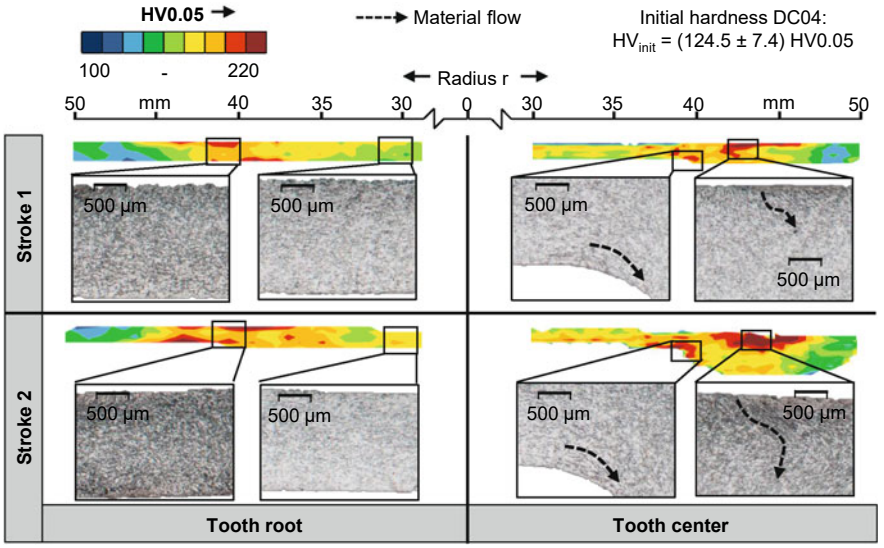

Fig. 6 Mechanical properties of the tailored blank in the tooth root and canter after each stroke. (Color figure online)

is accumulated in front of the rolling tool. Due to the levelling by the smoothing roll, there is a kind of upsetting process in the thickening area which leads, on the one hand, to the filling of the cavities and, on the other hand, to a strain hardening in this area. While in the tooth root the highest hardness values are (228.9 ± 19.8) HV0.05, the hardness values in the tooth centre are 21% higher. This is caused by the direction-dependent material flow. The tool contact of the rolling tool in addition to the rotary movement of the rotary table leads to a tangential material flow. Thus, the material accumulation in the intermediate area of the tooth root is displaced into the die cavities. Superimposed on the translational movement of the rolling tools and the resulting radial material flow, the material is higher strain hardened in the thickening area of the tooth centre, thereby hardness values of up to (279.9 ± 25.1) HV0.05 are reached. The same effect can be seen after the second stroke. Due to the higher vertical roll displacement and thus increased process forces, the quantity of material flow rises which leads to a stronger strain hardening. Due to the direction-dependent material flow, these areas must be considered for other materials for an application in the subsequent forming process to prevent failures.

4 Manufacturing of Functional Components

The manufactured tailored blanks are used in the process combination presented in Sect. 2.2. For an analysis of the volume of the functional components, the parts are also digitized by the strip light projection method for each forming step.

The resulting geometries after the deep drawing and upsetting process are shown in Fig. 7a. In the first step, the blank with the involute gearings is deeply drawn to form a cup. After the drawing process, the cup has a resulting height of $h_{d\text{-}tb}$ = 12.34 mm and the material volume in the teeth of the involute gearings amounts to V_G = 1,107.50 mm^3. Subsequently, the cup is formed with the adjusted upsetting force of F_{Up} = 1,000 kN. Thus, the component's height is reduced by about 40% to $h_{u\text{-}tb}$ = 7.43 mm, but the material volume in the functional elements grows up to V_G = 2,299.69 mm^3, as shown in Fig. 7b. In order to quantify the advantages of the application of semi-finished products with discrete functional elements, the same parts were manufactured using sheet metals with a thickness of t_0 = 2 mm. A comparative analysis of the cup height between the conventional and the tailored blank shows $h_{d\text{-}c}$ = 12.85 mm and Δ = 0.51 mm, a higher shape of the component with t_0 = 2 mm after the deep drawing process. This difference can be explained by the increased ironing caused by the drawing die in the area of the tooth root of the functional component. Due to the lack of an adapted thickness profile using the discrete functional elements, the volume in the gearing for the conventional sheet is 84% lower than for the tailored blank. After the upsetting process, the cup height of the part using a flat sheet amounts to $h_{u\text{-}c}$ = 7.89 mm and a material volume of V_G = 1,772.46 mm^3 in the involute gearing. Compared to the application of the tailored blank, a 23% lower die filling of the functional elements is reached. In addition to the geometric shapes of the functional elements, the strain hardening represents a

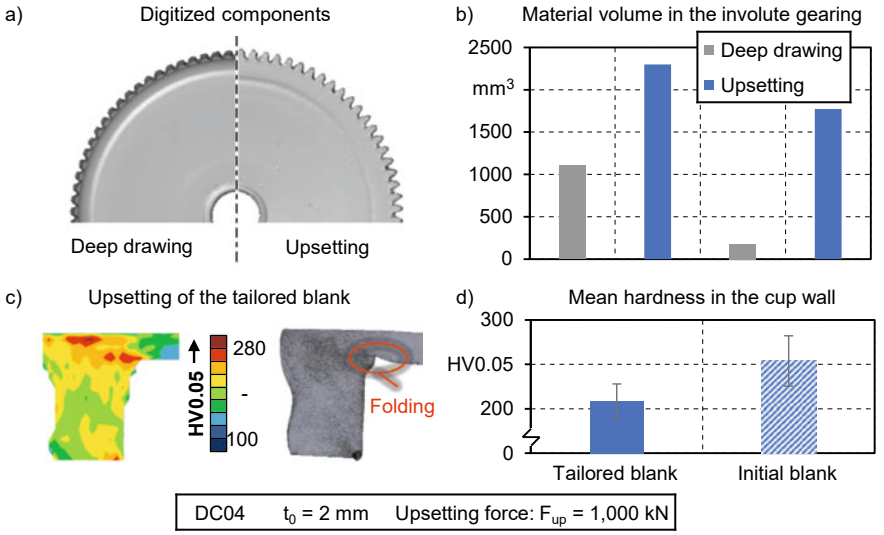

Fig. 7 Analysis of the functional components regarding **a** digitized components, **b** material volume in the involute gearing, **c** strain hardening and microstructure and **d** mean hardness in the cup wall. (Color figure online)

decisive result, especially with regard to the usability and tolerable load capacity of the functional components. For this reason, an analysis of the strain hardening and microstructure of one tooth was carried out after the upsetting process. In Fig. 7c higher hardness values of up to 263.4 HV0.05 are detectable in the area of the drawing radius compared to the tooth tip. This can be explained by the material flow into the cup bottom, which occurs during the upsetting process and results in a folding of the material. This can also be seen in the analysis of the microstructure. Previous investigations in [9] have shown that despite the application of tailored blanks, the folding cannot be prevented. However, the qualitative evaluation of the hardness distribution shows a homogenization of the strain hardening compared to the semi-finished product with the discrete functional elements. During the upsetting process of the cup wall, a radial material flow primarily takes place in the direction of the functional elements. Hence, there is a higher forming level in the inlet area of the involute gearing, which results in an increase in the strain hardening circumferential. This effect can also be seen in Fig. 7d, in which the mean hardness in the cup wall is compared for using a tailored blank and a flat sheet in the upsetting process. Due to the lower deformation by using tailored blanks with discrete functional elements, an average hardness distribution of (208.7 ± 19.3) HV0.05 is reached. This is about 18% less compared to the application of conventional semi-finished products. The significantly lower geometrical moment of inertia per unit by applying a sheet metal with $t_0 = 2$ mm in the upsetting process leads to an average hardness value of (253.8 ± 28.2) HV0.05.

Furthermore, within the framework of the investigations, it has to be taken into account that for the manufacturing of functional components with such a large material volume, tailored blanks with a circumferential material thickening as presented in [7] cannot be used for production in the combined deep drawing and upsetting process. Due to the negative shape of the gear geometry in the drawing die and the resulting process control, the material is ironed in the drawing gap, whereby a process limit is reached.

5 Summary and Outlook

For manufacturing functional components with higher complexity in short process chains, tailored blanks with discrete functional elements are introduced in this paper to improve the intended material flow. For achieving the target die filling of the functional elements in a flexible rolling process, a new process strategy with two rolling strokes is evolved. The orientation of the single strokes is one-directional from inside to outside. Thus, a material volume of up to 91% can be reached in the die cavities of the involute gearing. Hereby, the rolling process and the die cavities influence the strain hardening of the final tailored blanks geometry. Due to the tool contact and the interrupted thickening areas, the highest strain hardening occurs on the rolling side in the thickening area. These manufactured tailored blanks were applied in a combined deep drawing and upsetting process. It could be shown that the die filling of the involute gearing after the forming process can be increased significantly up to 84% compared to the application of conventional semi-finished products, due to the application of tailored blanks with a preform. However, the functional elements are not yet completely filled with material. Furthermore, it could be seen that the combined deep drawing and upsetting process leads to folding in the drawing radius. In this context, further research and an adaptation to the tailored blank layout are necessary. Additionally, it has to be investigated whether a complete die filling of the functional elements in the manufacturing of the tailored blanks is possible by using semi-finished products with a higher initial sheet thickness in order to shorten the process duration by using a calibration process only. To ensure widespread use and an increase in applicability towards the resistance of higher component loads, the transferability of the process regarding the application of higher strength steel materials or other classes of materials for both the flexible rolling and the deep drawing and upsetting process has to be analysed.

Roll Forming of Cup with Curved Rotary Profile

Baohong Zhang, Bin Hu, Chunyu Wei, and Xi Zhao

Abstract In order to improve the production efficiency and material utilization rate of metal cup with a curved rotary profile, a new method of roll forming (RF) is proposed. That is, a roll forming equipment with a set of pre-forming rollers and a set of shaping rollers is mounted on the drawing hydraulic press to form a curved rotary profile of cup. The influence of roller number on the roll forming was studied by numerical simulation. The results show that the open end of the rolled part is extremely uneven when two rollers are used. In addition, metal flows into the gaps between rollers, forming thin flashes which must be cut off after the pre-forming step. The open end of the rolled part is relatively even when three rollers or four rollers are used. No metal flows into the gaps between pre-forming rollers, and no folding is found after shaping. The accuracy of numerical simulation is verified by experiments, and aluminum cups with a curved rotary profile that meet the requirements were successfully formed.

Keywords Cup with rotary curve shape · Roll forming · Numerical simulation · Pre-forming · Shaping

1 Introduction

In modern manufacturing, metal cup parts with a curved rotary profile not only have extensive applications but also need large-scale production of parts, such as drill pipe joints and projectile bodies, whose final shape or the shape in a certain step during the forming process needs to be a curved rotary profile. In order to meet the requirements of high mechanical properties and mass production, cup with a curved rotary profile is usually traditionally manufactured using the production process of plastic forming

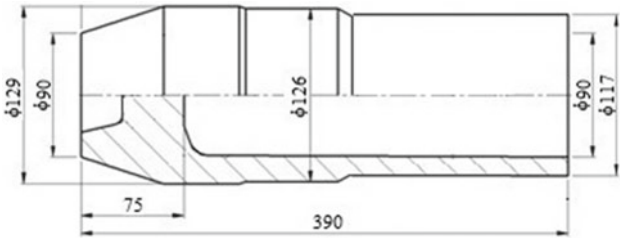

Fig. 1 Cup with curved rotary profile

and then machining [1–6]. However, the material utilization rate is relatively low using this traditional production process for cup with a curved rotary profile, and the longer the smaller-diameter section(s) of the part, the lower the material utilization rate. In order to improve the material utilization rate, Xu Hengqiu et al. used the hot-spinning method to form the curved rotary profile of cup and formed ideal samples [7, 8]. However, the production efficiency of hot-spinning is low, which cannot meet the requirements of mass production, and the mandrel is difficult to put out from the workpiece after hot-spinning. Therefore, the production of cup with a curved rotary profile does not use the hot-spinning process.

In order to increase the material utilization rate of cup with a curved rotary profile and meet the requirements of its production efficiency, a roll forming (RF) method is proposed in this paper. A kind of cup with a curved rotary profile is taken as an example (as shown in Fig. 1), and the influence of the number of rollers on the quality of the cup after roll forming was studied.

2 Principle of Roll Forming

On the basis of the analysis of forming methods such as roll forging and drawing, a method of RF for cup with curved rotary profile was proposed and the schematic of RF is shown in Fig. 2 [9–12]. At the time of RF, the punch is installed under the movable ram of the hydraulic press. The billet, which is pushed by the downwardly moving punch, makes the pre-forming rollers rotate, and the curved rotary profile of the cup is formed by the specific groove shape on the surface of the rollers. During the RF process, some metal will flow into the gap between the rollers and form a thin flash, which will make it difficult to do subsequent machining (as shown in Fig. 3). In order to avoid the formation of a thin flash, a triangular flash groove is designed between the adjacent pre-forming rollers. As a result, the metal that flows into the gap between the rollers will form a triangular flash, which can be eliminated by the shaping rollers installed below the pre-forming rollers. The shaping rollers rotate at an offset angle with respect to the forming rollers (as shown in Fig. 4). The essence of RF is to achieve wall thickness reduction and axial elongation of thick-walled

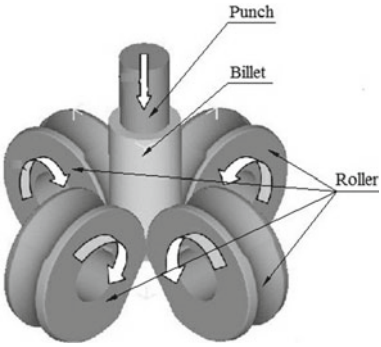

Fig. 2 Schematic diagram of RF

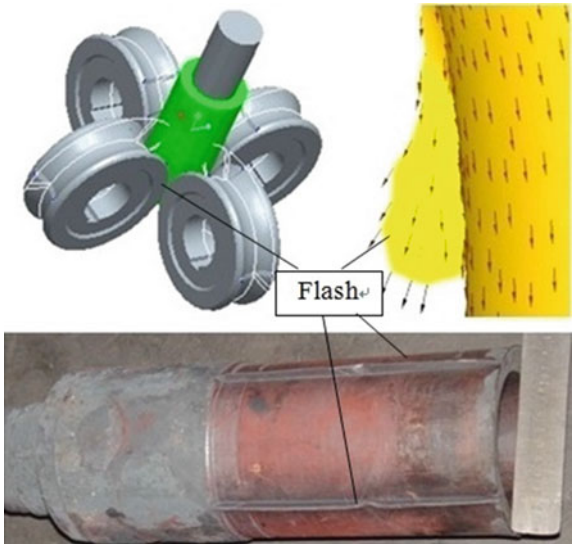

Fig. 3 Flash between rollers. (Color figure online)

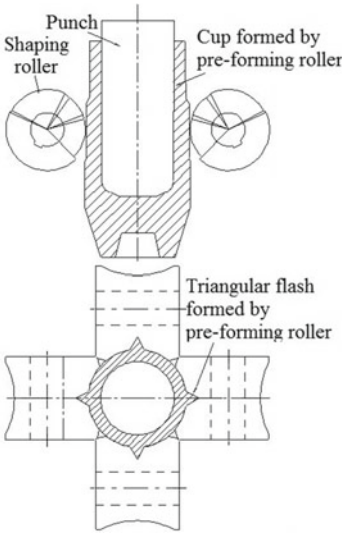
cups through the rotary extrusion of the roller. At the time of RF, two, three, or four rollers can be used, but the number of rollers will influence the flowing of metal and the quality of the rolled cup.

3 Numerical Simulation of RF

3.1 Model of Numerical Simulation

The Deform-3D finite element software was used to simulate RF with three kinds of roller number, which is two-roller, three-roller, and four-roller. The model of numerical simulation for RF is shown in Fig. 5, which consists of punch, billet,



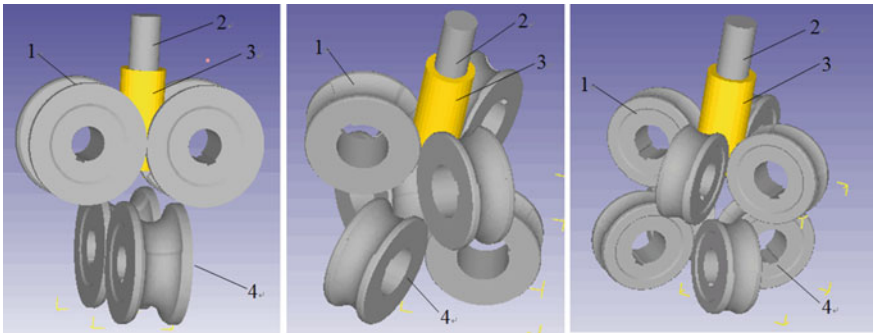


Fig. 4 Shaping of RF

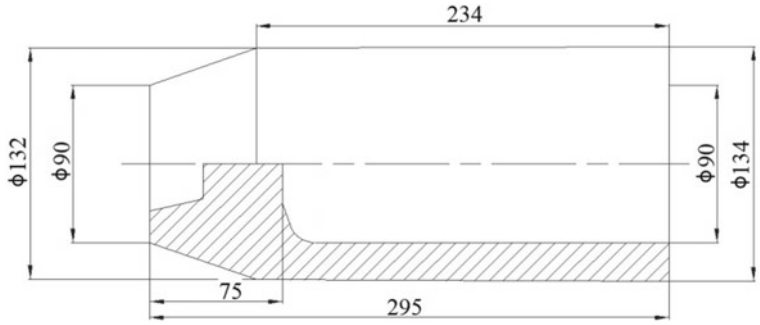
(a) Two-roller (b) Three-roller (c) Four-roll

Fig. 5 Model of numerical simulation. (1: Pre-forming roller; 2: Punch; 3: Billet; 4: Shaping roller). (Color figure online)

and rollers. The billet is a plastic body, and the rollers and punch are rigid bodies. The speed of punch is 10 mm/s. The material is pure aluminum 1060. The friction between the billet and the rollers and punch is based on a shear friction model and the friction coefficient is set to 0.3. The initial element of the billet is 28143, and the number of nodes is 129073. The initial temperature of the billet and the ambient temperature are 20 °C. The billet for RF is shown in Fig. 6.



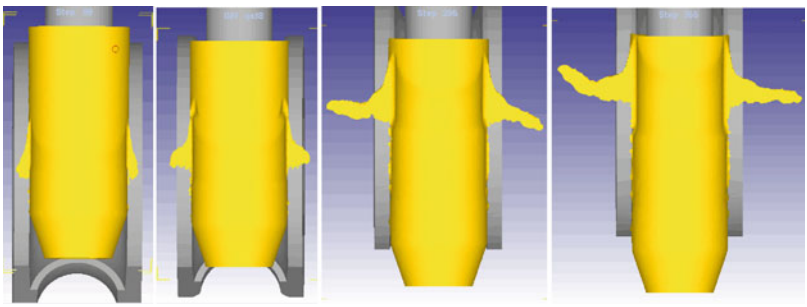


Fig. 6 Billet for RF

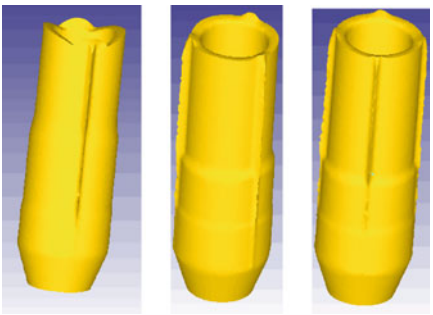
3.2 Results of Numerical Simulation



3.2.1 Pre-forming of RF

The pre-forming process of two-roller RF is shown in Fig. 7. It can be seen from Fig. 7 that during the process of two-roller pre-forming RF, the metal fills the flashing groove between the rollers and then flows into the gap between the rollers, which causes the forming of thin flashes. As the RF progresses, the flashes are cut off. During the pre-forming process of three-roller and four-roller, the metal did not completely fill the flash groove between the rollers, so the metal did not flow into the gap between the rollers to form a thin flash. The rolled part and the open end of the rolled part after pre-forming of RF are, respectively, shown in Figs. 8 and 9. It can be observed from Figs. 8 and 9 that the open end of the rolled part is extremely uneven when the two-roller is used. Due to large amount of metal flowing into the gap between rollers, the open end of the rolled part has a high boss at the corresponding position of the flash groove between rollers. The open end of the three-roller rolled part also formed a boss at the corresponding position of the flash groove between

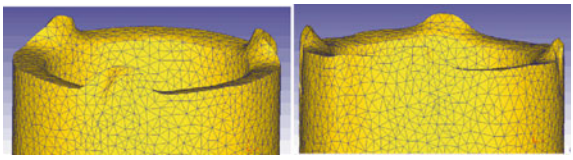
rollers, but the height of the boss is lower than that of the two-roller rolled part, and the open end is more even; the open end of the four-roller rolled part also formed a boss at the corresponding position of the flash groove between rollers, but the height of the boss is the lowest among the three kinds of rolled parts, and the open end is the most even. The difference between the two-roller and three- or four-roller is very obvious, but the difference between three-roller and four-roller is not obvious. The main reason for this phenomenon is that as the number of roller increases, the number of gaps between the rollers increases accordingly, so the metal is more uniformly deformed in the circumferential direction. The number of gaps between rollers for three- and four-roller, respectively, increased by 50% and 100% compared to that of two-roller, while the number of gaps between rollers for four-roller increased by only 33% compared to that of three-roller, which causes the differences of roller number is obvious or not.



3.2.2 Shaping of RF

The thin flash at the gap between the rollers was cut off during the pre-forming of two-roller, which not only wastes the metal but also will affect the RF of the next workpiece as the flash remains in the gap between the rollers. Therefore, the two-roller is not suitable for RF of the cup with a curved rotary profile, and the numerical

(a) Three-roller (b) Four-roller

Fig. 10 Rolled part after shaping of RF. (Color figure online)

(a) Three-roller (b) Four-roller

Fig. 11 Open end of rolled part after shaping of RF. (Color figure online)

simulation of shaping with two-roller was not performed. The rolled parts of three-roller and four-roller after shaping of RF are shown in Fig. 10. It can be observed from Fig. 10 that the flashes formed by pre-forming of RF were eliminated after the shaping of RF; the surface of rolled part is smooth and there are no defects such as folding and cracking in the rolled part; new flash wasn't formed at the gap between the shaping rollers. It can be observed from Fig. 11 that the height of the boss at the open end of the rolled parts increases slightly after shaping of RF compared with the pre-forming of RF.

4 Experiment

As the difference between the simulation results of three-roller and four-roller is relatively small, and the three-roller RF equipment is simpler and easier to control than that of four-roller, experiments were carried out with the three-roller equipment. The three-roller RF equipment shown in Fig. 12 was used to perform the RF experiment on a hydraulic press. The RF equipment has three pre-forming rollers and three shaping rollers. At the time of RF, the speed of the hydraulic press is 10 mm/s. The

Fig. 12 RF equipment of three-roller. (Color figure online)

material of billet is pure aluminum 1060 and it is carried out at room temperature. The cup with a curved rotary profile obtained by RF is shown in Fig. 13. It can be observed from Fig. 13 that the cup with a curved rotary profile has no defects such as folding and cracking. The error between the roll-formed parts and the simulation results at the length in the axial direction and the height of the open end is less than 10%. The other dimensions and shapes of the roll-formed parts obtained in the experiments were consistent with the simulation results.

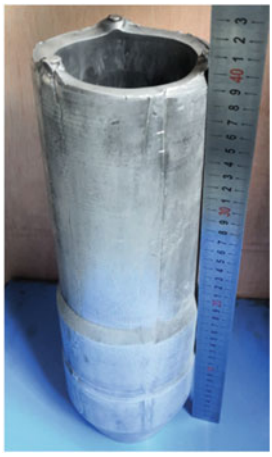


Fig. 13 Roll-formed parts. (Color figure online)

5 Conclusion

Roll forming can be used for the production of cup with a curved rotary profile to improve the material utilization rate and production efficiency, and thus it reduces machining and production costs. The thin flash at the gap between the rollers is formed and cut off during the pre-forming of two-roller, which will affect the roll forming of the next workpiece. Therefore, the two-roller is not suitable for roll forming. Three-roller or four-roller can form ideal parts and they are recommended for roll forming of cup with a curved rotary profile.

Investigation of Machine Learning Models for a Time Series Classification Task in Radial–Axial Ring Rolling

Simon Fahle, Thomas Glaser, and Bernd Kuhlenkötter

Abstract The great potential of machine learning models in different domains has been shown in recent years. Based upon initial research regarding preprocessing methods for time series classification in the hot forming technology of radial–axial Ring Rolling, this paper takes the next step to further investigate the suitability of different machine learning models for a classification task regarding the ovality of a formed ring. This is achieved by implementing several models of the time series classification domain in machine learning and training them on actual production data of thyssenkrupp rothe erde Germany. The data set consists of different production days and ring geometries, and thus includes a plurality of challenges of radial–axial ring rolling real-world data. Different experiments will be performed and their results will be analyzed regarding performance, interpretability, and usability in the production environment. Thus, a suitable model for the underlying task will be investigated, which is essential for a future model deployment to improve the radial–axial ring rolling process further.

Keywords Ring rolling · Machine learning · Quality prediction

1 Introduction

In times of evolving amounts of time series data being produced in different industries such as wind energy [1], health care [2, 3], as well as remote sensing [4, 5], a transformation toward an application in the hot forming sector is necessary. Time series data is different in contrast to tabular data as it is not only independent and identically distributed but also has a time dependence [6] requiring different approaches when being analyzed. Thus, a time series classification (TSC) approach is used to analyze production data from radial–axial ring rolling (RARR). RARR is a well-established hot forming process capable of forming highly durable axial symmetrical products. Its complexity is high due to the instability of the hot forming aspect (temperatures up

to 1200 °C), the two opposing rolling gaps (radial and axial), as well as imperfections in stock material and previous production steps such as heating or punching. A study conducted in 2019 shows that process data from RARR in Germany has not been used to its full potential [7] and initial studies for the usability of machine learning have been presented. The aim of this research is to advance on the latest research regarding machine learning methods from TSC for quality prediction in RARR and evaluate the best-suited algorithm regarding its classification performance. Further, an initial study related to the interpretability of selected algorithms is conducted to extract information to improve the actual forming process by analyzing the algorithm's decision and derive process control strategies. Moreover, this study is based on actual production data from thyssenkrupp rothe erde Germany GmbH. The data set was acquired during different production days and inherits different geometries, thus representing typical samples of a RARR company. The data set is subject to a confidentiality agreement and must therefore not be made available to the public. This study compares several traditional, newer, and SOTA algorithms in the domain of TSC with hyperparameter tuning for their applicability to the underlying problem of predicting ring ovality. On the way to developing a whole framework for quality prediction and prevention, the next step of a most suitable model has to be taken since initial analysis regarding data acquisition and preprocessing has been conducted earlier by Fahle et al. [7, 8]. Figure 1 reflects the conducted experiments to find a suitable model to accurately predict quality in RARR and gain insights into decision interpretation of the used model.

2 Related Work

We start the related work section by giving examples of current advances regarding the relevant topics within this research. This will provide a deeper insight into the fields of RARR as well as TSC.

2.1 Radial–Axial Ring Rolling

Current research in RARR is pointed in different directions, such as simulation, process control, and innovations, as well as data analysis in recent years. With respect to simulations, many approaches use finite-element simulations to simulate and improve the process such as Allegri et al. with their research resulting in newly proposed milling curves that achieved good quality results with reduced process time and loads [9]. Another simulation-based approach toward an intelligent simulation for the rolling process of titanium alloy rings is proposed by Liang et al. They implemented a model using Abaqus/Explicit to control roll motions with regard to the material's temperature [10]. Regarding new process innovations and different combinations of the traditional RARR with other processes, Kuhlenkötter et al. investigated the suitability to combine the RARR process with thermal spraying to compact coatings in an innovative manner. The results show that by rolling thermally sprayed coatings a higher compressed residual stress can be induced, yet a final intact coating could not be established in the initial experiments [11]. Another approach where RARR has been combined with a different process is shown by Michl et al. They explored whether the use of additive manufacturing in the form of a wire arc additive manufacturing is suitable to produce better near-net shape preforms. Their results show that wire arc additive manufacturing shows promising results to lower process expenses and improve process efficiency [12]. Regarding the second core topic of this contribution, the machine learning in the form of TSC is currently researched by the aforementioned research by Fahle et al. in the RARR domain. One aspect of their research focused on data utilization and data analysis methods in RARR in 2019 for a variety of German ring rolling companies. Moreover, a framework for the RARR process was proposed to enable the RARR process to use data-driven methods such as machine learning for problems like quality prediction [7]. Furthermore, Fahle et al. investigated different preprocessing methods for TSC in RARR using common approaches as well as a domain-specific approach: using individual scaling with regard to RARR-specific rolling phases [8]. Moreover, another data-driven approach in the form of a meta-model is proposed by Havinga et al. within the metal forming mass production process of sheet bending. They mention several advantages by using data-driven techniques in metal forming as well as remaining research questions such as the model uncertainty and measurement accuracy in metal forming [13].

2.2 Time Series Classification

TSC is a highly researched area within data mining and is considered an important problem within data mining [14]. As temporal data became available [15], many algorithms, especially different deep learning architectures, have been proposed in the subdomain of TSC within the machine learning area. Examples for such deep learning

approaches are convolutional model based on the inception architecture named inception time [16] and a multivariate approach using long short-term memory cells and fully convolutional networks named MLSTM-FCN [17]. All these approaches try to establish the SOTA results using deep learning approaches as in recent years the SOTA performances were reached by using an ensemble of different TSC algorithms named HIVE-COTE. [18] Yet, according to Fawaz et al., this ensemble is not applicable to real-world problems because of its high training time complexity and thus unscalability into bigger data sets [16].

In order to compare the results of different classifiers, benchmark databases have been established within different domains of machine learning. A common representative for the task of image recognition was ImageNet [19] by providing a comparable base to validate performances of different models. With regard to TSC there is the UEA & UCR Time Series Classification Repository [20]. Different studies have been conducted searching for domain agnostic best models within the TSC domain [21]. A later study enhanced the said research by implementing deep learning models and their results on the benchmark repository [22]. Furthermore, there are different implementations for a variety of models and algorithms such as *tslearn* [23] and *sktime(-dl)* [6] that are partly used within the implementation for the proposed research in the domain of RARR.

3 Evaluation of Suitable Models for Quality Prediction in RARR

In this section, the core part of the contribution as well as all the corresponding information will be provided. We start by describing the data set used to evaluate the usability of the implemented TSC models for an application in RARR. We further discuss the used approach to include multivariate inputs as well as the model tuning performed within this research. We close this part by defining the initial requirements a suitable model has to offer.

3.1 Data Set

The current data set consists of 1078 samples from different production days of thyssenkrupp rothe erde Germany. The data set is preprocessed using different approaches, which have been explored by Fahle et al. for the application in RARR. The used data set is multivariate and provides up to five input features for this study. Those features range from radial and axial forces, ring growth rates, and motor current to several geometrical features from the process. During the evaluation not only parameter tuning within the algorithms is performed but also the number of features $(1, 3, 5)$ and their impact are explored. The inputs are limited as an even higher degree

of input features will be investigated in future research where up to 46 input features will be compared regarding their added benefit in a multivariate approach. Moreover, this will be analyzed with regard to potential computational drawbacks for online predictions, as the prediction time has to meet certain criteria from industrial control technology. The features are part of an actual ring rolling machine at thyssenkrupp and are accessed through their log files. The inputs used are the centering force on the inlet side, axial current, values for the diameter describing the radial rolling gap, and height describing the axial rolling gap, both derived through machine positions and the laser value. These features resulted in the highest univariate performances in an earlier study, which is described in the multivariate approach section. The features are stacked in the order they are listed for the multivariate approach with three and five features. Additional inputs that will be investigated in future research are, for example, revolution speeds, torques, and forces of the axial and radial rolls up to process-specific quantities such as the ring growth rate. Finally, an independent 3D measurement unit that is placed directly after the ring rolling process measures the target for each sample.

Due to a non-disclosure agreement, the data set must not be made available to the public and is still an object to grow, as the data acquisition process is still ongoing. The data set is almost evenly distributed, as the threshold for "ovality" is set such that the quality of produced rings will be increased, and only highly qualitatively rings will be produced. Rings that would break the threshold will be classified and, in a future process using an online (early) time series classification approach, immediately improved by assisting the worker in giving suggestions for parameter settings for the specific rolling process. The used preprocessing steps are standardization and phase-scaling, which are both described and evaluated by Fahle et al. [8]

The data set is split into a train and test split with an 80/20 ratio. Within the train split, there is another 80/20 split to form a validation or sometimes-called development set. This is done following the best practices because the process of hyperparameter tuning should not be done on the test set, as it would already induce some form of bias in the evaluation. Hence, the hyperparameter search will be conducted using five-fold cross-validation with random splits regarding the train and validation splits. After that, all tuned models will be retrained once on the whole training set and will predict the entirely separated test set they have never seen before. The results, both, tuning as well as testing, are shown in Tables 2 and 3.

3.2 Multivariate Approach

Moreover, the data set was split into different levels regarding multivariate inputs. All models were trained on a univariate data set only using a geometric input feature for the axial-slide, and different multivariate sets with three and five features. This experiment was conducted to evaluate whether different kinds of algorithms exceed the growing size of dimensions in the input space as well as to gain information about the benefit to include more than just one single input feature. The inputs are chosen

with respect to an earlier study regarding single feature performances on an earlier version of the data set that did not consist of the actual 1078 samples. The most important feature at that time was the inlet-sided centering force (Channel IFzE166 in the log) is in the univariate data set split. As feature inputs increase, features such as the current of the axial rolling parts and direct and indirect geometric features of the rolling gaps and the laser value are stacked to form the multivariate approach.

Some models do support a multivariate approach from the start, yet others do not. Two common approaches presented by Löning et al. within their *sktime* implementation are chosen and briefly described. One approach is to concatenate all input features to one long vector and use it as a single univariate input, whereas the other uses an ensemble where the classifier is trained on each dimension individually and all individual trainings are used to form an ensemble prediction where the majority vote is used, called column-wise-ensemble [6]. These approaches are implemented where needed, i.e. TSF and kNN.

3.3 Models and Methods

The implemented models are mainly derived from the *sktime* [6], *tslearn* [23] tools as well as individual implementation of their initial authors, i.e. Karim et al. [17]. All used models are shown in Table 1 and represent different TSC algorithm types.

Manual optimization was chosen for hyperparameter optimization. To start with, all baseline implementations were used as their initial authors provided them. For kNN, TSF, and Shapelet a grid-like search was conducted. The rocket transformer uses random kernels by default as to why it was not tuned. For all deep learning models, a random tuning with regards to author's statements for tuning was performed as this should result in better performances according to Bergstra et al. [24]. The values in brackets in Table 1 display the values with regard to each layer for each set. All other parameters were not changed and implemented as suggested by the authors or the corresponding implementation in *sktime(-dl)* and *tslearn.* No hyperparameter was tuned regarding ROCKET as the transformer implementation offered none.

The training was performed using five differently shuffled train-/test-/validation-splits, using the cross-validation approach to strengthen the validity of our conducted model training. All models were trained using the train data set, then the differently tuned models were evaluated on the validation split and the final "best" models parameters were lastly used to predict the test sets to have an unbiased result. For the deep learning models, a model checkpoint was used to ensure that the best iteration of all epochs was chosen in terms of validation loss. Epochs were only increased for larger architectures, as this was not necessary due to the size of the dataset in relation to the other architectures and their learning curves.

Table 1 Hyperparamter tuning

Used model	Type	Parameters	Values
KNN	Distance-based	Metric neighbors	dtw, ddtw, wdtw, lcss, erp, msm, twe 1, 3, 10

FCN	Deep-Learning	Filter number Kernel size Batch size	[128, 256, 128], [64, 128, 64], [64, 128, 32] [3, 5, 8], [1, 3, 4] 8, 16, 32
LSTM-FCN	Deep-Learning	LSTM Filter number Kernel size Batch size Epochs	8, 32, 64, 128 [64, 128, 64], [128, 256, 128], [128, 256, 64] [3, 5, 8], [1, 3, 4] 16, 32 100, 500

3.4 Requirements

For the underlying use case of a quality prediction and in a future version quality prevention model, the model has to have different properties. It has to reach a sufficiently high performance regarding classification accuracy to ensure that no unnecessary production process deceleration occurs where it was not needed because the rolled ring was achieving given quality standards either way. Moreover, the decision should be interpretable by the worker as a productive deployment in a production line highly benefits through process improvements triggered by the model's decision. There is literature to support the urge for the process of gaining trust in machine learning or artificial intelligence (AI) systems such as Siau and Wang [25] as well as

Linkov et al. [26], yet trust in an AI-driven decision-making system may be advantageous. An explainable decision in RARR would be needed for constant process improvement. The decisions made by the system could then be interpreted by an experienced technologist and give insights that might not have been looked at.

An open question is to what extent a prediction performance regarding sensitivity, sensibility, and accuracy should be reached to justify the effort and a potential process delay due to the automatic algorithmic interactions with the process control unit.

4 Results

The results for all the summarized validation accuracies throughout the splits for each of the best-tuned classifiers are shown in Table 2. The results show the mean accuracies as well as the standard deviation of all best hyperparameter tuned models for each classifier trained on the aforementioned five-fold split. It is apparent that most models preferred higher dimensionality, i.e. more input features than lower degrees of dimension, as the five best working models used five input features for their best mean prediction accuracy on the validation splits. Surprisingly, the TSF-Model, which is used only as a univariate time series for the best parameter set, reached the highest mean validation accuracy with a classification accuracy of 0.895. The second best was the FCN with 0.894 and the MLSTM-FCN with 0.892. The standard deviations of all classifiers were in the same range with MLP and kNN on the higher end with 0.030.

All model trainings and evaluation runs showed that for the case of RARR, a column-wise-ensemble method for every single feature is superior to the approach where all features are appended and one long vector is chosen as all best results originated from the column-wise-ensemble method for multivariable inputs.

From all tuned models, the ones with the best validation accuracy within each classifier are chosen and used to predict the classes for the unseen test data split,

Table 2 Validation performances of all classifiers

		Validation accuracy	
Classifier	nFeatures	Mean	Std
InceptionTime	3	0.890	0.025
FCN	5	0.894	0.023
MLP	5	0.829	0.030
CNN	3	0.874	0.025
MLSTM-FCN	5	0.892	0.025
RocketRidge	5	0.886	0.026
Shapelet	3	0.854	0.025
TSF	1	0.895	0.023
kNearestNeighbor	5	0.868	0.030

the split that every model sees only once. These results are displayed in Table 3. The results on the test set represent an unbiased generalized performance on the set. It can be observed that the TSF worked second best with a test accuracy of 0.875, outperforming all other models besides the MLST-FCN model with its test set accuracy of 0.880, keeping in mind it is only used as a univariate representation of the data set with the inlet-sided centering force IFzE166 as its only feature to predict ovality.

Two things are worth noting: for once, Hive-Cote was not regarded as its high-time complexity made the model unfeasible for the application at hand. Secondly, the inception time model managed to perfectly overfit the training set, thus reaching training accuracies (neither validation nor test) of 1.00, and leading toward an estimation that a substantial amount of effort put into fine-tuning that architecture could lead to better results with regard to generalization.

As for the interpretability of the given models is concerned, there are different methods to visualize each model's prediction or at least parts of their prediction process. For k-nearest-neighbor models, there is the visualization of the distances and their differences, which could somewhat loosely be interpreted by a human. For

Table 3 Final test results showing best generalization capabilities

Classifier	Test accuracy	Set of hyperparameters
MLSTM-FCN	0.880	LSTM: 64 Filter number: [64, 128, 64] Kernel size: [3, 5, 8] Batch size: 32 Epochs: 500
TSF	0.875	Estimators: 250 Criterion: entropy Max features: log2
RocketRidge	0.870	/
FCN	0.866	Filter number: [64,128,32] Kernel size: [3, 5, 8] batch size: 8
Inception	0.856	Filter number: 32 Kernel size: 21 Epochs: 100
Shapelet	0.852	L: 0.1 R: 3 Batch size: 32
CNN	0.852	Filter number: [6, 12] Kernel size: [5]
NearestNeighbor	0.843	Metric: wdtw Neighbors: 10
MLP	0.824	Dropout: [0.1, 0.2, 0.2, 0.3] Dense: [500, 500, 500]

the TSF, as far as the authors know, there is no direct representation such as the discovered shapelets by a shapelet model that can be visualized and interpreted regarding the production process. Similar to the discovered shapelets for some network architectures with a specific layer (global average pooling), there is the class activation map (CAM) that can be used to gain insights into where or what part of the data was significant [27]. This feature can be implemented for a TSC approach, as shown by Fawaz et al. [22]. This can be applied to the MLSTM-FCN architecture and thus be used to gain more insights into the model's prediction.

5 Conclusion

Concluding the conducted experiments, it can be stated that for the use case of quality prediction problems focusing on ovality, using time series classification in RARR, the MLSTM-FCN model seems to be the most suitable. With respect to the requirements in this domain, it has the highest test accuracy along with a promising method called class activation map to make the decision given by the model more interpretable. Nevertheless, especially the TSF with its second-best performance in terms of test accuracy should not be completely neglected, as its accuracy is only slightly worse than that of the MLSTM-FCN model, especially in view of the sparse univariate input of the TSF compared to the five multivariate features with the MLSTM-FCN. This leads to the conclusion to focus on those two models while building the final framework for the quality prediction task.

6 Future Work

Further research needs to be conducted to analyze the impact of even higher dimensional input data or a preferred selection of those on the prediction performance as well as the analysis of aforementioned CAMs produced by a model to gain more insights on to what extend or what part of a feature contributed to the classification prediction. The initial steps toward an analysis have been conducted, which showed promising results to deduce new insights from such visualizations. Moreover, an early prediction of time series will be investigated so that failure can not only be predicted but also prevented, as a prediction could be made before the rolled ring is finished and potential counter-measures can be activated.

Acknowledgments This work is funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation)—404517758. The authors would like to additionally thank Dr. Andreas Kneißler and thyssenkrupp rothe erde Germany GmbH for their support and access to their real-world data.

Toward Neural Network Models to Model Multi-phase Solids

Maysam B. Gorji, Julian N. Heidenreich, Mojtaba Mozaffar, and Dirk Mohr

Abstract In this study, a neural network model is developed to describe the large deformation response of a multi-phase material, i.e., a two-dimensional perforated plate. Using the finite element, virtual experiments are performed to generate stress–strain data for monotonic biaxial loading paths. Subsequently, a combination of fully connected and recurrent neural network models are trained and validated using the results from the virtual experiments. The predictions of a network show a remarkable good agreement with all the experimental data. The suggested neural network-based constitutive model does provide a robust solution to the problem at hand, providing a fully anisotropic, three-dimensional material model capable of covering all physical material properties. The suggested procedure promises to be generally applicable to any material class and can be paired with any numerical method.

Keywords Artificial intelligence · Fully connected neural network · Recurrent neural network · Plasticity · Multi-phase material

1 Introduction

An appropriate constitutive model to describe the plastic material flow behavior especially in sheet metal has always been a challenging assignment. In the framework of this research, we show the potential of a machine learning-based modeling framework for the homogenization of multi-phase material properties, which lends itself to different applications such as modeling of composite materials, granular materials used in (e.g.) lithium-ion batteries, metamaterials, and porous structures. The theory

of homogenization uses the asymptotic expansion to approximate the relevant field variables like displacements. This introduces an additive split of all field variables on average, constant value, and its perturbations as a result of heterogeneities on a microscopic level. Despite all the studies carried out and the progress that has been made so far, the homogenization of material properties still remains a challenge nowadays. Every new class of materials and categories of physical interaction of components requires a rigorous investigation and formulation of new mathematical formulations. Additionally, material sciences still advance much faster than the research regarding material characterization. In this study, we suggest a machine learning and especially neural network-based constitutive model to describe the plasticity response of a multi-phase material.

Machine learning (ML) offers superior alternatives to traditional approaches for modeling and decision-making. This especially applies to adaptive environments where a fixed set of rules cannot sufficiently predict the behavior or in cases where alternative modeling approaches are computationally expensive or too complex to make and maintain [1]. Fully connected neural networks (FCNNs) are a class of multilayer artificial neural networks (ANNs), in which each neuron receives the values of all neurons in its previous layer as inputs to perform its calculations. The FCNNs are used to predict the behavior of the materials in sheet forming processes [2, 3]. While FCNNs offer fast calculations and a simplistic implementation, their predictions are limited to a fixed number of time steps and allow restricted predictability of history-dependent features. Meanwhile, recurrent neural networks (RNNs) are a special class of ANNs that incorporate a recursive history signal in the network architecture that enables temporal predictions [4]. Training RNNs has long been considered a challenge due to extreme cases of vanishing and exploding gradients in the backpropagation process [5]. The long short-term memory (LSTM) [6] and the gated recurrent units (GRU) [7] are two successful formulations of RNNs that resolve the notorious training issues associated with RNNs. RNNs are used in [8] to predict the behavior of composites representative volume element (RVE) by combining temporal and non-temporal features under nonlinear loading. It is worth mentioning that aside from the versatile applications of ML as well as computing outputs explicitly from the inputs, ML starts to flourish extraordinarily when a large amount of data is accessible. In practice, a robot-assisted automated testing system is a reliable way to provide a large experimental data set [9]. In this work, the studied alloy is a 1.0 mm thick high-formable AA5182 sheet, which is widely used in the automotive body panels and reinforcement members due to its high strength and formability as well as its good corrosion resistance. Its material properties are obtained from Peters [10].

2 Artificial Neural Network

In this study, two approaches have been discussed to mimic the history-dependent, mechanical response of the material. The first architectures are based on FCNNs:

the key objection of using these structures is that they tend to neglect any notion of time order; the network is amnesic to the deformation history, i.e., the FCNN just learns, remembers, and predicts based on the formative moments of the training. The second approach relies on RNN: they manage to capture stress state evolutions by adding hidden state variables known as memory cells to the ANN architecture. Unlike the FCNN, the RNN output at time t is directly connected to its prior decisions by ingesting its own previous output at time $t - \Delta t$ as a new input into the sequence. So, the same strains as inputs, but with different deformation histories generate different outputs. In this work, we deploy GRUs as a gated mechanism by taking into account two sources of present inputs and recent past ones.

The training procedure of ANN can be summarized as the sequential feeding of samples as input vectors and adjustment of the network's weights and biases, learning the underlying function. The goal is to minimize the computed error of the network calculated between the desired and the actual response of the output layer. This type of learning is known as supervised learning, which originates from the fact that there is an external teacher to control and subsequently achieve the desired output. One path through the entire range of the training set is called an epoch. The error is calculated at the end of each epoch; weights and biases will then be updated with the new values. To measure the accuracy of the network, we define the so-called cost function with respect to the weights and biases of the network. The cost function in our feed-forward model is a mean squared error (MSE) defined by the difference between the predicted ANN outputs $\mathbf{Y}_i$ and given target responses $\widehat{Y}_i$. It reads as $\mathrm{MSE}(\Omega) = \frac{1}{n}\sum_{i=1}^{n}\left(\overline{Y}_i - Y_i\right)^2$, where Ω stands for all trainable parameters, including weight matrixes and bias values.

3 Results and Discussion for the Structural Application

3.1 Round Hole Staggered Perforated Plate

In this section, we demonstrate the ANN-based constitutive model of a perforated plate featuring a direction-dependent, anisotropic material response upon external loading. For this purpose, a round-hole staggered square plate is designed. As sketched in Fig. 1a, the perforation is introduced via a 10×10 grid. Holes are randomly distributed in the grid to lower the relative density, which is defined as the ratio of a solid area over the area of the 10×10 grid. In order to limit the number of possible perforated configurations, we introduce a four-fold rotational symmetry. In the smaller 5×5 grid (top left quadrant of Fig. 1a) 13 holes are randomly placed. The rotation of this structure around the center point yields the final 10×10 structure with a relative density of 0.74 resulting in 48 solid- and 52 hole-cells.

The training and testing datasets required for successful parameter identification are created with the help of numerical simulations using the implicit solver of FE-package LS-DYNA in conjunction with the Yld2000-2d plasticity model. The

AA5182 structure is discretized with the linear four-node shell elements and five integration points through the thickness; the total number of elements is about 40,000. The representative volume element (RVE) displayed in Fig. 1a is extended to an infinite medium using periodic boundary conditions, linking the displacements of the nodes at the outer perimeter to the applied displacement gradient. To do so, the local displacement field $\boldsymbol{u}$ is decomposed into $\widehat{u}$, the applied deformation on the unit cell, and $\widetilde{u}$, which can be interpreted as local fluctuations. The applied displacement field is linearly approximated using the displacement gradient $\mathbf{H}$:

$$\mathbf{u}(x) \widehat{=} \widehat{\mathbf{u}}(x) + \widetilde{\mathbf{u}}(x) \approx \mathbf{u_0} + \mathbf{H}x + \widetilde{\mathbf{u}}(x). \tag{1}$$

An additional constraint on the local fluctuations is introduced to enforce periodicity of the unit cells leads:

$$\tilde{u}(x) = \tilde{u}(x + nl_i e_i) \forall n \in Z. \tag{2}$$

.

These equations yield a translatoric invariance of the deformation response by shifts by a multiple of the unit cell dimension l_i along with the principal directions e_i of the structure. The mesh of the square unit cell is designed in a way that every node on the perimeter has a corresponding node on the opposite side of the unit cell at a distance of l_i along the unit face normal $\boldsymbol{n}$. Combining Eqs. 1 and 2 leads to the following relationship between each pair of nodes:

$$\boldsymbol{u}(x_1) - \boldsymbol{u}(x_2) = l_i \boldsymbol{H}\boldsymbol{n}. \tag{3}$$

Two control nodes are considered to control the deformation of each set of opposite faces of the two-dimensional unit cell. Hereby, the translatoric degrees of freedom of the control nodes represent the components of the applied displacement gradient. Equation 3 is implemented in the FE simulation via linear kinematic constraints on the nodal displacements. The resulting forces applied to the control nodes are equal to the components of the first Piola-Kirchhoff stress $\boldsymbol{P}^I$ tensor. Note that the sampled strain paths represent components of the Hencky strain tensor. The displacement gradient, which is applied to the RVE is determined via polar decomposition of the deformation gradient assuming rotation-free deformations.

3.2 Non-proportional Monotonic Loading

The 140 deformation paths in the normal strain space $\varepsilon_{xx} - \varepsilon_{yy}$ with the squared-length of 0.08 are delineated in Fig. 1b. The strain evolution follows the power-law function ($y = Ax^n$) with seven values for the exponent $\in [0.1, 0.25, 0.5, 1, 2, 4, 10]$. The three-dimensional input strain vector in $x' - y'$ space is thereupon simply computed using the rotational matrix $([\cos(\alpha) - \sin(\alpha); \sin(\alpha)\cos(\alpha)])$ for nine different angles $\alpha \in [0 : 10 : 80]$. For reference, the transformation of one exemplarily loading path ($\varepsilon_{xx} = 0.04$,$\varepsilon_{yy} = -0.04$ with the power law's exponent 10) to $x' - y'$ space is highlighted with the solid black lines in Fig. 1b.

The simulation results of one of the exemplary deformation patterns are shown in Fig. 2. Plot (a) depicts the strain inputs, while plots (b) and (c) illustrate the resulting stresses based on the forces in the x and y directions on the control points DN1 and DN2. Following the nomenclature used for introducing the deformation and displacement gradient, the evaluation of node DN1 yields the components $\boldsymbol{P}^I_{xx}$ and $\boldsymbol{P}^I_{yx}$ of the first Piola-Kirchhoff tensor and DN2 yields the components $\boldsymbol{P}^I_{yx}$ and $\boldsymbol{P}^I_{yy}$, respectively. Note that despite the fact that the input strains are based on monotonic functions, the resulting stresses do not necessarily conform to that rule. In an extreme case, this can lead to load reversal. For instance, the component $\boldsymbol{P}^I_{xx}$ in Fig. 2b starts out as compressive stress and changes to a tensile force after approximately one-third of the deformation has been applied to the structure. The contour plots in Fig. 2d depict the equivalent plastic strain throughout the deformation. As expected, we observe strain concentrations near the holes. The overall global change in geometry is dominated by the local deformation around the holes. Keep in mind that throughout

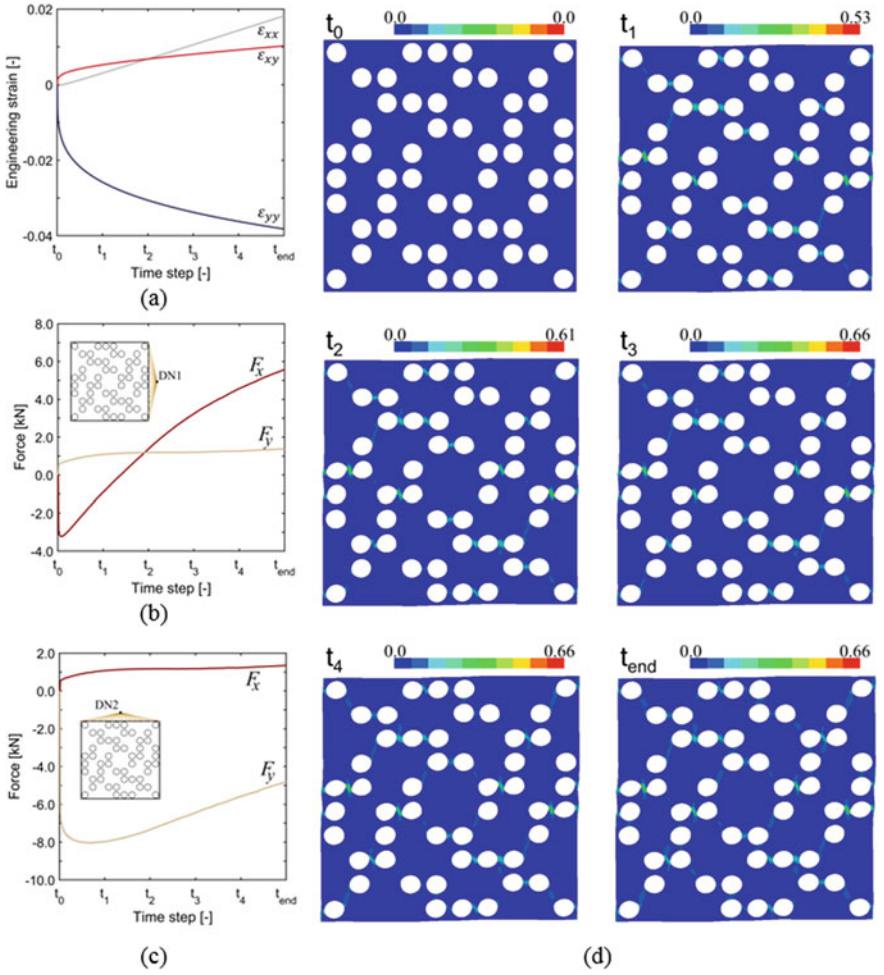

Fig. 2 Results from a representative virtual experiment (unit cell simulation): **a** Imposed strain histories and computed force histories for **b** control points DN1 and **c** DN2. **d** Deformed unit cells for selected time steps. The contour plot shows the equivalent plastic strain. (Color figure online)

this study and for all performed simulations, it is assumed that the local equivalent plastic strain stays below the fracture threshold.

3.3 Post-processing and Dataset Preparation

For consistency and later implementation in the numerical simulation scheme, the neural network is trained based on Hencky strains E_{Hencky} and Cauchy stresses σ.

Hence, the obtained displacement gradient and first Piola-Kirchhoff stress tensor have to be converted. In order to obtain the full three-dimensional displacement gradient, we need to monitor the Hencky strain in the thickness direction at each integration point. An effective measure of thickness strain is determined by averaging the extracted strains. The averaged effective strain is transformed into the engineering strain space and serves in the following as the zz-component of the displacement gradient. The Hencky strain tensor, as well as the Cauchy stress tensor, is calculated based on the following formulas:

$$\boldsymbol{E}_{\text{Hencky}} = \frac{1}{2}\ln\left(\boldsymbol{F}^{\mathrm{T}}\boldsymbol{F}\right) = \frac{1}{2}\ln\left((\boldsymbol{H}+1)^{\mathrm{T}}(\boldsymbol{H}+1)\right), \tag{4}$$

$$\boldsymbol{\sigma} = (\det(\boldsymbol{F}))^{-1}\boldsymbol{P}^{\mathrm{I}}\boldsymbol{F}^{\mathrm{T}} = (\det(\boldsymbol{H}+1))^{-1}\boldsymbol{P}^{\mathrm{I}}(\boldsymbol{H}+1)^{\mathrm{T}}. \tag{5}$$

3.4 A Neural Network-Based Constitutive Model

The final network is an assembly of two GRU cells with 100 neurons followed by one time-distributed fully connected layer. This structure is capable of predicting the elastoplastic behavior of the studied meta-material for over 500 time steps. The strains $\{\varepsilon_{xx}, \varepsilon_{yy}, \varepsilon_{xy}\}$ are defined as the input, while the stresses along with the thinning $\{\sigma_{xx}, \sigma_{yy}, \sigma_{xy}, \varepsilon_{zz}\}$ represent the output of the ANN model. Moreover, 945 loading paths out of the 1260 generated ones are used to train the RNN (75% of all generated paths), while the rest, 315 loadings (25% of all generated paths), are used to test the model. The network is trained for 1000 epochs, which leads to an MSE of 3.36E-4 and 6.70E-4 on training and test sets, respectively.

Figure 3a shows the evolution of an exemplarily untrained strain vector as a function of time for validation purposes. The target outputs are presented in Fig. 3b as solid black lines. The predicted ANN results are shown by dashed red lines, i.e., the progression of stresses is in excellent agreement with the numerical results. The explicit stress values at the last time step are $\sigma_{xx} = 94.19MPa$, $\sigma_{yy} = 87.97MPa$, and $\sigma_{xy} = 7.00MPa$. Accordingly, the prediction of the neural network is $\sigma_{xx}^{RNN} = 94.54MPa$, $\sigma_{yy}^{RNN} = 87.07MPa$, and $\sigma_{xy}^{RNN} = 7.07MPa$.

Developing the neural network model assists in predicting the stress distribution for any arbitrary non-proportional monotonic deformation. As an example, the stress evolution of 36 proportional monotonic loadings in the normal strain space $\varepsilon_{xx}, \varepsilon_{yy}, \varepsilon_{xy} = 0$ is predicted by the trained ANN model, which is shown as black solid lines in Fig. 3c. The total work (per unit volume) is computed based on the stresses derived from the ANN model alongside the input strains as

$$\psi(t) = \int_0^t \left(\sigma_{xx}\varepsilon_{xx} + \sigma_{yy}\varepsilon_{yy}\right)dt \tag{6}$$

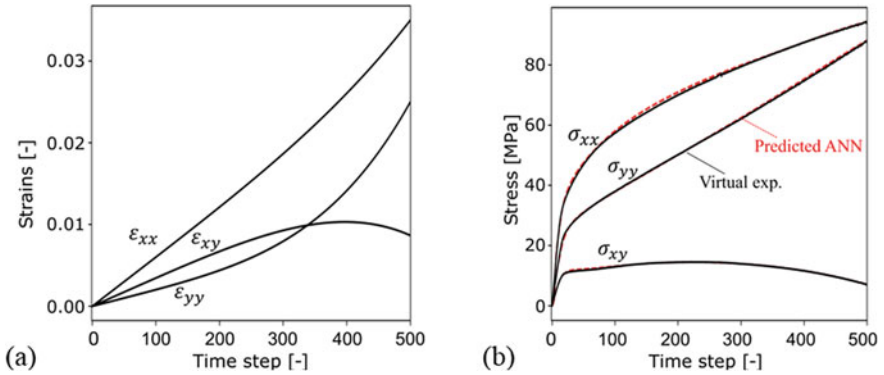

Fig. 3 **a** Testing of the trained GRU100-FCNN100 model for the 2D perforated plate: **a** shows the imposed strain histories, while **b** shows the corresponding stress histories predicted by the unit cell model (black curves) and the neural network model (red lines). (Color figure online)

With the help of these results, the energy surface of the studied perforated plate at three distinct levels, $\psi(t) = 0.10mj$, $0.75mj$, and $2.0mj$, are computed. The derived curves are sketched in Fig. 4a. Interestingly, all of the derived surfaces are convex, i.e., $\left(\sigma_{ij} - \sigma^*_{ij}\right).d\varepsilon_{ij} \geq 0$, where σ_{ij} is the present loading state in an elementary material system. This equation is valid for every σ^*_{ij}, which means that loading state σ_{ij}, associated with the present plastic increment of strain $(d\varepsilon_{ij})$ maximizes the infinitesimal total work. The red contour in Fig. 4a represents the total energy of $\psi(t) = 0.10mj$ and is assumed to represent the onset of plastification of the studied perforated plate. Taking this into account, the uniaxial tension along the x and y directions exhibits yield stress of about 48 MPa and 46.6 MPa, respectively. Under equi-biaxial loading, the studied perforated plate plastifies at $\sigma_{xx} = \sigma_{yy} = 45MPa$. In addition to that, Fig. 4b illustrates the NN approximation of the effective stress at an energy level of $\psi(t) = 0.10mj$. We define the effective stress as $\overline{\sigma}_{eff} = \sqrt{\sigma^2_{xx} + \sigma^2_{yy} + \sigma_{xx}\sigma_{yy}}$. The predicted maximum strength of the material reaches $\overline{\sigma}^{EBC}_{eff} = 78.5MPa$ under equi-biaxial compression, which is just 1% higher than the stress at equi-biaxial tension $\overline{\sigma}^{EBT}_{eff} = 78MPa$.

The perforated plate behaves almost identically when it is subjected to the uniaxial tension or compression loading. The lowest stress value is observed under shear loading with the $\overline{\sigma}^{SH}_{eff} = 32MPa$. The designed ANN model is also capable of delivering highly accurate results for the thickness reduction ε_{zz}. Thus, the NN approximation allows us to calculate a Lankford anisotropic coefficient as the ratio of the contractile strain in the width to the thickness direction. Under linear load paths and at a total energy of $\psi(t) = 0.10mj$, the Lankford ratios in the x and y directions are $r_x = 0.957$ and $r_y = 0.939$, respectively. Additionally, $r_{EBT} = \varepsilon_{yy}/\varepsilon_{xx} = 0.978$ when the perforated plate is subjected to equi-biaxial tensile loading.

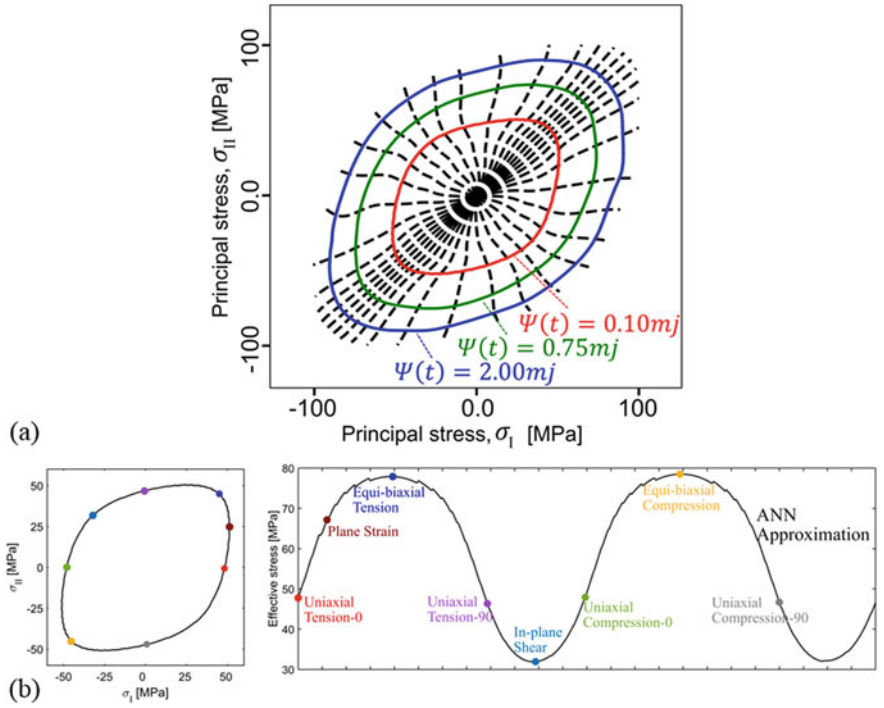

Fig. 4 **a** The predicted energy surface using neural network model (colored lines), the target outputs of implemented strains are drawn with the solid black lines. **b** The effective stress along the energy surface $\psi(t) = 0.10mj$. (Color figure online)

4 Summary and Conclusions

In this study, we show that ANNs are alternative tools that can assist in modeling a material response and predicting mechanical responses. The obtained multi-axial responses of the multi-phase material are then modeled by one of the two different ANN classes: (i) FCNN, fully connected neural network, or (ii) RNN, recurrent neural network. Simplicity in architecture and the low number of parameters in the FCNN approach make this network more facile. However, the RNN architectures are required in cases when the history of the input variables plays a critical role. The comparison illustrates that the RNN-based predicted results show a good agreement with the experimental targets. With this research, we would like to re-emphasize the tremendous potential of machine learning to generate a homogenized model of heterogeneous material properties. The structural behavior of a perforated plate with a relative density of 0.74 is studied under the non-proportional monotonic loadings. An RNN model is trained to retrieve the constitutive parameters of the studied material. The neural network model serves as a strong tool to define the yielding of the structure under different loading evolutions and loading directions.

Comparison of Linear Regression and Neural Networks as Surrogates for Sensor Modeling on a Deep Drawn Part

Matthias Ryser and Markus Bambach

Abstract Several developments in deep drawing aim at systematically determining modifications during tool tryout. Recent work deals with a simulation-based method to discover the current state parameters based on characteristic measurement quantities and infer a tryout proposal by comparing with the simulated robust optimum. While the simulation provides an accurate model of the drawing process, a low fidelity surrogate model is required to predict the influence of process parameters on the targets in a computationally efficient manner. In this work, training data is generated by a stochastic finite element simulation in AutoForm. The data points are used to fit and evaluate linear models as well as neural networks for regression. These models use process parameters as predictors to estimate the target parameters draw-in and local blank holder forces. Results show that simple models outperform complex models. No evidence was found that the model accuracy increases by using neural networks.

1 Introduction: On the Bias-Variance-Tradeoff in Modeling

Stochastic finite element simulations are used for different purposes in deep drawing. Despite the usage in the robustness analysis of the process, stochastic finite element simulations are also used for sensitivity analysis of process parameters on the process itself [1] or for predictive quality estimation [2]. Additionally, the ongoing work deals with inverse parameter modeling in deep drawing [3]. In each of these use cases, surrogate models describing relevant process quantities, like draw-ins or local blank holder forces dependent on the input parameters of the stochastic finite element simulation, are required.

Approaches, which are often used for this regression problem, are linear regression with ordinary least squares loss or other loss functions or artificial neural networks like the multilayer perceptron. In the core of the choice of modeling approach as well as its model parameters lies the bias-variance-tradeoff, which is visualized qualitatively in Fig. 1. The bias-variance-tradeoff describes the conflict of minimizing the estimator error during supervised learning, which can be decomposed into the error due to bias, variance, and the irreducible error due to noise. However, the latter results from the noise in the problem itself and cannot be reduced. The errors due to bias as well as variance are in competition with each other, meaning that, in general, a reduction of the error due to variance leads to a higher bias and vice versa. The analysis of the error components provides a framework to select the optimal model complexity for a given problem with a defined amount of data and can thus be used to identify suitable regression models for sensor modeling in deep drawing. The left part of the graph in Fig. 1 corresponds to simple models; for example, models with only a few degrees of freedom or models whose coefficients are determined using strong regularization. The prediction error of these models consists mainly of the model bias, which is the error occurring since the model is not capable of describing the underlying relationship in the data. On the other hand, the right-hand side in Fig. 1 belongs to models with very high complexity. These models are capable of describing the underlying functional relationship, but due to their high flexibility, they also tend to overfit to noise in the training data, leading to a high variance in the prediction among different training datasets. The model complexity best suited for

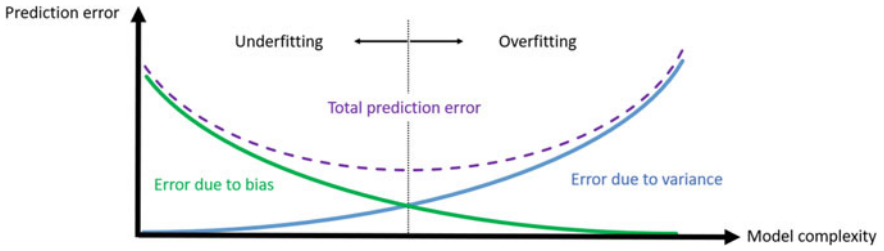

Fig. 1 Qualitative illustration of the bias-variance-tradeoff and its consequence on the choice of model complexity. (Color figure online)

a specific problem is found by a tradeoff between these two extrema and identified by the minimum total prediction error in the middle of Fig. 1. Note that the optimal model complexity does not only depend on the underlying relationship but also on the amount of available training data. In general, using more data points for training leads to less variance of the trained model, which therefore moves the minimum total prediction error to the right, and to higher model complexity in the optimum case [4].

Bishop [4] provides a mathematical description and more in-depth analysis about the bias-variance-tradeoff for the use in pattern recognition and machine learning. Although advanced mathematical understanding of the bias-variance-tradeoff is available, no analysis on draw-in or drawing aid force modeling in deep drawing has been found. In this work, the bias-variance-tradeoff is examined on a deep drawn part. For the modeling, draw-in as well as drawing aid force signals generated by stochastic finite element simulations are used for the evaluation of different modeling approaches. All programming is done in python using scikit-learn 0.24.0 for all machine learning-related tasks. The following questions are answered:

- What does the curve depicted in Fig. 1 applied on draw-ins and spacer forces of a deep drawn part look like in reality?
- How well do neural networks as highly parameterized models perform in sensor modeling compared to linear regression as a low parameterized modeling approach?
- What modeling complexity of the two mentioned approaches leads to the highest model accuracy of draw-ins or drawing aid forces in deep drawing?

2 Approaches Used for Sensor Modeling in This Work

2.1 Unregularized and Regularized Linear Regression

The very basic approach for regression problems is linear regression, representing a linear or nonlinear mapping from the predictor variable X on the target variable y. Such models are linearly dependent on the model coefficients ω. In this case, the model complexity depicted in Fig. 1 can be either controlled by adding a regularization term with an additional model parameter λ to the loss function or by using a preceding feature transformation into higher dimensions. In case of the simultaneous use of the L_1 and the L_2 norm on the model coefficients, elastic-net regression results are obtained, whose loss function for model training is given in Eq. 1, where ω are the model coefficients, λ is the regularization strength, M is the number of model coefficients, and N is the number of data points used for training. This formulation is also used in this work.

$$L(\omega) = \frac{1}{2}\sum_{n=1}^{N}(x_n\omega_n - y_n)^2 + \lambda\left(\frac{1-\alpha}{2}\sum_{m=1}^{M}\omega_m^2 + \alpha\sum_{m=1}^{M}|\omega_m|\right) \tag{1}$$

2.2 *Artificial Neural Networks*

Another approach for the regression problem is the use of artificial neural networks. In its simplest form, the input of the multilayer perceptron X is fully connected to the output y by several hidden layers with a given number of neurons, and the information is only fed in the forward direction. The simple case with three hidden layers and four neurons (circles) in each hidden layer is depicted in Fig. 2. Each neuron contains an activation function which is applied on the input from the previous layer. In the case of neural networks, the model complexity is controlled mainly by the number of hidden layers as well as neurons in each hidden layer. Additionally, model complexity can also be controlled again by a regularization term on the model coefficients or by further methods like drop-out which are not used in this work. As nonlinearity, the ReLu-activation function is consistently used in this work. Goodfellow et al. [5] motivate the use of neural networks in contrast to linear regression models for two reasons: First, whereas approaches like linear regression require the manual definition of a feature map into nonlinear features in the nonlinear case before model fitting, neural nets automatically train the feature map with the model parameters by using different levels of hidden layers. Therefore, no manual decision on the feature mapping has to be made. Second, due to the inherent hierarchical structure, neural nets are also capable of solving problems with hierarchical information structure, for example in computer vision analyzing pixels in an image for detection of edges, then detection of contours, and finally type of objects.

3 Simulation Setup

During data generation, a stochastic finite element simulation is performed on a mini engine hood. The process is a single action drawing process using punch, blank holder, and die, which are depicted in Fig. 3. The tool contains three drawbeads as well as five drawing aids, as illustrated in Fig. 3. The drawing aids are modeled as elastic blocks with a stiffness of 400 kN/mm, allowing a local reduction of the

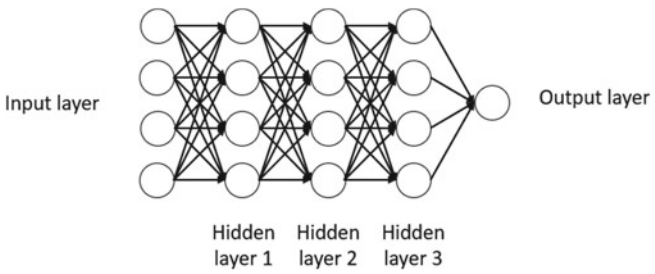

Fig. 2 Architecture of the multilayer perceptron with three hidden layers and four neurons per hidden layer

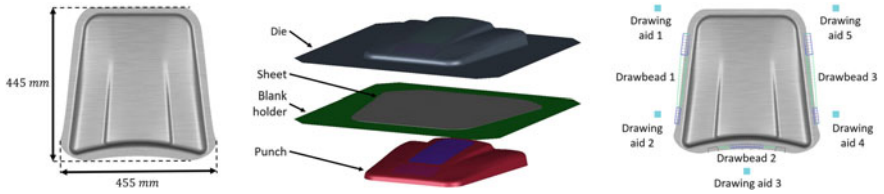

Fig. 3 Setup of the stochastic finite element simulation used in this work. **a** Mini engine hood geometry, **b** Setup of tools in simulation: die, blank holder, sheet and punch, **c** Drawbeads and drawing aid positions relative to the part. (Color figure online)

pressure between the blank holder and the sheet, and thus adjusting the local draw-in. The height of the drawing aids is variable and varied throughout the stochastic finite element simulation as will be shown later. The blank holder force is produced by columns, which allow small tilting angles of the blank holder due to an eccentric pressure distribution between the blank holder and the die. The total blank holder movement from upper to lower dead center is 75 mm. The simulations are performed in AutoForm R8.

3.1 Material Description

The material used for the forming operation is Aluminum EN AW-6016 with a thickness of 1.0 mm. The material data was taken from the material database from AutoForm R8 (6016_T4P) without any modification. The flow behavior is described using a combined approach with Swift [6] and Hockett-Sherby [7]. For the description of the yield locus, the anisotropic formulation according to Barlat and Lian [8] is used. For the yield locus, the exponent $M = 8$ was used.

3.2 Setup of Stochastic Finite Element Simulation

In the finite element simulation, material, tool, and process parameters are varied to account for uncertainties inherent in the deep drawing process. Regarding material parameters, yield stress, tensile strength, and the R-values in all three directions are varied. To reduce the number of independent parameters and thus the number of total simulations, these material parameters are all varied fully correlated. In the tool, the height of all three drawing aids as well as the drawbeads are varied independently. As process parameters, the friction coefficient and the global blank holder force are also varied. Variation in blank thickness is considered too. As a reference, the values of the variation range are chosen experience-based and in a way that results in no defective parts. All varied parameters as well as their nominal value and variation range are given in Table 1. The setup of the simulation leads to 12 independent parameters in

Table 1 Input parameters and range used for the stochastic finite element simulation

Parameter description	Nominal value	Min value	Max value	Correlated with
Friction coefficient μ	0.14	0.09	0.15	–
Blank thickness t_{sheet}	1.00 mm	0.99 mm	1.01 mm	–
R-value R_0	0.64	0.62	0.66	–
R-value R_{45}	0.50	0.48	0.52	R_0
R-value R_{90}	0.71	0.69	0.73	R_0
Yield stress $Rp_{0.2}$	127.4 MPa	117.4 MPa	137.4 MPa	R_0
Tensile strength R_m	241.4 MPa	226.4 MPa	256.4 MPa	R_0
Blank holder force F	690 kN	552 kN	828 kN	–
5 Drawing aid heights (independent)	1.05 mm	1.00 mm	1.15 mm	–
3 Drawbead heights (independent)	6.0 mm	4.5 mm	6.0 mm	–

total. The design of experiments for the stochastic finite element simulation is finally obtained by using Latin hypercube sampling. To make sure a well-grounded dataset is generated for the following experiments, 300 simulations are performed.

3.3 Extraction of Sensor Data

The extracted data from the simulation consists of three parts: First, the independent parameters varied in the design of experiments are stored. Second, the draw-in at the boundary of the blank is extracted for each simulation at 120 locations, uniformly distributed around the part. The draw-in is measured perpendicular to the part boundary as in optical measurement and not in the direction of material flow. To take into account the evolution over time, the draw-in is not only extracted in the bottom dead center but extracted over time in 12 steps at blank holder position 74, 60, 50, 40, 30, 25, 20, 15, 10, 5, 2, and 1 mm before the bottom dead center. An example of such a draw-in signal is given in Fig. 4 on the left side. In addition to

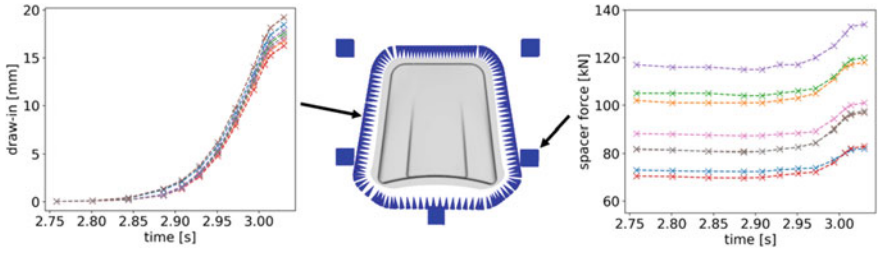

Fig. 4 Example data for draw-in (cones) and spacer (cubes) force signals for one sensor each and seven simulations, evaluated at 12 blank holder positions. (Color figure online)

the draw-in signal, the force in each drawing aid is also used as output. The force signal is not available in the current Version R8 in the GUI, but AutoForm stores the acting force for each drawing aid and each increment in the output file, which can be then read using an external script. The force signal is also extracted at the same blank holder positions as the draw-ins. As an example, a force signal over time is given in Fig. 4 on the right side.

4 Surrogate Modeling of Sensor Signals

For the modeling of the sensor signals obtained in the finite element simulations, the parameters from the design of experiments are used as input and the signal for each sensor as output variable. Independent models are then fitted for each timestep on a training set, whose size in terms of data points is calculated as the training point ratio R_{train} times the total number of simulations. The models are then evaluated on the test set of size $(1 - R_{train})$ times the total number of simulations. For each sensor signal, the evaluation metric is averaged over all 12 timesteps, resulting in one scalar for each sensor describing its modeling accuracy. As an evaluation metric, the R^2 metric is used which describes the proportion of explained variance by the model relative to the total variance in the output data. Before training the models, the datasets are standardized by subtraction of the mean value and division by the standard deviation.

4.1 Surrogate Modeling of Draw-Ins

For the draw-in modeling, the elastic-net is used with preceding feature transformation of first up to sixth order. Four multilayer perceptrons are trained with one hidden layer and one neuron, one hidden layer with 12 neurons (equals number of input parameters), two hidden layers with 12 neurons, and three hidden layers with 12 neurons each. Additionally, a k-nearest-neighbor model is used which simply looks for the nearest point in the train set and predicts its value, assuming k is set to one (only 1 neighbor).

The kNN model is used as a reference since it represents a model that simply memorizes but is inherently not able to learn functional relationships. The results of the draw-in models are illustrated in Fig. 5. The left column contains the results for the elastic-net regression and the right column the results for the MLP; the results are separated for better visibility. For a small dataset for training, for example 30 simulations, the linear elastic-net shows the highest score on the test set. At approximately 60 data points, the elastic-net with quadratic features outperforms the linear. This result is remarkable since the fully quadratic model for a 12-dimensional input contains 92 model coefficients (including intercept), which means that the model coefficients are still not uniquely defined. The standard deviation between the model

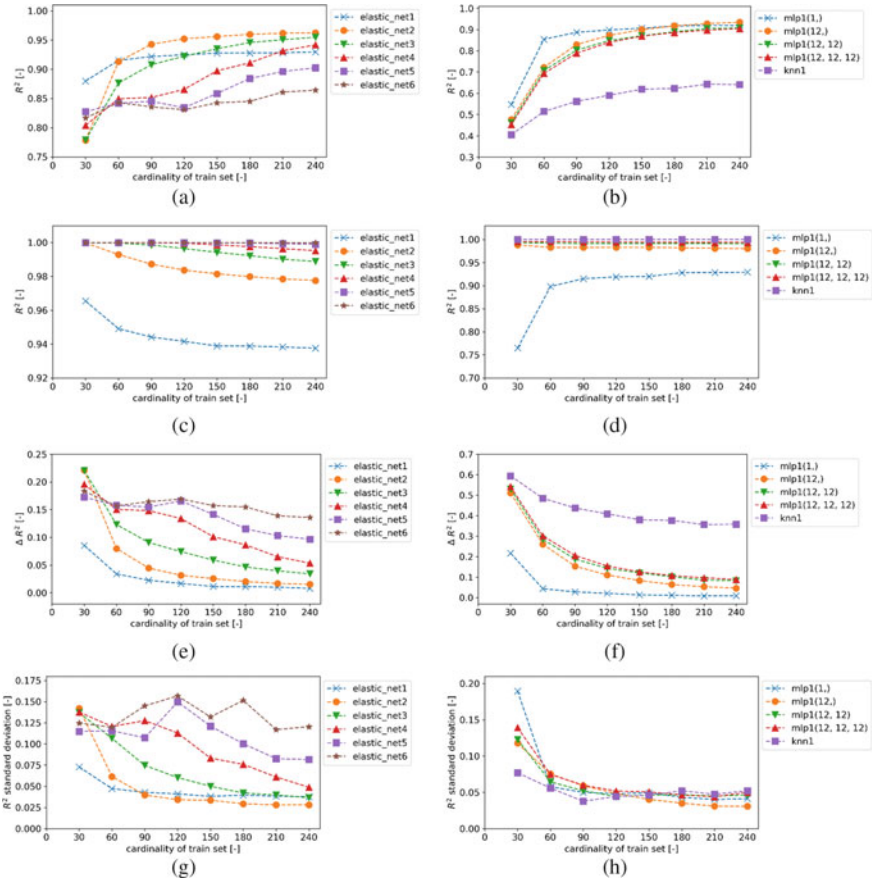

Fig. 5 Evaluation of the modeling results of the draw-in based on the R^2 metric (number in parentheses denotes size of hidden layers of MLP, numbers directly after algorithm name denote order of feature transformation). **a** R^2 on the test set while using elastic-net, **b** R^2 on the test set while using MLP and kNN, **c** R^2 on the training set while using elastic-net, **d** R^2 on the training set while using MLP and kNN, **e** Difference between training and test set for elastic-net, **f** Difference between training and test set for MLP and kNN, **g** Standard dev. of R^2 between draw-ins for elastic-net, **h** Standard dev. of R^2 between draw-ins for MLP and kNN. (Color figure online)

quality of the quadratic model on the bottom left, which also includes the variance of the estimators due to the choice of training points, shows that for 90–120 training points, the variance starts to flatten and remains approximately constant. From this amount of training data, the parameters of the quadratic model are fully defined and lead to the best modeling score from this point. Comparison with higher-order models of the elastic-net shows clear overfitting, due to the low test score (1st row) but high training score (2nd row), thus a high difference between these two which is denoted as bad generalization ability (3rd row) and larger variance as can be seen in the 4th row. On the other side, the high training error on the first-order model

shows clear signs of underfitting, since the model is not capable, in contrast to the quadratic model, of capturing quadratic functional relations as well as interactions between input parameters. All models lead to a higher test score compared to the nearest neighbor method, meaning that learning of the underlying relationships has improved the modeling accuracy.

Since the neural network in the right columns contains much more parameters, the test score is worse (1st row). Note that the version with one hidden layer containing one neuron has a similar structure compared to the linear elastic-net since a multi-dimensional mapping is only done from the input to the hidden layer, leading to a similar result on the test score between these two. The MLP does not significantly benefit by adding more complexity, which leads to overfitting as can be seen by the high training score (2nd row) but low test score (1st row) and therefore bad generalization (3rd row).

4.2 Surrogate Modeling of Drawing Aid Forces

For the modeling of the drawing aid forces, the same modeling approaches are chosen as for the draw-in signals. The result is shown in Fig. 6. High modeling quality is already reached by using elastic-net regression and linear features only. For the linear elastic-net, an almost perfect test score of 0.999 is obtained at 240 data points for training. All elastic-net models show low test error (1st row), similar training error (2nd row) compared to the test error, and therefore good generalization ability (lower values in the 3rd row). Independent of the degree of features, the elastic-net leads to similar prediction accuracy. A comparison of the result of feature transformations from 1st order to 6th order shows a monotonically decreasing model quality if only 30 data points are used for training. Again, the most complex MLPs are overfitting, which results in a low test score but high training score. As can be seen on the data in the right column, the modeling of spacer forces does not benefit from the use of more complex models like the neural network with multiple hidden layers neither.

An explanation for this result can be found by studying the influence of the process parameters on the resulting drawing aid forces by analyzing the force distribution between the blank holder and the die. The most influential quantity on the drawing aid force is the height of the same drawing aid. The secondary influential quantities are the blank holder force, which on increase will increase the drawing aid forces globally; the sheet thickness on reduction increases the drawing aid forces; and the drawbead height on reduction results in less drawbead uplift force, thus shifting more force to the drawing aids. Since the drawing aid height is by far the most influential quantity and the drawing aid is modeled purely elastic with constant stiffness, it results in almost linear behavior. The same also holds for the blank thickness since a reduction of blank thickness has a comparable effect with the increase of the drawing aid height.

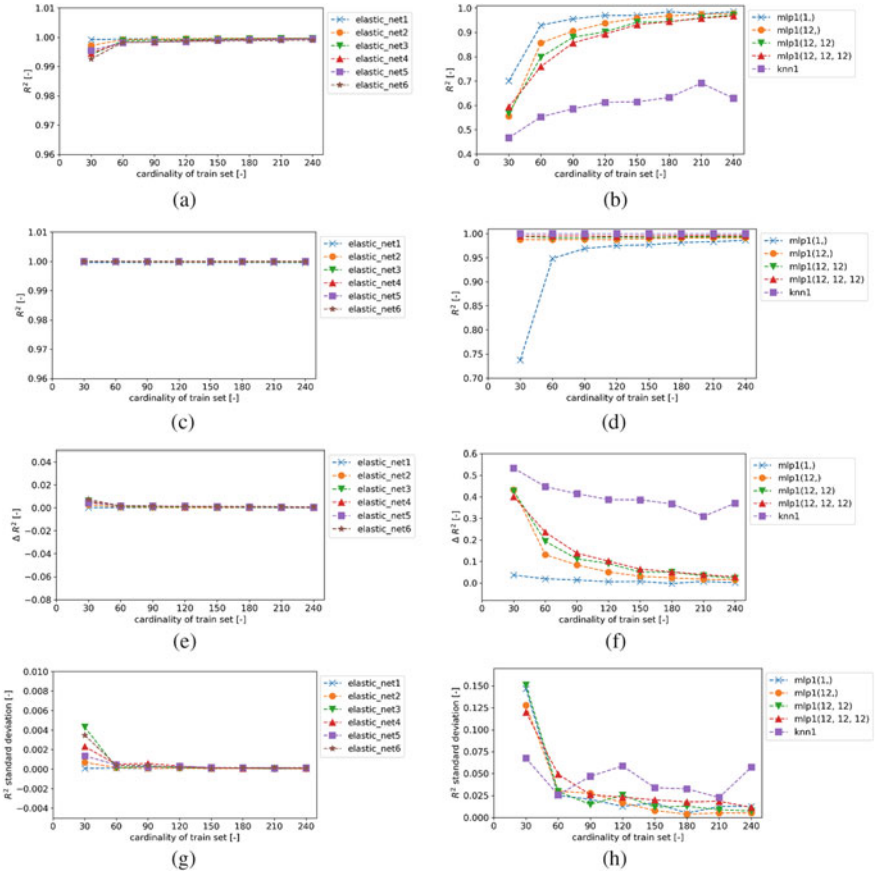

Fig. 6 Evaluation of the modeling results of the drawing aid forces based on the R^2 metric (number in parentheses denote size of hidden layers of MLP, numbers directly after algorithm name denote order of feature transformation). **a** R^2 on the test set while using elastic-net, **b** R^2 on the test set while using MLP and kNN, **c** R^2 on the training set while using elastic-net, **d** R^2 on the training set while using MLP and kNN, **e** Difference between training and test set for elastic-net, **f** Difference between training and test set for MLP and kNN, **g** Standard dev. of R^2 between draw-ins for elastic-net, **h** Standard dev. of R^2 between draw-ins for MLP and kNN. (Color figure online)

4.3 Comparison of Training Duration

Another point of interest during model selection is the time required for training. Figure 7 contains the training times for one sensor signal for the models used above, which is calculated as the average over all sensors (draw-in and drawing aid force). Since each signal contains 12 timesteps, in fact 12 independent regression models are trained for each sensor. Each duration that is mentioned thus corresponds to fitting 12 models. The kNN algorithm needs only a minimum amount of time since it does not perform any modeling steps. With an average of 0.008 s, the elastic-net with

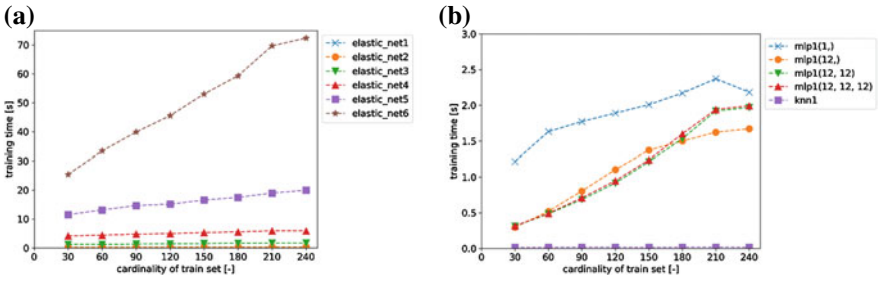

Fig. 7 Comparison of training time for the models used. **a** Training time for elastic-net estimators, **b** Training time for kNN and MLP estimators. (Color figure online)

linear features is the fastest model, followed by the elastic-net with second-order features (0.29 s). All MLPs except the simplest require around 1.1 s on average and are already faster than the elastic-net with third-order features (1.5 s). Figure 7 also shows a dramatic increase in training time if high feature orders are used, especially if the training set gets larger, which can make the use of these models impractical. Analysis of the training time for the $mlp1(1,)$ shows that the model requires much more iterations during training, leading to an increased training time although the number of parameters is significantly smaller compared to the other MLPs.

4.4 Visualization of Model Quality Dependent on Model Complexity

In the introduction, the bias-variance-tradeoff was illustrated in a qualitative manner. The data gained in this study allows determining the discrete values for the modeling quality dependent on model complexity and expressing the relationship, as shown in Fig. 1, with real data in a quantitative manner. The analysis is done on the elastic-net of the draw-in modeling. Since the y-axis in Fig. 1 is an error-like quantity (the lower the better), $\left(1 - R^2\right)$ is used on the y-axis which leads to the same qualitative behavior. The result is shown in Fig. 8. The lowest error corresponds to second-order features, except for the blue curve representing the use of only 30 training points. Note that the result of only 30 data points for training leads to only poor models; therefore, it is of very limited expressiveness from a statistical point of view.

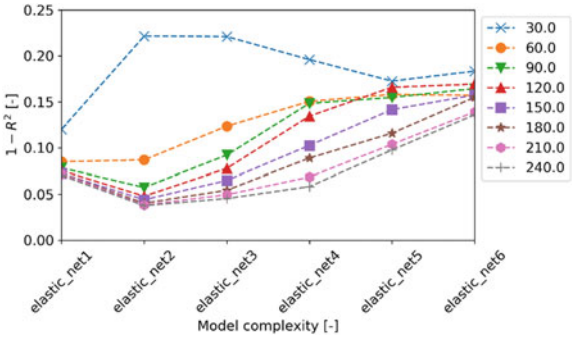

Fig. 8 Model error dependent on its complexity (draw-in data). (Color figure online)

5 Conclusion

In this work, the bias-variance-tradeoff in modeling of draw-in as well as drawing aid force signals was analyzed in a quantitative manner on a deep drawn part. The following conclusions are drawn:

- Given the range of number of training samples used to train surrogate models, the quadratic model showed the highest modeling score if the ratio between number of training points and model coefficients exceeds 0.62 for the draw-in signal.
- Linear models are in general not sufficient to describe the draw-in accurately. The only exception where linear models perform best is the case if only a very small amount of training data is available.
- For the modeling of drawing aid forces on the part examined above and with the given amount of training data, linear models have proven to be sufficient, independent of the ratio of training data compared to model coefficients.
- The result shows no evidence that the modeling quality increases by using either features of higher order than 2 or more complex approaches like neural networks, which is true for draw-ins as well as drawing aid forces. It cannot be ruled out that these more complex models perform better in a more complex case, for example if splits or wrinkles occur.

In summary, the result from this study shows that linear regression approaches provide a powerful tool for surrogate modeling in practical use in deep drawing. The linear regression models lead to high model quality combined with short training periods. Additionally, it is also worth mentioning that the simple regression models also allow the interpretation of model coefficients, which is not possible anymore for more complex models like MLPs with multiple hidden layers.

Development of Mechanical Cards for Finite Element Analysis of Mild Steels by Parameter Optimization

M. Emin Tamer, Eda Çapa Kızıltaş, and B. Celal Seyalıoğlu

Abstract Material card generation has a significant role for characterizing the mechanical behaviour to estimate accurate deformation in finite element analysis. Regarding this, the most commonly used characterization test for sheet metals is the uniaxial tension test due to its simplicity and well-defined testing standards. The mechanical properties such as ultimate tensile strength can be determined by tensile tests. However, the strain level can reach to a specific value which is low as compared to strain levels reached in cold forming operations. In this paper, the experimental data is optimized with finite element analysis and a good consistency between experimental and simulation results is achieved. Parameter optimization is used as a guiding tool to extend strain levels according to 3 mechanical equations: Swift, Hockett-Sherby, and Combined material model. The user interface is designed with the detailed graphs and optimized parameters with the help of MATLAB tool.

Keywords Material cards · Optimization · Mechanical characterization

1 Introduction

Nowadays, finite element (FE) modelling in the automotive industry has a potent influence on sheet metal forming. Numerical simulations allow the reduction of expensive and time-consuming trials, before mass production of a stamping component on press line. Furthermore, finite element analysis is used for optimizing the design of sheet metal forming processes. The robustness of the analysis has been developed recently to integrate process deviations and material disperse in the analysis [1]. The significant point in numerical simulations is proper mechanical characterization. The predictive capabilities of simulations, especially in deep drawing process are entirely prompted by the quality of the material characterization. The researcher can analyze the problems due to the influence of characterization and

improve the reliability of the results with the help of optimization of the mechanical parameters [2].

Mechanical characterization tests are vital requirement for numerical simulations to obtain efficient deformation results and process design. There are several studies to model the constitutive equations and characterization parameters. The effect of material property is accurately modelled when the variations and correlations in the input parameters are represented with values close to the physically observed ones [3, 4]. The Hill quadratic function is corresponded with strain ratios commonly used in industrial applications, on the contrary, the yield function doesn't describe material anisotropy in a wide perspective [5, 6]. The reliability of the numerical analysis is limited since the engineers use incomplete material knowledge in FE analysis. In the literature, there are also sufficiently flexible non-quadratic yield functions [7–9]. Moreover, new researches are performed to improve the flexibility of the yield functions [10–12].

In this study, the mechanical characterization test datum was evaluated and optimized with finite element analysis by a new algorithm with the help of MATLAB tool. The usage of two material models for the calculation of the flow curves and the optimization of the parameters with tensile test simulation is the new way explained in this study. Regarding this, tensile and compression tests are performed, and this novel algorithm processed those data using three material equations: Swift, Hockett-Sherby, and Combined material model. This study depends on quick data processing, generally when raw data obtained there several methods to process and prepare for simulations. In the first part of this study, the raw data were measured from mechanical tests and the second part includes the optimization with finite element analysis program. The evaluation of finite element analysis is done at Ls-Dyna environment (Fig. 1a). For the validation of the calculated material model parameters, tensile test simulation was performed, and force-displacement data is compared with experimental results. According to ASTM-E8 standard, a tensile test specimen was used for the analysis. Before the simulation, the new algorithm processes and evaluates

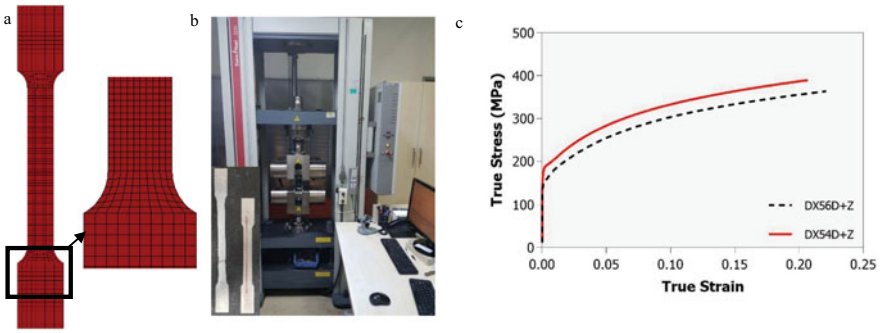

Fig. 1 **a** The mesh of tensile specimen having 2 mm of element size at gauge area, **b** Tensile testing device in Borcelik and test specimen before and after deformation, and **c** Average true stress and true strain curves. (Color figure online)

the data and creates flow curve. Afterwards, the novel algorithm exports the material card including flow curve and 3 material equation parameters. After the several tensile test simulations, the algorithm prepares and exports final material card for sheet metal forming processes. The validation is done with the real measurement's force-displacement curve.

2 Experimental Study

To evaluate the mechanical tests DX54D + Z and DX56D + Z tensile specimens were performed. The DX54D + Z and DX56D + Z material, continuous annealed and hot dip galvanized IF steels, were chosen owing to its wide application range in automotive industry. The nominal thickness of the sheet materials was 0.7 mm, in contrast the individually measured thicknesses were in the range of 0.68–0.72 mm for DX54D + Z and 0.69 - 0.71 mm for DX56D + Z, respectively. The whole tests were performed with three repetitions in each direction (rolling, diagonal, and transverse) with Euro norm test speed. The average values with standard deviation of the test results in three directions are demonstrated in Table 1. Displacement, force, true strain, and stress values were exported form ZwickRoell TestXpert software and used in the algorithm as input values. The average true stress versus true strain curves and the test setup is shown in Fig. 1b, c.

To obtain biaxial flow curve and anisotropy the stack compression and compression tests were executed in this study. The stack compression test was first proposed by Pawelski [13], in which an alternative experiment for acquiring flow curve in a wide range of strain values due to its deformation state. This method is not standardized and different researches are still being made [14, 15]. The stack compression test made use of multi-layer cylinder like specimens (Fig. 2) that were assembled by gathering up circular discs cut from the same material by electric discharge machine. The preparation of the circular flat specimens was critical for ensuring that all the layers were concentric and had identical cross-sectional area provided with frictionless conditions along the contact interface. The tests were performed as 3 repetitions for each sample including 5 circular discs each. The tests are conducted at ZwickRoell 250 kN tension compression testing device with the speed of 2 mm/min.

Table 1 The average mechanical properties of DX54D + Z and DX56D + Z

Material	t (mm)	Yield stress(MPa)	Tensile stress (MPa)	A_g (%)	A_{80} (%)	n	r
DX54D + Z	0.70 ± 0.02	184.7 ± 3	316 ± 5.3	18.6 ± 0.8	39 ± 2.2	0.22	2.1 ± 0.017

3 Material Optimization Interface

Based on material equations, a new interface for quick material card generation has been developed by authors that consists of three major modules:

- Displays tensile test results in three directions including yield stress, strain hardening coefficient, and anisotropy values.
- Extends and displays three material equation graphs up to 1 strain value.
- The comparison of force-displacement graphs and combined model's material equation parameters.

The algorithm involves two major parts; the first part evaluates the raw material data and calculates flow curves according to Swift, Hockett-Sherby, and Combined model (consists of Swift and Hockett-Sherby material equations with a coefficient) up to 1 strain value. The second part optimizes the equation parameters executing the series of tensile test simulation. The structure of the new interface is illustrated

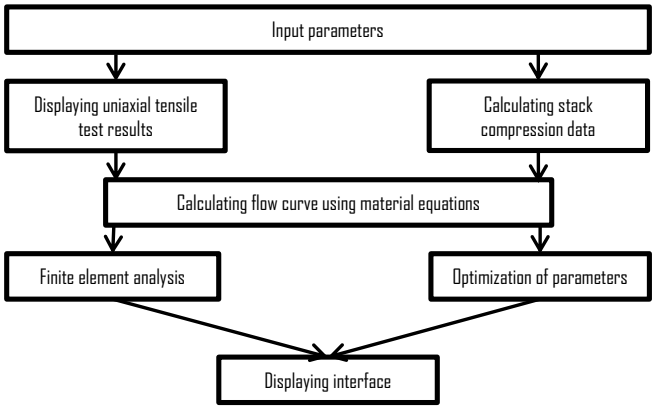

Fig. 3 Structure of the new interface

in Fig. 3, where the structure presents the process of the material card generating interface, as well as their interaction.

The tensile and stack compression test datum from ZwickRoell Z250 kN are exported which involves true stress and true strain data. Then the algorithm imports this raw data and evaluates by using strain hardening material equations. The unknown coefficients are calculated according to the true stress–true strain curve by curve fitting methods using MATLAB. In curve fitting method, it was implemented linear regression type curve fitting due to convenience with the objective functions. The fitted curve is adapted according to minimum error target with least square and gradient descent approach. In this method, R-Square values are aimed to be over 0.9 for appropriate equation fitting. The unknown parameters stated in the paper are related with extended true stress-strain curve. The aim is to find most convenient (Swift, Hockett-Sherby, and Combined material equations) parameters for best fitting equation according to true stress-strain curve. Therefore, data set is extended both true strain and true stress pairs. The true strain points were configured as training set and applied curve fitting algorithm through real output true stress. The linear regression type curve fitting was implemented due to suitability with those equations mentioned above. The fitted curve is adapted according to minimum error target with least square and gradient descent approach. The mentioned minimum error is based on sum of the square of errors; which is the objective function for optimization, that is, sum of difference between calculated stress and observed stress. The gradient descent approach is followed while updating parameters in each iteration by integrating error according to strain values. After an approximate result, the true stress–strain curves were extended to 1 strain value. For the sake of user experience, both experimental and calculated curves were overlapped through graph. After obtaining extended flow curves according to the all strain hardening model, the optimization was held for combined model. The other material equations can be preferable, however, the combined model is the best fitted equation for optimization with its parameter variety. Optimization part was run in Ls-Dyna software to decide most appropriate parameter combinations by reducing overall difference in force-displacement outcomes of numerical and experimental results. K (Strength coefficient), SS (Saturation stress), a (Strength hardening law exponent), and p (Strength hardening law exponent) are the parameters that are iteratively changed through this new algorithm.

The equations used in this method are given below:

Swift equation: $\sigma = K(\varepsilon_0 + \varepsilon)^n$
Hockett-Sherby Equation:$\sigma = SS - (SS - \sigma_0) * e^{-a\varepsilon^p}$
Combined Equation: $\sigma = (1-\alpha)\left[K(\varepsilon_0 + \varepsilon)^n\right] + \alpha[S - (SS - \sigma_0) * e^{-a\varepsilon^p}]$

The basis of iterations depends on evaluated values in the beginning of the algorithm. These parameters were chosen taking the following bases into account:

– Decreasing the running time due to iterations.
– The effects towards the equations.

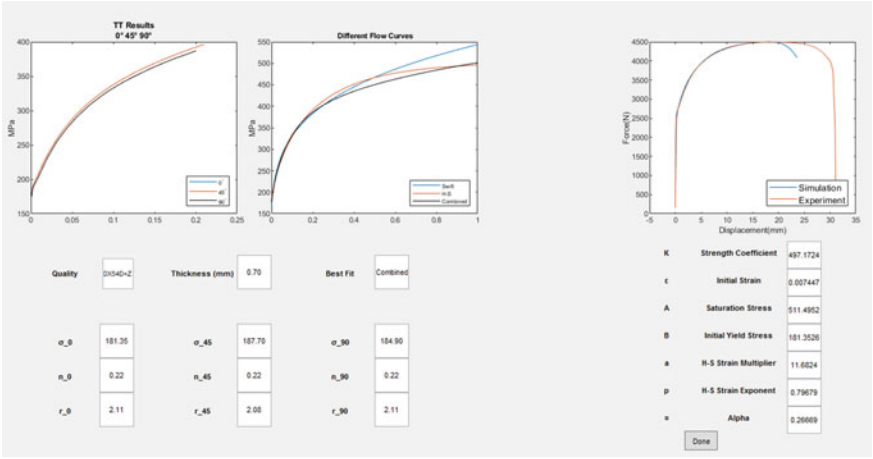

Fig. 4 The interface of the material card generating algorithm. (Color figure online)

To sum up, the final numerical and experimental force-displacement graphs that optimized parameters are published in interface result window (Fig. 4).

In Fig. 4, the different flow curves with different material models are obtained only in rolling direction (00-direction). Moreover, at the right-hand side of the figure, the force-displacement graph includes 0 directional experimental and finite element analysis results.

To compare the results of new algorithm and conventional material model, a real car body component was analyzed for the validation. A rear side of inner door panel has been used for the case study (Fig. 5). The deep drawing analyses were performed in Autoform environment.

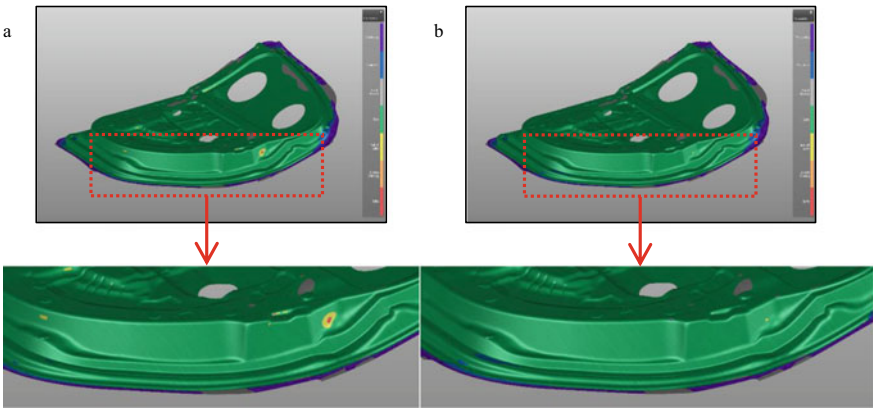

Fig. 5 The comparison of formability results between the new algorithm and conventional material model. (Color figure online)

The model illustrated in Fig. 5a was analyzed by BBC yield surface and non-optimized Swift and Hockett-Sherby material model. As can be seen in the figure, there are some tearing tendencies and critical regions at certain locations. On the contrary, In Fig. 5b, the potential tearing regions were disappeared. As mentioned above, the new algorithm calculates the unknown parameters using curve fitting method in MATLAB. Therefore, the simulation with new material card including optimized parameters improved the formability.

4 Conclusion

In this paper, a new algorithm for material characterization with optimizing the mechanical parameters of material equations was presented. Despite limited levels in flow curve measuring tests, higher trusted values are achieved with material equations by this new interface. Material card generation has a major role for characterizing the mechanical behaviour to obtain reliable simulation results. The calculated material data is used in series of tensile test simulation. The algorithm runs up to the force-displacement data of experimental and simulation results are convenient, in other words; with the optimization of the material parameters such as strength coefficient, strain law exponents (a and p), and saturation stress, material card based on extended virtual data has converged to the real-life measurement. In conclusion, the algorithm can be used for improving the reliability of the finite element analysis of sheet metal forming operations.

5 Future Work

Future investigations are necessary to validate these kinds of conclusions that can be drawn from this study. Future research should assist the investigation of the effects on the results upon the application of new steel grades. Also, this new interface should be developed taking the effects of other material equations into account and by increasing the iterations on parameter optimization. It appears from the current work that further attempts will be beneficial to retest the reliability of numerical simulations in sheet metal forming analysis.

Part IX
Characterization of Plasticity and Ductile Fracture of Metals under Proportional and Non-proportional Loading

Cyclic Loading Tests Based on the In-Plane Torsion Test for Sheet Metal

Chong Zhang, Yanshan Lou, Till Clausmeyer, and A. Erman Tekkaya

Abstract In-plane torsion test has attracted a lot of attention recently. As a novel shear test, it can avoid unwanted reaction torque compared with the traditional in-plane shear test. The in-plane torsion test with circular groove specimens can avoid early fracture at the free edges, and thus achieve actual fracture strain under pure shear state because it has no free boundaries. In this study, digital image correlation is implemented to measure the torsion angle to obtain the precise torque-torsion angle curves. For specimens with slits, strain hardening is calibrated by inverse engineering approach. The strain path at the center of the shear zone during the torsion test is observed to be very close to a pure simple shear state. Cyclic shear loading tests are carried out for twin bridge shear specimen. The combined isotropic-nonlinear kinematic hardening model, Yoshida–Uemori two-surface model, and homogeneous anisotropic hardening model are evaluated to characterize the cyclic loading behaviors.

Keywords Bauschinger effect · Cyclic shear loading · In-plane torsion test · Kinematic hardening · Distorted hardening

1 Introduction

A proper material model considering the forward–reverse loading behavior has become necessary particularly for the springback prediction of materials like high strength steels and aluminum alloys. There are two main types of phenomenological models to model the forward–reverse loading behavior which including the bauschinger effect, transient behavior, permanent softening, and unloading modulus. One is the well-accepted kinematic hardening models with back-stress such as

nonlinear kinematic (NLK) hardening approaches [1–3], Yoshida–Uemori (YU) model, including the yield surface and bounding surface [4–6]. The other alternative to account for the forward–reverse loading behavior is the distortional plasticity models without considering the back-stress such as homogeneous anisotropic hardening (HAH) model [7, 8].

Two main types of testing procedure are widely accepted to evaluate the forward–reverse loading behavior, including the widely used in-plane tension–compression [5, 9, 10], and in-plane forward–reverse simple shear tests [11–13]. The in-plane tension–compression tests need the clamping tools to avoid buckling, which occurs during the compressive process. However, the clamping tools make strain measurement difficult by digital image correlation (DIC) and need extra efforts to eliminate the influence of friction between the specimen and clamping tools. The in-plane forward–reverse simple shear test provides a large strain range without clamping tools to prevent the buckling occurs. The strain distribution fields can be measured during the forward–reverse loading processes by DIC. However, inhomogeneous strain deformation at the edge of shear zone make it difficult to calculate the forward–reverse stress–strain data analytically. The inverse method is recommended to eliminate errors caused by inhomogeneous strain deformation. There is another novel shear test: in-plane torsion test has attracted a lot of attention recently [12–15]. It can avoid unwanted reaction torque compared with the traditional in-plane shear test including twin bridge shear specimen, stress-adjusted groove specimen, etc. The in-plane torsion test with stress-adjusted groove specimen can achieve continuous strain measurement in the stress-adjusted groove. Therefore, the stress–strain data can be calculated analytically as a standardized specimen. Zang et al. also proposed a new approach to calibrate the hardening parameters inversely from the springback profiles of three-point bending tests with pre-strained sheets [16].

In this study, the cyclic loading tests of twin bridge shear specimen based on the in-plane torsion test are conducted for an AA5182 aluminum alloy. The combined isotropic-nonlinear kinematic hardening (IH + NLK) model, YU, and HAH models are evaluated to characterize the cyclic loading behavior.

2 Phenomenological Models

The anisotropic study for the AA5182 aluminum alloy is not involved in this article. Yld2000-2d yield function is employed with its isotropic form for body-centered cubic (BCC) material. Hardening models for cyclic loading behavior evaluation are employed as below.

2.1 Isotropic Hardening (IH) Model

Voce hardening law is employed in this study to describe the isotropic hardening behavior of AA5182 as below

$$\tilde{\sigma} = A - (A - B)exp\left(-C\overline{\varepsilon}^{p}\right) \tag{1}$$

where $\tilde{\sigma}$ is the effective stress, $\overline{\varepsilon}^{p}$ is the equivalent plastic strain, and A, B, and C are parameters.

2.2 Combined Isotropic-Nonlinear Kinematic Hardening Model

The IH+NLK model is a mixed hardening rule as a superposition of nonlinear isotropic and kinematic hardening.

$$f = \phi(\boldsymbol{S} - \boldsymbol{\alpha}) - R - \sigma_0 = 0 \tag{2}$$

where $\boldsymbol{S}$ is stress deviator tensor, $\boldsymbol{\alpha}$ is back-stress, σ_0 is initial yield stress, and R is the isotropic part of the hardening. R enlarges with the increment of effective plastic strain dp as

$$dR = b(Q - R)dp \tag{3}$$

where b and Q are parameters of isotropic hardening part.

Several back-stresses are developed as below

$$\boldsymbol{\alpha} = \sum_{m=1}^{M} \boldsymbol{\alpha}^{(m)} \tag{4}$$

$$d\boldsymbol{\alpha}^{(m)} = \frac{2}{3}c^{(m)}d\boldsymbol{\varepsilon}^{\boldsymbol{p}} - \gamma^{(m)}\boldsymbol{\alpha}^{(m)}dp \tag{5}$$

where $c^{(m)}$ and $\gamma^{(m)}$ are parameters of nonlinear kinematic hardening part.

2.3 Yoshida-Uemori (YU) Model

YU model [4] belongs two-surface model which including the yield surface f and bounding surface F as below

$$f = \phi(\boldsymbol{S} - \boldsymbol{\alpha}) - \sigma_0 = 0 \tag{6}$$

$$F = \phi(\boldsymbol{S} - \boldsymbol{\beta}) - R - B = 0 \tag{7}$$

where $\boldsymbol{\beta}$ denotes the center of the bounding surface, and B and R are its initial size and isotropic hardening. Back-stress $\boldsymbol{\alpha}$ consists of two components as

$$\boldsymbol{\alpha} = \boldsymbol{\alpha}_* + \boldsymbol{\beta} \tag{8}$$

where $\boldsymbol{\alpha}_*$ is the relative motion of the yield surface with respect to the bounding surface F.

$$\boldsymbol{\alpha}_* = c(\frac{a}{\sigma_0}(\boldsymbol{S} - \boldsymbol{\alpha}) - \sqrt{\frac{a}{\|\boldsymbol{\alpha}_*\|}}\boldsymbol{\alpha}_*)\dot{p} \tag{9}$$

where c is the parameters, $\dot{p}$ is the effective plastic strain rate, and a is the difference between the size of bounding surface and yield surface.

$$\dot{p} = \sqrt{\frac{2}{3}\left\|\varepsilon^{\dot{p}}\right\|} \tag{10}$$

$$a = B + R - \sigma_0 \tag{11}$$

$$\dot{R} = m(R_{sat} - R)\dot{p} \tag{12}$$

where B and R_{sat} are parameters.

Kinematic hardening $\boldsymbol{\beta}$ for the bounding surface F is developed as

$$\dot{\boldsymbol{\beta}} = m(\frac{b}{Y}(\boldsymbol{S} - \boldsymbol{\alpha}) - \boldsymbol{\beta})\dot{p} \tag{13}$$

Since the work hardening stagnation is not exhibited for the studied material, the surface g to modify the evolution of the bounding surface F is not presented in this study.

YU model also considers the variable Young's modulus and as a function of the accumulated plastic strain p

$$E = E_0 - (E_0 - E_a)(1 - e^{-\xi p}) \tag{14}$$

where E_0 and E_a are the values of Young's modulus for initial and infinitely large pre-strained material, and ξ is a material parameter.

2.4 Homogeneous Anisotropic Hardening (HAH) Model

Barlat et al. proposed an approach without considering the back-stress which is called homogeneous yield function-based anisotropic hardening model. In this model, the yield surface does not translate in stress space, but its shape distorted. The original HAH model [7] is defined as

$$\begin{aligned}\phi(\boldsymbol{s}) =&(\phi^q + \phi_h^q)^{\frac{1}{q}} \\ =& (\phi^q(\boldsymbol{s}) + f_1^q \left|\widehat{\boldsymbol{h}}^{\boldsymbol{s}} : \boldsymbol{s} - \left|\widehat{\boldsymbol{h}}^{\boldsymbol{s}} : \boldsymbol{s}\right|\right|^q + f_2^q \left|\widehat{\boldsymbol{h}}^{\boldsymbol{s}} : \boldsymbol{s} + \left|\widehat{\boldsymbol{h}}^{\boldsymbol{s}} : \boldsymbol{s}\right|\right|^q)^{\frac{1}{q}} = \tilde{\sigma}(\overline{\varepsilon}^p)\end{aligned} \tag{15}$$

where $\phi^q(\boldsymbol{s})$ is the component of the stable yield function, ϕ_h^q is the fluctuating component to controls the distortion of yield surface for the prediction of Bauschinger effect. q is a constant, f_1 and f_2 are state variables, and $\widehat{\boldsymbol{h}}^{\boldsymbol{s}}$ is the normalized microstructure deviator.

$$\widehat{h}_{ij}^s = \frac{h_{ij}^s}{\sqrt{\frac{8}{3} h_{kl}^s h_{kl}^s}} \tag{16}$$

The state variables f_1 and f_2 can be expressed as a function of other variables g_1 and g_2

$$f_1 = (g_1^{-q} - 1)^{\frac{1}{q}} \text{and} f_2 = (g_2^{-q} - 1)^{\frac{1}{q}} \tag{17}$$

.

When plastic deformation occurs, the evolution laws for the state variables g_1 and g_2 are detailed in [7].

3 Experiments

Cyclic twin bridge shear tests are conducted based on the in-plane torsion test as illustrated in Fig. 1. The rotation speed is set to 0.043°/s which results in a quasi-static strain rate of about 0.005 s^{-1} on the center of shear zone. The shear anisotropy is not studied in this paper and specimens are tested along the rolling direction.

One forward–reverse shear test results with three different pre-strain are conducted as show in Fig. 2. When the torsion angle reaches 0.5°, 1°, and 1.5° degrees, respectively, the reversal begins until failure. The equivalent mises strain along the transverse section cut at different torsion angle is plotted in Fig. 1b, which indicate that 0.5°, 1°, and1.5° correspond to a pre-strain of 0.05, 0.1, and 0.15, respectively. Cyclic forward–reverse shear tests also are conducted. Figure 3 shows the torsion angle-time curves during cyclic shear test. The angle is measured by DIC and the slope of the angle vs. time is about 0.04°/s, which is slightly lower than the control speed. The DIC measurement method for torsion angle is recommended because it calculates torsion angles based on the speckle pattern on the sheet surface. Therefore, the measurement error caused by transmission clearance of the transmission system and elastic deformation of the tool can be avoided.

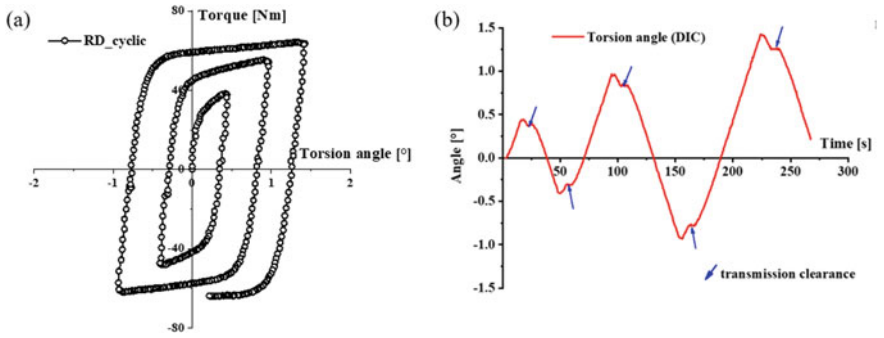

Fig. 3 Cyclic forward–reverse shear test results: **a** torque–angle curves; **b** torsion angle versus time curves. (Color figure online)

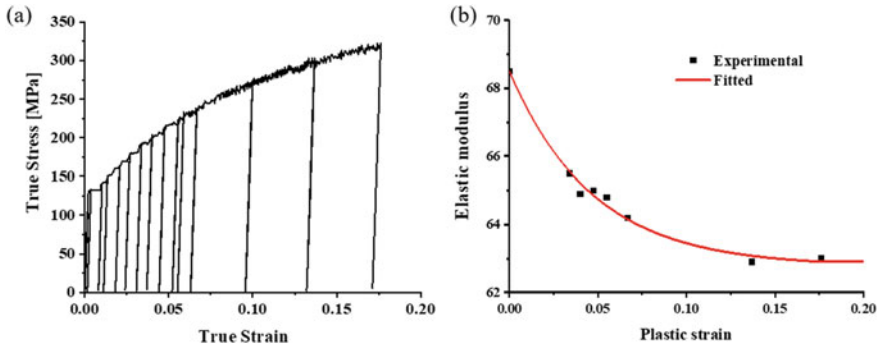

Fig. 4 Cyclic loading–unloading uniaxial tensile tests: **a** true stress versus true strain curves; **b** unloading modulus versus plastic strain curves. (Color figure online)

Cyclic loading–unloading uniaxial tensile tests are also conducted to obtain the unloading modulus under different plastic strain as show in Fig. 4 and the data are fitted according to Eq. (14).

4 Calibration and Results

Since the strain distribution on the shear zone is not uniform as mentioned in Sect. 3. The cyclic shear stress–strain curves cannot be calculated analytically. The inverse engineering method is recommended to calibrate the constitutive models by conducting the reliable numerical simulation. Schematic of the inverse engineering calibration method for twin bridge shear test is shown in Fig. 5. The difference $Total_error$ between the simulated torque-torsion angle curves and experimental data is taken as objective function to minimize as Eq. (18). Optimized model parameters are finally determined through multiple iterations as shown in Table 1.

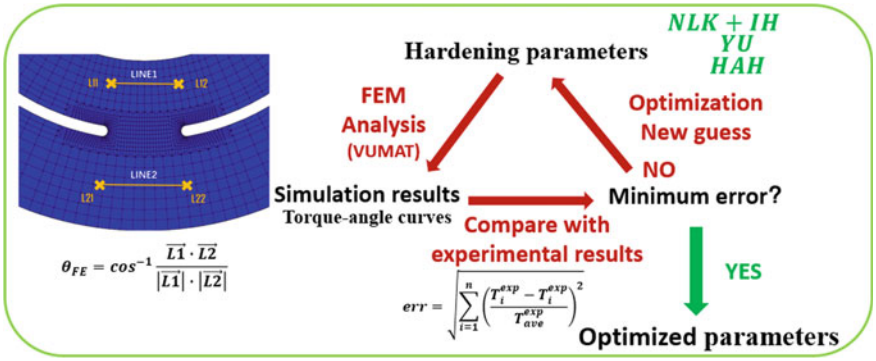

Fig. 5 Schematic of the inverse engineering calibration for twin bridge shear test. (Color figure online)

$$Total_error = {err_m}^{0.5deg} + {err_m}^{1.0deg} + {err_m}^{1.5deg} \tag{18}$$

$$err_m = \sqrt{\sum_{i=1}^{n} \left(\frac{T_i^{exp} - T_i^{num})}{T_{ave}^{exp}} \right)^2} \tag{19}$$

where n is the number of samples, T_i^{exp} and T_i^{num} are the experimental and numerical simulated torque values corresponding to the i sample, and T_{ave}^{exp} is the average torque values of the experimental torque-torsion angle curves.

The predicted torque–angle curves are compared with the experiments for one forward–reverse shear tests in Fig. 6. It can be seen that, when compared with the IH model, the other three models consider the bauschinger effect can better simulate the cyclic loading behavior of materials. The comparison of $Total_error$ shows that HAH and YU models perform better than the NLK + IH model which cannot accurately predict the "re-yielding" and transient behavior of the material. For cyclic forward–reverse shear tests, predicted torque–angle curves are consistent with the experimental data until the final third reversal. The transient behavior and permanent softening are not correctly predicted by all models. That's probably because the calibration procedure is based on the one forward–reverse tests, but the cyclic forward–reverse experimental data are not included (Fig. 7).

5 Conclusions

Cyclic shear tests are completed based on the twin bridge shear tests for an aluminum alloy. The inverse engineering approach is recommended to calibrate the hardening models by conducting multiple simulations. After multiple iterations, the difference between the predicted curves and experimental results are finally minimized. The

calibrated results show that models considering the kinematic hardening or distorted hardening can better describe the cyclic loading behavior than isotropic hardening. HAH model and YU model perform better than the NLK + IH model. For cyclic forward–reverse shear tests, all models cannot predict the transient behavior and

permanent softening correctly about the final third reversal. The cyclic forward–reverse experimental data must be included in calibration procedure.

Plastic and Fracture Characteristics of WE43 Mg Alloy Under Complex Stress States

Pengfei Wu, Chong Zhang, Yanshan Lou, Qiang Chen, and Haiqing Ning

Abstract This paper investigates the deformation behavior and fracture characteristics of WE43 Mg alloy under various stress states, including tension, compression, and shear. The digital image correlation technique is adopted to obtain highly accurate experimental data and stress–strain curve. The result indicates that the plastic deformation behavior under different stress states has a great difference and fracture already obviously occurs before necking. After calibrating the material constants of yield function and hardening equation, numerical and experimental result are compared. The result shows that the prediction accuracy of FE is very high. The fracture strain under different loading states is ensured through a hybrid experimental-numerical method. The fracture locus is constructed based on DF2016 criterion and the predicted fracture strain is compared with the experimental result. The result reveals that DF2016 ductile fracture criterion can correctly predict the fracture limit strain under various stress states.

Keywords Deformation behavior · Hybrid experimental-numerical method · Fracture characterization · Various loading states

1 Introduction

Magnesium (Mg) alloys are applied in the industry of transportation, chemistry, aerospace, and medicine due to their high strength-to-density ratio, enhanced specific stiffness, and excellent process property [1, 2]. However, as a hexagonal close-packed metal, the deformation mechanism during plastic flow is very complex due to a variety of slip systems and twinning modes, resulting in the tension–compression

asymmetry [3–6]. In addition, the forming capacity of Mg alloys is poor, which limits its application [7]. For the purpose of overcoming these disadvantages, an alloying method, namely adding rare earth (RE) elements to Mg crystal, becomes one of the effective ways [8]. As one of Mg-RE system, WE43 alloy has outstanding strength and plasticity at room temperature [9].

The paper aims to characterize the plastic and fracture behavior of WE43 alloy. Mechanical experiments under different stress states are carried out including tension, compression, and shear. The plastic flow is simulated using Drucker yield function and Swift-Voce hardening equation. Ductile fracture behavior is characterized through DF2016 criterion. The numerical result is compared with the experimental data to verify the accuracy of established model on the plastic flow and fracture behavior of WE43 alloy.

2 Experiment

The chemical composition of WE43 alloy is shown in Table 1, and five types of specimens are manufactured along rolling direction (RD) of raw material with the structure illustrated in Fig. 1. These specimens include uniaxial tension (UT), uniaxial compression (UC), plane strain tension (PT), plane strain compression (PC), and in-plane torsion for shear (TS). All experiments are conducted in 100kN INSTRON

Table 1 Chemical composition of WE43 alloy material (wt%)

Y	Nd	Ce	La	Zr	Si	Fe	Cu	Ni	Mg
3.7 ~ 4.3	2.4 ~ 3.0	0.3	0.2	0.5	0.001	0.015	0.001	0.001	REM

machine and self-developed torsion device. The loading process from initial to fracture is recorded through the XTOP optical non-contact digital image correlation system. The data of force, stroke, and engineering strain is measured. Each experiment is carried out with a constant loading velocity at least three times to ensure the accuracy of mechanical testing.

3 Results

Force-stroke curves of UT and UC specimens are shown in Fig. 2a. The 20 mm length medially on the region of φ6 mm along the axial is selected as the gauge of UT specimen. The center-symmetric 6 mm length along the axial is the gauge of UC specimen. It can be clearly seen that the load gradually rises with the increase of loading stroke. The deformation process of WE43 alloy is from elastic to elastic-plastic and till to fracture. Besides, the loading force drops immediately when the load reaches to the maximum value, which indicates that fracture obviously occurs before necking [10]. Through the corresponding calculation using the equation of stress–strain, true stress-plastic strain relationships under uniaxial tension and compression are presented in Fig. 2b. It is clearly indicated that WE43 alloy possesses smaller tension-compression asymmetry comparing with traditional Mg alloys, such as AZ31 [11]. The ultimate stress and plastic strain are higher than some common Mg alloys, which reflects the effectiveness of this alloying method.

The macroscopic fracture morphologies of UT and UC specimens are shown in Fig. 3. It can be seen that the fracture is a gray and dark cup-cone shape with an oblique angle under uniaxial tension. Under uniaxial compression, the fracture surface presents the 45° shear fracture. The phenomenon indicates that the fracture of WE43 alloy belongs to the ductile fracture.

4 Material Model

4.1 Yield Function

As shown in Fig. 2b, the yield stress of WE43 alloy under uniaxial tension and compression is identical. Therefore, the Drucker isotropic equation [12] is selected as the yield function of finite element (FE) simulation. The yield criterion considers the effect of second and third deviatoric stress invariants J_2, J_3 and the equation of that is expressed as below

$$f(\sigma_{ij}) = a[(J_2^3 - cJ_3^2)^{1/6}] \tag{1}$$

where a and c are two material constants. Equation (1) is transformed to von Mises yield function when the value of parameter c is 0. Drucker yield function also can be written as

$$\bar{\sigma} = a\left\{\frac{1}{27} - c\frac{4L^2(L^2-9)^2}{729(L^2+3)^2}\right\}^{1/6}\sigma_{Mises} \tag{2}$$

with

$$L = \frac{2\sigma_2 - \sigma_1 - \sigma_3}{\sigma_1 - \sigma_3} = \frac{(\sigma_2 - \sigma_3) - (\sigma_1 - \sigma_2)}{\sigma_1 - \sigma_3} \tag{3}$$

$$a = \left\{\frac{1}{27} - c\frac{4}{729}\right\}^{-1/6} \tag{4}$$

where σ_1, σ_2, and σ_3 are three principal values of stress tensor $\boldsymbol{\sigma}$, L denotes the Lode parameter, and σ_{Mises} represents the von Mises stress. In this paper, the value of parameter c is set as 2.0 and the value of parameter a is calculated as 1.8652 through Eq. (4) [13].

Table 2 Material constants of yield function and hardening equation for WE43 alloy

Material constants	F-E
a	1.8652
c	2
k (GPa)	22.0957
ε_0	0.0004
n	0.0017
A (GPa)	−21.1186
B (GPa)	−21.5116
C	3.2921
α	0.5

4.2 Hardening Equation

At room temperature, the metallic material during the plastic deformation mainly possesses the hardening behavior. Generally, the plastic flow of metal is described by a hardening equation. There are several material models, such as Swift, Voce, and Swift-Voce with the form of

$$\sigma = k(\varepsilon_0 + \varepsilon)^n \tag{5}$$

$$\sigma = A - (A - B)\exp(-C\varepsilon) \tag{6}$$

$$\sigma = \alpha k(\varepsilon_0 + \varepsilon)^n + (1 - \alpha)(A - (A - B)\exp(-C\varepsilon)) \tag{7}$$

where σ is the equivalent stress, ε is the equivalent plastic strain (PEEQ), and k, ε_0, n, A, B, C, and α are material constants calibrated from the material tests. The Swift-Voce model is selected as the hardening equation in this study due to the multi-parameter flexibility.

Based on the experimental result presented in Fig. 2b, these material constants in Eq. (6) are calibrated and listed in Table 2.

4.3 Fracture Criterion

In order to characterize ductile fracture under various loading conditions, DF2016 fracture criterion [14, 15] is adopted, which is expressed as follows:

$$\left(\frac{2\tau_{\max}}{\sigma_{Mises}}\right)^{C_1}\left(\frac{f(\eta, L, C)}{f(1/3, -1, C)}\right)^{C_2}\varepsilon_f^p = C_3 \tag{8}$$

where C, C_1, C_2 , and C_3 are four material constants, η denotes the stress triaxiality, and ε_f^p is the fracture limit strain. The function $f\ (\eta, L, C)$ is suggested to write in this form of

$$f(\eta, L, C) = \frac{\sigma_1}{\overline{\sigma}} + C = \eta + C_4 \frac{(3 - L)}{3\sqrt{L^2 + 3}} + C \tag{9}$$

C_4 is also a constant considering the effect of L on the torsion voids coalescence.

5 Fracture Prediction

Adopting the unconstrained nonlinear optimization method of MATLAB software, the formula of error is defined with the form of

$$err = \sum_1^n \left(\frac{S_{cal}^i}{S_{\exp}^i} - 1\right)^2 \tag{9}$$

where n denotes the number of calculation, and $S_{\exp}^i$ and S_{cal}^i are the experimental and calculated value.

In order to obtain the result of mechanical property under different stress states, a hybrid experimental-numerical method is adopted. It is assumed that the FE predictions of the whole field of stress and strain tensors in the specimen are in agreement with the corresponding actual ones if the FE simulation predicts coincident load-displacement curve [16]. Other assumption is also followed that the fracture first appears inside the gauge center. The comparison of FE prediction and experimental result is shown in Fig. 4, which indicates that the prediction has a high accuracy.

Based on the acquired data, material constants of DF2016 fracture criterion are calibrated and summarized in Table 3. The fracture locus of DF2016 ductile fracture

criterion is constructed, as shown in Fig. 5. It can be seen that prediction accuracy is high. Besides, the fracture locus in the principal stress space of (σ_I, σ_{II}) is constructed, as illustrated in Fig. 6.

6 Conclusion

In this work, experiments under various stress states are conducted and deformation behavior of tension and compression is investigated. The result indicates that WE43 alloy possesses the lower tension-compression asymmetry. The fracture belongs to the ductile fracture through the analysis of macroscopic fracture morphology. In the situation, the Drucker yield function, Swift-Voce hardening equation, and DF2016 fracture criterion are selected as the theoretical model. After calibrating material constants of these models, the plastic deformation under various stress states is simulated by a hybrid experimental–numerical method. By the comparison of numerical and experimental results, the result indicates that the predicted accuracy of model is high. It also implies that the established model can be used in the FE simulation of plastic deformation for WE43 alloy.

Strain Hardening of AA5182-O Considering Strain Rate and Temperature Effect

Hongchun Shang, Pengfei Wu, and Yanshan Lou

Abstract Strain hardening properties of AA5182-O metal sheet are experimentally studied and analytically modeled at different temperature in this research using a dogbone specimen. The strain rate hardening and thermal softening behaviors are then modeled by popular analytical models to consider the strain rate and thermal effects. The high nonlinear strain hardening with the effect of strain rate and temperature is also illustrated by artificial neural network. The results show that the strain hardening with strain rate and thermal effect can be accurately modeled by the neural network compared with the conventional models, but its computation efficiency is much lower than the analytical models.

Keywords Strain rate · Thermal softening · Neural network

1 Introduction

Aluminum alloy has become the main lightweight material to replace automotive steel, due to its high specific strength, corrosion resistance, and many other advantages. However, the room-temperature formability of aluminum sheet is lower than that of steel sheet, so its application in automobile body and chassis components is greatly restricted [1–4]. In order to solve this problem, the warm forming process of aluminum alloy sheet has received extensive attention. The problem of concern in engineering applications is how to accurately model the influence of temperature and strain rate on the forming performance of aluminum sheet.

This paper experimentally investigates the effect of strain rate and temperature on strain hardening behavior of AA5182-O alloy. Their effects are analytically modeled by the Johnson–Cook, Zerilli—Armstrong, and Lim–Huh models. The artificial neural network (ANN) is also used to model the coupled strain rate and thermal effect of the alloy. The traditional constitutive and ANN models are all implemented in numerical simulation to predict the reaction force of the alloy at different stretching

velocity and temperature. The predicted load-stroke curves are compared with experimental results to evaluate their prediction accuracy with strain rate and thermal effect.

2 Experiments

The samples were obtained by milling an aluminum plate with a size of 500 × 500 mm along the rolling direction. The samples were widely known as dogbone specimens as shown in Fig. 1. The tensile tests were conducted on INSTRON universal testing machine. Five specimens were tested for each loading conditions to ensure the repeatability of experiments. The experiment covered a wide temperature range (300–573 k), and the strain rate range is 0.001–0.5/s. The gauge length was 20 mm for the stroke measurement by XTOP digital image correlation system.

The measured force-displacement curve before necking was then used to calculate the stress-strain curves of AA5182-O at different strain rates and temperatures, as shown in Fig. 2. It can be observed that at 300 k, when the strain rate increases from 0.001/s to 0.5/s, this material exhibits a slight negative strain rate sensitivity. It can be observed that at 300 k, when the strain rate increases from 0.001/s to 0.5/s, this material exhibits a slight negative strain rate sensitivity. The DSA effect shows that as the stretching speed increases, the stress intensity decreases. We have confirmed this conclusion through repeated experiments. When the temperature is 373 k, the flow stress is the highest at 0.01/s and the lowest at 0.5/s. When the temperature is 423 k, the flow stress at 0.001/s has been significantly reduced, compared to the other three curves. For the temperature after 473 k, with the increase of strain rate, the change trend of flow stress is consistent. The experimental results show a significant strain rate strengthening effect and the flow stress increases as the stretching rate increases. And with the increase in temperature, the gap between the four groups of experimental curves with different strain rates becomes larger and larger. Finally, we compare the experimental results at different temperatures under the same strain rate. As the temperature increases, the strain before the maximum force becomes smaller and smaller. This shows a significant temperature softening effect. When the

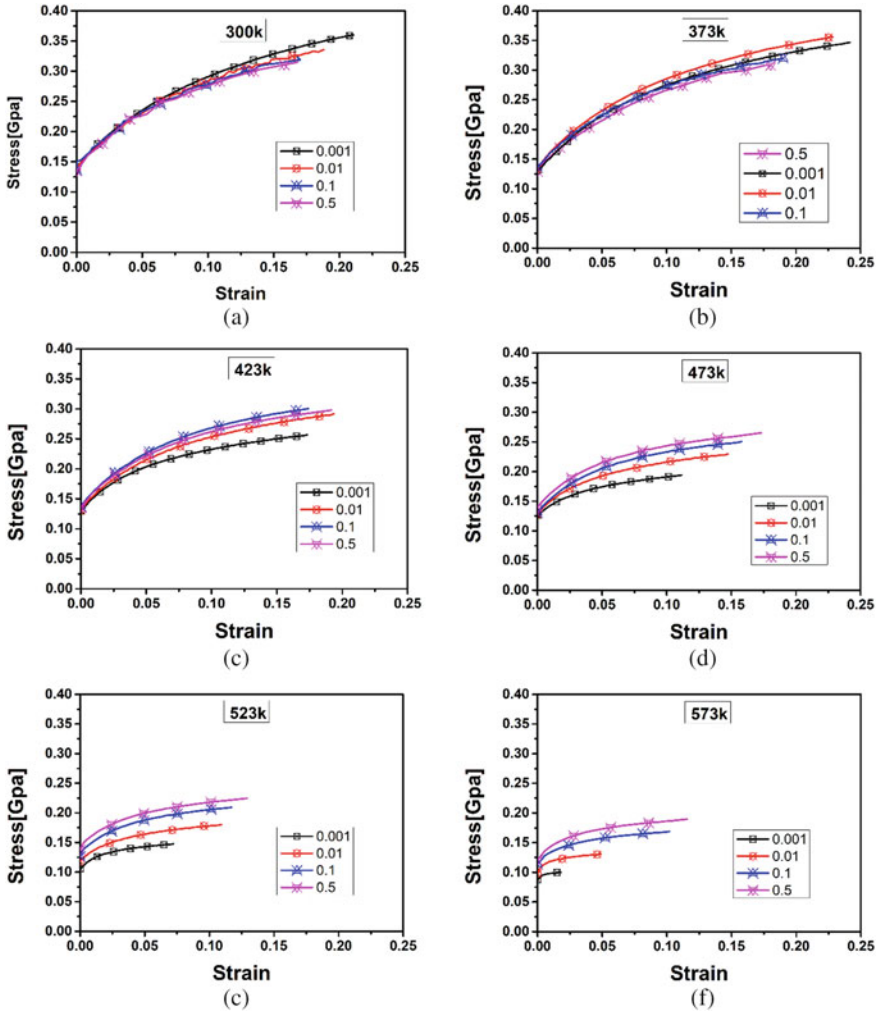

Fig. 2 Experimental true stress–true strain curves at different strain rates and temperatures. (Color figure online)

temperature reaches 573 k, the strain with a strain rate of 0.001/s is only 0.018. To sum up, through the comparison of 24 sets of experiments, it is found that AA5182-O exhibits a strong temperature and strain rate coupling effect.

3 Constitutive Model

Johnson and Cook (1983) [5] proposed a dynamic hardening model for metal deformation under high strain, high strain rate, and high temperature conditions. This model is highly accepted in computer simulation programs due to its simple form and easy accessibility of material constants for wide range of materials in literature. Moreover, JC model is available in many FE simulation platforms such as ABAQUS, DEFORM, etc. The original Johnson–Cook constitutive model can be expressed as

$$\begin{aligned}\sigma(\varepsilon, \dot{\varepsilon}, T) =& [\sigma_{\mathrm{r}}(\varepsilon)] \cdot [\sigma_{\dot{\varepsilon}}(\dot{\varepsilon})] \cdot [\sigma_{\mathrm{T}}(T)] \\ =& \left[A + B(\varepsilon)^n\right] \cdot \left[1 + C \ln \frac{\dot{\varepsilon}}{\dot{\varepsilon}_0}\right] \cdot \left[1 - \left(\frac{T - T_{\mathrm{r}}}{T_{\mathrm{m}} - T_{\mathrm{r}}}\right)^m\right]\end{aligned} \tag{1}$$

Zerilli and Armstrong (1987) [6] proposed a material dynamic constitutive model based on the dislocation mechanism. Through their observations, it is found that different crystal structures have different dislocation mechanisms. Therefore, the Z-A constitutive model gives different flow stress expressions for the two crystal structures:

$$\sigma = C_0 + \left[C_1 + C_2\sqrt{\varepsilon}\right]\exp[-C_3 T + C_4 T \ln \dot{\varepsilon}] + C_5 \varepsilon^n \tag{2}$$

For FCC,($C_1 = C_5 = 0$): $\sigma = C_0 + C_2 \varepsilon^{-1/2} \exp(-C_3 T + C_4 T \ln \dot{\varepsilon})$

Huh et al. (2014) [7–9] tested 4340 steel, OFHC copper, and Ti6Al4V alloy at different strain rates, and compared and verified different types of dynamic hardening models. However, its hardening behavior at high temperatures has some shortcomings. In order to express the thermal softening effect at high temperature, Piao et al. [8] added a thermal softening term involving rate to the Lim–Huh model, expressed as

$$\begin{aligned}\sigma_{(\varepsilon,\dot{\varepsilon},T)} =& [\sigma_{\mathrm{r}}(\varepsilon)] \cdot [\sigma_{\dot{\varepsilon}}(\varepsilon, \dot{\varepsilon})] \cdot [\sigma_{\mathrm{T}}(T, \dot{\varepsilon})] \\ =& A(\varepsilon + \varepsilon_0)^n \cdot \left[\frac{1 + q(\varepsilon)\dot{\varepsilon}^{p(\varepsilon)}}{1 + q(\varepsilon)\dot{\varepsilon}_r^{p(\varepsilon)}}\right] \cdot \left[1 - \left(\frac{T - T_{\mathrm{r}}}{T_{\mathrm{m}} - T_{\mathrm{r}}}\right)^{m(\dot{\varepsilon})}\right]\end{aligned} \tag{3}$$

where $q(\varepsilon) = \frac{q_1}{(\varepsilon + q_2)^{q_3}}$, $p(\varepsilon) = \frac{p_1}{(\varepsilon + p_2)^{p_3}}$, $m(\dot{\varepsilon}) = m_1 + m_2 \cdot \ln \frac{\dot{\varepsilon}}{\dot{\varepsilon}_{\mathrm{r}}}$, $\dot{\varepsilon} > \dot{\varepsilon}_r$ and $T_{\mathrm{r}} \leq T \leq T_{\mathrm{m}}$.

Artificial Neural Network (ANN) [10–12] is a data-driven nonlinear mapping model constructed according to the principle of human brain organization and activity. The basic idea of BP neural network is that the learning process is composed of two processes: forward propagation of signals and back propagation of errors. In forward propagation, samples are imported from the input layer, processed by various hidden layers, and finally passed to the output layer. Error back propagation is to pass the output error back to the input layer by layer through the hidden layer in some

form, and apportion the error to all units in each layer. The process of constant weight adjustment is the network training process. This process continues until the error of the network output is reduced to an acceptable level, or until the preset number of learning times.

Data normalization is a preprocessing technology. MinMaxscaler technology is selected to project all input variables onto the interval [0,1], which is defined as follows:

$$\overline{x}_i = \frac{x_i - x_{\min}}{x_{\max} - x_{\min}} \tag{4}$$

Each neuron in each layer is connected to the neuron of the next layer with a different weight. When the connection is passed, the weight will change.

$$H_i^{(k)} = tanh\left[\sum_{j=1}^{p} W_{ij}^{(k-1)} H_j^{(k-1)} + b_i^{(k-1)}\right] \tag{5}$$

The hyperbolic tangent is selected as the activation function to calculate the output layer.

$$\overline{y} = tanh\left[\sum_{j=1}^{p} W_l^{(k)} H_l^{(k)} + b^{(k)}\right] \tag{6}$$

Finally, the output variable is scaled linearly from [0,1]. The mean square error (MSE) defined by the following equation quantifies the ability of the neural network to predict flow stress:

$$MSE = \frac{1}{N}\sum_{i=1}^{N}\left(\frac{\sigma_{exp} - \sigma_{pred}}{\sigma_{exp}}\right)^2 \tag{7}$$

4 Results and Discussion

The predicted stress-strain curves are compared with experimental results at different strain rates and temperatures in Fig. 3. The yield stress comparison between the experiment and each model is compared in Fig. 4. The comparison shows that the LH model predicts better accuracy than JC and ZA FCC models. The artificial neural network's prediction matches with experimental results with the highest accuracy.

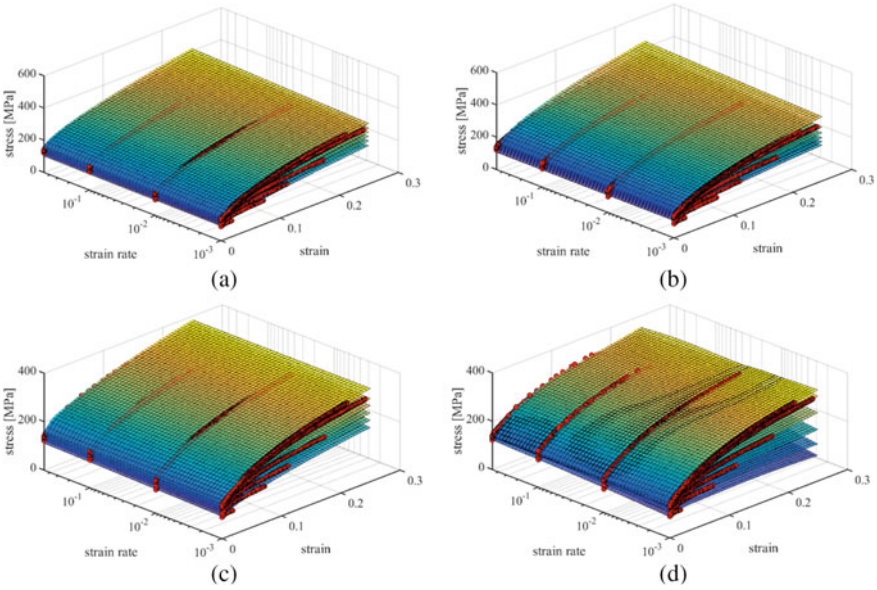

Fig. 3 Comparison of calculated flow stress with experimental data: **a** JC; **b** ZA FCC; **c** LH; **d** Artificial neural network. (Color figure online)

ABAQUS user material subroutines (ABAQUS/Explicit VUMATs) are developed and tested, including JC, ZA, and LH hardening functions, and the developed artificial neural network constitutive model [13]. It can be observed from Fig. 5a that the finite element simulation results of the artificial neural network are completely consistent with the experimental results. In addition, it can accurately calibrate the influence of negative strain rate at 300 k. It is found from Fig. 5c that the calibration results of the four traditional models except the artificial neural network are lower than the experimental values. The theoretical calibration results of the artificial neural network are exactly the same as the experimental results, but the finite element simulation results are slightly lower than the theoretical results in the second half. This is because the stretching speed is faster and the thermal effect is more obvious. The results shown in Fig. 5e are performed in the highest temperature environment in this batch of experiments. The theoretical calibration results of the neural network are still completely consistent with the experimental values. Because of the thermal softening effect, the finite element simulation results of the neural network are still slightly lower than the theoretical calibration results. It can be seen from Fig. 5f that only the curve predicted by the artificial neural network can pass the experimental points.

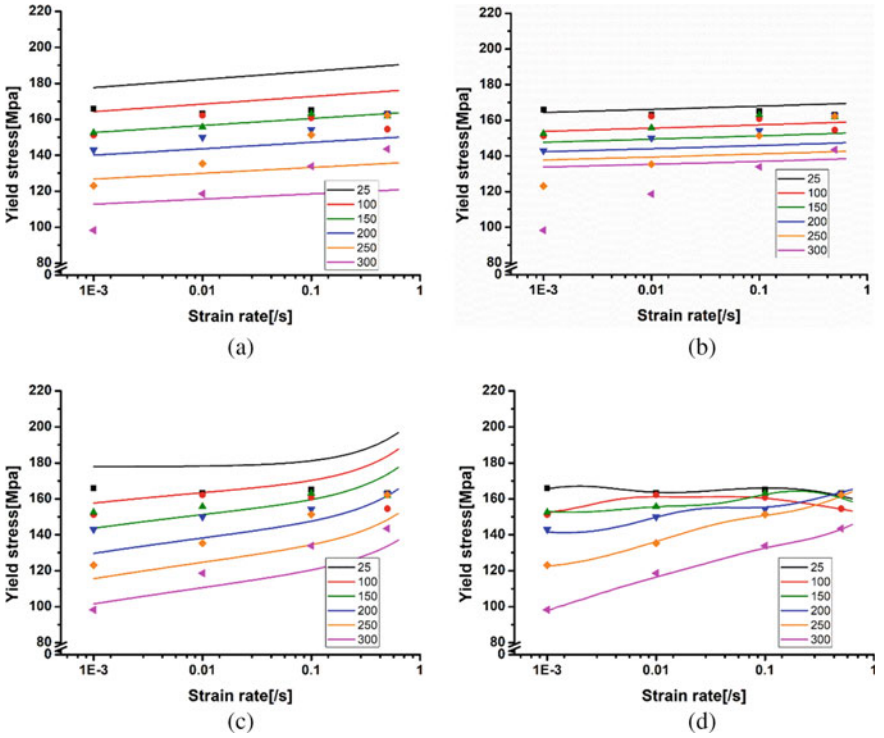

Fig. 4 Comparison of calculated yield stress with experimental data at a plastic strain of 0.01: **a** JC; **b** ZA FCC; **c** LH; **d** Artificial neural network. (Color figure online)

5 Conclusions

This paper studies the flow behavior of AA 5182-O in the temperature range of 300–573 k and the strain rate range of 0.001–0.5/s. ABAQUS user material subroutines are developed and tested for JC, ZA, LH hardening functions, and the ANN model. The calibration results of each model are quantitatively compared by MSE error. The results show that the new constitutive model can well describe the negative strain rate effect and the non-monotonic temperature effect. But its computational cost is much larger than traditional models.

New Methods for Fracture Detection of Automotive Steels

J. Noder, P. Samadian, J. Dykeman, A. Abedini, A. Zhumagulov, M. Worswick, and C. Butcher

Abstract The VDA 238-100 tight radius bend test has received significant attention from industry over the past decade because it provides a proportional plane strain–plane stress state until fracture. It will be demonstrated that the adoption of the vertical punch force as the unique metric for failure detection can lead to false positives. The punch force will reduce at large bend angles due to the mechanics of the test even in the absence of material failure. Two novel detection methods based on the nominal principal stress and the plastic work were evaluated on six different steel grades with a nominal ultimate tensile strength of approximately 590 MPa. Three 590R advanced high-strength steels provided by three different suppliers and three variants of the Ductibor® 500 are studied. The stress-based metric can be seen as an improvement over the VDA 238-100 load methodology since it accounts for thinning of the specimen cross-section and can identify false positives when the material forms a full bend in the absence of fracture but drops at bend angles greater than 160°. For performance ranking of materials with the same strength level, the plastic work metric is found to be sufficiently sensitive to distinguish between various 590 MPa steel grades since the material hardening rate is directly embedded.

into layers that undergo plane strain tensile stretching (above the neutral axis) and material layers below the neutral axis that are compressed in plane strain compression. The induced through-thickness strain gradient mitigates the formation of a through-thickness neck prior to fracture, thus the effective forming limit becomes the fracture limit [1].

A popular approach to characterize the material behavior in plane strain tension involves notched tensile specimens which accommodate testing in a regular tensile frame. On the downside, notched tensile tests suffer from tensile instabilities since fracture occurs under a triaxial stress state on the specimen mid-plane where strains cannot be measured with Digital Image Correlation (DIC) techniques [2–4]. Therefore, inverse Finite Element (FE) analysis is required to extract the strain history and stress state of the element in the neck. The VDA 238-100 [5, 6] tight radius bend test offers an attractive alternative; the specimen is deformed over a sharp punch tip radius of 0.2 mm or 0.4 mm and a roller spacing of about twice the sheet thickness. Since the material is deformed in a plane strain bending mode, necking is suppressed and fracture is initiated on the convex (outer) specimen surface where strains can directly be measured utilizing the inverted V-bend test frame with full-field stereoscopic DIC measurements developed at the University of Waterloo [7].

Following the VDA 238-100 specification, the vertical punch load is adopted as the unique metric for failure identification and the bend angle serves as the performance metric for material ranking. In light of the inverted V-bend test frame adopted for this study, which incorporates DIC, the failure strains will be reported as well. Depending on the material type and sheet thickness, a reduction of 30 N or 60 N from the peak punch load is adopted for failure identification. It will be shown in this study that the punch force will decrease at large bend angles (>100°) due to kinematic boundary conditions even in the absence of material failure thus resulting in potentially too conservative failure strains and bend angles. A novel proposed methodology by Noder et al. [8] considers a stress-based metric that accounts for sheet thinning measured using DIC or an empirical equation that can successfully detect false positives. The primary advantage of the methodology of Noder et al. [8] is that the stress metric can be readily calculated using the available data in the VDA bend test. If a fracture occurs due to cracking, then the results obtained using the stress metric are in agreement with the VDA load drop criterion. A comprehensive evaluation of seven automotive steels with a strength level from 270 MPa to 1500 MPa revealed that the stress metric can successfully be utilized to identify materials that fold over or lose contact with the punch, referred to as punch lift-off. Further, Noder et al. [8] proposed a plastic work metric that has the material hardening rate directly embedded and served to rank the performance of alloys with similar strength levels. In this study, the alternative detection methods of Noder et al. [8] are applied to six steel grades with a nominal ultimate tensile strength of approximately 590 MPa to determine if the differences between similar grades can be detected. Additionally, AHSS of 590 MPa ultimate strength are particularly challenging since their moderate strength and relatively high ductility can lead to folding over in the bend

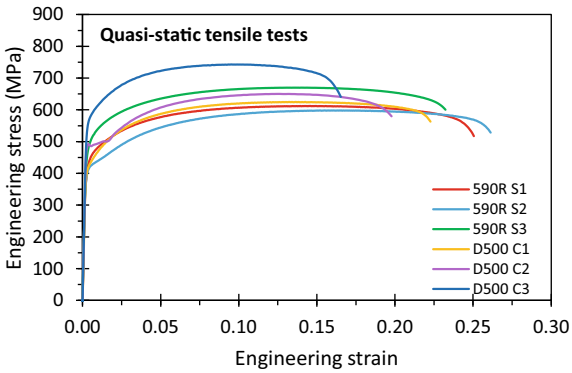

Fig. 1 Tensile performance of studied steel grades in the sheet transverse direction obtained in quasi-static tensile tests utilizing JIS No. 5 tensile geometries. A virtual extensometer length of 50 mm was adopted. (Color figure online)

test or cracking at large bend angles. It was found that the plastic work metric can be used to distinguish the material performance in the tight radius bend test even when the material performs a full bend and does not exhibit clear fracture.

2 Material Selection

Automotive steel grades with an ultimate tensile strength (UTS) of approximately 590 MPa are commonly used for energy-absorbing structures in the body-in-white owing to their superior formability and moderate strength level. Six steel grades were selected. Three JAC590R alloys were provided by different suppliers, hereinafter referred to as 590R S1, 590R S2, and 590R S3. Three variants of the hot stamping steel, Ductibor® 500, were created by changing the die pressure and die temperature for quenching. The blank was austenized at a temperature of 930 °C and held for 5 min followed by rapid transfer (10 s) into the die set where the blank was quenched and held for 15 s. The first condition (i), hereinafter referred to as D500 C1, was quenched at a die temperature of 25 °C and a pressure of 15 MPa, (ii) D500 C2 corresponds to a die temperature of 150 °C and a pressure of 26 MPa, and (iii) D500 C3 was quenched in 7 °C chilled dies at a pressure of 26 MPa.

The quasi-static constitutive response of the six steel grades was studied in the sheet transverse direction using JIS No. 5 tensile specimens. Full-field stereoscopic DIC strain measurements using the Vic-3D® software from Correlated Solutions Inc. were adopted. The stress–strain response is depicted in Fig. 1 and the mechanical properties and sheet thicknesses are recorded in Table 1.

3 Experimental Procedure

The conventional VDA 238-100 tight radius bend apparatus does not consider the use of optical strain measurements on the convex specimen surface and its design is not readily amenable for camera access of the convex surface where fracture will be initiated. The V-bend frame utilized for this study has been inverted and

Table 1 Tensile mechanical properties of the studied 590 MPa steel grades. The values in brackets correspond to the standard deviation. The uniform and total elongation are based on a virtual extensometer length of 50 mm. The R-value was obtained over a plastic strain range of 2–18.4% for the 590R S1, 2–19.5% for the 590R S2, 2–10% for the 590R S3, 2–12.4% for D500 C1, 2–11.7% D500 C2, and 2–9.6% for the D500 C3

D500 C3, 1.6 mm	585 (± 23)	744 (± 32)	10.0 (± 0.7)	16.3 (± 3.2)	0.84 (± 0.02)

was developed by Cheong et al. [7] to facilitate full-field stereoscopic DIC of the entire bending width. The primary difference in the VDA 238-100 set-up lies in the stationary punch and the chamfered rollers (30 mm diameter) which descent to bend the specimen. A schematic of the V-bend test frame is shown in Fig. 2a and the reader is referred to Cheong et al. [9] for further details.

Following the VDA 238-100 guidelines, a gap size of two times the sheet thickness plus 0.5 mm was selected for all tested steel grades. In light of the advanced ductility of the studied alloys, the sharper punch tip radius of 0.2 mm (0.21 mm as-fabricated) was selected instead of the 0.4 mm radius punch. A test velocity of 20 mm/min was selected for all tests. The VDA bend angle is computed such that

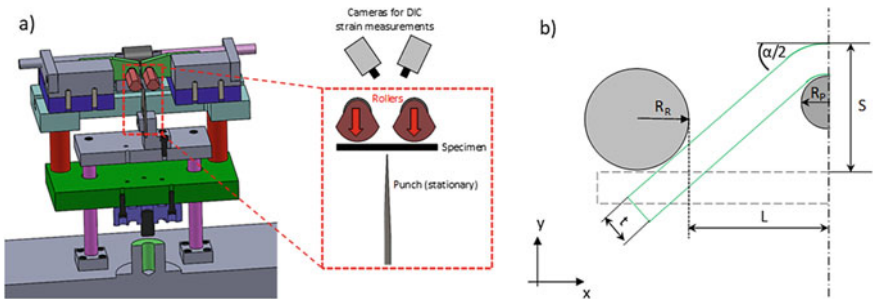

Fig. 2 Schematic of inverted V-bend test frame at the University of Waterloo (**a**) and for computation of the bend angle (**b**). The variable *L* refers to half of the roller gap width. (Color figure online)

$$\alpha_{VDA}(R_R, t, L, S) = 2\left(-\tan^{-1}\left(\frac{1}{d}\sqrt{c^2-(d+b)^2}-(c-S)\right)\frac{180^\circ}{\pi}\right) \quad (1)$$

where $b = R_R + \frac{L}{2}$, $c = R_R + t$, $g = b^2 + (c-S)^2$, $d = \frac{-\sqrt{h^2-4gi}-h}{2g}$

$$h = -2c^2b + 2b^3 + 2(c-S)^2b$$

$$i = c^4 - 2b^2c^2 - c^2(c-S)^2 + b^2(c-S)^2 + b^4$$

where the reader is referred to Fig. 2b for clarification of the adopted variables.

Specimens were machined to a width and length of 60 mm except for the D500 C2 and D500 C3 which were machined to a width and length of 50 mm to provide a plane strain bending condition for all tested steel grades. The specimens were tested in the transverse direction to be aligned with the primary loading condition. For full-field logarithmic strain measurements, a random black speckle pattern with white background paint was created and images were collected at a frequency of approximately 10 frames per second. The Vic-3D® software from Correlated Solutions Inc. was adopted with a strain filter of 7 pixels and a step size of 2 which resulted in a virtual strain gage length (VSGL) of approximately 0.5 mm. Five line slices perpendicular to the crack location were extracted from the specimen and imported into a custom MATLAB® script following the ISO12004-2 standard [10] for formability analysis. Based on the work of Cheong et al. [9], the peak strain was identified for each line slice and the average value reported. Figure 3 representatively shows the uniform strain distribution in the bending zone and highlights the proportional plane strain condition throughout the test for the 590R S3.

4 Detection Methods in the VDA 238-100 Tight Radius Bend Test

4.1 V-Bend Mechanics

Prior to exploring different failure detection methods, it is paramount to establish a fundamental understanding of the bending mechanics in the tight radius bend test. Figure 4 schematically illustrates the evolution of the bend angle and the force components. For low bend angles (α_1-α_2), the assumption of a three-point bending scenario with the punch force, F_y, as the primary force component is reasonable. For large bend angles, however, the contact points between the specimen and the punch are gradually shifted from the initial punch center to the left and right edge of the punch tip radius, causing a tangential force component. The transition to a four-point bending condition illustrated for bend angle α_3 is reflected by an almost horizontal resultant force for which the horizontal force component dominates and the

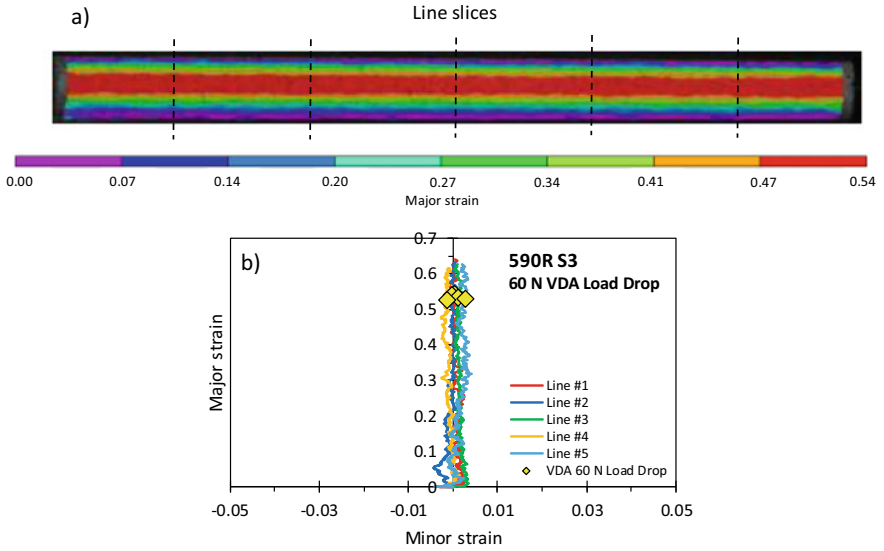

Fig. 3 Strain distribution (**a**) and strain path evolution obtained in the V-bend test representatively shown for the 590R S3 (**b**). (Color figure online)

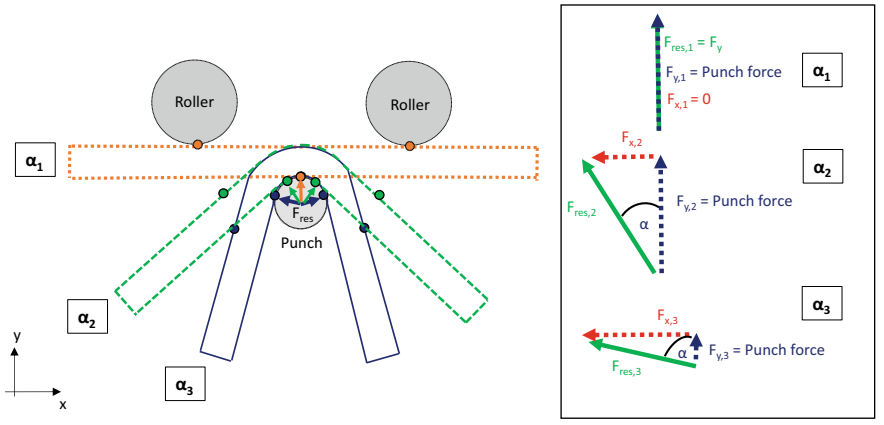

Fig. 4 Evolution of the bend angle and resultant force and evolution of the force components. A decrease in the punch force does not necessarily indicate material failure but can result as a natural consequence of the kinematic boundary conditions in the test set-up. (Color figure online)

punch force is minor. Consequently, a reduction in the load drop does not necessarily indicate material failure and requires additional efforts such as optical inspection of tested specimens.

Adoption of the bending moment of the cross-section naturally accounts for the decrease in the punch force by consideration of the resultant force and the change in

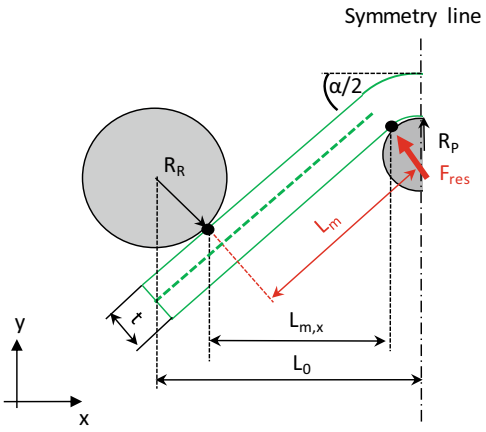

Fig. 5 Schematic of mechanics in the VDA 238-100 tight radius bend test for the derivation of the bending moment methodology. Note that the dashed green line refers to the position of the neutral axis that is assumed to remain aligned with the sheet mid-plane for a rigid perfectly plastic material and that punch lift-off does not occur. (Color figure online)

the contact points reflected in the resultant moment arm. Following the procedure of Troive [11] and referring to Fig. 5, the bending moment of the cross-section can be approximated from the resultant force, F_{res}, and the moment arm, L_m such that

$$M = F_{res} L_m = \frac{F_y}{2\cos\left(\frac{\alpha}{2}\right)} \frac{L_{m,x}}{\cos\left(\frac{\alpha}{2}\right)} \tag{2}$$

where $L_{m,x}$ approximately corresponds to the moment arm in the x-direction, assuming a straight flange as

$$L_{m,x} \approx L_0 - (R_R + R_P)\sin\left(\frac{\alpha}{2}\right) \tag{3}$$

and R_R and R_P are the roller radius and the punch radius, respectively. Half of the width of the roller gap including the roller radius, denoted as L_0, yields

$$L_0 = (t + 0.25) + R_R \tag{4}$$

Assembly of Eqs. (2)–(4) yields the following expression for the bending moment of the cross-section

$$M = F_{res} L_m = \frac{F_y}{2}\left(\frac{t + 0.25 + R_R - (R_R + R_P)\sin\left(\frac{\alpha}{2}\right)}{\cos^2\left(\frac{\alpha}{2}\right)}\right) \tag{5}$$

and the total energy associated with deformation of the cross-section is

$$U = \int_0^{\alpha} M d\alpha \tag{6}$$

The evolution of the bending moment can now be readily calculated with Eq. (5) using the same experiment data available in the conventional V-bend test. Note that Eq. (5) is for the bending moment of the cross-section and that the hardening response and through-thickness strain gradient are embedded. The plastic response within the cross-section is complex due to the severe bending strain gradient, a shifting of the neutral axis toward the concave specimen side, and a stress reversal of some layers from being initially in compression into tension. An integration of the material response at each layer of material through-thickness would produce the moment of the cross-section. Nevertheless, adoption of the bending moment is a rather non-intuitive quantity compared to using a nominal stress or punch force. Noder et al. [8] also highlighted potential complications for alloys with a low hardening rate that can produce an approximately constant bending moment. A stress-based metric is preferable since it accounts for the sample dimensions and avoids the ambiguity of using force-based thresholds. Fortunately, adopting the closed-form solution for a *rigid, perfectly plastic* material [12], the bending moment can be related to the yield stress, σ_y, and a stress metric, Σ, can be defined, where w corresponds to the specimen width such that

$$M_{rigid-plastic} = \frac{\sigma_y t^2 w}{4} = \text{constant} \tag{7}$$

It is important that the instantaneous specimen thickness in Eq. (8) is used. Larour et al. [13] showed that the specimen undergoes thinning of up to 30% during the bending process which was in reasonable agreement with DIC measurements for a series of alloys presented by Noder et al. [8]. Owing to the stationary punch in the V-bend frame at the University of Waterloo, thinning of the cross-section can be retrieved from the out-of-plane displacement. The amount of thinning is material dependent and is directly linked to the hardening response. Noder et al. [8] also provided a basic phenomenological equation for approximation of the engineering thinning strain

$$\Sigma = \frac{4}{t^2 w} M(F_y, \alpha) \tag{8}$$

$$\varepsilon_t = A - A \exp\left(-B(\alpha)^C\right) \tag{9}$$

where $A = 0.2110$, $B = 0.0012$, and $C = 1.4636$. Note that Eq. (9) does not account for the effect of bend severity which will be the subject of future work.

The volume of the deformed material is estimated using the bend radius at the mid-thickness as

$$V = wt\left(\frac{R_o + R_i}{2}\right)\alpha(rad) \tag{10}$$

where R_i and R_o correspond to the inner and outer sheet radius, respectively. Assuming that the inner radius of the bend corresponds to the punch, the approximate plastic work of the cross-section can be readily determined from the total energy of Eq. (6) and the volume of Eq. (10) as

$$W = \int \sigma d\varepsilon = \frac{U}{V} = \frac{\int_0^{\alpha} M d\alpha}{wt\left(1 + \frac{t}{2R_p}\right) R_p \alpha(rad)} \tag{11}$$

5 Results and Discussion

For baseline comparison of the new methodologies, the 60 N load threshold upon the peak punch force was adopted for failure identification following the VDA 238-100 specification. One representative load curve for each tested steel grade is depicted in Fig. 6a and clearly indicates a reduction in the punch force at VDA bend angles ranging from 110° to 123° in Fig. 7a, while optical inspection at the load threshold in Fig. 8 confirmed the absence of visible cracks on the specimen convex surface. Since the regular VDA 238-100 V-bend apparatus does not consider DIC strain measurements, the bend angle is commonly adopted as a unique metric for material ranking. Following this procedure, the performance of the 590R S3 would be ranked first and the D500 C3 last. Cheong et al. [9] demonstrated that the bend angle at failure is dependent upon the bend severity, t/R_p, and that the plane strain failure strain is the unique metric which governs the bend performance. Interestingly, the major strain at failure summarized in Fig. 7b identifies the D500 C3 to be superior and the D500 C1 to be at the lower end with a major strain of 0.59 and 0.50, respectively.

Consideration of the stress metric indicates that the observed reduction in the punch force was caused as a natural consequence of the kinematic boundary conditions in the V-bend frame. The evolution of the stress metric in Fig. 6b shows an increasing trend past the 60 N VDA load threshold but drops at bend angles

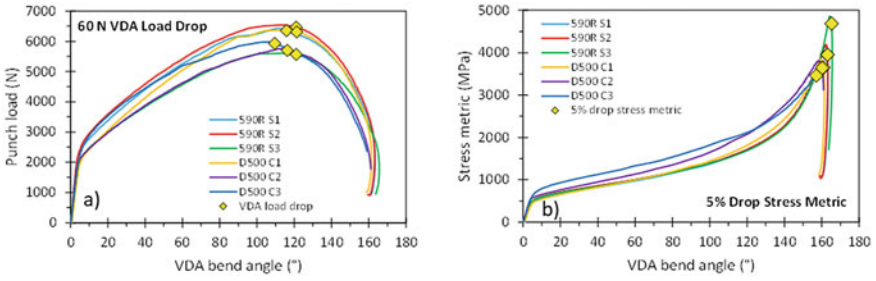

Fig. 6 Evolution of the punch load (**a**) and the stress metric (**b**) representatively shown for one repeat per tested alloy. (Color figure online)

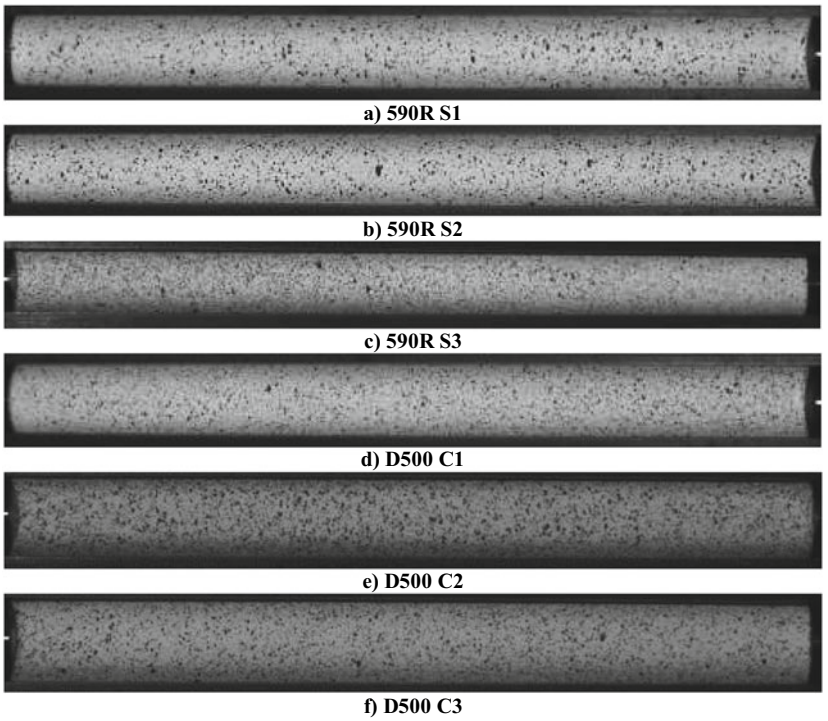

Fig. 8 Optical inspection of the specimen surface at the 60 N VDA load drop for the tested steel grades

exceeding approximately 160° as summarized in Fig. 9a. Comparison of the failure strains in Fig. 9b using a 5% reduction in the stress metric records failure strains that are approximately 0.26-40 strain higher than recorded by the VDA 238-100 specification.

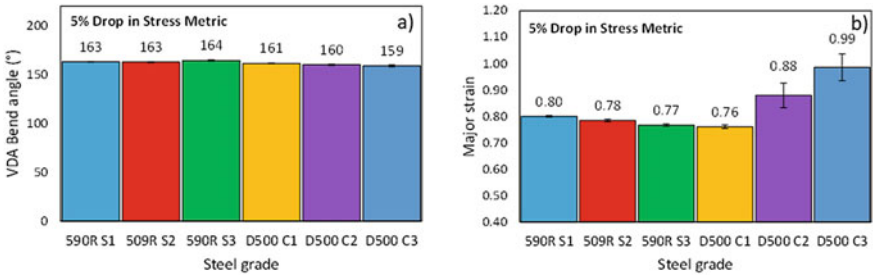

Fig. 9 VDA bend angle (**a**) and major strain (**b**) adopting a 5% drop in the stress metric. (Color figure online)

A viable concern in the V-bend test is potential punch lift-off which renders the test invalid since the inner bend radius does no longer conform to the punch tip radius and the effective bend severity increases and fracture occurs at a lower bend angle. For plane strain fracture characterization, the strain state remains plane strain bending on the outer surface and the measured fracture strain remains valid. Since the punch is stationary in the current set-up, the evolution of the out-of-plane displacement in Fig. 10 was utilized to determine punch lift-off. Note that the displacement is assumed to be positive, thus thinning is represented by an increase in the out-of-plane displacement which is observed up to a bend angle of approximately 147°. Interestingly, the punch force decreased much earlier at bend angles of about 123°, indicating that the reduction in the punch force appears to occur prior to punch lift-off for the considered steel grades. The stress metric correctly indicates the absence of failure until bend angles larger than 160° but needs to be limited to the maximum bend angle when punch lift-off occurs. The same restriction applies to instantaneous

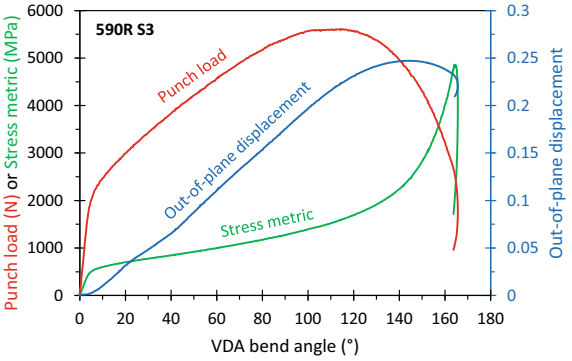

Fig. 10 Visualization of the shortcomings of the VDA 238-100 failure detection method representatively shown for the 590R S3. The reduction in the punch force is not related to material failure that was correctly captured by the stress metric. The out-of-plane displacement indicates that punch lift-off occurred at a bend angle of approximately 147°. (Color figure online)

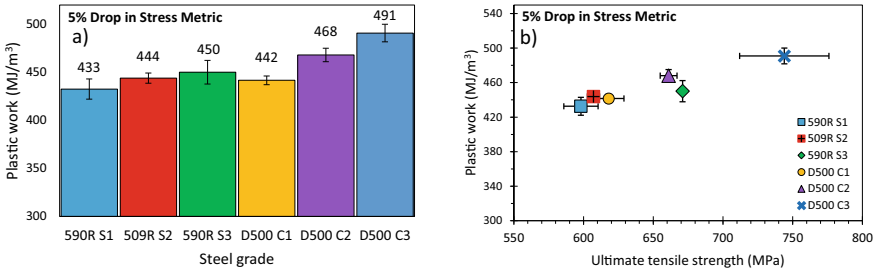

Fig. 11 Comparison of plastic work (**a**) and correlation with the material UTS (**b**) for the studied steel grades. (Color figure online)

thinning from DIC measurements, which is only valid prior to punch lift-off. For empirical thinning in Eq. (9), a limitation to bend angles of 140° is recommended.

While the stress metric provided a noticeable improvement over the VDA 238-100 load threshold methodology, it drops at bend angles greater than 160° when the punch force has decreased by about 80%. To differentiate the performance of alloys of the same nominal strength level, the work per volume using Eq. (11) can be adopted. The advantage of a plastic work metric lies in the hardening behavior which is directly embedded in the bending moment evolution. Comparison of the plastic work clearly demonstrates the superior performance of the D500 C3 followed by the D500 C2 and the 590R C3 that correlates well with the strength level shown in Fig. 11.

6 Conclusion

This paper provided a comprehensive study on the material plane strain fracture performance of six steel grades with a strength level of approximately 590 MPa using various metrics for performance ranking. The primary conclusions are as follows:

- Adoption of the VDA 238-100 load methodology resulted in false positives for the studied steel grades since the reduction in the load drop was not associated with material fracture but the kinematic boundary conditions of the test frame.
- The novel stress metric accounts for thinning of the cross-section and can detect false positives but drops at bend angles greater than 160°.
- Computation of the plastic work allowed clear distinction between the studied material grades and has the hardening rate embedded in the bending moment.

Acknowledgments Financial support for this study was provided in part by the Natural Sciences and Engineering Research Council of Canada, the American Iron and Steel Institute (AISI), and Honda Research Americas (HRA). The authors would particularly like to thank Willie Bernert and Chris Brown from ArcelorMittal, Dr. Hesham Ezzat of AISI, and Dr. Kishore Pydimarry of HRA

for their support of the project. We would also like to gratefully acknowledge Kenneth Cheong from the University of Waterloo for his valuable discussion on V-bend experiments.

Evaluation of Isotropic and Anisotropic Constitutive Models on Plasticity Prediction of AA7075 Extruded Tube Under Tension–Tension and Tension–Compression

Sobhan A. Nazari Tiji, Amir Asgharzadeh, Taejoon Park, Madhura Athale, and Farhang Pourboghrat

Abstract Plasticity of AA7075-O extruded tube under tension–tension (T-T) and tension–compression (T-C) was characterized using multiaxial tube expansion test method. Three different yield functions, von-Mises, Hill's 1948, and Yld2004 were considered to model the anisotropic plasticity of the AA7075-O tubes under T-T and T-C. The anisotropic models were calibrated based on the measured biaxial stresses and the conjugate plastic strain rates as strain-rate potential based on plastic work equivalency. As shown, this calibration method is an accurate and more flexible way of calibrating the advanced yield functions with no necessity for having proportional loading paths. It was also shown that the three yield functions predict the strain paths under T-C conditions almost similarly, however, the strain paths under T-T conditions are predicted better as the number of anisotropy parameters in the yield functions increases.

Keywords AA7075 · Tube bulging · Anisotropic plasticity · Multiaxial loading

1 Introduction

Multiaxial testing has been considered in different studies as an accurate method to characterize the anisotropic plasticity of different materials [1–4]. Tube-free bulging as one of the multiaxial testing methods has been widely used for plasticity characterization of tubular materials [1, 5–9]. Except for the very recent studies conducted by Zhang et al. [6] and the authors of this paper [1], in all other studies either the first quadrant (Tension–Tension) or the second quadrant (Tension–Compression) of the

stress space was characterized and used for anisotropic plasticity modeling of tubular materials. However, characterizing tubular materials under both Tension–Tension and Tension–Compression provides sufficient and accurate data for calibration of advanced anisotropic yield functions to accurately predict tubular materials behavior under complex loading. Moreover, to account for the strain data for anisotropic plasticity characterization of the tubular materials, the Lankford coefficients (R values) in three cases, r_0 (R value in longitudinal direction), r_{90} (R value in hoop direction), and r_b (R value in balanced biaxial condition) were generally considered so far in all the previous studies. The R value in tubular materials longitudinal direction, r_0, is easy to measure using standard uniaxial tensile test; however, measuring the R values in hoop direction, r_{90}, and balanced biaxial condition, r_b, has always been challenging because of the geometrical constraints of the tubular materials. Different techniques have been used to measure r_{90} and r_b. Ring hoop tension test [10] has been used as a technique to measure the R value in hoop direction of the tubular materials. However, because of the friction issue in this technique, its reliability has always been questioned. In other studies [5, 6, 8] r_{90} and r_b were measured by performing a controlled tube bulging experiments that require a sophisticated and expensive feedback control system that would control the deformation of the bulging tube to maintain the deformation mode throughout the test in real time.

In the authors' previous study [1], an experimental tube expansion test setup was developed for plasticity characterization of tubular materials under biaxial tension and tension–compression. In that study, AA7075-O extruded tube was characterized both in stress space (Yield Surface) and plastic strain rate space (Strain-rate Potential) under biaxial tension and tension–compression. It was shown that, unlike all the other previous studies, it is not necessary to generate proportional loading using a sophisticated and expensive real-time feedback control system to characterize the yield surface for tubular materials. The authors showed that any nonlinear or linear loading paths can be used to characterize the yield surface of the tubular materials based on plastic work equivalency. Therefore, the authors suggested that, considering the linear and nonlinear loading paths during tube expansion, the data in the stress space and their conjugate plastic strain rates as the strain-rate potential to account for the strain data can be used directly from the biaxial tests to characterize the plasticity of the tubular materials without any need for ring hoop tension test or any real-time sophistical and expensive controlled tube expansion tests. In this study, the data obtained after characterization of the AA7075-O tube in both stress and plastic strain rate spaces in [1] are used to calibrate Hill's 1948 and Yld2004 anisotropic yield functions. Then, the calibrated yield functions are used to predict the strain paths evolved based on the internal pressure and axial feed that were used during the experiments. It must be mentioned that the VUMAT developed by Esmaeilpour et al. [11] was used for the FEM simulations using the Yld2004 yield function.

2 Experimental Procedure

AA7075-O extruded tubes with an outer diameter (OD) of 38.1 mm, thickness (t_0) of 1.67 mm, and bulge length (L_B) of 88 mm were used in this study. Figure 1 shows the schematic of the tube with the clamping.

First, the uniaxial tensile test was performed based on the ASTM E8 standard on the dog-bone specimen cut along the longitudinal direction of the tube. Then, tube bulging simulations with von-Mises yield function based on the uniaxial tension test flow curve using FEM with a proportional–integral–derivative (PID) controller algorithm (as a user-subroutine) integrated with it were performed to generate the required boundary conditions (Internal pressure and axial feed profiles) for eight different biaxial tests. To generate the boundary conditions, first, the desired strain paths at the pole of the tubes were defined in the user-subroutine. Then the PID user-subroutine integrated with the tube bulging FEM model would generate the internal pressure and the axial feed in a way that would result in the desired strain paths at the pole of the tubes. The details of this boundary condition generation method can be found in [1]. The boundary conditions generated and used for the experiments are shown in Fig. 2. As can be seen, eight biaxial tests were performed, four biaxial tension tests (a, b, c, and d) and four tension–compression tests (e, f, g, and h). 3D DIC system was used for all the experiments in order to capture the strain evolution of the bulging tube. The internal pressure and the axial stroke/load over time were also recorded by the control station of the tube hydroforming machine. Figure 3a shows the experimental setup and Fig. 3b shows the surface of the bulging tube with the evolved Mises strain map on it measured by the 3D DIC system.

3 Modeling

3.1 Principal Stresses Calculation

As Fig. 3b shows, the principal stresses at the pole of the tube were calculated based on the force equilibrium on a membrane using Eqs. (1) and (2).

$$\sigma_{axial} = \frac{P\pi\left(r_{hoop} - t\right)^2 - R_{F_{axial}}}{2\pi\left(r_{hoop} - \frac{t}{2}\right)t} \tag{1}$$

$$\sigma_{hoop} = \frac{(r_{axial} - t)\left(2r_{hoop} - 2t\right)}{(2r_{axial} - t)t}P - \frac{2r_{hoop} - t}{2r_{axial} - t}\sigma_{axial} \tag{2}$$

In Eqs. (1) and (2), P is the internal pressure, $R_{F_{axial}}$ is the axial reaction force on the actuators, r_{hoop} and r_{axial} (shown in Fig. 4) are the bulging tube curvature at the pole section of the tube in hoop and axial directions, respectively, and t is the thickness of the tube at the pole which is calculated using the initial thickness (t_0) and the major and minor strains at the pole (Eq. 3).

$$t = t_0 e^{-\left(\varepsilon_{axial} + \varepsilon_{hoop}\right)} \tag{3}$$

It also has to be mentioned that the axial and hoop curvatures of the bulging tubes at the pole section are calculated based on the least mean square method to fit a circle to the points on the surface of the tube at the pole section in axial and hoop directions.

Fig. 4 Schematic of the bulged tube with axial and hoop curvatures

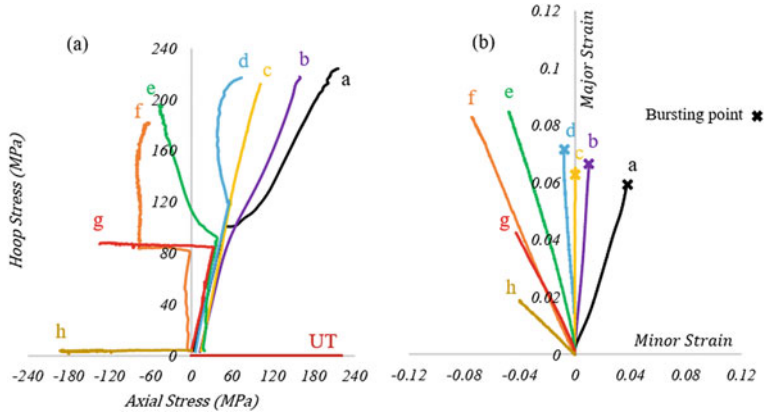

Fig. 5 **a** Stress paths at the pole of the tubes under T-T (a-d) and C-T (e-h) and **b** Strain paths at the pole of the tubes under T-T (a-d) and C-T (e-h). (Color figure online)

Figure 5a shows the principal stresses calculated at the pole of the tubes for all the eight biaxial tests plus the uniaxial tensile test, and Fig. 5b shows the measured principal strains at the pole of the tubes.

3.2 Yield Functions Calibration

In this study, three different yield functions, von-Mises, Hill's 1948, and Yld2004 were considered for the elastoplastic modeling of the AA7075-O tubes under tension–tension and tension–compression. In Eq. (4) (Hill's 1948), $\overline{\sigma}$ is the effective stress, F, G, H, L, M, and N are anisotropic coefficients, and in Eq. (5) (Yld2004), $\widetilde{S}_i'$ and $\widetilde{S}_i''$ are the principal values of two tensors defined by two linear transformations on the stress deviator. In Eq. (5), a is considered 6 for BCC materials and 8 for FCC materials. Details of the Yld2004 model can be found in [12].

$$\begin{aligned}\varphi^2 =& F(\sigma_{22}-\sigma_{33})^2 + G(\sigma_{33}-\sigma_{11})^2 \\ &+ H(\sigma_{11}-\sigma_{22})^2 + 2L\sigma_{23}^2 + 2M\sigma_{31}^2 + 2N\sigma_{12}^2 = \overline{\sigma}^2\end{aligned} \tag{4}$$

$$\varphi = \varphi(\bar{S}', \bar{S}'') = \left|\bar{S}_1' - \bar{S}_1''\right|^a + \left|\bar{S}_1' - \bar{S}_2''\right|^a + \left|\bar{S}_1' - \bar{S}_3''\right|^a + \left|\bar{S}_2' - \bar{S}_1''\right|^a + \left|\bar{S}_2' - \bar{S}_2''\right|^a + \left|\bar{S}_2' - \bar{S}_3''\right|^a + \left|\bar{S}_3' - \bar{S}_1''\right|^a + \left|\bar{S}_3' - \bar{S}_2''\right|^a + \left|\bar{S}_3' - \bar{S}_3''\right|^a = 4\bar{\sigma}^a \tag{5}$$

A single tensile test is enough to calibrate von-Mises yield function. However, to calibrate the anisotropic coefficients of Hill's 1948 and Yld2004, first, the principal stresses at a particular plastic work level as an equivalent hardening state for all the loading paths were characterized in stress space as well as their conjugate plastic

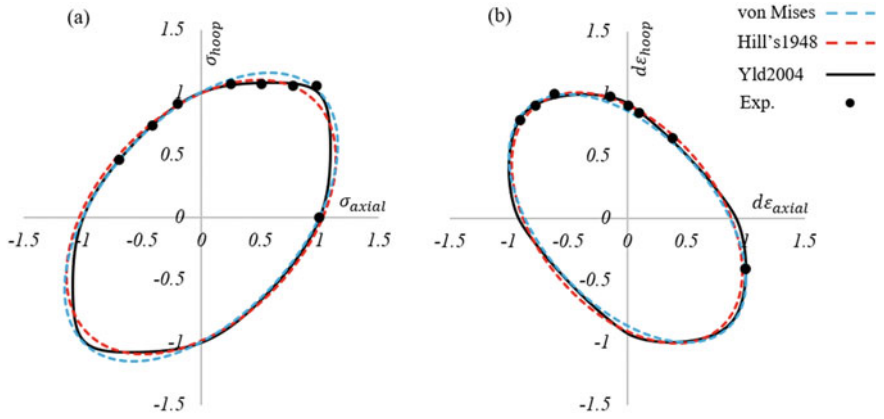

Fig. 6 **a** Normalized yield surface (Stress values were normalized to the uniaxial tension stress) and **b** Normalized strain-rate potential (Strain rates were normalized to the axial plastic strain rate in uniaxial tension) at plastic work level of 7 MPa. (Color figure online)

strain rate in strain rate space as can be seen in Fig. 6. It has to be mentioned that the plastic strain rates were calculated by calculating the derivative of the plastic strain with respect to the plastic work at a particular plastic work level considered as the equivalent hardening state. To determine the anisotropic coefficients of Hill's 1948 and Yld2004 yield functions, the error function given in Eq. (6) was minimized. In Eq. (6), c' and c'' represent the anisotropic parameters, q represents the number of experimental flow stresses, l represents the number of experimental conjugate plastic strain rate ratio, and W_q and W_l are the weights for the flow stresses and plastic strain rate ratios, respectively.

It also has to be mentioned that $\frac{\partial\varphi/\partial\sigma_{ii}}{\partial\varphi/\partial\sigma_{jj}}_{l}$ in Eq. (6) represents the direction of the plastic strain rate based on the normality rule for yield function φ based on associated flow rule assumption.

$$E\left(c'_{ij}, c''_{ij}\right) = \sum_{q} W_q \left(\sigma_q\big|_{pr} - \sigma_q\big|_{ex}\right)^2 + \sum_{l} W_l \left(\frac{\partial\varphi/\partial\sigma_{ii}}{\partial\varphi/\partial\sigma_{jj}}_{l} \big|_{pr} - \frac{d\varepsilon^p_{ii}}{d\varepsilon^p_{jj}}_{l} \big|_{ex} \right) \quad (6)$$

As Eq. (6) shows, to calibrate the anisotropic Hill's 1948 and Yld2004 yield functions, the stress space data as well as the plastic strain rate space data in the form of strain-rate potential are used. Figure 6a shows the calibrated von-Mises, Hill's 1948, and Yld2004 yield functions' yield surfaces and Fig. 6b shows the calculated strain-rate potentials' for the three yield functions. It must be mentioned that since it is experimentally very difficult to measure the out-of-plane parameters, and also because, in the thin-walled tube-free bulging tests, the out-of-plane stresses are negligible, the isotropic parameters were considered for the out-of-plane anisotropic parameters of the Hill's 1948 (L = 1.5, and M = 1.5) and Yld2004 ($c'_{55} = c'_{66} = c''_{55} = c''_{66} = 1$). Tables 1 and 2 show the calibrated anisotropic parameters for Hill's 1948 and Yld2004, respectively.

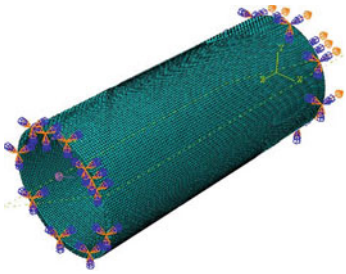

Fig. 7 FEM model of the tube for multiaxial expansion test. (Color figure online)

3.3 FEM Modeling

The calibrated yield functions were used for FEM simulations of the tube expansion tests under biaxial tension and tension–compression. In the FEM model, the eight-node linear brick element with reduced integration (C3D8R) was used, and three through-thickness elements were considered for the tube. The dimensions of the tube in the FEM model were also identical to the actual tubular samples' size. As for the boundary conditions, the same internal pressure and axial feed that were used in the experiments were also applied to the tube in the FEM model. Figure 7 shows the FEM model of the tube with the boundary conditions. As can be seen, one end of the tube is fixed and the other end can move axially, which is identical to how the tests were performed experimentally.

4 Results and Discussion

Figure 8 shows the strain paths measured compared to the ones predicted by the FEM simulations using von-Mises, Hill's 1948, and Yld2004 yield functions.

As can be seen in Fig. 8, with no surprise, as the material model gets more sophisticated with more parameters to be calibrated from von-Mises to Hill's 1948

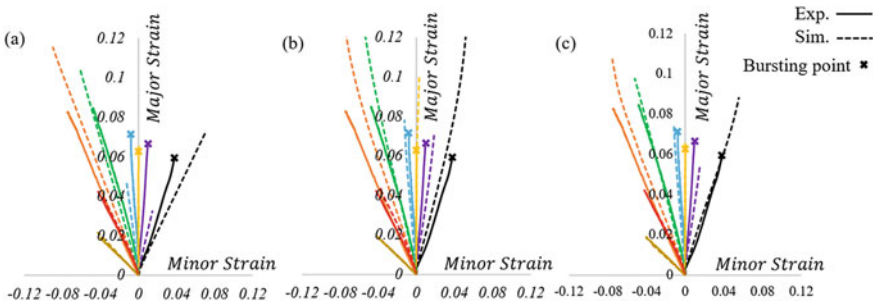

Fig. 8 FEM simulation results compared to the experiments for **a** von-Mises, **b** Hill's 1948, and **c** Yld2004 yield functions. (Color figure online)

to Yld2004, the FEM results show a better agreement with the measured strain paths. The point that is proven with these results is that proportional loading is not necessary for plasticity characterization, and as shown in Fig. 5, not all the loading paths are necessarily proportional; however, the yield functions can be calibrated using these experimental data based on plastic work equivalency. Also, it can be seen in Fig. 8 that using strain-rate potential, which was directly calculated based on the biaxial data, to account for the strain data in the calibration process is an accurate and flexible method and results in reasonable prediction instead of using R values for particular cases ($r_{0,}$ $r_{90,\text{ and}}$ $r_{b)}$ that are difficult to obtain for tubular materials or are not reliable and enough for advanced anisotropic yield functions with a high number of coefficients such as YLD2004. The other point to mention is that, as can be seen in Fig. 8, the isotropic von-Mises yield function is predicting the strain paths in tension–compression as good as Hill's 1948 and Yld2004, which means that this material shows isotropic behavior under tension–compression, while the anisotropic plasticity is significant under tension–tension, where Hill's 1948 and Yld2004 are predicting better with Yld2004 predicting the maximum elongation limit also better than Hill's 1948.

5 Conclusions

- It was shown that direct use of the biaxial data in the stress and strain rate spaces for the calibration of the yield functions is an accurate and flexible method, especially for the yield functions with a high number of coefficients.
- R value measurement in different directions for yield function calibration is very difficult for tubular materials. However, strain-rate potential that is the conjugate to the stress data for a particular plastic work can be used with any linear or nonlinear loading paths to account for the strain data for yield functions calibration.
- All the yield functions from simple isotropic quadratic von-Mises to anisotropic quadratic Hill's 1948 to anisotropic non-quadratic Yld2004 almost similarly

capture the isotropic plasticity of AA7075-O extruded tube under tension–compression. While, the anisotropic plasticity of the AA7075-O tube, which is significant under tension–tension, is captured more accurately with the yield function with a higher number of coefficients compared to the others.

Estimation and Prevention of Strain Localization in Shear Tests

Heinrich Traphöner, Till Clausmeyer, and A. Erman Tekkaya

Abstract The localization of strain in conventional shear tests and in-plane torsion tests is analysed for three different materials, namely CP1000, DP1000, and DC04. The influence of material properties, such as strength, strain hardening, and strain gauge length on the measurement of shear strains is investigated experimentally and by a new analytical approach. The weakly hardening high-strength complex-phase steel CP1000 shows experimental and analytical deviations up to 25% of the determined strain depending on the evaluation strategy. Such deviations will lead to crucial errors for the calibration of fracture curves and damage models. By a new grooved in-plane torsion test specimen shear tests can be performed without the influence of the localization of strain. Strain measurements can thus be performed more exactly nearly regardless of the strain gauge length and hardening behaviour. In the first experimental results, the deviation is below 4.6% for CP1000 and below 0.5% for DC04.

1 Introduction

Numerical simulations as well as the optical measurement of strains are based on a discretization of the surface of a continuum into individual areas. Local strains within these single "elements" can only be determined for the entire area. Local differences within the elements are not measured. One characteristic of shear tests, such as the Miyauchi shear test [1] or the in-plane torsion test [2], is the increasing stress gradient, which leads to the localization of shear strain in a narrow area of the sample. The intensity of the localization is influenced by the shape of the specimen and the mechanical properties of the materials. For some applications, such as the characterization of the Bauschinger effect using the in-plane torsion test, this stress

gradient is useful for efficient material characterization. Cyclic flow curves can be determined at different positions of the sample and thus with different strains during load reversal [3]. For many conventional shear tests, a locally varying cross-section, and hence a gradient of stress, is even necessary to produce the desired simple shear deformation in the test area [4]. For other applications, such as determining flow curves with very little or no strain hardening, the strain gradient is a major issue [5]. Strain localization in a narrow range around the position of maximum stress occurs, which can no longer be accurately measured by the discretization of the optical strain measurement. This work pursues three objectives:

- a sensitivity analysis for the relation between strain hardening and the resulting strain field in shear tests.
- an analytical calculation of the error due to discretization in shear tests for conventional shear tests and the in-plane torsion test.
- a presentation of a new grooved sample for the in-plane torsion test exhibiting no localization of the strain.

2 Experimental Analysis of Strain Localization in Shear Tests

2.1 Materials

Three materials were characterized to analyse the influence of strain localization to evaluate the amount of localization and the differences in the determined strain by a defined variation of the discretization size (strain gauge length). The study examined the ductile and strongly strain hardening DC04 steel, the high-strength dual-phase steel DP1000, and the complex-phase steel CP1000. The flow curves of the investigated materials are shown in Fig. 1. These were determined in the tensile test in the rolling direction according to the SEP1240 standard and extrapolated with flow curves from the in-plane torsion test. DC04 has a pronounced strain hardening (n

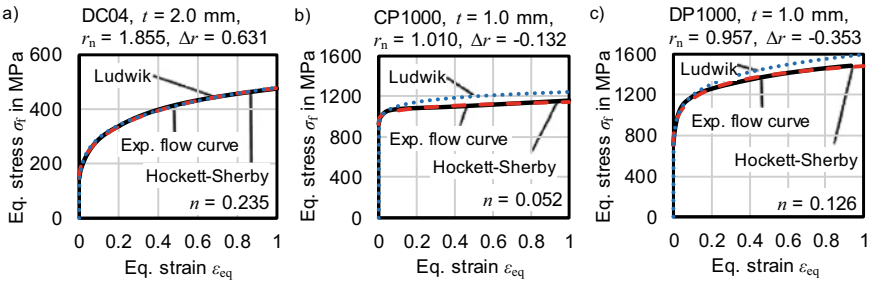

Fig. 1 Experimental flow curves and hardening exponent n for the investigated materials **a** DC04, **b** CP1000, and **c** DP1000. (Color figure online)

= 0.235). The initial yield stress is low at approx. 200 MPa and increases by approx. 150% at $\varphi = 1$. For CP1000, a slight hardening ($n = 0.052$) can be seen. After a high initial strength of 1000 MPa, the yield stress increases rapidly to about 1150 MPa and then rises only very slightly. DP1000 combines high initial strength with moderate strain hardening ($n = 0.126$). Due to the different strength and hardening levels, in principle, different localization properties are expected for these materials. The experimental flow curves were approximated using Hockett–Sherby and Hollomon equation. The hardening exponent n from the Hollomon approximation is a measure of the rate of increase in strength of the materials and is directly taken from the tensile test results. The approximated curves are applied in the analytical calculations in Sects. 3.3 and 4.1.

2.2 Experimental Setup and Specimen

Three different shear test samples shown in Fig. 2 were used to illustrate the localization behaviour. These are a conventional shear test with a shear length L_0 of 4 mm and a radius R_l of 1 mm (Fig. 2a) and the in-plane torsion test with the planar specimen (Fig. 2b) and with circular groove (Fig. 2c). The conventional shear test is loaded linearly parallel to the shear zone with the force F in a uniaxial testing machine. The in-plane torsion test is loaded with a torque M between inner and outer clamping. The inner clamping radius r_I is 15 mm and the outer clamping radius r_O is 30 mm. The groove has a radius r_{groove} of 4 mm and half the sheet thickness at the root of the groove. Details of the in-plane torsion test setup can be found in [6]. The strain on the specimen surface is measured by a 3D-DIC system.

2.3 *Influence of Strain Gauge Length on Strain Measurements Using DIC*

The specimen shown in Fig. 2 was tested and the strain field is measured using DIC. The strain gauge length was adjusted successively to defined values after the test by varying the DIC facet size and distance. A detailed description of the DIC settings is given in [5]. Each of the three specimens was evaluated with a different strain gauge length l_0 between 0.15 and 0.5 mm, and the mean strain along a line is measured at an equal position on the specimen.

2.3.1 Strain Distribution in Conventional Shear Tests

The influence of strain gauge length on the optical strain measurement between 0.15 mm and 0.5 mm is shown in Fig. 3 for the conventional shear test. The mean equivalent strain along the position of maximum strain and the deviation of the measured strain from the reference configuration ($l_0 = 0.15$ mm) are shown in each DIC strain field. DC04 shows only slight differences in the measured strain. A wide area of high strains is observed. Even larger strain gauge lengths do not lead to significant deviations. For CP1000, a very narrow deformation band and a strongly decreasing gradient of strain result. The measured strains for a strain gauge length of 0.5 mm are 16% smaller than for a gauge length of 0.15 mm. Strain measurement for CP1000 therefore shows a strong sensitivity to the strain gauge length. The deviation in the measured strain (7–8%) for DP1000 falls between the measured

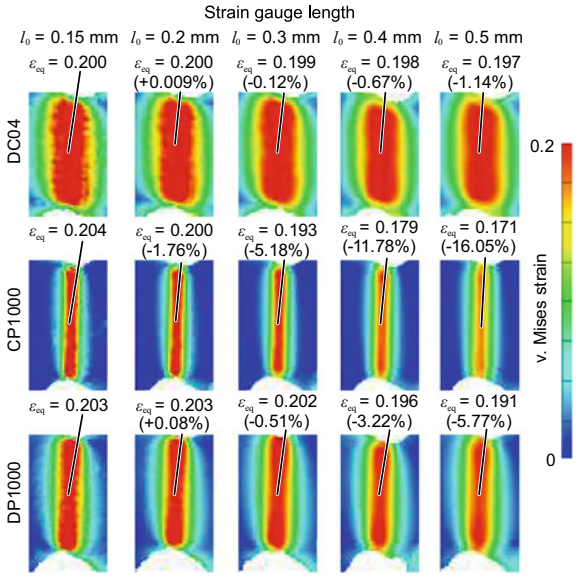

Fig. 3 Experimental deviations of the strain measurement with variation of the strain gauge length in the conventional shear test. (Color figure online)

ranges for DC04 and CP1000. Measurement deviations show a strong correlation with the hardening coefficient *n*. The smaller the hardening coefficient, the higher the deviation of the measured strains.

2.3.2 Strain Distribution in In-plane Torsion Tests

In-plane torsion tests were performed analogous to the conventional shear test. The strain gauge length is varied between 0.2 and 0.5 mm as shown in Fig. 4a. The radially decreasing strain gradient is comparable to the conventional shear test. In correlation with the work hardening of the materials, the intensity is stronger or weaker. In addition, for larger strain gauge lengths, the points close to the inner clamping can no longer be determined correctly, since the larger facets also make it

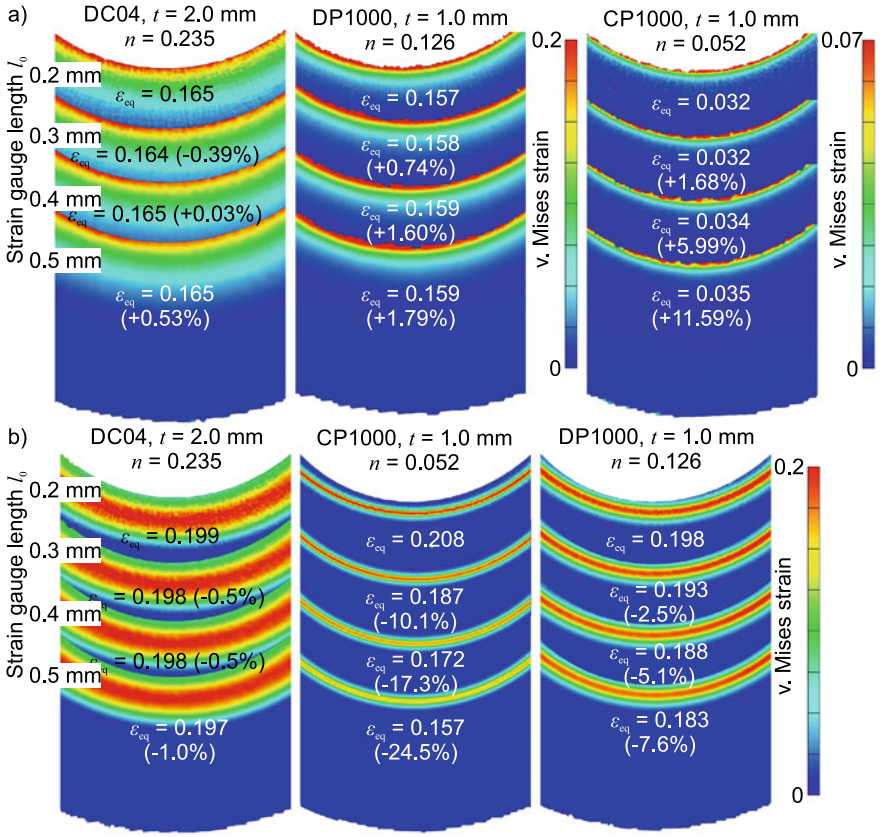

Fig. 4 Results of the strain measurement for DC04, CP1000, and DP1000 using different strain gauge lengths in the in-plane torsion test with **a** planar specimen and **b** conventional groove according to Fig. 3b [5]. (Color figure online)

impossible to measure a larger area near the inner clamping (at least ½ facet distance to the inner clamping). For this reason, the strain measurement was performed at a distance of 0.5 mm from the inner clamping ($r = 15.5$ mm). In comparison to the conventional shear test the measured strains increase with increasing gauge length. For the CP1000, an increase of the measured strain of approx. 11.6% can be seen.

The radially decreasing stress and strain gradient are even more pronounced when using a specimen with a circular groove. Figure 4b shows the equivalent strain for one specimen each of DC04, CP1000, and DP1000. Especially, the CP1000 steel with low hardening exhibits up to 25% deviation of the measured strain with respect to the smallest gauge length due to the strong localization of strain ($n = 0.052$) in a narrow range. DC04 ($n = 0.235$) shows only deviations of 1% of the measured strain. The larger the hardening of the materials, the lower the deviation is as the strain gauge length is increased, since the gradient of the strain at the maximum does not decrease so much. The smaller the strain gauge length, the more precise the strain measurement. The exact strain of highly localizing materials with strong strain gradients is therefore reasonably measurable only with very small optical facets.

3 Analytical Estimation of Measurement Errors Due to Strain Localization in Shear Tests

The experimental results from Sect. 2.3 show that the material-dependent localization of strain has a major impact on DIC-based shear strain measurement. In the following section, the error caused by the discretization is estimated analytically depending on the specimen geometry, the material properties, and the strain gauge length. With the described method, on the one hand, it is possible to analytically predict the measurement deviation and, on the other hand, to derive approaches for improving the measurement accuracy using DIC-based measurement of shear strains. The discretization error is defined as the ratio of measured shear strain for a discrete region γ_{dis} of size l_0 to the exact local strain γ:

$$\zeta = \frac{\gamma_{\mathrm{dis}}}{\gamma} - 1. \tag{1}$$

The discretization error ζ may have positive or negative values depending on whether the discrete strains γ_{dis} are larger or smaller than the exact strain γ. Figure 5a shows the deformation of an initially straight line for the conventional shear test. When the sample is loaded, the line deforms depending on the local stress in the test area. The exact local strain corresponds to the local shear angle η. The shear angle $\eta(l_0)$ for the discrete element of size l_0 is an integral measure resulting from the displacement dy along l_0. With nonlinear deformation of the line, there will be deviations of the measured shear angle from the exact local shear angle ($\eta \neq \eta(l_0)$). For $l_0 = 0$, the discretization error ζ is 0 and the strain measurement is exact. Figure 5b and c shows the deformation of a radial line for the in-plane torsion test

without groove and with groove. The discrete shear angle is here an integral measure over the circumferential angle θ.

For the subsequent analytical estimation of the discretization error, some assumptions are made as follows:

1. There is ideal simple shear in the test area, meaning that the cross-section (shear length and local sheet thickness) of the sheared area does not change.
2. There are no edge effects or inhomogeneity. Shear stress and shear strain are constant along the shear plane (for shear test: $\tau(x) = \text{const}$; for in-plane torsion: $\tau(\theta) = \text{const}$).
3. The shear stress can be calculated exactly from the force and the cross-section.
4. There is an isotropic material behaviour following the v. Mises yield criterion.
5. The flow curve of the material is known and can be approximated analytically.

3.1 Calculation of Local Shear Strains

With known elastic–plastic material properties, the local strain can be calculated analytically from the local shear stress τ. The shear strain γ is

$$\gamma(\tau) = \gamma_{\text{el}}(\tau) + \gamma_{\text{pl}}(\tau). \tag{2}$$

The elastic shear strain γ_{el} results from Hooke's law in dependency of the shear modulus *G*. The plastic shear strain $\gamma_{\text{pl}}(\tau)$ results from any hardening law:

$$\gamma_{\text{el}}(\tau) = \frac{\tau}{G} \text{ and } \gamma_{\text{pl}} = f(\tau). \tag{3}$$

The von Mises yield criterion is used to calculate shear stress and shear strain from the equivalent stress and strain:

$$\varepsilon_{\text{eq}} = \frac{\gamma_{\text{pl}}}{\sqrt{3}} \text{ and } \sigma_{\text{y}} = \sqrt{3} \cdot \tau. \tag{4}$$

The hardening law according to Ludwik,

$$\sigma_{\text{y,Ludwik}} = \sigma_0 + C \cdot \varepsilon_{\text{eq}}^n, \tag{5}$$

for example, results in the plastic shear strain.

$$\gamma_{\text{pl}}(\tau) = \sqrt{3} \cdot \left(\frac{\sqrt{3} \cdot \tau - \sigma_0}{C} \right)^{\frac{1}{n}} \text{ for } \tau > \frac{\sigma_0}{\sqrt{3}} \cdot \tag{6}$$

The shear stress τ is the force *F* referred to the cross-section in the shear region *A*.

$$\tau = \frac{F}{A}. \tag{7}$$

3.1.1 Conventional Shear Tests

For conventional shear tests as shown in Fig. 2a, the force F is directly measured and for the cross-section A follows:

$$\begin{aligned} A(x) &= t(x) \cdot L(x) \\ &= t \cdot \left(L_0 + 2 \cdot \left(R_l - \sqrt{R_l^2 - x^2} \right) \right). \end{aligned} \tag{8}$$

3.1.2 In-plane Torsion Test

The radius-dependent force *F,*

$$F(r) = \frac{M}{r}, \tag{9}$$

in in-plane torsion tests is calculated from the torque *M,* and the cross-section is calculated as

$$A(r) = 2 \cdot \pi \cdot r \cdot t(r) \tag{10}$$

with a constant sheet thickness t for the planar specimen (Fig. 2b) and a radius-dependent sheet thickness.

$$t(r) = t_{\text{root}} + r_{\text{groove}} - \sqrt{r_{\text{groove}}^2 - (r_{\text{root}} - r)^2} \tag{11}$$

for the grooved specimen according to Fig. 2c. With Eqs. (2)–(11) and known material parameters, the local shear strain can be determined exactly for all presented specimen shapes.

3.2 Calculation of Measured Discrete Shear Strains

The discrete shear strain is determined by integrating the displacements along the deformed lines. Due to the different coordinate systems (Cartesian and polar), the conventional shear test and the in-plane torsion test are to be considered separately.

3.2.1 Conventional Shear Tests

The local shear strain

$$\gamma = \tan(\eta) = \frac{dy}{dx} \tag{12}$$

is calculated from the local slope of the deformed line. For a discrete element with initial edge length l_0 follows from Eq. (12):

$$\gamma_{\text{dis}} = \frac{\Delta y}{\Delta x} = \frac{\Delta y}{l_0} \tag{13}$$

with

$$\Delta y = \int_{x_1}^{x_2} dy = \int_{x_1}^{x_2} \gamma(x) \cdot dx. \tag{14}$$

Inserting Eq. (14) into Eq. (13) follows for the discrete strain.

$$\gamma_{\text{dis}} = \frac{1}{l_0} \cdot \int_{x-\frac{l_0}{2}}^{x+\frac{l_0}{2}} \gamma(x) \cdot dx. \tag{15}$$

The required exact local strain $\gamma(x)$ is defined as described in previous Sect. 3.1.

3.2.2 In-plane Torsion Test

The calculation of the integral shear strain as a function of the strain gauge length for the in-plane torsion test is analogous to the conventional shear test. Shear strain is calculated from the local slope of the radial line:

$$\gamma = \tan(\eta) = r \frac{d\alpha}{dr}. \tag{16}$$

The discrete strain for a radial section $\Delta r = l_0$ is

$$\gamma_{\mathrm{dis}} = r\frac{\Delta\alpha}{\Delta r} = r\frac{\Delta\alpha}{l_0} \tag{17}$$

with the angular difference $\Delta\alpha$ from the integral of the incremental angle change $\mathrm{d}\alpha$.

$$\Delta\alpha = \int_{r_1}^{r_2} d\alpha = \int_{r-\frac{l_0}{2}}^{r+\frac{l_0}{2}} \frac{\gamma}{r} dr. \tag{18}$$

It follows for the discrete strain.

$$\gamma_{\mathrm{dis}} = \frac{1}{l_0} \cdot \int_{r-\frac{l_0}{2}}^{r+\frac{l_0}{2}} \frac{\gamma(r)}{r} dr. \tag{19}$$

$\gamma(r)$ is defined as described in Sect. 3.1.

3.3 Example Calculations for the Experimental Materials

The estimation of the measurement deviation was carried out for the materials investigated in Sect. 2. For this purpose, the flow curves of the materials were approximated according to Hockett and Sherby

$$\sigma_{\mathrm{y,HS}} = \sigma_\infty - (\sigma_\infty - \sigma_0) \cdot e^{-m\varepsilon_{\mathrm{eq}}^n} \tag{20}$$

as shown in Fig. 1 and the discretization error ζ is calculated according to Eq. (1). Figure 6 shows the discretization error in dependence of the equivalent strain for the conventional shear test. The strain gauge length l_0 was varied from approximately 0 mm (1×10^{-5} mm) to 0.5 mm in 0.1 mm steps.

3.3.1 Measurement Deviations During Elastic–plastic Transition

Figure 6 shows a strong increase of the discretization error at low strain for all materials. This is due to the measurement of test areas, which experience partially elastic and partially plastic strain as schematically illustrated in Fig. 7. If, for example, the local strain at the radius r is to be determined and this is just elastic, but the regions of the smaller radius within the same discrete element are already plastically

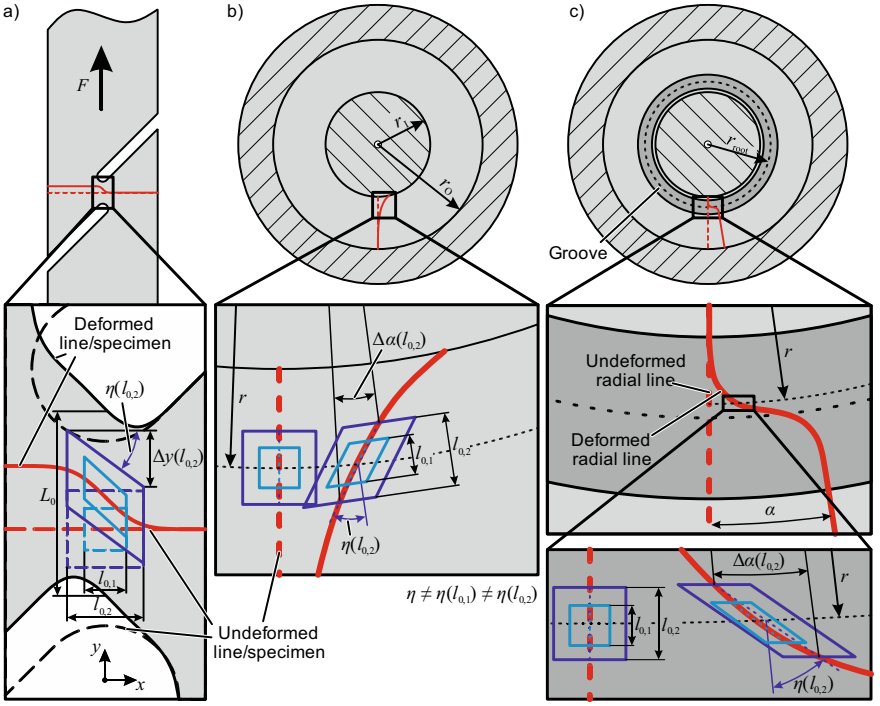

Fig. 5 Idealized deformation of an initially linear line in **a** the ASTM shear test, **b** the full in-plane torsion specimen, and **c** the in-plane torsion test with a grooved geometry. (Color figure online)

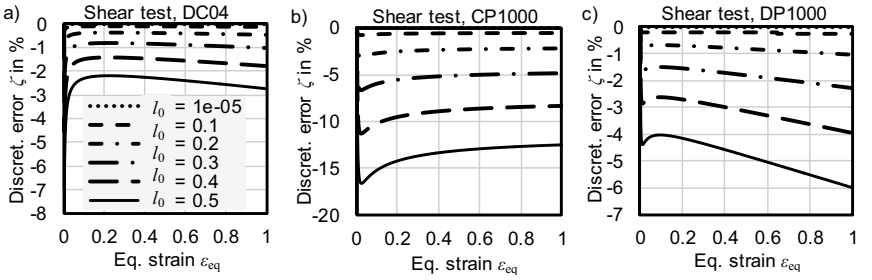

Fig. 6 Analytical calculated discretization errors for the investigated materials **a** DC04, **b** CP1000, and **c** DP1000 for conventional shear tests according to Fig. 2a

deformed, then the total distortion of the element in relation to the local distortion at the radius r is significantly greater and thus also the measured strain. The plastic strain is significantly greater than the elastic strain so that the integral determination of the strain always leads to an averaging of very small and in comparison very large strains and thus leads to large errors to the real local strain. The greater the proportion of the

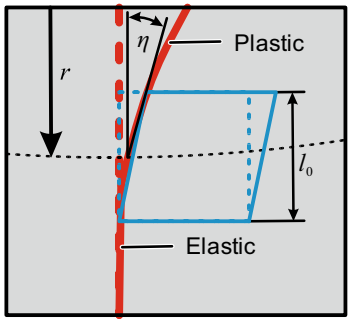

Fig. 7 Illustration of measurement deviation during elastic–plastic transition within the discrete element. (Color figure online)

purely elastic or subsequently the plastic region of the discrete measuring element, the lower the measurement deviation. The greatest deviation occurs when reaching the elastic–plastic transition at radius r, in which half of the range is elastic and the other half is already plastic. The softer the elastic–plastic transition, the lower the measurement deviation.

4 Prevention of Measurement Errors Due to Strain Localization in Shear Tests

It has been shown that measurement errors occur depending on the material properties, the sample geometry, and the settings of the DIC system. To reduce or avoid measuring errors using measuring systems with discrete measuring ranges, the following strategies can be used:

1. The strain gauge length must be reduced so far that errors are negligible.
2. The sample shape must be designed in a manner that localization does not occur. Both methods are briefly presented below.
   Furthermore, other methods are possible. These are not part of the present work.
3. Determine the error and then correct the measured strain by the error. For this, all sample-specific, material-specific, and system-specific parameters must be known exactly. Since the purpose of performing shear tests is to quantify the material-specific parameters, these are usually not available a priori.
4. Alternative measuring methods can be used. These include, e.g., the evaluation of the shear strain from the grain structure or, in the case of the in-plane torsion test, the determination of the shear strain from torque and angle of rotation [5].

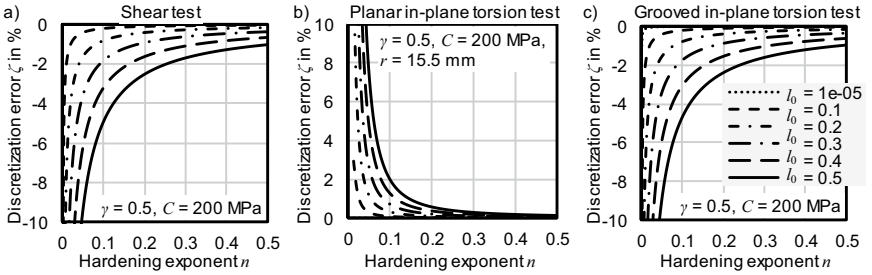

Fig. 8 Discretization error in dependency of the hardening exponent n for **a** the conventional shear test, **b** the planar in-plane torsion test at radius $r = 15.5$ mm, and **c** the grooved in-plane torsion test

4.1 Definition of Strain Gauge Length Based on the n*-Value*

Assuming the Hollomon (1945) hardening law

$$\sigma_{\mathrm{y}} = C \cdot \varepsilon_{\mathrm{eq}}^{n} \tag{21}$$

and neglecting elastic strains, the estimated measurement error in dependency of the hardening exponent n can be derived. It can be shown that the measurement deviation is nearly independent of the linear parameter C and independent of the shear strain γ, but mainly on the hardening exponent n. Figure 8 shows the expected measurement error as a function of the hardening exponent n and the strain gauge length l_0 for the three specimen types shown in Fig. 2. Using the given information, an estimation of the expected measurement deviation can already be made with knowledge of the n-value from the tensile test or the other way around, a suitable setting of the DIC system can be selected for which the deviation is sufficiently small.

4.2 Prevention of Strain Localization Using a New Grooved Specimen for In-Plane Torsion Tests

For the classic design of a groove, the shape of the groove is first defined, and then the resulting stress and strain along the groove contour result. The stress and strain state can then be further improved by inverse modification of the geometry. With the following new design method, the desired radial stress or strain profile is first defined, and then the local sheet thickness is defined based on it. Figure 9a shows the principle of the design for the new stress-adjusted groove in comparison with the stress distribution for the planar specimen and the specimen with conventional circular groove. The stress profile of the novel groove shape represents the following requirements:

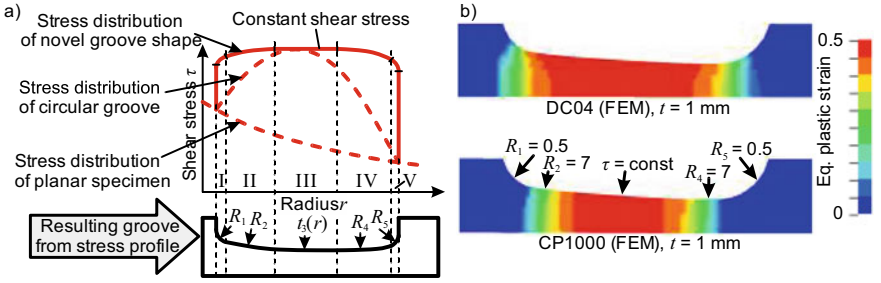

Fig. 9 **a** Principle of stress-adjusted groove shape. The local sheet thickness is defined depending on the required stress distribution. **b** Numerical analysis of the strain distribution for the stress-adjusted groove contour for DC04 and CP1000 in $t = 1$ mm sheet thickness [5]. (Color figure online)

1. The stress in the test area (zone III) of the groove should be constant along a radial section: $\tau(r) = \text{constant}$. The resulting strain will be constant as well. Thereby, the influence of the strain gauge length on the strain measurement (see Fig. 4b) can be avoided since no strain localization will occur. As long as the strain gauge length is not larger than the radial section with constant strains (size of zone III), the strain gauge length should have no influence on the measured strains.
2. Inside (zone II) and outside (zone IV), the gradient of stress should be weak to avoid locating the strain at transitions between the zones.
3. At the transitions to the surface of the sheet, a strong stress gradient is desirable to minimize the width of the groove. The wider the groove, the lower the maximum stress.
4. The stress profile should be continuous.

As a result, the shape of the groove results directly from the given requirements. The radius-dependent sheet thickness $t(r)$ can be calculated analytically from the calculation of stresses:

$$\tau(r) = \frac{M}{2 \cdot \pi \cdot t(r) \cdot r^2} \stackrel{!}{=} \text{constant}. \tag{22}$$

The sheet thickness $t(r)$ in the area of constant stress Δr_{const} (Zone III) results in

$$t(r) = \frac{t_{\text{mean}} \cdot r_{\text{mean}}^2}{r^2}. \tag{23}$$

A finite-element analysis is performed and the equivalent plastic strain for a section through the novel groove with radially constant stress is shown in Fig. 9b. The used flow curves correspond to the investigated DC04 (Fig. 1a) and CP1000 (Fig. 1b) materials as presented in Sect. 2. The element size is 0.05 mm. The sheet thickness

t is 1 mm and the width of Zone III Δr_{const} of 1.5 mm is arbitrary and should be at least the size of the strain gauge length of the measurement settings. On both sides, circular transitions with initially low stress gradient (radius 7 mm) and then strong stress gradients (radius 0.5 mm) complete the groove. There is a continuous transition between all zones. The strain in the centre of the groove (Zone III) is almost constant and homogeneous. Both materials show no difference in this area. A difference in the strain distribution due to the different amounts of localization can only be observed at the radii R_1–R_5.

The first experimental determined strain fields for the in-plane torsion test with the new groove manufactured by electro-discharge machining (EDM) are shown in Fig. 10. The investigated materials DC04, CP1000, and DP1000 are equal to the previous sections. Each specimen was evaluated with a different strain gauge length l_0 between 0.2 and 0.5 mm and the averaged strain along a circumferential circular line at the mean radius r_{mean} was measured. For CP1000, the deviation at 0.5 mm strain gauge lengths is reduced to 4.6% for the illustrated specimen at v. Mises strains of approx. 0.2 (Fig. 10b). The conventional circular groove shows 25% deviation (Fig. 4b). For an equivalent strain of approx. 0.5, the deviation is even reduced to 1.4%. The deviation for DC04 and DP1000 is below 0.7%. The remaining difference can be attributed to production-related deviations from the target local sheet thickness. The measured groove contour does not agree exactly with the analytical design, the stress along the radius is no longer perfectly constant,

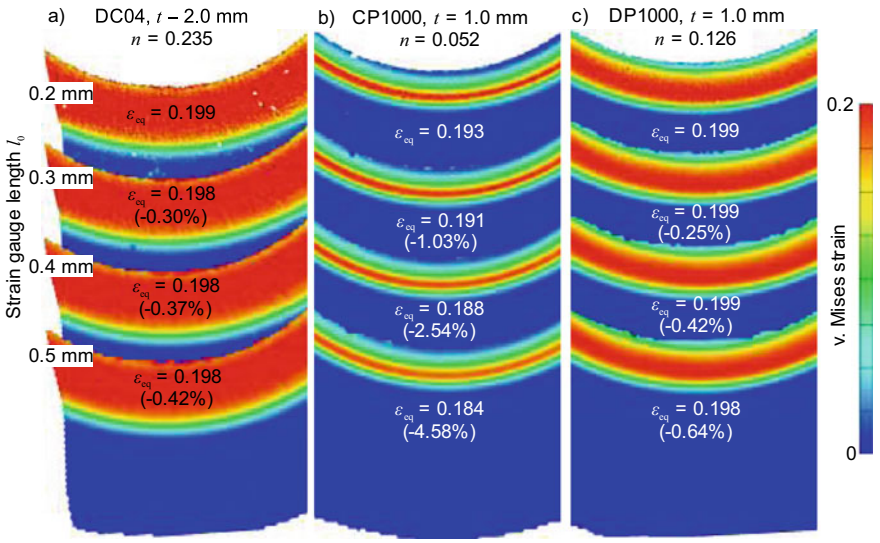

Fig. 10 Experimentally determined strain field for **a** DC04, **b** CP1000, and **c** DP1000 using the new stress-adjusted grooved specimen evaluated with different strain gauge lengths at $\varepsilon_{eq} = 0.2$ equivalent strain. (Color figure online)

and errors due to localization occur. In addition, other factors, such as the planar anisotropy, may influence the homogeneous strain field. Although this influence was negligible for the materials examined, it could be relevant for other materials and should therefore be examined in future works.

5 Conclusion

The influence of strain gauge length on the measurement of shear strains using DIC was investigated for three materials. The lower the work hardening of the material, the greater the measurement error due to the optical elements selected too large. Deviations up to 25% were measured for CP1000 material while DC04 only exhibits 1% deviation using the same setting. Through the presented analytical approach, the error can be estimated depending on the material properties and the specimen shape for conventional shear tests as well as for the in-plane torsion test. From the analytically determined dependence of the measurement deviation on the hardening exponent n, a material-specific setting of the measuring system can be defined. The necessary information can be taken directly from the results of the tensile test. The newly presented in-plane torsion test specimen with a stress-adjusted groove can also completely avoid the shear strain localization. However, this requires the exact production of the necessary groove contour. Any deviation from the ideal contour leads to a deviation from the homogeneous strain profile. Other influences on the test results, such as the planar anisotropy, must be examined in future works.

Experimental and Numerical Studies on Plastic Deformation and Failure Behavior of Carbon Nanotube-Reinforced Al Composite Sheet Under Uniaxial Loading Condition

Zhenming Yue, Xinrui Min, Zhanqiu Tan, Junyan Ni, Zhiqiang Li, Jun Gao, and Jie Zhang

Abstract The carbon nanotube (CNT) reinforced aluminum has been expected as one ideal metal matrix composite characterized by superior strength and high elastic modulus. However, the reduction of its ductility is often a serious drawback. Nonuniformity in the microstructure makes it difficult to maintain the structural integrity during the deformation. In this study, the mechanical property of CNT/Al2024 composite sheet of 1.0 mm will be investigated through uniaxial tensile tests. Meanwhile, the simulations based on micro- and macro-mechanical constitutive are conducted to reveal the relationship between the evolution of microstructure, like grain size, dislocation density and interfacial bonding, and macro deformation responses. This work can be helpful to better understand the key factors that influence the plastic deformation and failure of CNT/Al2024 composite under complex loading conditions.

1 Introduction

Carbon nanotubes (CNTs) are a kind of ideal reinforcement for metal matrix composites with the advantages of high modulus, good toughness, and stable structure. After the addition of CNTs, the metal matrix composites can be improved in strength and modulus at the same time to obtain excellent specific strength, specific stiffness, shock absorption, and other characteristics [1]. So the composite material has been widely used in aerospace, ship, automobile, electronics, and other fields. At present, the research on carbon nanotube-reinforced aluminum matrix composites mainly focuses on the production process, mechanical properties, microstructure, and so on.

Kwon et al. [2] used the method of hot pressing and sintering before extrusion to achieve uniform distribution of carbon nanotubes (CNTs). The results showed that the strength of CNT/Al composites increased with the increase of CNTs volume fraction. Kuzumaki et al. [3] conducted uniaxial tension tests on carbon nanotube-reinforced aluminum matrix composites, and the results showed that carbon nanotubes had a significant effect on the improvement of mechanical properties of the aluminum matrix. Esawi et al. [4] prepared the carbon nanotube-reinforced aluminum matrix composite by powder metallurgy, and the test results showed that the tensile strength of the composite was 21% higher than that of the aluminum matrix. With the breakthrough of preparation technology, the research on plastic deformation and damage fracture mechanism of carbon nanotube-reinforced aluminum matrix composites is just beginning. How to explain the mechanical strength and fracture damage failure mechanism of composite materials from the perspective of microstructure has become an urgent problem to be solved. Jian et al. [5] established a cohesive force model based on interfacial atomic van der Waals force interaction and studied the relationship between interfacial stress and interfacial displacement. Tan et al. [6] studied the macroscopic mechanical properties of carbon nanotube-reinforced composites based on the cohesion model and the theoretical basis of micromechanics. Finite element simulation analysis is a common method to analyze the mechanical characteristics of materials. Combined with the representative volume element (RVE) method, the mechanical responses of composites with different reinforcement bodies randomly distributed can be studied. But the plastic deformation and damage behavior of the composites are still less studied through the crystal model.

In this paper, the two-dimensional mesoscopic model of CNT/Al composites was established by the Voronoi algorithm based on the representative volume element (RVE) method. The mechanical properties of the Al matrix were studied by the crystal plastic model. The interface properties of carbon nanotube composites are represented by the cohesive model, and the plastic deformation and damage behavior of CNT reinforced aluminum matrix composites were studied.

2 Crystal Plasticity Model

Carbon nanotube reinforced aluminum matrix composites can be regarded as composed of two parts: the homogeneous matrix phase of aluminum alloy and the influence zone phase of carbon nanotube reinforcement. The matrix phase will be described by crystal plasticity, so as to obtain the effect of microstructure on plasticity and damage, and the plastic deformation and damage evolution of carbon nanotube-reinforced aluminum matrix composites will be studied at the mesoscopic level. Taylor [7] first introduced the concepts of slip and lattice rotation. Subsequently, Hill [8], Rice [9], and Asaro [10] established and developed the crystal plasticity theory to describe the plastic deformation of crystals. Crystal plastic constitutive model is widely used to characterize the macroscopic and microscopic evolution of polycrystalline materials, especially the evolution of crystal structure. The single crystal plastic constitutive equation [11, 12] adopted in this paper is as follows:

$$\dot{\sigma} = C : D - \sum_{\alpha=1}^{n} R_a \cdot \dot{\gamma}_\alpha \tag{1}$$

$$R_\alpha = C : P_\alpha - \sigma \cdot Q_\alpha + Q_\alpha \cdot \sigma \tag{2}$$

$$P_\alpha = \frac{1}{2}(s_\alpha \otimes m_\alpha + m_\alpha \otimes s_\alpha) \tag{3}$$

$$Q_\alpha = \frac{1}{2}(s_\alpha \otimes m_\alpha - m_\alpha \otimes s_\alpha) \tag{4}$$

$$\dot{\gamma}_\alpha = \dot{\gamma}_0 \left(\frac{\tau_\alpha}{g_\alpha} \right)^n sign(\tau_\alpha) \tag{5}$$

where $\dot{\sigma}$ is the Jaumann rate of the Cauchy stress tensor, C is the fourth-order elastic tensor, $\dot{\gamma}_\alpha$ is the plastic sliding shear rate, s_α denotes the slip direction, m_α denotes the normal direction of the slip surface, and g_α denotes the strain hardening state of the crystal. In the cubic system, the hardening law can be expressed as follows:

$$\dot{g}_\alpha = \sum_{\beta=1}^{n} h_{\alpha\beta} \left| \dot{\gamma}_\beta \right| \tag{6}$$

$$h_{\alpha\beta} = q h_0 (1 - \frac{g_\alpha}{g_s})^a \tag{7}$$

In the formula, $h_{\alpha\beta}$ is the hardening modulus matrix containing the self-hardening modulus and the latent hardening modulus, q is hardening matrix parameters, g_s is the saturation slip resistance, and h_0 and a are the hardening parameters for constitutive details.

3 Geometrical Modeling Based on Voronoi

To accurately predict the mechanical response of composites material, it is necessary to describe the microstructure accurately. In this study, a geometric model close to the microstructure of carbon nanotubes is established based on the Voronoi diagram. The Voronoi diagram is a spatial partition structure based on the proximity principle [13]. This model provides a more realistic microstructure for the simulation of polycrystalline materials and has more advantages in characterizing the random crystal orientation of polycrystalline materials.

3.1 CNT/Al Composite Material Model Based on Voronoi Diagram

In this paper, a two-phase polycrystalline model of Al alloy matrix and CNT/Al influence region was established based on the ABAQUS platform and the RVE model combined with the basic algorithm of the Voronoi diagram. The model dimension is 1×1 μm, as shown in Fig. 1. The crystal orientation was randomly assigned to each grain in the generated Voronoi diagram. Table 1 shows the parameters of the Al alloy matrix in the crystal plasticity model.

The properties of the affected zone of CNTs were expressed by the elastoplastic model individually, and Table 2 shows the CNT material parameters. In the table,

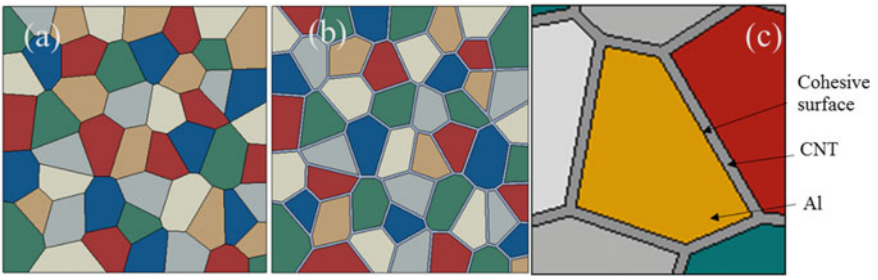

Fig. 1 The RVE model based on the Voronoi diagram. **a** Only the Al alloy matrix is considered in the RVE model, **b** Both matrix Al and reinforcement CNT are considered in the RVE model, **c** A schematic diagram considering the cohesion relationship between the CNTs and Al interfaces. (Color figure online)

Material	Elastic constants/MPa			ν	$\dot{\gamma}_{\alpha 0}$	n	h_0 MPa	g_s MPa	a	q
	C_{11}	C_{12}	C_{44}							
Al	106750	60410	28340	0.3	0.001	10	85	75	2.25	1

Table 2 The material parameters of CNT

Material	ν	E/GPa	σ_b/GPa	ρ/(g/cm^3)
CNT	0.2	1000	100	2.25

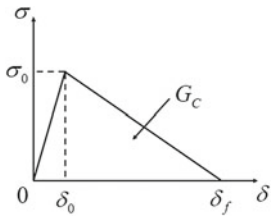

Fig. 2 Constitutive relation of bilinear cohesive elements

Table 3 Interface property parameters of cohesion model

Parameter	E/GPa	σ_0/MPa	δ_0/μm	δ_f/μm	G_C/(N/m)
Value	100	550	0.002	0.01	2.75

ν is Poisson's ratio, E is the elastic modulus, σ_b is the tensile strength, and ρ is the density.

The interfacial strength between the affected zone and the matrix phase was expressed by the cohesion model. In this paper, the bilinear cohesion model is adopted based on the ABAQUS platform, as shown in Fig. 2.

Where σ_0 is the initial stress of damage, δ_0 is the initial displacement of damage,δ_f is the displacement of damage failure, and G_C is the normal fracture energy. The interface property parameters of the cohesion model are shown in Table 3.

3.2 Boundary Conditions

During the loading process, in order to avoid the phenomenon of neck constriction and uneven distribution of strain, the boundary nodes of the constructed RVE model were restricted to make the distribution of strain more uniform, so as to obtain more accurate average strain and stress. As shown in Fig. 3, it is a schematic diagram of the boundary conditions of the RVE model after meshing. In Fig. 3, Top and Bottom are the set of nodes on the horizontal edge, Left and Right are the set of nodes on the vertical edge. A, B, C, and D are the nodes of the four corners, respectively. RP-1 and RP-2 are two reference points. The general constraint equation between nodes is shown below:

$$A_1 u_i^1 + A_2 u_j^2 + \cdots + A_N u_{\mathrm{k}}^{\mathrm{N}} = u \tag{8}$$

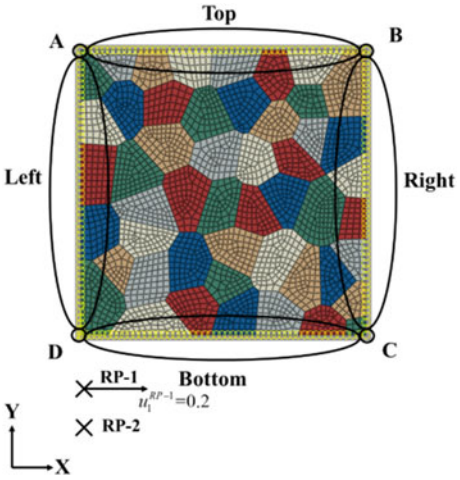

Fig. 3 Schematic diagram of the boundary conditions of the RVE model after meshing. (Color figure online)

where A_1, A_2, and A_N are the node coefficients, $u^1, u^2 \cdots u^N$ are the displacement of the corresponding node, i, j, and k are the degrees of freedom of the node, and u is the displacement of the reference point. In this paper, the simulation is performed in the X-axis direction. Therefore, the nodes A, D, and the node set Left have the same displacement in the X-axis direction, as do the nodes B, C, and the node set Right. The nodes constraint equation are shown below:

$$u_1^A = u_1^D = u_1^{Left} \tag{9}$$

$$u_1^B = u_1^C = u_1^{Right} \tag{10}$$

$$u_1^{Right} - u_1^{Left} = u_1^{RP-1} \tag{11}$$

In the Y-axis direction, the displacements of nodes A, B, and node set Top are the same and the displacements of nodes C, D, and node set Bottom are also the same. The nodes constraint equation are shown below:

$$u_2^A = u_2^B = u_2^{Top} \tag{12}$$

$$u_2^C = u_2^D = u_2^{Bottom} \tag{13}$$

$$u_2^{Top} + u_2^{Bottom} = u_2^{RP-2} \tag{14}$$

where u_1^{RP-1} is the displacement of the reference point RP-1 in the X-axis direction; u_2^{RP-2} is the displacement of the reference point RP-2 in the Y-axis direction. In this study, $u_1^{RP-1} = 0.2$ and $u_2^{RP-2} = 0$.

4 Results and Analysis

In order to show the effect of CNTs on the overall mechanical properties of composites, the mechanical response comparison curves of Al alloy matrix and CNT/Al composites in the uniaxial tensile simulation are presented in Fig. 4. The results showed that with the introduction of CNT into the Al matrix, its mechanical properties are significantly improved. The yield strength and elasticity modulus of CNT/Al composites have been increased correspondingly, which also proves that the reinforcement has a strengthening effect on the mechanical properties of the composite material.

Figures 5 and 6 show the distribution cloud diagram of stress and strain of Al matrix and CNT/Al composites under different tensile strain variables, respectively. By comparing the stress–strain distribution cloud map in Figs. 5 and 6, it can be found that with the addition of CNTs, the overall stress–strain cloud map of the composite material is more uniform. Meanwhile, the strain of CNTs is always the minimum, while the stress is always the maximum. The reason is that CNT has a larger elastic modulus than Al, so in the whole deformation process of composite materials, the deformation of CNT is the lowest, but the stress is the highest. By comparing the maximum stress and strain values, it can be clearly found that the maximum strain of CNT/Al composite material is lower than that of Al matrix, while the maximum stress is higher than that of Al matrix, indicating that the addition of CNTs makes the

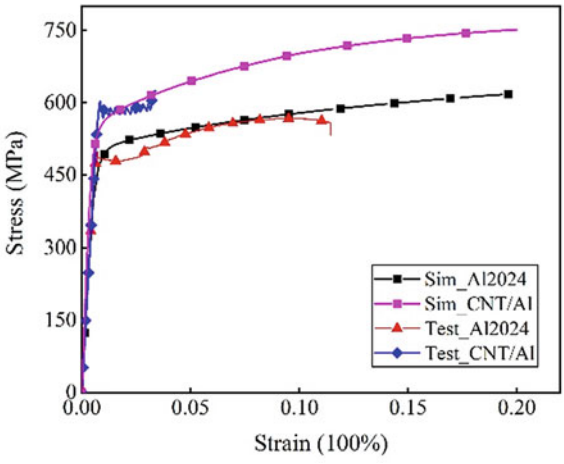

Fig. 4 Stress–strain curves of Al matrix and CNT/Al composites. (Color figure online)

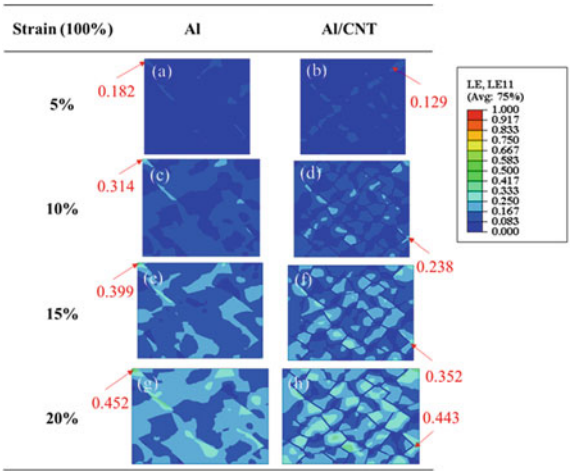

Fig. 5 Cloud diagram of strain distribution. (Color figure online)

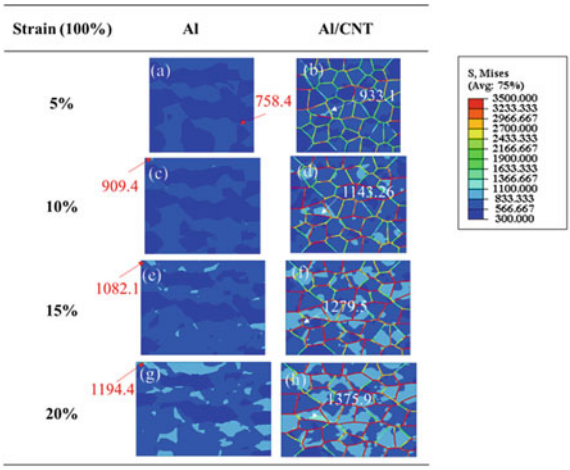

Fig. 6 Cloud diagram of equivalent stress distribution. (Color figure online)

deformation of Al matrix in the composite material more consistent and the plastic strain distribution more uniform. At the same time, it also shows that CNTs play a major bearing role in composite materials.

Through the setting of cohesive surface in ABAQUS, the whole process of damage and destruction of CNT/Al composite material can be viewed more clearly. In the elastic bearing stage, as the amount of deformation increases, the strength of the CNTs affected zone gradually increases and reaches the maximum value. In this stage, there is no damage in the affected zone (SDEG = 0), as shown in Fig. 7a. At this point, the strength of the affected zone plays a role in stress transfer between the CNTs and Al, so that the stress is more distributed on the CNTs. Therefore, the ductility of CNT/Al composites can be improved to some extent by increasing the

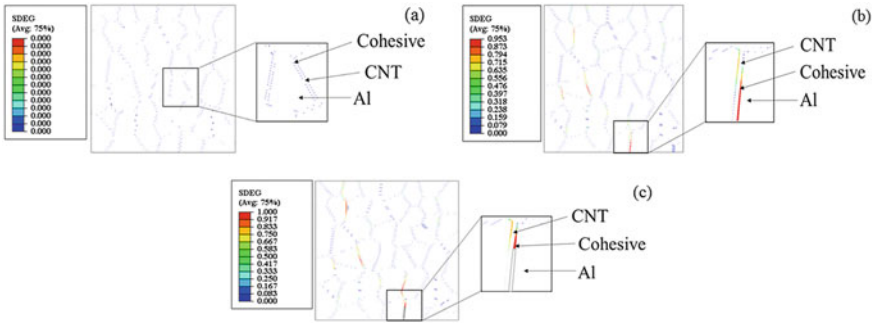

Fig. 7 The process of interface damage. **a** The diagram of elastic bearing stage, **b** The diagram of damage accumulation stage, **c** The diagram of crack propagation stage. (Color figure online)

strength of the interface. After the strength of the affected area reaches the maximum value, the affected zone enters the damage accumulation stage. With the increase of deformation, the damage gradually accumulated, as shown in Fig. 7b. In this stage, the interface strength gradually decreases, the stress transferred at the interface decreases, and the bearing capacity of CNTs and Al decreases. When SDEG = 1, the CNTs affected zone is completely damaged, and at this time, the affected zone enters the crack propagation stage. As the amount of deformation increases, the crack gradually expands, as shown in Fig. 7c. The failure zone no longer plays the role of transferring stress, and the CNTs and Al around the failure interface lose their bearing capacity.

5 Conclusions

In this paper, the elastoplastic and damage behaviors of CNT/Al composites were studied. A two-dimensional RVE model of composites was constructed in combination with the Voronoi algorithm. The mechanical behavior of the aluminum alloy was described by crystal plasticity theory. The cohesive model is used to describe the bonding ability of the matrix phase and the enhanced phase. The following conclusions are obtained through simulation studies.

During the entire deformation process of CNT/Al composites, the strain in the affected zone of CNTs was always the minimum and the stress was always the maximum. The addition of CNTs made the plastic strain distribution of matrix phase in the composites more uniform, playing a major bearing role in composite materials. The damage evolution of CNT/Al composites during loading deformation can be roughly divided into three stages: the elastic loading stage, the damage accumulation stage, and the crack propagation stage. In the elastic bearing stage, the interface plays a role in transferring stress, and the stress is mainly distributed in the affected zone of CNTs. In the damage accumulation stage, the strength of the interface gradually decreases, the stress transferred from the interface decreases, and the bearing capacity

of the CNTs affected zone and Al matrix phase decreases. In the crack propagation stage, the crack gradually develops and expands, the interface completely fails, and the CNT affected zone and Al matrix phase lose the bearing capacity. Increasing the interface strength between the CNT affected zone and the Al matrix phase can improve the overall ductility of the CNT/Al composite to a certain extent.

Experimental Study on Uniaxial Strain Cyclic Behavior of GS-20Mn5

Zongyuan Zou, Shuting Han, Hongzhong Wang, Qun Li, Baofeng Guo, and Shiyan Zhao

Abstract Due to the common discontinuity of the structure and non-uniform load, local high stress phenomenon tends to appear in the mechanical structure under repeated loading, and even local small plastic deformation may occur. In this case, the cyclic elastic–plastic mechanical properties of the structural steel are the key elements for the reasonable and accurate assessment of structural safety. In order to study the cyclic mechanical properties of GS-20Mn5, which is a commonly used steel in load-bearing mechanical equipment, corresponding strain cyclic loading tests were performed. The cyclic elastoplastic deformation characteristics under strain-controlled cyclic loading with different strain ratios ($R = -1, 0.5$) are studied, and the cyclic hardening/softening and mean stress relaxation features are revealed. The results show that the cyclic hardening/softening features are affected by the strain amplitude and cycles. This test material tends to show cyclic hardening at higher strain amplitudes. The cyclic stress–strain curve is obtained by the incremental step test, and the corresponding yield strength is about 4.8% larger than that under uniaxial tension. When $R = 0.5$, the test material exhibits obvious mean stress relaxation. When the strain amplitude is 0.16%, 0.30%, and 0.40%, the mean stress decreases and then stabilizes at about 25 MPa, −3 MPa, and −6 MPa, respectively. For the mechanical equipment made of GS-20Mn5 with local small plastic deformation under cyclic loading, the obtained cyclic mechanical performance of GS-20Mn5 can provide a reference for the analysis and evaluation of the structural safety.

1 Introduction

Most mechanical structures and components are often subjected to cyclic load when they are in service. Due to the complexity of the load and structure, the local high stress phenomenon occurs frequently during loading, and even local small plastic deformation happens. The elastoplastic properties of materials under cyclic loading are different from those under monotonic loading, such as cyclic hardening/softening and mean stress relaxation. More and more scholars pay attention to the cyclic deformation characteristics of materials and their influence on the fatigue life and loading capacity of structures. The cyclic hardening and softening characteristics of low-yielding steel BLY160 under cyclic loading were investigated, and the constitutive model to describe the cyclic deformation characteristics of the material was established [1]. The cyclic deformation response of 9–12% Cr steel under different loading conditions and its influence on fatigue life were analyzed [2]. The low cycle fatigue tests on 2121-t851 aluminum alloy with different strain ratios were conducted, and the effects of strain amplitude and strain ratio on low cycle fatigue behavior and micromechanism were analyzed [3]. Furthermore, the uniaxial cyclic elastoplastic deformation and fatigue failure of API-5L X65 steel under different loading conditions were studied [4]. Many researchers demonstrate that the cyclic hardening/softening characteristics, mean stress relaxation, and other cyclic plasticity properties of materials have significant effects on load-bearing capacity and life of structures. Therefore, clarifying the cyclic deformation characteristics of materials is important for rational mechanical structure design, analysis, and safety evaluation.

The cast steel GS-20Mn5(conforming to Germany standard DIN17182-1992) is commonly used for the column, beam, workbench of press, subjected to repeated load when the press is working. The studies of GS-20Mn5 mostly focused on its welding technology, and yet, the cyclic hardening/softening under cyclic loading and the mean stress relaxation characteristics have not been found in academic literature. In this work, the monotonic tension test and cyclic loading tests for strain ratio of -1 and 0.5 with different strain amplitudes were performed for GS-20Mn5, then the cyclic hardening/softening characteristics and the mean stress relaxation were studied, and the mechanical properties and deformation laws under cyclic loading of GS-20Mn5 were analyzed, which can provide a reference for strength and safety evaluation of mechanical structure made of GS-20Mn5.

2 Specimen and Equipment

The uniaxial tension specimen and cyclic loading specimen are shown in Figs. 1 and 2, respectively. The test equipment used, as shown in Fig. 3, is Instron 8801 hydraulic servo fatigue testing machine.

3 Experimental Investigation

3.1 Uniaxial Tension Test

In the test, the contact extensometer (Instron 2620-601) was used to measure the strain of the uniaxial tension process in real time, the strain rate is 0.1%/s, three repeated tests were carried out, and the resulted uniaxial tension stress–strain curve of GS-20Mn5 material is shown in Fig. 4. The test results show that GS-20Mn5 has an obvious yield platform in the uniaxial tensile deformation process, with a strain range of about 0.00156–0.0099 mm/mm, the yield limit is about 310 MPa, and the elastic modulus is about 212GPa.

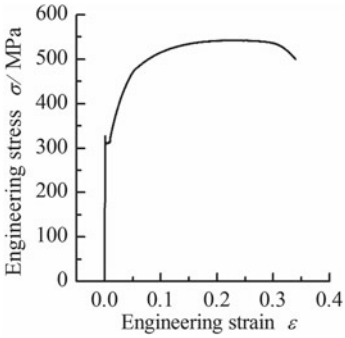

Fig. 4 Uniaxial tensile stress–strain curve

3.2 Experimental Study on Cyclic Hardening/Softening Characteristics

In the cyclic loading test, Instron's Wavematrix software was applied to set up the strain-controlled loading program to realize the closed-loop control and data acquisition of the test. Triangular wave was selected for the loading waveform, and the loading rate was 0.1%/s.

3.2.1 Single Step Cyclic Loading Test

Strain-controlled cyclic loading tests with strain ratio $R = -1$ were performed under three different strain amplitudes of 0.16%, 0.30%, and 0.40%, respectively. The number of cycles is 300 per strain amplitude. The response curves of stress amplitude with cycles of different strain amplitudes are shown in Fig. 5. It can be seen that when the strain amplitude is 0.16%, the stress amplitude decreases with the increase of the cycles, and finally stabilizes, in other words, the material shows cyclic softening characteristics during the initial cycles (about 200 cycles), and finally reaches cyclic stabilization; when the strain amplitude is 0.30%, the stress amplitude decreases first

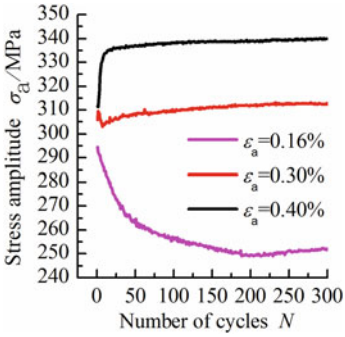

Fig. 5 Response curve of stress amplitude with cycles. (Color figure online)

and then increases with the increase of the cycle numbers, and finally stabilizes, that is, the material undergoes a slight cyclic softening first, then exhibits cyclic hardening characteristics, and finally tends to cyclic stabilization; and when the strain amplitude is 0.40%, the stress amplitude increases with the increase of cycles, and finally stabilizes, that is, the material first exhibits cyclic hardening characteristics, and finally reaches cyclic stabilization. That is to say, under cyclic loading conditions with different strain amplitudes, the response stress amplitude of the test material changes with the cycles differently. Both the strain amplitudes and the cyclic numbers are the factors that affect the cyclic hardening/softening characteristics. For the test material, a cyclic softening/hardening transition occurs with a strain amplitude in the range of [0.16%, 0.40%], and the cyclic softening gradually transforms to cyclic hardening with the increase of strain amplitude.

3.2.2 Incremental Step Cyclic Loading Test

Cyclic stress–strain curve of materials can be measured by the incremental step test [5, 6], and the cyclic stress–strain curve is used to reflect the mechanical properties of the material after cyclic loading. By comparing the cyclic stress–strain curve with the uniaxial tensile stress–strain curve, the cyclic hardening/softening characteristics of the material can be analyzed. The strain amplitudes of the incremental step test in this paper are 0.04%, 0.08%, 0.12%, 0.16%, 0.20%, 0.25%, 0.30%, 0.35%, 0.40%, 0.45%, and 0.50%. In order to obtain the hysteresis loop of steady state, 300 cycles of each strain amplitude is performed. The cyclic stress–strain curve of GS-20Mn5 is shown in Fig. 6.

According to the comparison between the cyclic stress–strain curve and the uniaxial tensile stress–strain curve in Fig. 6, it can be seen that when the strain amplitude is less than 0.30%, the cyclic stress–strain curve is lower than that of the uniaxial tensile stress–strain curve. That is to say, compared with the monotonic tension, the cyclic stabilization state of the material is characterized by cyclic softening. When the strain amplitude is greater than 0.30%, the cyclic stress–strain curve is higher than the uniaxial tensile stress–strain curve, and the material shows cyclic

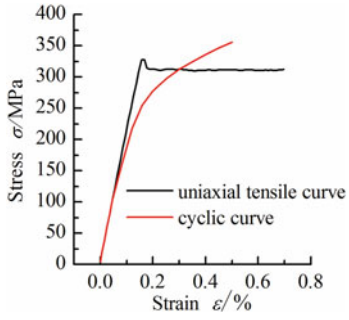

Fig. 6 Comparison of uniaxial tensile and cyclic stress–strain curve. (Color figure online)

hardening characteristics. The yield strength corresponding to the cyclic stress–strain curve is 325 MPa, which is about 4.8% higher than the yield strength corresponding to the uniaxial tensile stress–strain curve.

3.3 Experimental Study on Mean Stress Relaxation

The asymmetric strain-controlled cyclic test with strain ratio R of 0.5 was performed under different amplitudes of 0.16%, 0.30%, and 0.40% respectively to study the mean stress relaxation characteristic. About 2400 cycles were conducted for each strain amplitude. The mean stresses along with cycles of different strain amplitudes are shown in Fig. 7. It can be seen from that, under the three strain amplitudes, the material shows obvious mean stress relaxation characteristic. With the increase of cycles, the mean stress gradually decreases and tends to stabilization. When the strain amplitude is 0.16%, 0.30%, and 0.40% respectively, the mean stress eventually stabilizes to about 25 MPa, −3 MPa, and −6 MPa. It is worth noting that dimensionless form of mean stress is adopted as σ_{mn}/σ_{m1} to reflect the relaxation more clearly, and the curves of mean stress ratio with cycles are shown in Fig. 8. Here, σ_{mn} is the mean stress of the N_{th} cycle and σ_{m1} is the initial mean stress. It can be seen from Fig. 8 that the greater the strain amplitude is, the greater the mean stress relaxation rate is.

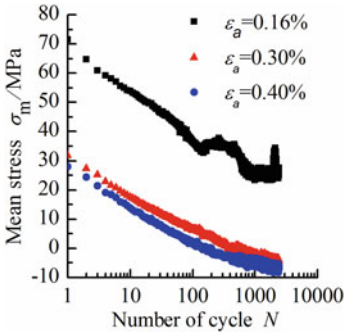

Fig. 7 Evolution of mean stress with cycles. (Color figure online)

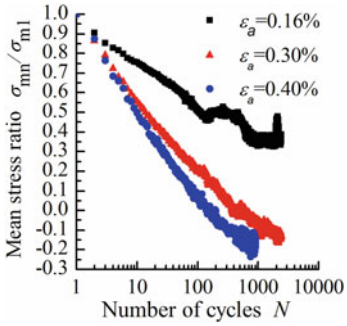

Fig. 8 Evolution of mean stress ratio with cycles. (Color figure online)

4 Conclusion

By uniaxial tensile test and strain-controlled cyclic loading test of GS-20Mn5, the following conclusions are concluded:

(1) The cyclic hardening/softening characteristics are affected by strain amplitude and cycles. Within the condition of experiment research, the experimental material is characterized by cyclic hardening behavior under larger strain amplitude (0.40%), while it is characterized by cyclic softening characteristic under lower strain amplitude (0.16%). In addition, under the strain amplitude (0.30%), the cyclic softening and hardening shift with the increase of cycles.

(2) According to the cyclic stress–strain curve with a strain range of [0−0.50%] obtained from the symmetrical strain incremental step test, when the strain amplitude is less than 0.30%, the stable state of the test material is characterized by cyclic softening compared with the monotonic tension, while when the strain amplitude is greater than 0.30%, the material is characterized by cyclic hardening. The yield strength corresponding to the cyclic stress–strain curve is 325 MPa, which is about 4.8% higher than the yield strength of 310 MPa under uniaxial tension.

(3) Under the asymmetric strain-controlled cyclic loading (strain ratio 0.5, strain amplitude 0.16%, 0.30% and 0.40%), the larger the strain amplitude is, the larger the mean stress relaxation rate and the smaller the mean stress stable value are.

Influence of Deformation on Texture Development During Cold Drawing of Tubes

P. Bella, P. Burik, P. Bucek, and M. Ridzon

Abstract Cold drawing of tubes is a metal forming process that allows manufacturers to produce high precision tubes. The anisotropy is a natural phenomenon in the tube wall thickness, in this method of manufacture. The EBSD measurements have been made on several Ferritic–pearlitic steels (8.9 wt% pearlite content) with different deformations for the detection of the effect composition has on the texture formation. The development of the crystallographic texture can be clearly explained by the stress–strain state at the material flow. This article was pointed out and connected between the development of the texture and stress state during the cold drawing process by turning the body-centered K8 grid (BBC). A significant influence on the texture change is also the heat treatment, where grains have the different ability of recrystallization. The cognition of this process will make it possible to achieve a tube with the optimum texture for the cold drawing process.

Keywords Cold drawing · Texture · Finite-element method

1 Introduction

Cold tube drawing is a metalworking process used to produce high-quality seamless tubes with precise dimensions, good surface finish, and high mechanical properties. Seamless tubes are used for applications where the homogeneity of strength, microstructure, and extended product life are important design parameters. For this particular technology, a hot rolled seamless steel tube serves as a feedstock for multiple cold drawing operations with intermediate heat treatment [1]. There are two processes employed for cold drawing seamless steel tube: drawing with the fixed plug and hollow sinking process (Fig. 1). Drawing with the fixed plug reduced outer diameter and wall thickness. The fixed cylindrical or fixed conical plug is used depending on the thickness of the input feedstock. The conical plug allows to use

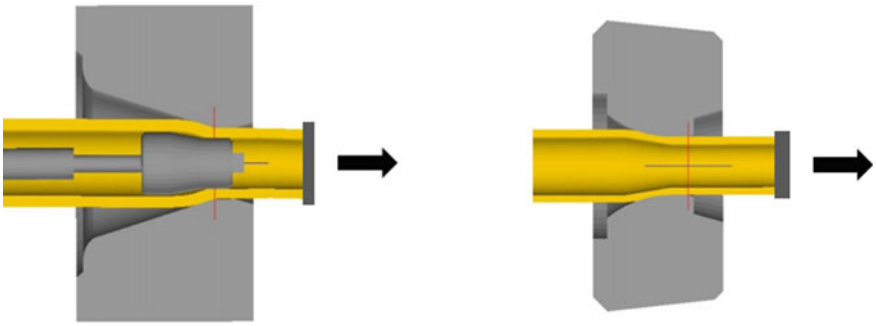

Fig. 1 Numerical scheme of drawing with the fixed plug (left) and hollow sinking process (right). (Color figure online)

higher drawing speed thanks to its geometry which provides a better flow of material. Hollow sinking is the final process in which the wall thickness remains the same, and the outer dimension is reduced [2, 3]. The change in wall thickness during deformation depends on the input dimensions of the tube and die geometry [4].

The low temperature during the cold drawing process does not allow dynamic recrystallization and thus the material hardening occurs due to the accumulation of dislocations. During the forming process, individual grains are elongated in the direction of the main deformation. Too high level of deformation and hardening is associated with a depletion of material plasticity and the risk of defects, and therefore recrystallization annealing is required. During annealing, the new deformation-free equiaxial grains are formed and the material is further deformed [5–7]. Given the demanding nature of the production process and strict requirements placed on tube diameters, the process was being looked into by means of the finite-element method (FEM) in DEFORM-3D simulation software. This numerical method provides an insight into the plastic deformation process and enables to investigate different physical fields in the modeled body, e.g., mechanical stress, deformation, deformation rate, damage criteria, material flow, etc. The technological process can be further optimized based on simulation results [8, 9]. For material flow analysis, sophisticated approach was chosen. By means of electron backscattering diffraction (EBSD), the texture of cold-drawn tubes was observed in cylindrical coordinates with respect to the drawing direction. Different grain orientations have different forming abilities. It is assumed that material with an optimal texture achieves high formability. Sample analysis for the EBSD method is very demanding and time consuming. We try to find a connection between the development of the texture and the stress state during plug drawing and hollow sinking process by rotation of the body-centered K8 grid (BBC). The cognition of this process will make it possible to achieve a tube with the optimum texture for cold drawing process. According to the literary overview, there has been little attention focused on this topic. This issue was solved in the works [10, 11]. The change of grain orientation by means of a tensile or compress stress was explained according to the scheme in Fig. 2. When the [100]–[110] boundary

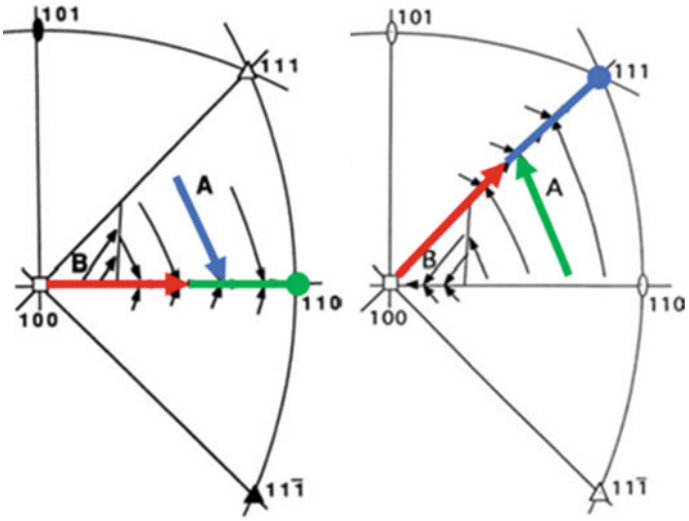

Fig. 2 Lattice rotation for BCC crystals: in tension (left); in compression (right). (Color figure online)

is reached, the combined slip in the [11–1] and [111] directions will cause rotation toward the [110] orientation, which is the stable end orientation (Fig. 2a). For a BCC crystal with pencil glide slip systems, the crystal atoms (CA) rotates away from the active slip direction. If the CA lies in region A, it will end up rotating toward the [111] end stable orientation (Fig. 2b), whereas if the CA lies initially in region B, it will rotate toward the [100] end orientation [12].

2 Material, Simulation, and Experiment

Technological exams were carried out on drawing bench TS 400. The used material was of grade E235 (Ø22 × 1.25 → Ø18 × 0.9 mm). The output diameter of the die land was 18 mm. The plug with outer diameter of 16.2 mm was used to achieve the required wall thickness. The outer diameter and the wall thickness were measured immediately after the pass. After that, the hollow sinking pass (Ø18 × 0.9 → Ø12 × 0.95 mm) which was carried out on drawing bench TS 3P–125 was selected from the same technological process. The output diameter of the die land was 12 mm. During the drawing process, the oil was being injected constantly. The outside diameter and the wall thickness of the tube were measured immediately. Forming tools were created in CAD program according to drawing setting and they were imported into the software DEFORM-3D with suitable file. Forming tools were defined as rigid objects. The tube was defined as a plastic object, which is suitable for modeling cold forming processes under certain conditions. In order to shorten the calculation

time, it is possible to use the 1° symmetry for the modeled domain. The tube was defined by FEM brick mesh. The wall thickness was described by ten elements due to high precision. Material data were defined by means of tensile tests. The tensile test defines the true strain to only $\varepsilon = 0.2$. The curve of flow stress was calculated by extrapolation to deformation $\varepsilon = 0.7$ according to [13]. This value is typical for cold-drawn tubes. The material temperature was 20 °C and no heat transfer between the material and the tools was considered. The friction boundary condition between the feedstock and the tools has been estimated according to a plant trial during which we recorded the electrical power of the bench and calculated the corresponding drawing force. In Table 1, there is a comparison of drawing force obtained from the plant trial and from DEFORM-3D simulation. A good agreement between experimental and simulation results confirmed that the material data and the friction coefficient were estimated correctly and also a good agreement between calculated dimensions and measured dimensions from technology has been achieved (Tables 2 and 3). The FEM formulation was of a Lagrangian incremental type. The drawing carriage was given the drawing velocity of $v = 400$ mm/s (as in technology). The results were evaluated in postprocessor DEFORM-3D in a steady state of the simulation (Eulerian point of view), which inherently oscillated due to the numerical nature of the model. Particular areas were described according to the cylindrical coordinate system for transparent analysis $[R, \theta, Z]$ (Fig. 3).

The crystallographic orientation of grains with individual orientations was examined by means of the EBSD method. The samples were taken from the longitudinal section of the tube. ESBD maps were acquired on an area ~ 200 × 150 μm using

Table 1 Comparison of drawing force F

Drawing pass	Ft [kN]	Fs [kN]	Difference [kN]	Difference [%]	Friction coefficient

3 Results and Discussion

Figures 4, 5, and 6 show results cold drawn with fixed plug from tube dimensions Ø22 × 1.25 mm to the dimensions of Ø18 x 0,9 mm. In the radial direction, the plug reduced wall thickness (Fig. 4). The radial strain was calculated by the value $\varepsilon_R = -0.27$ after the deformation zone. According to the rotation scheme of lattice that compress stress has caused an increase in the volume fraction of grain orientation <111> at the expense of grain orientation <101> and <100>. In the tangential direction (Fig. 5) was recorded compress strain ($\varepsilon_\Theta = -0.19$) because of reduction of the outer diameter of the tube. The change in the volume fraction is similar to that in the radial direction. In the axial direction (Fig. 6), there is a dominant effect on the axial strain $\varepsilon_Z = 0.50$. The grain orientation in the axial direction rotated by effect tensile stress into a stable grain orientation <101> in the BCC grid. Figures 7, 8, and 9 show results of hollow sinking process from dimensions Ø18 × 0.9 mm to Ø12 × 0.95 mm. In the radial direction, low tensile strain values ($\varepsilon_R = 0.08$) and the absence of compress stress are observed, since it is a hollow sinking process and there is no reduction in the wall thickness (Fig. 7). The low tensile component caused a low roughen of wall thickness. Just in the radial direction was observed a considerable change of development in the grain orientation in comparing to the plug drawing. The tensile stress in the radial direction caused a roughen/thicken of wall thickness. We can declare, according to volume fracture of grain orientation, that tensile stress has an influence on increasing grain orientation (101) from (111) and

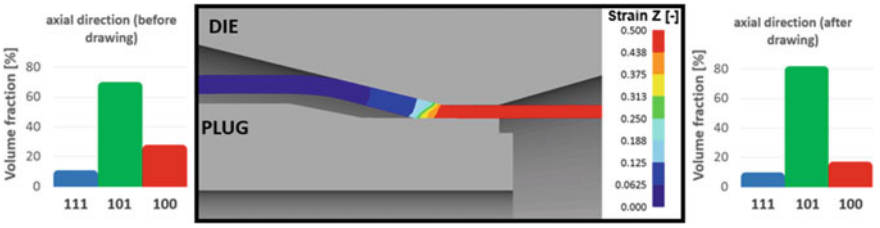

Fig. 6 Axial strain (middle) and texture before (left) and after plug drawing (right). (Color figure online)

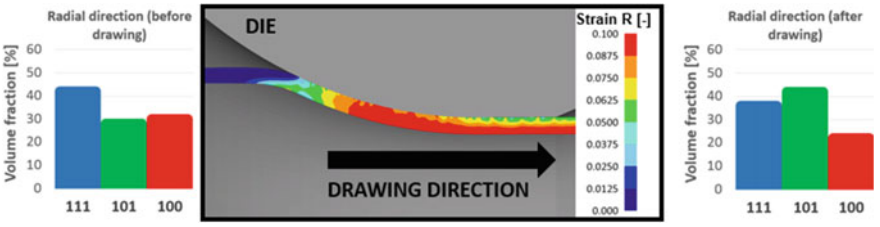

Fig. 7 Radial strain (middle) and texture before (left) and after hollow sinking (right). (Color figure online)

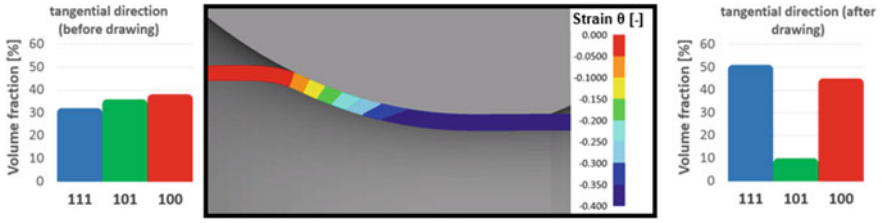

Fig. 8 Tangential strain (middle) and texture before (left) and after hollow sinking (right). (Color figure online)

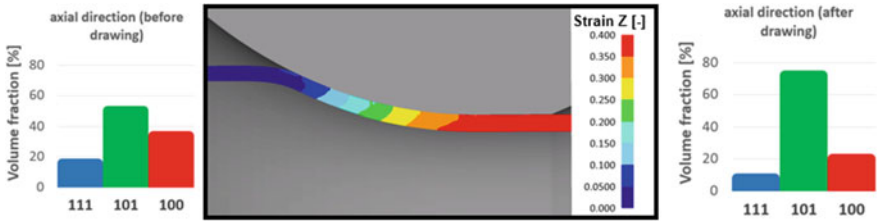

Fig. 9 Axial strain (middle) and texture before (left) and after hollow sinking (right). (Color figure online)

(100). In the tangential direction was the tube loaded by dominant compress strain $\varepsilon_\Theta = -0.44$ as illustrated in Fig. 8. The dominant effect of compress stress caused a reduction in the outer diameter of the tube after drawing. And also, compress stress caused increasing density of poles in texture (111). In the grain orientation (101), the density of poles was reduced. In the axial direction (Fig. 9) was the tube loaded by dominant tensile strain $\varepsilon_Z = 0.37$. The dominant tensile stress caused an increasing volume fraction of grain orientation (101) at the expense of grain orientation (111) and (100). The crystal plane (101) in the body-centered cubic (BCC) lattice of ferrite is most densely occupied by atoms and therefore the deformation occurs by sliding in this orientation.

On the basis of the results obtained, it is possible to create a simple model of texture development when cold steel tubes are drawn.

3.1 Scheme of Texture Development During Drawing with the Fixed Plug

Grain orientations in radial and tangential direction rotated by effect compress the stress into a stable orientation (111) in the BCC grid. Grain orientations in the axial direction rotated by effect tensile stress into a stable orientation (101) in the BCC grid (Fig. 10).

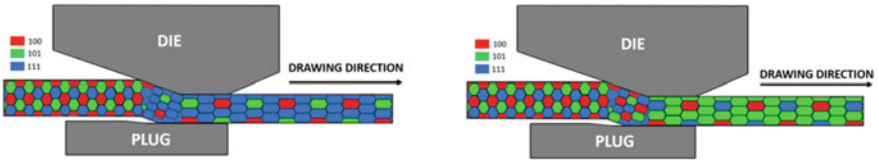

Fig. 10 Scheme of texture development during plug drawing in radial, tangential (left), and axial directions (right). (Color figure online)

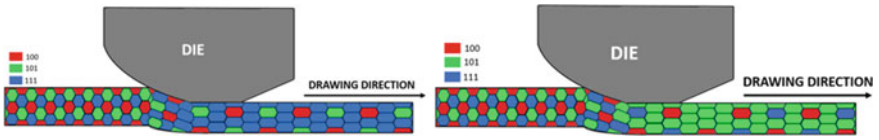

Fig. 11 Scheme of texture development during hollow sinking in tangential (left), axial, and radial directions (right). (Color figure online)

3.2 Scheme of Texture Development During Hollow Sinking Process

Grain orientations in tangential direction rotated by effect compress the stress into a stable orientation (111) in the BCC grid. Grain orientations in the axial direction rotated by effect tensile stress into a stable orientation (101) in the BCC grid. The texture development in radial direction depends on the change of wall thickness. If the wall thickness roughens/thickens, the orientation (101) will increase (Fig. 11).

4 Conclusions

We were able to find a connection between the development of the texture and the stress state during plug drawing and hollow sinking process by rotation of the body-centered K8 grid (BBC). We tried to estimate the value of stresses that cause rotation of the crystallographic grid, and thus change the percentage of the preferred crystallographic grid (or orientations) in the given direction of the cylindrical coordinate system. To simplify the concepts, we have developed models of texture development for plug drawing and hollow sinking process. Mastering this process will make the optimum texture for cold drawing process possible. Our next goal will be to confirm these models with further experiments.

Dynamic Recrystallization Behaviors of 5083 Aluminum Alloys with Different Initial Microstructures Under Hot Compression

Sheng Ding and Jun Yanagimoto

Abstract To study the dynamic softening behaviors of 5083 aluminum alloys with different initial microstructures under hot compression, hot compression tests of extruded and homogenized specimens were conducted at a strain rate ranging from 0.1 to 10/s and deformation temperatures ranging from 350 to 450 °C. The obtained true stress–strain curves of homogenized specimens were lower than those of extruded specimens especially at the initial deformation stage, suggesting that the effect of different initial microstructures on flow stress is significant especially at the initial deformation stage. Electron backscatter diffraction (EBSD) was used to observe the microstructure evolution process. The characteristics of continuous dynamic recrystallization, particle-stimulated recrystallization, and discontinuous dynamic recrystallization were confirmed. The experiments deformed at the same temperature and strain rate but with different strains showed the transition from continuous to discontinuous recrystallization. The recrystallization mechanism of 5083 aluminum alloys with different initial microstructures is thus finally illustrated.

Keywords Aluminum alloy · Hot compression · Dynamic recrystallization · Microstructure evolution

1 Introduction

Hot working is an important method in manufacturing to change the mechanical and geometrical properties of metals and alloys, especially for non-heat treatable ones [1]. During hot working, dynamic softening behaviors including dynamic recovery (DRV) and dynamic recrystallization (DRX) contribute greatly in decreasing the flow stress and thus lowering the load in manufacturing. Generally, the metals and alloys with high stacking fault energy seldom experience dynamic recrystallization during hot working, because dynamic recovery is enough for reducing the stored energy during deformation [2]. Aluminum alloys which have high stacking fault

energy are exceptions. They were revealed to experience dynamic recrystallization, including different series: 2xxx [3], 5xxx [4], 6xxx [5], and 7xxx [6] series. However, the mechanism of how the dynamic recrystallization process evolves for metals and alloys with high stacking fault energy in the previous research is still unclear, as there should be a difference compared with conventional dynamic recrystallization process. Moreover, homogenized initial microstructure is usually adopted to study the dynamic recrystallization process because the simple initial microstructure makes the research much easier. It is more challenging and meaningful to study the dynamic recrystallization process starting with a complicated initial microstructure, such as an extruded or rolled one, as they more often appeared in the manufacturing process.

In this study, hot compression tests of extruded and homogenized specimens deformed at different strain rates and temperatures were conducted to obtain the true stress–strain curves and study the deformation behaviors. For understanding the dynamic recrystallization process during deformation, hot compression tests deformed at different strains were also conducted. The following electron backscatter diffraction (EBSD) analysis identified the different mechanisms of dynamic recrystallization process during deformation.

2 Experimental Procedures

A commercial extruded rod of A5083BE-O aluminum alloy was used to prepare the test specimens for compression tests, whose chemical composition is 0.1Si, 0.15Fe, 0.04Cu, 0.82Mn, 4.5 Mg, 0.09Cr, 0.03Zn, 0.01Ti, and balanced Al. Two types of test specimens with different initial microstructures (extruded and homogenized) were prepared. The extruded test specimens with 8 mm diameter and 12 mm height were directly cut from the extruded rod. For preparing the homogenized test specimens, billets with 20 mm diameter and 45 mm height were first cut from the original extruded rod. Then a homogenizing treatment including a cold compression up to a true strain of 0.3 and a furnace homogenizing at 520 °C for 4 h was applied to these billets. Finally, the homogenized test specimens with 8 mm diameter and 12 mm height were cut from these homogenizing treated billets. The initial microstructures of extruded and homogenized test specimens are shown in Fig. 1.

Hot compression tests were conducted by the Thermecmastor-Z machine. Different temperatures (350, 400, and 450 °C) and strain rates (0.1, 1, and 10/s) were selected to obtain flow curves under various experimental conditions. To reveal the microstructure evolution during deformation, hot compression tests at the same experimental conditions (400°C and 1/s) but with different strains (0.1, 0.5, 0.9) were conducted.

To identify the DRX grains in EBSD observations, grains with lower grain orientation spread (GOS) and within a desired grain size range are considered as recrystallized grains [7], while the other grains are thus to be deformed grains.

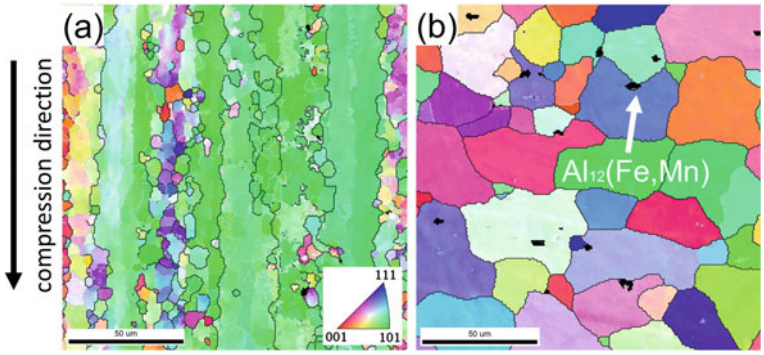

Fig. 1 Inverse pole figure (IPF) maps presenting the **a** extruded and **b** homogenized initial microstructures. (Color figure online)

3 Results and Discussion

3.1 True Stress–Strain Curves

True stress–strain curves of extruded and homogenized specimens obtained from hot compression tests are presented in Fig. 2. Flow stress decreases during deformation can be observed for all conditions, suggesting that dynamic recrystallization occurs during deformation. Flow stress level decreases with increasing temperature or decreasing strain rate. It is worth noting that at the initial deformation stage, as highlighted in dashed elliptical areas, the flow stress of extruded specimens is always higher, proving that different initial microstructures have a big influence on flow curves at the initial deformation stage. In contrast, at the final deformation stage, flow stress levels of extruded and homogenized specimens tend to be similar.

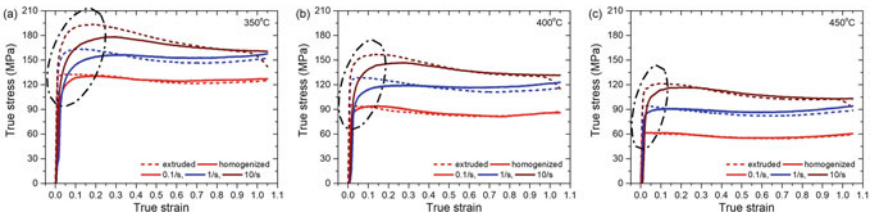

Fig. 2 True stress–strain curves deformed at **a** 350 °C, **b** 400 °C, and **c** 450 °C. (Color figure online)

Table 1 Arrhenius material constants

Initial microstructure condition	α MPa	n_{cst}	ln A_{cst} s^{-1}	Q kJ/mol
Extruded	0.008	6.80	35.71	205.46
Homogenized	0.008	7.43	36.83	211.26

3.2 Activation Energy of Deformation

Generally, the influence including both strain rate and temperature on flow behaviors can be expressed by only one parameter, i.e., the Zener–Hollomon parameter Z [8], as

$$Z = \dot{\varepsilon}\exp\left(\frac{Q}{RT}\right) \tag{1}$$

where R is the universal gas constant and Q is the activation energy of deformation (kJ/mol). Besides, the relationship between the Zener–Hollomon parameter Z and flow stress can be expressed by using an Arrhenius type equation as

$$Z = A_{cst}[\sinh(\alpha\sigma)]^{n_{cst}} \tag{2}$$

where α, n_{cst} , and A_{cst} are Arrhenius material constants. However, considering the flow stress range, the relationship between the Zener–Hollomon parameter Z and flow stress can also be expressed in power and exponential equations, respectively:

$$Z = \begin{cases} A'_{cst}\sigma^{n'_{cst}} & \alpha\sigma < 0.8 \\ A''_{cst}\exp(\beta\sigma) & \alpha\sigma > 1.2 \end{cases} \tag{3}$$

where A'_{cst}, n'_{cst}, A''_{cst} , and β are material parameters in different equation forms. These Arrhenius material constants can be obtained by regression analysis from stress–strain data, and they are summarized in Table 1. The activation energy of extruded specimens is smaller, suggesting that the dynamic recrystallization process of extruded specimens is easier compared with that of homogenized specimens. This can be confirmed by the later microstructure observations.

3.3 Microstructure Evolution

(1) Under different temperatures and strain rates

Under the whole experimental conditions, a fully recrystallized microstructure cannot be obtained, indicating that despite dynamic recrystallization, dynamic recovery is

still active and not replaced by dynamic recrystallization at the final deformation stage. When deformed at the same temperature with different strain rates, as shown in Fig. 3e, f for extruded specimens and Fig. 3m, n for homogenized specimens, a higher volume fraction of DRX can be observed under a lower strain rate condition, suggesting that a lower strain rate promotes the dynamic recrystallization process. When deformed at the same strain rate with different temperatures, as shown in Fig. 3e, g for extruded specimens and Fig. 3m, o for homogenized specimens, a higher volume fraction of DRX can be observed under a higher temperature condition, suggesting that a higher temperature promotes the dynamic recrystallization process. The reason for this is that a lower strain rate offers more time for energy accumulation

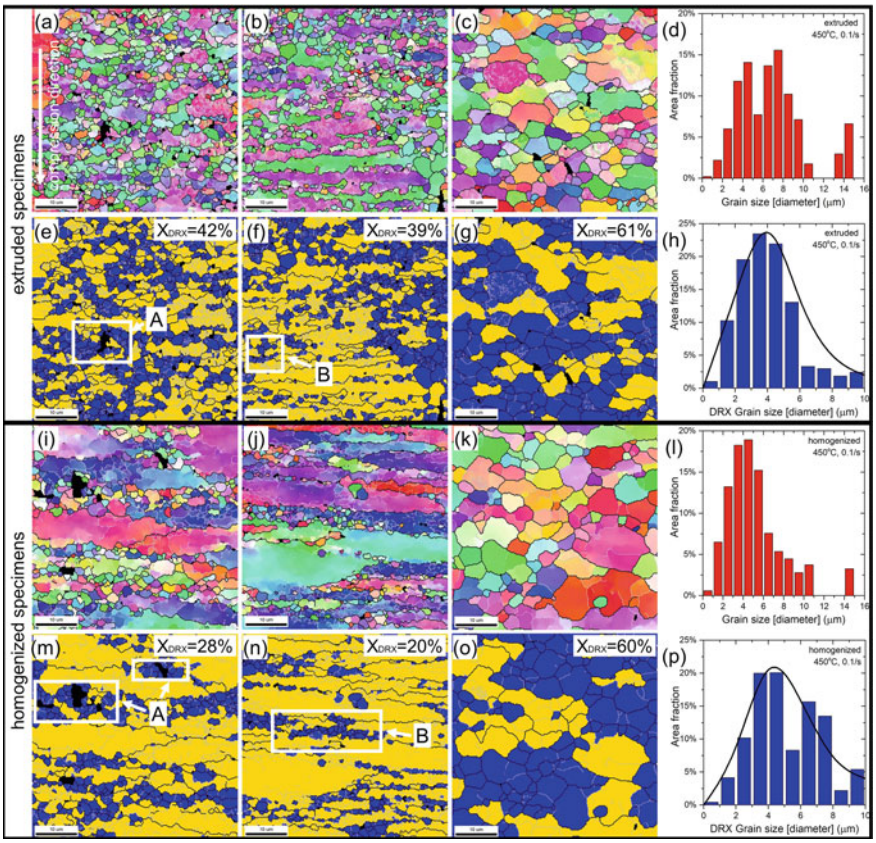

Fig. 3 IPF maps of extruded specimens deformed at **a** 350 °C, 0.1/s; **b** 350 °C, 10/s; and **c** 450 °C, 0.1/s, **e**–**g** corresponding to microstructures partitioned by GOS (grains in blue and yellow are recrystallized and deformed grains, respectively). IPF maps of homogenized specimens deformed at **i** 350 °C, 0.1/s; **j** 350 °C, 10/s; and **k** 450 °C, 0.1/s, (m-o) corresponding to microstructures partitioned by GOS. **d**, (l) grain size distributions of extruded and homogenized specimens deformed at 450 °C, 0.1/s, respectively. **h**, (p) grain size distributions of DRX grains of extruded and homogenized specimens deformed at 450 °C, 0.1/s, respectively. (Color figure online)

and a higher temperature provides more mobility of grain boundary, which both can enhance the dynamic recrystallization process [9].

It is worth noting that when the Zener–Hollomon parameter value Z is relatively low, which means dynamic recrystallization is more active, as shown in Fig. 3c, k for extruded and homogenized specimens, and no big differences between these two deformed microstructures can be observed, especially when compared with Fig. 3a, i, or b, j. The reason is that the average grain sizes of recrystallized grains for extruded and homogenized specimens are almost the same, as compared in Fig. 3h, p, i.e., initial microstructure has less effect on DRX grain size. Besides, when the volume fraction of DRX is relatively high, DRX grains become dominant. As a result, the grain size distributions of compressed microstructures, although start with different initial microstructures, are almost the same, as shown in Fig. 3d, i.

(2) Under different strains at the same temperature and strain rate

To reveal the microstructure evolution during a specific deformation process, compression tests at the same temperature and strain rate but with different strains were conducted including the major deformation stages from initial deformation stage (before critical strain, $\varepsilon = 0.1$), intermediate deformation stage (after critical strain, half of total strain, $\varepsilon = 0.5$) to final deformation stage (approach total strain, $\varepsilon = 0.9$).

At the initial deformation stage, as shown in Fig. 4a, d, no recrystallized grains can be observed in the homogenized specimen, while just a few recrystallized grains can

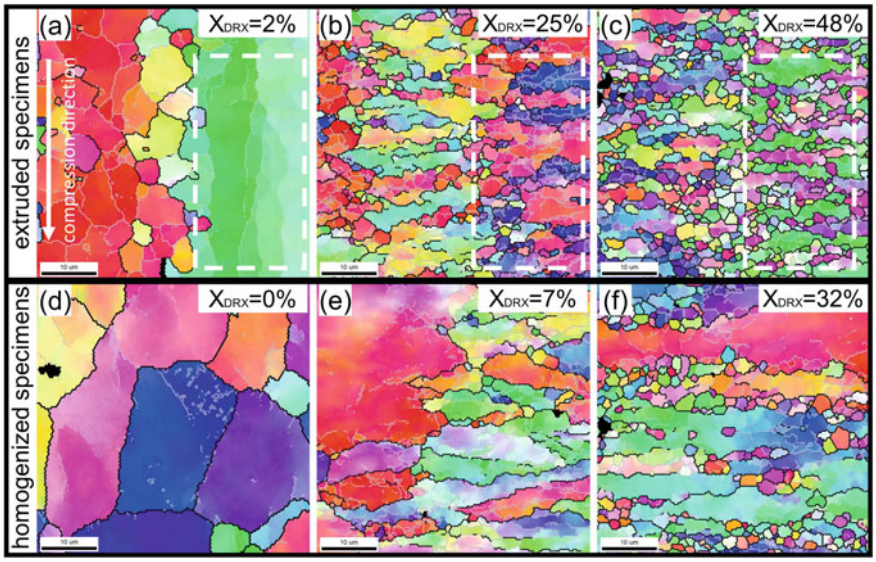

Fig. 4 IPF maps of extruded specimens deformed at 400 °C, 1/s with a true strain of **a** 0.1, **b** 0.5, **c** 0.9. IPF maps of homogenized specimens deformed at 400 °C, 1/s with a true strain of **d** 0.1, **e** 0.5, **f** 0.9. (Color figure online)

be observed in the extruded specimen. Sub-grain boundaries start to generate within the original grains. And the original grain boundaries become serrated with further compression. When the stored deformation energy is enough for dynamic recrystallization to occur, i.e., after critical strain, small equiaxed recrystallized grains can be observed, as shown in Fig. 4b, e. At the final deformation stage, a partially recrystallized microstructure including pancaked deformed grains and equiaxed recrystallized grains is observed for both extruded and homogenized specimens, as shown in Fig. 4c, f. And the recrystallized volume fraction of extruded specimen is always higher than that of homogenized specimen.

Besides, from the crystallographic directions shown in the IPF maps of extruded specimens, the prior elongated structure can still be distinguished, as shown in the dashed frames highlighted in Fig. 4a–c, and the similar colors in these areas suggest that these pancaked deformed grains are originated from a same elongated grain.

3.4 *Mechanism of Dynamic Recrystallization with Different Initial Microstructures*

Figure 5 presents the dynamic recrystallization process of extruded and homogenized specimens during compression. Intermetallic particles exist in both extruded and homogenized specimens. During deformation, dislocation density and misorientation can easily increase around these particles since they do not deform. As a result, recrystallized grains occur much more easily at these places (particle-stimulated recrystallization, PSN-DRX) [10], as shown in region A in Fig. 3e, m.

For the extruded specimens, its initial microstructure mainly consists of large elongated grains and small equiaxed grains. Sub-grain structures already exist within

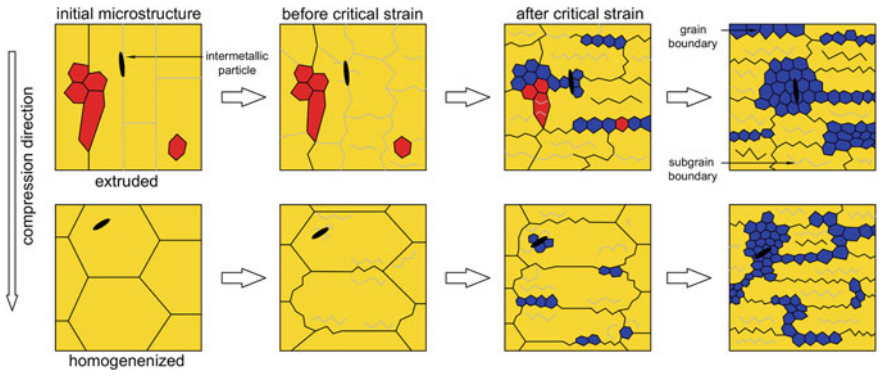

Fig. 5 Illustration of dynamic recrystallization process for A5083 aluminum alloys of extruded and homogenized specimens (Yellow grains: original grains/deformed grains; red grains: small grains exist in extruded initial microstructure; blue grains: recrystallized grains). (Color figure online)

elongated grains, some of these sub-grain boundaries progressively evolve to high-angle grain boundaries during deformation, and thus divide the original large elongated grain into pancaked deformed grains. Meanwhile, some of those sub-grains boundaries transfer to become recrystallized grains by progressive lattice rotation (continuous dynamic recrystallization, cDRX) [11]. With further deformation, grain boundaries of pancaked deformed grains become serrated, supporting a potential area for recrystallization by grain boundary bulging (discontinuous dynamic recrystallization, dDRX) [2], as shown in region B in Fig. 3f.

For the homogenized specimens, its initial microstructure is simple with only homogenized grains. There are almost no sub-grain structures within its initial microstructure. When deformation starts, sub-grain structures generate, especially near the original grain boundaries and triple junctions. With further deformation, original grains become pancaked, and their grain boundaries become serrated. sub-grain structures at these serrated grain boundaries and triple junctions can transform into new grains, as shown in the region B in Fig. 3n.

To conclude, sub-grain structures transfer to high-angle grain boundaries by cDRX, and further compression creates serrated grain boundaries, these serrated grain boundaries together with the areas around particles and triple junctions offer potential areas for dDRX. More sub-grain structures in extruded specimens make the dynamic recrystallization process faster than in homogenized specimens.

4 Conclusions

Hot compression tests of extruded and homogenized specimens were conducted at different strain rates, temperatures, and strains to study deformation behaviors and dynamic recrystallization process of 5083 aluminum alloy under different initial microstructures. The major conclusions can be summarized as follows.

(1) Flow stress of extruded specimens during deformation is always higher than that of homogenized specimens, especially at the initial deformation stage, showing the effect of different initial microstructures on flow stress.
(2) Microstructural observations confirmed the occurrence of dynamic recrystallization including particle-stimulated, continuous, and discontinuous dynamic recrystallization. Besides, the dynamic recrystallization process with different initial microstructures was illustrated.

Application of Barlat's Yld 2000-2d Yield Criterion to Predict the Anisotropic Response of Stainless Steel

Mauricio Vicente Donadon and José Divo Bressan

Abstract The plastic anisotropic response of stainless steel materials is investigated in this paper by using Barlat's Yld 2000-2d yield criterion. A new set of anisotropy coefficients is proposed and calibrated based on material experimental data. The new set of coefficients for the Lankford anisotropy coefficient, normalized yield stress, and equal biaxial stress were numerically obtained using the Newton–Raphson method. Study cases for AISI 409L and AISI 430 materials are presented and discussed. Correlations between predictions and experimental results indicate that Barlat's yield stress criterion and plastic stress potential for stainless materials are not coincident. Hence, the Barlat's non-associate flow rule gives better fitting with the experimental Lankford's coefficient of anisotropy results.

Keywords Stainless steel · Plastic anisotropy · Barlat's Yld 2000-2d yield criterion

1 Introduction

Anisotropy is a very commonly observed phenomenon whereby properties of material vary, depending on the direction along which they are measured. This obviously cannot apply to volumetric properties like density or specific heat, but virtually all other types of behaviour are susceptible to being anisotropic [1]. These can even include some chemical behaviour such as corrosion rates, but for the sake of simplicity, within the paper content it will be restricted to mechanical properties, particularly the yielding behaviour of metals. In general, the materials in the family of stainless steel such as austenitic and ferritic grades are isotropic materials. The existence of anisotropy behaviour in the stainless steel plates by a small amount is unavoidable due to the manufacturing process of a plate such as rolling. For instance,

the mechanical properties of Duplex stainless steel vary significantly with respect to the different directions due to the presence of both ferrite and austenite phases in its matrix [2, 3], where the orientation of the grains on the rolled plate plays a major role in the variation of mechanical properties. There are two types of anisotropy possibilities in any material, i.e. crystallographic anisotropy produced by severe plastic deformation during the rolling and the mechanical fibering due to the second phases present in the direction of working.

In order to address yield modelling in metals, several yield criteria can be found in the open literature. For instance, Tresca yield criterion [4], von Mises yield criterion [5], and modified versions of von Mises yield criterion proposed by Hershey [6] and Hosford [7] are widely used for isotropic materials. Despite their accuracy to predict yielding behaviour of isotropic materials in general, they do not account for material directionality effects such as changes in mechanical properties induced by the rolling process, where high anisotropy can be observed in the longitudinal and transverse directions of the elongated grains. The first theoretical studies on yield modelling of anisotropic material date back to 1948 where Rodney Hill [6] proposed a yield stress criterion for anisotropic material with orthotropic anisotropy in metal forming operations. The criterion was further improved in [7] to accommodate metals with normal anisotropy $R < 1$, introducing seven anisotropy parameters in the yield function. Bassani [8] proposed a different form of yield criterion for anisotropic polycrystalline metals which covers a wide range of transversely isotropic properties or planar isotropy, but material with normal anisotropy. Ferron et al. [9] proposed a parameterized yield stress criterion for planar anisotropy, which involves nine parameters for describing the plastic anisotropy of sheet metals. Barlat et al. [10] presented, in 1997, a phenomenological yield stress function asserting that it was more suitable for anisotropic aluminium alloy sheets, the Yld96 yield stress function. Based on Hershey [6] and Hosford [7] yield stress criteria for isotropic material and on Yld96 yield stress criterion, Barlat et al. [11] proposed the Yld 2000-2d anisotropic yield stress criterion applied to sheet metal forming under plane stress condition for pressure-independent metals exhibiting orthotropic anisotropy.

The present paper investigates the plastic anisotropic response of stainless steel materials by using Barlat's Yld 2000-2d yield criterion [11] and the correspondent Barlat's non-associated flow rule to calculate the Lankford's coefficient of anisotropy, r_θ values. Comparisons between theoretical predictions and experimental results for AISI 409L and AISI 430 are presented and conclusions are drawn.

2 Barlat's Yld 2000-2d Anisotropic Yield Stress Criterion

The Barlat's Yld 2000-2d anisotropic yield stress criterion can be written in terms of Cauchy stress tensor components for plane stress conditions as follows:

$$\varphi(\sigma_{xx},\ \sigma_{yy},\ \tau_{xy}) = \frac{1}{2^m}\left|a_1\,\sigma_{xx} + a_2\,\sigma_{yy} + \left[\left(a_3\,\sigma_{xx} - a_4\,\sigma_{yy}\right)^2 + \left(2a_8\tau_{xy}\right)^2\right]^{1/2}\right|^m + \\ + \frac{1}{2^m}\left|a_1\,\sigma_{xx} + a_2\,\sigma_{yy} - \left[\left(a_3\,\sigma_{xx} - a_4\,\sigma_{yy}\right)^2 + \left(2a_8\tau_{xy}\right)^2\right]^{1/2}\right|^m + \\ + \left|\left(a_5\,\sigma_{xx} - a_6\,\sigma_{yy}\right)^2 + \left(2a_7\tau_{xy}\right)^2\right|^{m/2} = 2\bar{\sigma}^m = 2\sigma_o^m(1+\bar{\varepsilon}/\varepsilon_o)^{n\,m} \quad (1)$$

where a_i are the coefficients of plastic anisotropy. Assuming Barlat's yield stress criterion as the flow stress potential, the strain increments $d\varepsilon_{ij}$ can be calculated from the associated flow rule as [12]

$$d\varepsilon_{ij} = d\lambda\,\frac{\partial\,\varphi\left(\sigma_{xx},\sigma_{yy},\tau_{xx}\right)}{\partial\,\sigma_{ij}} \quad (2)$$

where σ_{ij} are the stress components and $d\varepsilon_{ij}$ are the strain increments in the principal anisotropy directions: $d\varepsilon_{xx}$ is in the rolling direction RD and $d\varepsilon_{yy}$ is in the transverse direction TD. For a standard tensile test specimen cut at angle θ to RD, under the uniaxial tensile stress σ_θ in x′-axis of the specimen tensile direction and y′-axis of the width direction, for plane stress condition, the stress components and strain increments in the anisotropy (x,y)-axis or (RD,TD)-axis can be obtained through a coordinate transformation matrix $T(\theta)$ that relates the global (specimen) stresses to local stresses in the anisotropy axes (x,y). By doing so, assuming associate flow rule and applying the Euler's identity theorem for a homogeneous stress function of degree 'm' to the Barlat's yield stress criterion function $\varphi\left(\sigma_{xx},\sigma_{yy},\tau_{xy}\right)$ one can demonstrate that the Lankford's coefficient of anisotropy can be calculated by

$$r_\theta = \frac{d\varepsilon_{widh}}{d\varepsilon_{thickness}} = -\frac{sen^2\theta + \left(d\varepsilon_{yy}/d\varepsilon_{xx}\right)\cos^2\theta - 2\left(d\varepsilon_{xy}/d\varepsilon_{xx}\right)sen\theta\cos\theta}{1+\left(d\varepsilon_{yy}/d\varepsilon_{xx}\right)} \\ = \frac{2m\,\bar{\sigma}^m}{\left[1+\left(d\varepsilon_{yy}/d\varepsilon_{xx}\right)\right]\sigma_\theta\frac{\partial\,\varphi}{\partial\,\sigma_{xx}}} - 1 \quad (3)$$

In addition, the balanced biaxial coefficient of anisotropy is calculated by

$$r_b = \frac{d\varepsilon_{TD}}{d\varepsilon_{RD}} = \frac{d\varepsilon_{yy}}{d\varepsilon_{xx}} = \frac{\partial\varphi/\partial\sigma_{yy}}{\partial\varphi/\partial\sigma_{xx}} \quad (4)$$

For a tensile test specimen under a uniaxial tensile stress σ_θ, the equivalent stress can be expressed as $\bar{\sigma} = A\,\sigma_\theta$, where $A = \left\{2^m F + |B + C|^m + |B - C|^m\right\}^{1/m}/2^{1+1/m}$ and the Lankford's coefficient of anisotropy calculated from the associate flow rule is simplified to

$$r_\theta = \frac{2m\, A^m \sigma_\theta^{m-1}}{\frac{\partial \varphi}{\partial \sigma_{xx}} + \frac{\partial \varphi}{\partial \sigma_{yy}}} - 1 \tag{5}$$

The derivatives of the yield stress function $\varphi\left(\sigma_{xx}, \sigma_{yy}, \tau_{xy}\right)$ are obtained from Eq. (1), including the derivative sign for the modulus function, and are obtained as

$$\begin{aligned}\frac{\partial \varphi}{\partial \sigma_{xx}} &= mE\sigma_\theta^{m-1} a_5 + \frac{m}{2^m}|B + C|^{m-1}\{a_1 + D\, a_3\}\sigma_\theta^{m-1} \\ &\quad + \frac{m}{2^m}|B - C|^{m-2}(B - C)\{a_1 - D\, a_3\}\sigma_\theta^{m-1}\end{aligned} \tag{6}$$

$$\begin{aligned}\frac{\partial \varphi}{\partial \sigma_{yy}} &= mE\sigma_\theta^{m-1}(-a_6) + \frac{m}{2^m}|B + C|^{m-1}\{a_2 - D\, a_4\}\sigma_\theta^{m-1} \\ &\quad + \frac{m}{2^m}|B - C|^{m-2}(B - C)\{a_2 + Da_4\}\sigma_\theta^{m-1}\end{aligned} \tag{7}$$

Finally, substituting Eqs. (6) and (7) into Eqs. (4) and (5), the generalized Lankford's coefficient of anisotropy r_θ and the balanced biaxial coefficient of anisotropy r_b are calculated by

$$r_\theta = \frac{2^m F + |B + C|^m + |B - C|^m}{2^m E(a_5 - a_6) + |B + C|^{m-1}(a_1 + a_2 + D_{34}) + |B - C|^{m-2}(B - C)(a_1 + a_2 - D_{34})} - 1 \tag{8}$$

$$r_b = \frac{2^m (a_5 - a_6)^m + |(a_1 + a_2) + |a_3 - a_4||^m + |G|^m}{2^m (a_5 - a_6)^{m-1} a_5 + |(a_1 + a_2) + |a_3 - a_4||^{m-1}(a_1 + a_3) + |G|^{m-2} G\,(a_1 - a_3)} - 1 \tag{9}$$

where

$$B = a_1 \cos^2\theta + a_2 sen^2\theta,\; C = \left[\left(a_3 \cos^2\theta - a_4\, sen^2\theta\right)^2 + 4a_8^2\, sen^2\theta \cos^2\theta\right]^{1/2} \tag{10a}$$

$$D = \left(a_3 \cos^2\theta - a_4\, sen^2\theta\right)/C,\; D_{34} = D(a_3 - a_4) \tag{10b}$$

$$E = \left|\left(a_5 \cos^2\theta - a_6\, sen^2\theta\right)^2 + 4a_7^2\, sen^2\theta \cos^2\theta\right|^{(m/2)-1}\left(a_5 \cos^2\theta - a_6\, sen^2\theta\right) \tag{10c}$$

$$F = \left|\left(a_5 \cos^2\theta - a_6 sen^2\theta\right)^2 + 4a_7^2\, sen^2\theta \cos^2\theta\right|^{m/2} \tag{10d}$$

$$G = (a_1 + a_2) - |a_3 - a_4| \tag{10e}$$

For a uniaxial tensile test specimen under loading at 0° RD, the stress components are $\sigma_{xx} = \sigma_0$ and $\sigma_{yy} = \tau_{xy} = 0$, where σ_0 is the yield stress. Then, the Barlat's Yld 2000-2d anisotropic yield stress criterion, Eq. (1), is further reduced to

$$|2\,a_5\,|^m + |a_1 + a_3\,|^m + |\,a_1 - a_3\,|^m = 2^{1+m}\left(\frac{\bar{\sigma}}{\sigma_o}\right)^m \tag{11}$$

Imposing the condition that the equivalent stress at any yielding stress condition in uniaxial tensile test at nominal strain rate condition should be $\bar{\sigma} = \sigma_o(1 + \bar{\varepsilon}/\varepsilon_o)^n$, thus

$$|2\,a_5\,|^m + |a_1 + a_3\,|^m + |\,a_1 - a_3\,|^m - 2^{1+m}(1 + \bar{\varepsilon}/\varepsilon_o)^n = 0 \tag{12}$$

However, it is possible to assume a different plastic stress or strain condition, as for example $\bar{\sigma} = \sigma_b$ at balanced biaxial stress state. For a sheet metal specimen under plane stress and equal biaxial stress condition and aligned to RD, $\sigma_{xx} = \sigma_{yy} = \sigma_b$ *and* $\tau_{xy} = 0$, hence Eq. (1) becomes

$$2^m(a_5 - a_6)^m + |(a_1 + a_2) + |a_3 - a_4|\,|^m + |\,(a_1 + a_2) - |a_3 - a_4|\,|^m = 2^{1+m}\left(\frac{\bar{\sigma}}{\sigma_b}\right)^m \tag{13}$$

Assuming that the equivalent stress is equal to the current flow stress, $\bar{\sigma} = \sigma_o(1 + \bar{\varepsilon}/\varepsilon_o)^n$, at current yielding condition, thus the normalized equi-biaxial stress is calculated by

$$\frac{\sigma_b}{\sigma_o} = \frac{2^{1+1/m}(1 + \bar{\varepsilon}/\varepsilon_o)^n}{\left\{2^m(a_5 - a_6)^m + |(a_1 + a_2) + |a_3 - a_4|\,|^m + |\,(a_1 + a_2) - |a_3 - a_4|\,|^m\right\}^{1/m}} \tag{14}$$

For tensile test specimens under uniaxial tensile stress σ_θ, the equivalent stress of Eq. (1) is simplified to $\bar{\sigma} = A\,\sigma_\theta$. Consequently, the normalized yield stress at any angle θ to RD is

$$\frac{\sigma_\theta}{\sigma_o} = \frac{\left\{|2\,a_5\,|^m + |a_1 + a_3\,|^m + |\,a_1 - a_3\,|^m\right\}^{1/m}}{\left\{2^m F + |\,B + C\,|^m + |\,B - C\,|^m\right\}^{1/m}} \tag{15}$$

For a specimen under pure shear stress test, the stress components are $\sigma_{xx} = \sigma_{yy} = 0$ and $\tau_{xy} = \tau_o = k$, where $\tau_0 = k$ is the material shear yield stress. Then, Eq. (1) is reduced to

$$a_7 = \pm 2^{(1/m)-1}\frac{\sigma_o}{\tau_o} = \pm 2^{(1/m)-1}\frac{\sigma_o}{k} \tag{16}$$

2.1 Determination of the Anisotropic Coefficients a_i Values

In order to solve the set of nonlinear equations in terms of a_i, i=1,…8, Eqs. (8), (9), (12), (14), and (15) can be rearranged as follows:

$$s_o(a_i) = |2\,a_5\,|^m + |a_1 + a_3\,|^m + |\,a_1 - a_3\,|^m - 2^{1+m}(1+\bar{\varepsilon}/\varepsilon_o)^n = 0 \quad (17)$$

$$s_\theta(a_i,\sigma_\theta) = \frac{\left\{|2\,a_5\,|^m + |a_1 + a_3\,|^m + |\,a_1 - a_3\,|^m\right\}^{1/m}}{\left\{2^m F + |\,B + C\,|^m + |\,B - C\,|^m\right\}^{1/m}} - \frac{\sigma_{\theta\,\exp}}{\sigma_o} = 0 \quad (18)$$

$$s_b(a_i) = \frac{2^{1+1/m}(1+\bar{\varepsilon}/\varepsilon_o)^n}{\left\{2^m(a_5 - a_6)^m + |(a_1 + a_2) + |a_3 - a_4|\,|^m + |\,G\,|^m\right\}^{1/m}} - \frac{\sigma_{b\,\exp}}{\sigma_o} = 0 \quad (19)$$

$$r_\theta(a_i,\theta) = \frac{2^m F + |\,B + C\,|^m + |\,B - C\,|^m}{2^m E(a_5 - a_6) + |\,B + C|^{m-1}(a_1 + a_2 + D_{34}) + |B - C|^{m-2}(B - C)(a_1 + a_2 - D_{34})} - 1 - r_{\theta\,\exp} = 0 \quad (20)$$

$$r_b(a_i) = \frac{2^m(a_5 - a_6)^m + |(a_1 + a_2) + |a_3 - a_4|\,|^m + |G|^m}{|(a_1 + a_2) + |a_3 - a_4||^{m-1}(a_1 + a_3) + |G|^{m-2}G\,(a_1 - a_3) + 2^m(a_5 - a_6)^{m-1}a_5} - 1 - r_{b\,\exp} = 0 \quad (21)$$

This set of nonlinear equations can be rewritten in a compact matrix form given by Eq. (22)

$$\{\psi(\{a\})\}^T = \left\{ \{s_\theta(\{a\})\}^T \; \{r_\theta(\{a\})\}^T \; s_b(\{a\}) \; r_b(\{a\}) \right\} = \{0\}$$

$$\{a\}^T = \left\{ a_1 \; a_2 \; a_3 \; a_4 \; a_5 \; a_6 \; a_7 \; a_8 \right\} \quad (22)$$

where $\{s_\theta(\{a\})\} \in \mathbb{R}^p$, $\{r_\theta(\{a\})\} \in \mathbb{R}^q$; defining p and q as the number of experimental yield stresses and r-values of interest such that $(p+q) = 8$. According to Barlat recommendation [38] to calculate the coefficients of anisotropy a_i, the definition of the set of equations to be solved should have equal numbers of r-values and yield stresses, s-values, which are defined by the following parameters:

$$\{\psi(\{a\})\}^T = \left\{ s_o(\{a\}) \; s_{45^0}(\{a\}) \; s_{90^0}(\{a\}) \; r_o(\{a\}) \; r_{45^0}(\{a\}) \; r_{90^0}(\{a\}) \; s_b(\{a\}) \; r_b(\{a\}) \right\}$$
$$\{a\}^T = \left\{ a_1 \; a_2 \; a_3 \; a_4 \; a_5 \; a_6 \; a_7 \; a_8 \right\} \quad (23)$$

The linearization of the function $\{\psi(\{a\})\}$ about the point $\{a\}$ leads to

$$\{\psi(\{a\} + \{\delta a\})\} = \{\psi(\{a\})\} + [J(\{a\})]\{\delta a\} \quad (24)$$

where $[J(\{a\})]$ is the Jacobian matrix (of size 8×8) made up of the partial derivatives

$$J_{ij} = \frac{\partial \psi_i}{\partial a_j} \quad (25)$$

By setting $\{Z(\{a\} + \{\delta a\})\} = \{0\}$ and letting $\{a\} + \{\delta a\}$ be the improved solution, we find the following expression for the iterative predictor $\{\delta a\}$:

$$\{\delta a\} = [J(\{a\})]^{-1}\{\psi(\{a\})\} \tag{26}$$

In order to improve accuracy and achieve converge to solve convex unconstrained problems, a relaxation factor can be added to find the correction between successive iterations. For this case the new correction predictor can be rewritten as follows:

$$\{\delta a\} = \eta[J(\{a\})]^{-1}\{\psi(\{a\})\} \tag{27}$$

where $\eta = 1/2^N$ is the relaxation factor. N is an user-defined integer number defined within the interval $N \in [0, N_{\max}]$, where no general rule can be given for the choice of an optimum N and suitable values for a particular set of nonlinear equations are usually defined by using a trial and error procedure. The set of nonlinear equations are iteratively solved by using the following procedure:

1. Estimate the initial solution vector $\{a\}$;
2. Evaluate $\{\psi(\{a\})\}$.
3. Compute the Jacobian matrix $[J(\{a\})]$ from Eq. (25).
4. Compute $\{\delta a\}$ from Eq. (12).
5. Let $\{a\} \leftarrow \{a\} + \{\delta a\}$ and repeat steps 2–5 until $\|\{\delta a\}\| < \varepsilon$, where ε is the assumed error tolerance.

3 Materials Anisotropy Parameters

The coefficients of plastic anisotropy, a_i, of Barlat's Yld 2000-2d yield criterion were calibrated based on material experimental data for simple uniaxial tension, biaxial stress, and compression in-plane tests available in the literature, and listed in Tables 1 and 2. The plastic anisotropy parameters of the stainless steels used to calibrate the

4 Analyses and Discussion

Tables 3 and 4 show the calculated plastic anisotropy coefficients of Barlat's Yld 2000-2d yield stress criterion for the AISI 409L and AISI 430 stainless steels for different combinations of normalized yield stress (s-values) and anisotropy coefficients (r-values).

The results for AISI 409L and AISI 430 are plotted in Figs. 1 and 2, respectively, for different normalized yield stress (s-values) and anisotropy coefficients (r-values).

Figure 1a, e, f indicate a fairly good agreement between experimental and the predicted normalized yield stress and r-values obtained using the Barlat's Yld 2000-2d yield stress criterion for different theta values with respect to the rolling direction. Despite of a good agreement in terms of normalized stresses, a very poor correlation was found for the r-values depicted in Fig. 1b, c, d. This poor correlation indicates that the assumption of the yield stress criterion and the plastic flow stress potential functions does not hold for this kind of material due to its anisotropic nature. The same behaviour was also depicted in Fig. 2c–d for the AISI 430, where a significant discrepancy between the predicted r-values obtained using the Barlat's Yld 2000-2d yield stress criterion and the experimental results was found. Conversely, Fig. 2e, f show good agreement between the predicted and the experimental r-values but poor correlation between the predicted and experimental results in terms of s-values. This implies that additional experimental anisotropy parameters are required in order to improve the accuracy of the Barlat's Yld 2000-2d yield stress criterion for the AISI 409L and AISI 430 stainless steel alloys studied herein.

5 Concluding Remarks

A detailed study on the applicability of the Barlat's Yld 2000-2d yield stress criterion to predict the anisotropic behaviour of stainless steel alloys was presented herein. The main conclusions of the present work are listed as follows:

1. A new set of equations to calculate the Lankford's and equal biaxial coefficients of anisotropy (r-value), and the normalized yield stress (s-value) for uniaxial and equal biaxial stress testing, and plastic anisotropy a_i values were proposed to describe the Barlat's Yld 2000-2d yield stress criterion.
2. Results from the present study indicate the Barlat's Yld 2000-2d yield stress criterion and the plastic flow stress potential of examined stainless steels were not coincident. This implies that a non-associated plastic flow rule is required to describe the anisotropy parameters, r-values.

2 s + 6r	6	−0.99487	2.213079	0.754523	0.867442	1.076023	0.166716	0.856082	−1.34457

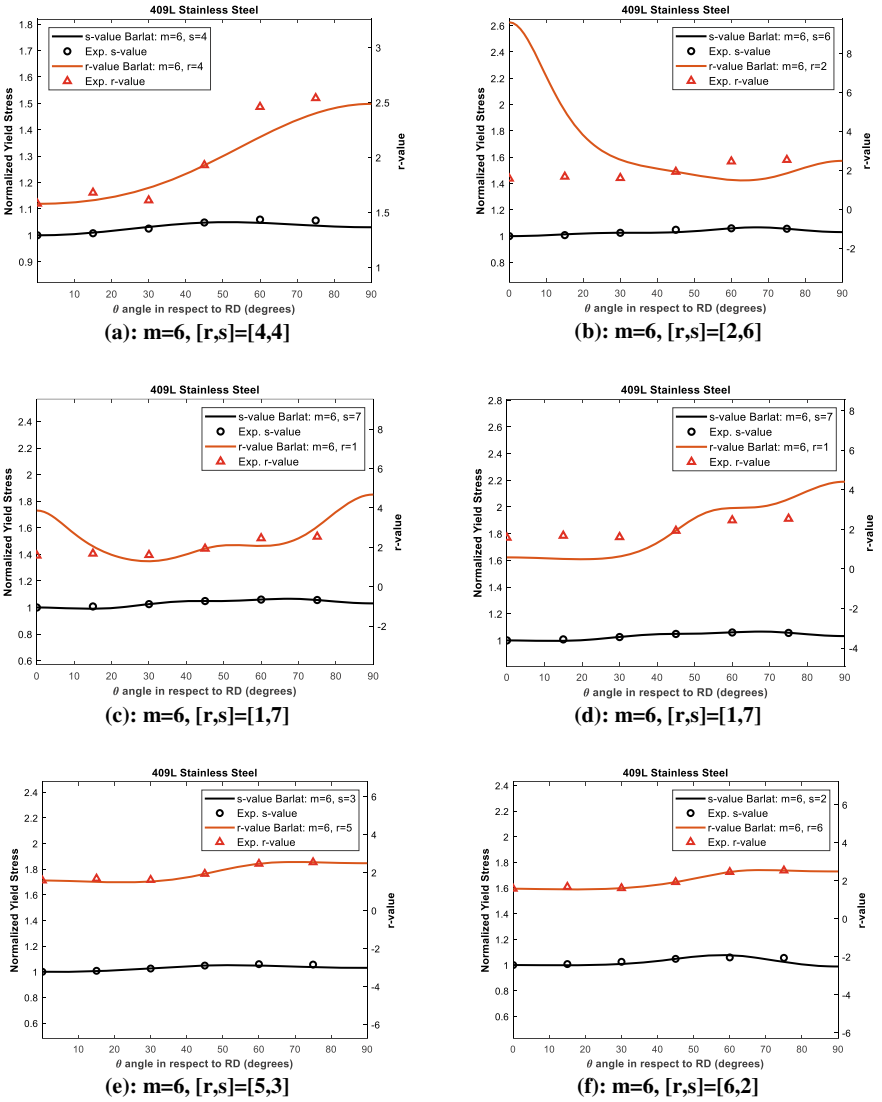

Fig. 1 Comparison of Barlat's Yld 2000-2d prediction curves with the experimental results for tensile tests of AISI 409L. (Color figure online)

3. Barlat's Yld 2000-2d stress function can be employed to characterize suitably both the yield stress criterion and the flow stress potential, but they are not coincident for the stainless steel alloys studied herein. This implies that additional experimental anisotropy parameters are required for accurate curve fitting.

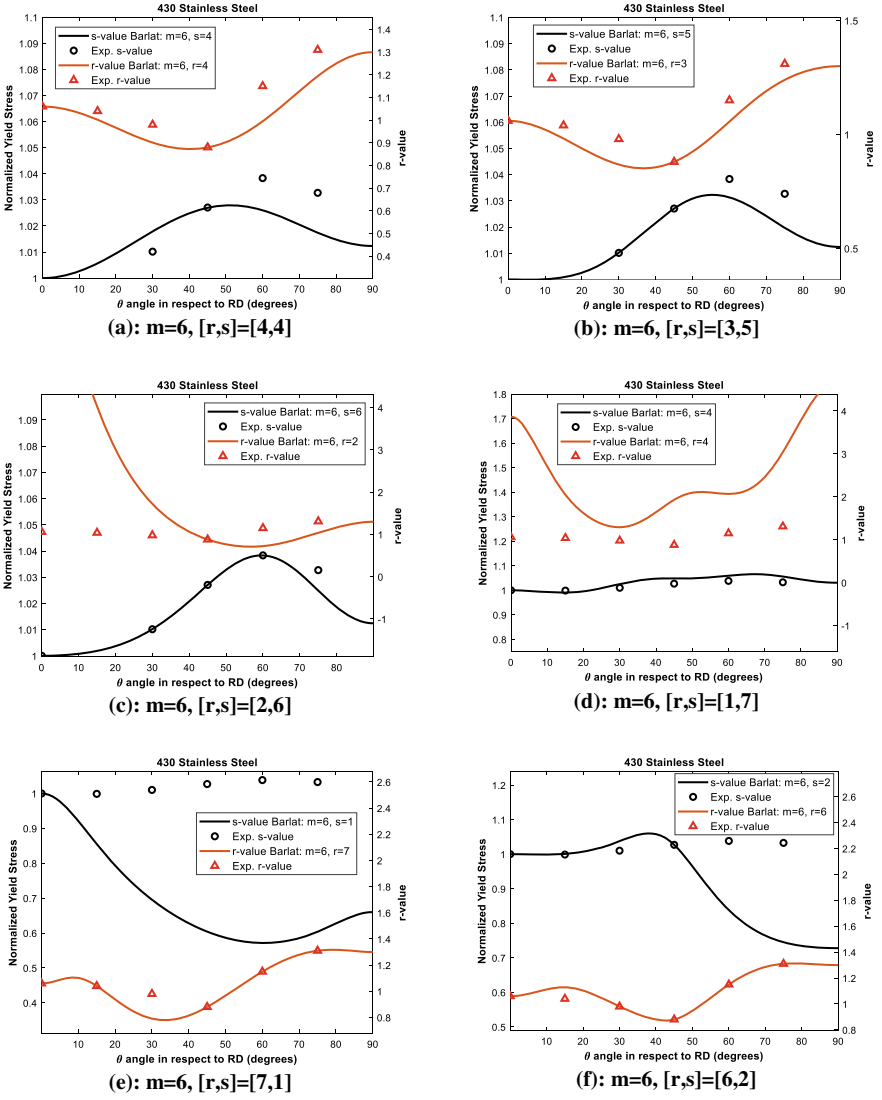

Fig. 2 Comparison of Barlat's Yld 2000-2d prediction curves with the experimental results for tensile tests of AISI 430. (Color figure online)

4. Thus, the accuracy of Barlat's Yld 2000-2d stress function, which requires eight anisotropy coefficients, is similar to Barlat's Yld 2004-18p three-dimensional yield stress criterion that requires 18 anisotropy coefficients.
5. The proposed Newton–Raphson method with relaxation has shown to be a robust and accurate method to determine the plastic anisotropy a_i values.

Evaluation of Press Forming Technique for Bent Automotive Body Parts Using In-Plane Shear Deformation

Yusuke Fujii, Masaki Urabe, Yuji Yamasaki, and Yoshikiyo Tamai

Abstract A basic evaluation of a new press forming technique using in-plane shear deformation was carried out to suppress fracture and wrinkle of parts bent in the height direction, supposing auto body parts such as the front side member rear. This two-step technique comprises two processes. The first process is deep draw forming with a rectangular blank to induce in-plane shear strain in the blank. The second process is bending the pre-formed blank into a part shape with a U-shaped cross section. According to experiments, in-plane shear deformation was induced in the blank in the first process when the press stroke changed along the part longitudinal direction, and increasing the induced in-plane shear deformation made it possible to form a part with a higher bent angle in the height direction in the second process. The results suggested that complex bent parts which were difficult to form by the conventional press forming technique can be formed without fracture or wrinkle when appropriate in-plane shear deformation is induced in the blank in the first process.

Keywords Press forming technique · In-plane shear deformation · Pre-forming

1 Introduction

To achieve both weight reduction and collision safety in automobiles, strengthening of auto body parts by using ultra-high-strength steel sheets is effective [1]. However, two major problems in press forming of ultra-high-strength steel sheets are fracture, which occurs due to the low ductility of the steel, and wrinkles due to its high yield strength [2]. For example, draw forming is generally applied to auto body parts which are bent in the height direction, as shown in Fig. 1. In draw forming, the

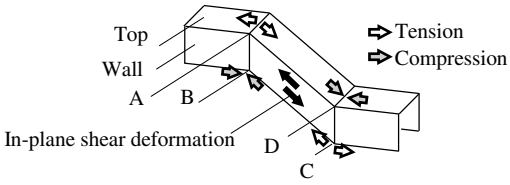

Fig. 1 Schematic of bent parts and deformation caused in conventional press forming

outer side portions of the blank are held with a die during press forming, and tensile deformation on the outer side of the bent portions in the side view (portions A and C) and compressive deformation on the inner side (portions B and D) occur in the blank. Fracture and wrinkle caused, respectively, by this tensile and compressive deformation are major problems when applying higher strength steel sheets to parts with geometries of this type.

The proposed countermeasures against fracture include reducing the tension of the punch shoulders by reducing the frictional resistance or deformation resistance of the material [3, 4] and enhancing the strength of the material at the punch shoulder [5]. However, the effects of these countermeasures are insufficient for ultra-high-strength steel sheets due to their low ductility and high deformation resistance. As a countermeasure against wrinkles, generally, there is a method in which some additional shapes are provided at the bottom of the punch to absorb the excessive material surplus [6], but this is not applicable when there are restrictions on the punch shape.

During forming of parts bent in the height direction, in-plane shear deformation also occurs in the wall defined by ABCD in the straight portion (Fig. 1), and when this in-plane shear deformation occurs, tensile and compressive deformation can be reduced corresponding to the size of the deformation. Therefore, in this study, we evaluated a new press forming technique for bent parts by adding a pre-forming process to intentionally induce large in-plane shear deformation in the wall ABCD of the straight portion.

2 Aim of Press Forming Technique Using In-Plane Shear Deformation

In order to form a part which is bent in the height direction without fracture or wrinkle, as described above, it is important to suppress tensile deformation and compression deformation in the bent portions of the part. We considered that the tensile and compressive deformation at bent portions could be *suppressed* by adding a pre-process which induces in-plane shear deformation in the wall ABCD of the straight portion. To induce in-plane shear deformation in this first step, we evaluated a pre-forming process, as shown in Fig. 2a, in which the press stroke direction was the AD direction and the shapes of the die and blank were cylindrical and rectangular, respectively. When the material flowed into the sidewall from the flange side, the timing of inflow in the blank width direction was different. Specifically, the timing

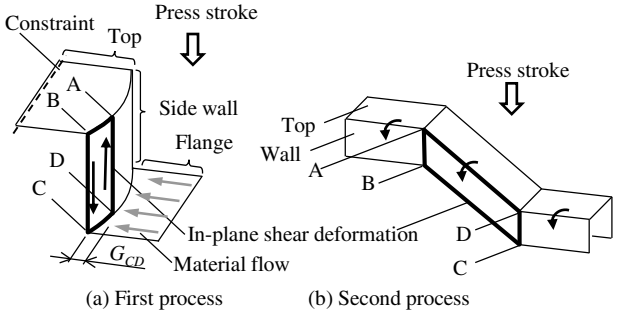

Fig. 2 Schematics of first and second processes in new forming technique

at the width-direction edge was delayed by a distance G_{CD} compared with that at the center. This difference of the inflow velocity between the center and the edges causes shear deformation. In-plane shear deformation is induced in the whole region ABCD because this shear deformation occurs sequentially at the die shoulder. Therefore, in the second process, a part bent in the height direction can be formed easily simply by bending the ridge line AD, as shown in Fig. 2b, because the region ABCD where in-plane shear deformation was induced in the first process is formed into the wall of the straight portion.

In this paper, first, the occurrence of in-plane shear deformation in the first process was confirmed by the finite element method (FEM). Then, experiments were conducted to measure the amount of in-plane shear deformation induced in the first process, and the effect of in-plane shear deformation on the bent angle of the final formed part was investigated by forming in the second process.

3 Prediction of In-Plane Shear Deformation by FEM Analysis

3.1 FEM Analysis Conditions

The amount of in-plane shear deformation caused in the first process was predicted by FEM analysis. Figure 3 shows an analysis model of the die and blank. Four types of punch radius R_p were examined: 12.5, 16.5, 20.0, and 25.0 mm. The blank was a rectangle with a width of 30 mm and length of 180 mm, and was shaped symmetrically at M–M′. The shoulder radii of both the punch and die were 5 mm. The forming height was 50 mm. The solver was LSDYNA® Ver 9.7.1 R5 (Livermore Software Technology Corp.) using the dynamic explicit method. Table 1 shows the mechanical properties of the test material used in the FEM analysis. The blank was a shell element with an element size of 2 mm. The blank holder force was 9.8 kN, and the friction coefficient was 0.15. In this paper, in-plane shear strain was defined as engineering shear strain.

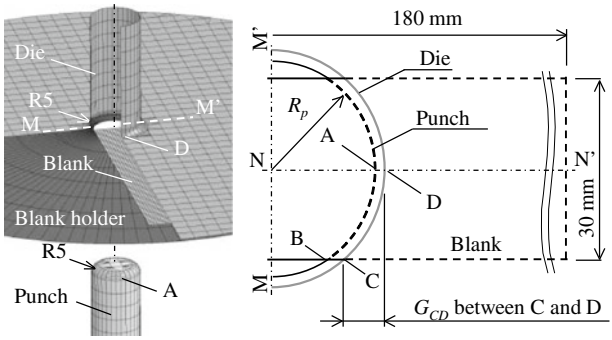

Fig. 3 Details of FEM model used in first process to obtain in-plane shear deformation

Table 1 Mechanical properties of test material

Grade	Thickness (mm)	YS (MPa)	TS (MPa)	El (%)
270	0.5	163	297	50

3.2 FEM Analysis Results

An example of the predicted in-plane shear strain distribution after the first process is shown in Fig. 4. The occurrence of in-plane shear strain in the region ABCD of the sidewall was predicted. Figure 5 shows the distribution of shear strain in cross-section O–O′ in the middle of the sidewall in the width direction. In-plane shear strain was negligible at point O at the center of the blank width and at point O′ at the edge, and displayed its maximum value at the center between those two points. Figure 6 shows the effect of the punch radius R_p on the average value of in-plane shear strain γ_{Ave} generated in the range of positions from 2 to 12 mm from the blank width center in Fig. 5. As the punch radius R_p decreased, in-plane shear strain increased. The reasons for this change are considered in the following section.

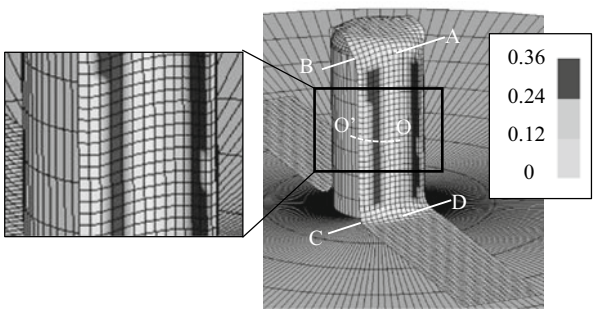

Fig. 4 Calculated distribution of in-plane shear strain at sidewall of punch in case of $R_p = 12.5$ mm and Grade 270 MPa

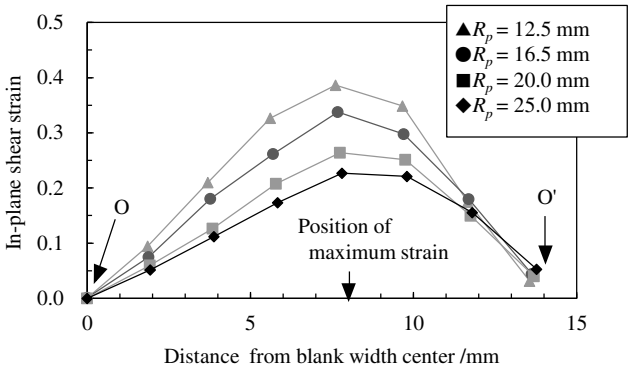

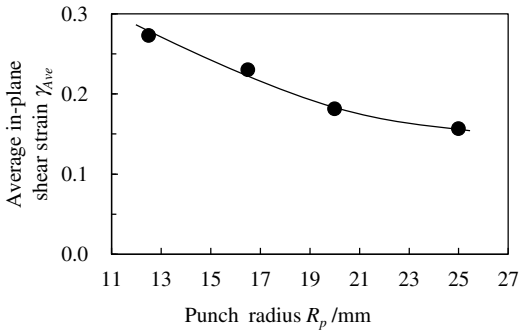

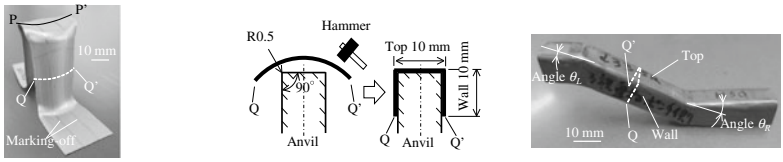

Fig. 5 Calculated distribution of in-plane shear strain in section O–O′ in first process

Fig. 6 Relationship between average in-plane shear strain γ_{Ave} and punch radius R_p in the first process

3.3 Discussion

Since the shapes of the die and blank are symmetrical on the M and M′ sides with respect to N-N′, as shown in Fig. 3, in-plane shear deformation is canceled at point O in the center of the blank width. On the other hand, because the material inflow in the circumferential direction is not restricted at point O′ near the edge, material inflow to the sidewall occurs with size reduction deformation in the circumferential direction. For this reason, it is considered that the difference in the inflow velocity between the edge side and the center in the width direction is reduced, and the in-plane shear deformation is less likely to occur at those points. As a result, it is estimated that in-plane shear strain distribution shown in Fig. 5 is generated between the point O and point O′ and reaches its maximum near the center. Since the distance G_{CD} increases as the punch radius R_p decreases, it is considered that in-plane shear strain becomes larger as the difference of the inflow velocity to the sidewall increases.

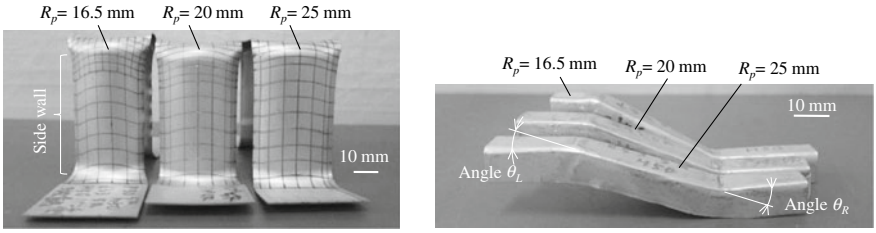
4 Experimental Method and Results



4.1 Purpose and Method of Experiment

In order to evaluate the effect of in-plane shear deformation on the bent angles of formed products bent in the height direction, the formed specimens in which in-plane shear deformation was induced in the first process were bent in the second process, and the bent angles in the height direction were examined.

The die used in the first process was the same as that in the FEM analysis (Fig. 3). The punch radii R_p were 16.5, 20.0, and 25.0 mm, and various in-plane shear deformation was given to the blanks. The blank material was the 270 MPa grade steel sheet in Table 1. The blank was lined with orthogonal grids at intervals of 5 mm, and was then draw-formed using a 500 kN deep-drawing instrument and cut along P-P′, as shown in Fig. 7a. In the second process, the pre-formed part was formed to a part with U-shaped cross-section by sheet metal processing using a hammer and jig, as shown in Fig. 7b. When the second bending process is carried out by press forming using an ordinary die, the pre-formed part is formed to the pre-determined die shape. Because this is not suitable for the purpose of this experiment, in which we investigated the degree of the bent angle in the height direction, sheet metal processing was used as the second process to reproduce the sequence of material deformation during press forming with an ordinary die as closely as possible. First, the pre-formed part was bent along the ridge lines at the positions where the widths of the top portion and vertical walls were each 10 mm. Next, the curved surface was flattened in the order of the top and vertical wall, and then processed so that the angle between the top and walls was 90°. The influence of in-plane shear deformation on the bent angle was determined by measuring angles θ_R and θ_L of the formed parts obtained by sheet metal working as described in Fig. 7c.

4.2 Experimental Results

The formed parts obtained in the first and second processes are shown in Fig. 8. The blanks could be formed without fracture or wrinkle under all conditions. The

(a) First process (b) Second process

Fig. 8 Formed parts in each process

ruled lines were distorted in a parallelogram shape between the width center and the edge portions at the sidewall of the first process, confirming that in-plane shear deformation occurred (Fig. 8a). In the second process, the formed parts bent in the height direction were obtained, and the effect of applying in-plane shear deformation was demonstrated (Fig. 8b).

As shown in Fig. 9, the four areas indicated by the broken lines were selected from the center of the sidewall of the first process, and the average value γ_{Ave} was obtained by calculating the in-plane shear strain from the lattice deformation. The relationship between this average in-plane shear strain γ_{Ave} and the punch radius R_p is shown in Fig. 10. As the punch radius R_p became smaller, γ_{Ave} increased. Moreover, these values were in good agreement with the FEM analysis results. The bent angles θ_L and θ_R after the second process became larger as the punch radius R_p in the first process became smaller. Figure 11 shows the effect of the average in-plane shear

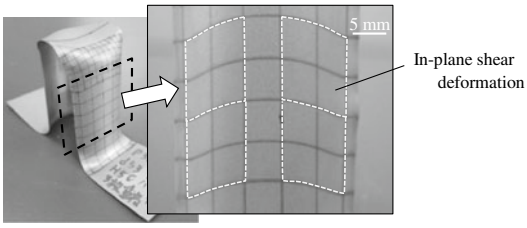


Fig. 9 Draw-formed panel (left) and enlarged view of wall portion (right)

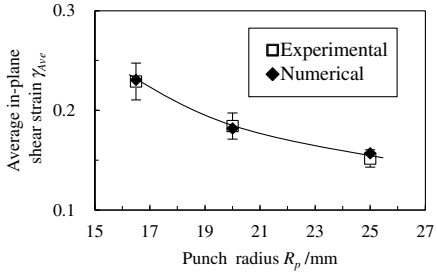

Fig. 10 Relationship between average in-plane shear strain γ_{Ave} and punch radius R_p in the first process

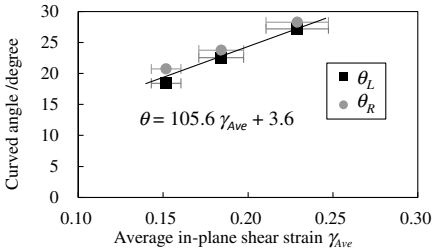

Fig. 11 Effect of average in-plane shear strain γ_{Ave} on bent angle in the height direction

strain γ_{Ave} in the first process on the bent angle after the second process. The bent angle was proportional to γ_{Ave}, and the sizes of bent angles θ_L and θ_R were almost the same.

The degree of contribution of in-plane shear deformation to the bent angle of the formed part measured in the above experiment was verified. Figure 12 shows a schematic diagram explaining the effect of in-plane shear deformation at the straight wall and elongation at the bent portion on the bent angle in the height direction. When the wall portion deforms to a parallel four-sided shape as a result of in-plane shear deformation, an angle change in the height direction occurs. Therefore, using the average in-plane shear strain γ_{Ave}, the bent angle θ_γ in the height direction caused by in-plane shear deformation was geometrically calculated by the following equation. Here, π indicates the circumference ratio.

$$\theta_\gamma = 180/\pi \cdot \tan^{-1} \gamma_{Ave} \tag{1}$$

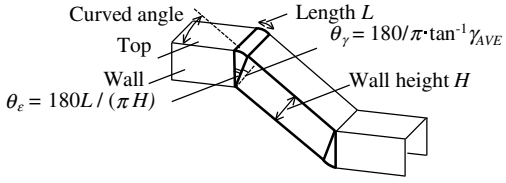

Fig. 12 Schematic of effect of bent angle on in-plane shear strain and stretched deformation

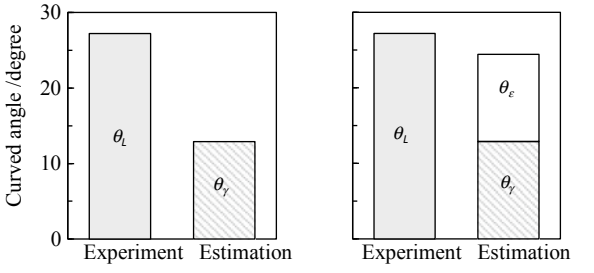

Fig. 13 Experimental and estimated bent angle (R_p = 16.5 mm)

Figure 13a shows the result of a comparison of the calculated bent angle θ_γ and the measured angle θ_L when the punch radius R_p was 16.5 mm. The angle θ_γ calculated from the measured value of in-plane shear deformation was smaller than the measured value θ_L, which was about 47%. This means that another factor also contributes to the angle θ_L of the second formed part. Next, therefore, the contribution of elongation at the bent portion was verified. The elongation in the longitudinal direction caused by tensile deformation by the punch and the shoulder portions in the first process was L, and the angle change θ_ε of the formed part after the second process was geometrically calculated by the following equation. Here, H represents the height of the longitudinal wall of the second formed part.

$$\theta_\varepsilon = 180L/(\pi H) \tag{2}$$

The elongation L predicted by the FEM analysis at the punch shoulder in the first process was substituted into Eq. (2) to obtain the predicted value θ_ε. Figure 13b shows the sum of the predicted value θ_ε and the predicted value θ_γ of angle change due to in-plane shear strain. The sum of θ_ε and θ_γ was almost equal to the measured value θ_L. Based on the above results, it was found that the developed technique for draw forming a rectangular blank in a cylindrical shape in the first process causes the bent angle in the side view of the formed part in the second process due to a combination of in-plane shear deformation of the sidewall and the tensile deformation at the punch and die shoulders in the first process.

5 Conclusion

(1) A press forming technique which enables forming of parts bent in the height direction without fracture or wrinkle by addition of a pre-process to induce in-plane shear deformation in the wall of the straight side of the bent part was proposed, and the possibility of this technique was verified by an FEM analysis and experimental study.
(2) It was possible to induce in-plane shear deformation in the wall by drawing the rectangular blank in the part longitudinal direction, and parts bent in the height direction could be formed easily by using this shear deformation.
(3) It was found that the bent angle increased when the in-plane shear deformation applied in the first process was increased.

Simulation of Cold Forging Processes Using a Mixed Isotropic-Kinematik Hardening Model

Lander Galdos, Julen Agirre, Nagore Otegi, Joseba Mendiguren, and Eneko Saenz de Argandoña

Abstract Cold forging is a manufacturing process where a bar stock is inserted into a die and squeezed with a second closed die. It is one of the most widely used chipless forming processes, often requiring no machining or additional operations to get tight tolerances. Because materials to be formed are increasingly harder and the geometrical complexity is greater, the finite element simulation is becoming an essential tool for process design. This study proposes the use of the Chaboche hardening model for the cold forging simulation of a 42CrMoS4Al material industrial automotive ball pin. The material model has been fitted with experimental data obtained from cyclic torsion tests at different reversal plastic strains as well as monotonic torsion tests at different strain rates. Comparison between the classical isotropic hardening and the new mixed hardening model are presented for the different forging steps.

Keywords Cold forging · Numerical simulation · Mixed hardening

1 Introduction

The cold forging is a bulk forming process that aims to obtain near net shape semi-finished components. Unlike the hot forging, the cold forging process produces very precise components having tight geometrical tolerances and good surface finishing.

Usually small to medium components are produced by this technology using high production rate horizontal presses. Typical components are bolts, geared shafts and pins among others [1, 2].

Like in many metal-forming processes, cold forging industry is increasingly using the finite element modelling for process and tool design. In this regard, the numerical modelling is becoming state of the art in the cold forging companies and usual outputs are the material flow, used for checking the die filling and folds, and the punch forces. Advanced features that are not fully stablished in the sector are the advanced fracture criteria as proposed by [3, 4] and the analysis of the resulting residual stresses and their influence on the final properties [5, 6].

Because the accuracy level demanded to the numerical models is high during cold forged process definition, take into account that geometrical accuracy is often cents of millimeter, the accuracy of numerical inputs is of high importance. Regardless the mesh quality, the remeshing strategy and the numerical method used to solve the problem, the material and contact definition are critical for getting the desired reliability. Latest works for properly identifying the friction coefficient for cold forging simulation have being led by the "Lubrication" Subgroup of the International Cold Forging Group (ICFG). An inter-laboratory comparison using different friction tests was done by different re-known authors and conclusions were presented in [7]. Regarding the material modelling, Bruschi et al. presented a deep review about the modelling of material behaviour in sheet metal forming [8]. In the paper, relevant hardening models for capturing metals Bauschinger effect are explained. The use of mixed isotropic and kinematic hardening models influence the final accuracy of the numerical models, especially in terms of springback and residual stresses. These hardening models have been rarely employed in the cold forging process simulations.

For this reason, the main objective of this paper is to show the influence the hardening model has on the numerical results of an industrial automotive ball pin forging. The state of the art for cyclic behavior modelling and cyclic material characterization is presented and experimental results obtained by using cyclic torsion tests are presented and discussed by the authors for a cold forging steel.

The Chaboche and Lemaitre mixed hardening model is presented and the material parameters identification procedure is explained using the experimental data obtained in the cyclic torsion tests. Finally, the numerical results obtained using an isotropic hardening material model and the fitted mixed hardening model are shown and compared by using an industrially often-used FEM software.

Table 1 Chemical composition of 42CrMoS4Al case hardening steel

2 Material Cyclic Characterization

2.1 Material Properties

The 42CrMoS4Al case hardening steel used to produce automotive ball pins was selected for the current study. 26 mm diameter steel rods were used for the experimental testing. The material was obtained in the annealed condition, which is the as-received state used in the forging companies for producing the selected component. Material composition is shown in Table 1.

The as received material microstructure is shown in Fig. 1. The edging used for revealing the microstructure was the Nital-Beraha. Ferrite is colored in white, the Martensite is dark brown and Bainite is light brown.

2.2 Monotonic and Cyclic Material Testing: State of the Art

In metal forming operations and cold forging processes, the metals are normally subjected to very complex strain paths that include loading reversal. For this reason, complex phenomenological hardening models are increasingly being introduced in finite element modelling codes to provide accurate predictions of material behavior. Four types of hardening may arise during forming processes: (i) isotropic hardening, which refers to the proportional expansion of the initial yield surface; (ii) kinematic

hardening, if the deforming material shows a yield surface that does not change in form and size, but translates in the stress space; (iii) rotational hardening, which causes the yield locus to rotate; (iv) distortional hardening, which causes the yield locus to distort [8].

Mixed isotropic and kinematic hardening models are becoming of common use in the sheet metal forming simulations since they significantly influence the springback prediction accuracy and are able to reproduce different phenomenon such as the Bauschinger effect, the transient behaviour, the permanent softening and ratcheting [9–11]. The different phenomenon that appear during the reverse loading are illustrated in Fig. 2.

Different authors have proposed several reverse loading tests needed for the cyclic characterization of sheet metals and the analysis of these phenomena. Experimental data using a tension–compression test were obtained for different materials by Silvestre et al. [12]. The test was valid for plastic strain levels up to ±3%. Brunet et al. [13] identified the hardening parameters by using bending tests of a mild steel. The results showed some limitations and uncertainties due to the fact that the strain state in the sample was not exactly a pure strain state of bending. The cyclic three point bending test was also used to determine various hardening laws of DP600 and 220 IF steels by Eggertsen and Mattiasson [14].

Other authors combined different tests, such as Weiss et al. [15], who used bending and simple shear tests for studying the Bauschinger effect of various DP steel grades at high strain levels. Miyauchi et al. presented a very interesting test for cyclic shear

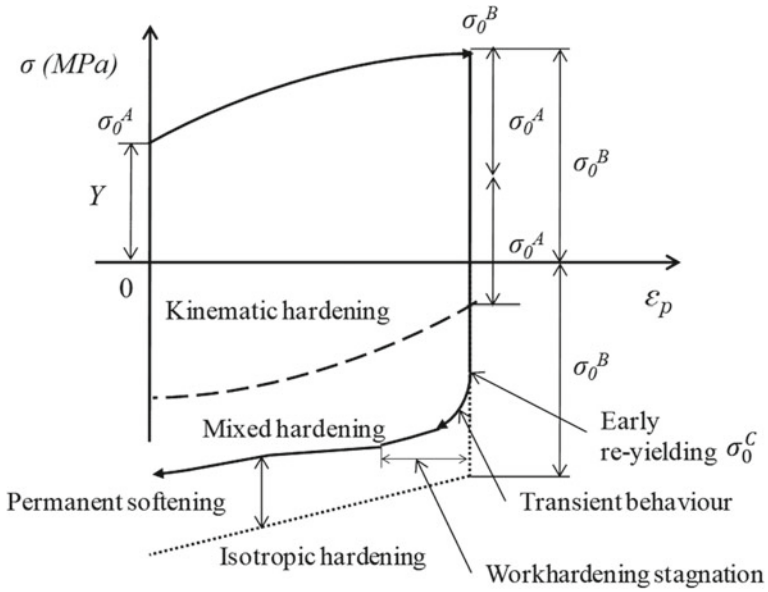

Fig. 2 As received microstructure of 42CrMoS4Al case hardening steel

testing of metal sheets [16] and Tekkaya et al. extended the in plane torsion test for the characterization of sheet metals at very high strain levels [17].

The above-mentioned works show that the sheet metal forming community is well advanced in the cyclic characterization of materials. Many authors used tension-compression tests for the characterization of the kinematic behaviour of solid samples at very low strain levels with the aim to be used in fatigue modelling. However, very few works intended for forming process modelling of bulk material were found during the literature review. Madej et al. used tension-compression tests of solid samples cut from thick sheets for the study of the high temperature levelling of thick plates [18]. Strain levels were small compared to cold forging. Narita et al. used small size shear samples cut from wire to study the influence of the hardening model in the springback prediction of cold forged extruded components [19–21]. Strains up to 35% were achieved before strain reversal and the Yoshida-Uemori model was used in their works for the cyclic behaviour modelling of the initial wires. The estimated final extruded diameter by the Yoshida-Uemori model was more uniform and closer to the experimental results.

Finally, it is worth to mention that torsion tests of solid samples are suitable for high strain level testing of metallic materials. In this regard, Badiola et al. used this experimental procedure to study the cyclic behavior of rods and understand the austenite–ferrite phase transformation in a Nb-microalloyed steel at high temperature [22]. Her et al. recently presented a new method to obtain high strain flow curves for cold forging including kinematic hardening by using a combination of extrusion plus tensile or compression tests [23].

2.3 Cyclic Torsion Tests

Cyclic torsion tests were used for the kinematic characterization of the material at strain levels similar to the ones reached during cold forging. It is well known that torsion tests are capable to reach very high strains due to the stress state that is present in the material during the test as it was mentioned before. The geometry of the sample and the torsion tester are shown in Fig. 3.

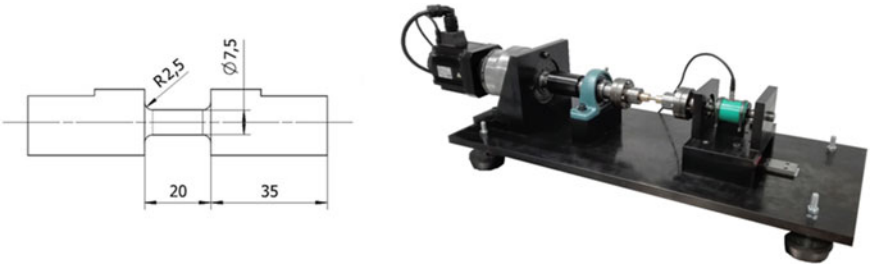

Fig. 3 Torsion sample dimensions and torsion test bench. (Color figure online)

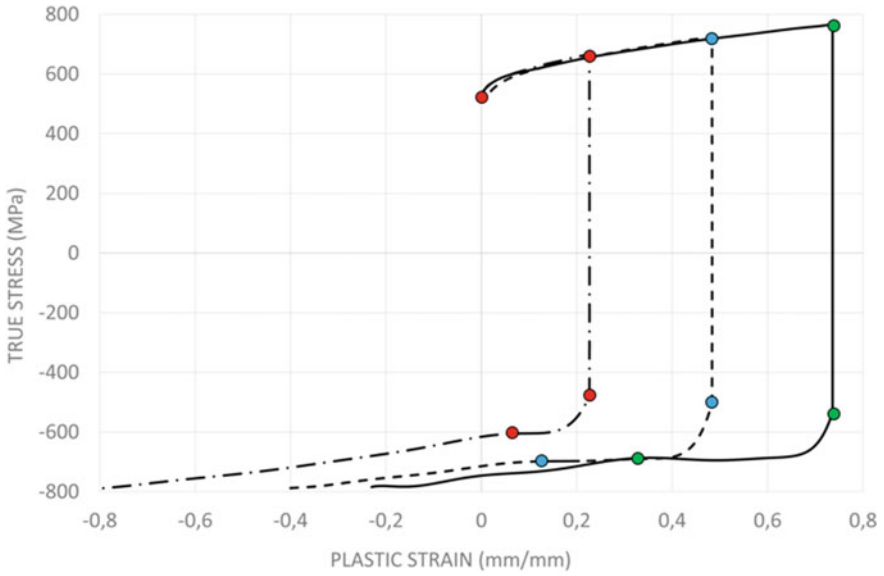

Fig. 4 Experimental stress-strain curves at different reversal angles. (Color figure online)

Cyclic tests were performed using three different reversal angles: 100º, 200º and 300º (approximate equivalent total strains of 0.25, 0.5 and 0.75). After clockwise twisting of the samples up to the desired reversal angle the rotation direction was inversed and the material was twist counterclockwise until rupture occurred. The elastic part of the cyclic curves was removed using the 0.2% offset method, which is equal to approximately 1º offset. Finally the torque–twist angle data was converted into shear stress–shear strain according to the method proposed by Fields and Backofen [24] and then, into true stress–true strain by applying the Von Mises criterion. The experimental stress–strain curves are shown in Fig. 4.

2.4 Evolution of the Kinematic Behavior of the Analyzed Steel

The analysis of the cyclic experimental curves was performed to understand the kinematic behavior of the selected steel. The evolution of the tension and compression yield stress ratio (σ_0^B/σ_0^C) was analysed for the different cyclic reversals. As it is shown in Fig. 5 the Bauschinger effect reaches an asymptotic value after an initial decrease and thus, the isotropic hardening or yield surface expansion suffered by the material is continuously compensated in the same ratio by the kinematic hardening or the translation of the yield surface. The evolution of the transient softening and the work hardening stagnation is shown in Fig. 6. The definition of the measured

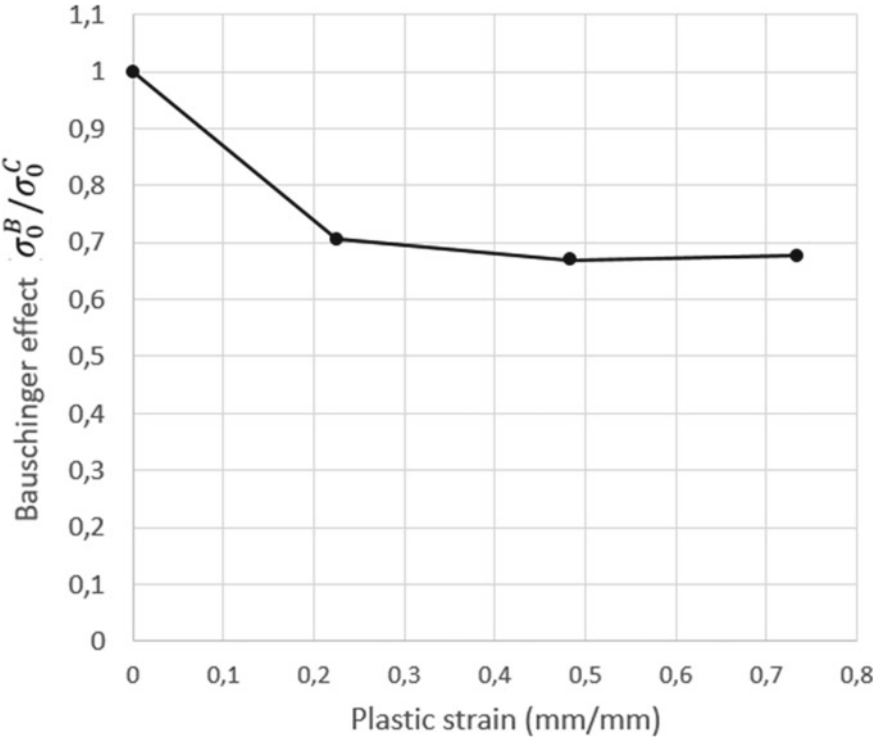

Fig. 5 Evolution of Bauschinger ratio

lengths for both variables are detailed in Fig. 1. The transient softening length or strain is almost constant for all the cyclic reversals while the work hardening stagnation increases with the applied prestrain. This is a well-known phenomena for stress reversal at large strains. Transmission Electron Microscope observations revealed the main features of the evolution of dislocation substructures under stress reversal. During the strain-hardening stagnation, preformed dislocation walls gradually disintegrate. The amount of reverse strain which is necessary for the complete dissolution of these walls increases with the prestrain [25].

Finally, the evolution of the isotropic hardening and the kinematic hardening have been analyzed. From Fig. 7 and for the uniaxial cyclic loading case the values of the isotropic hardening R and the kinematic hardening X can be calculated analytically for the different reversal strains as follows:

$$R = \left(\frac{\sigma_0^B - \sigma_0^C}{2}\right) - \sigma_0^A \tag{1}$$

$$X = \sigma_0^B - \left(\sigma_0^A + R\right) = \frac{\sigma_0^B + \sigma_0^C}{2} \tag{2}$$

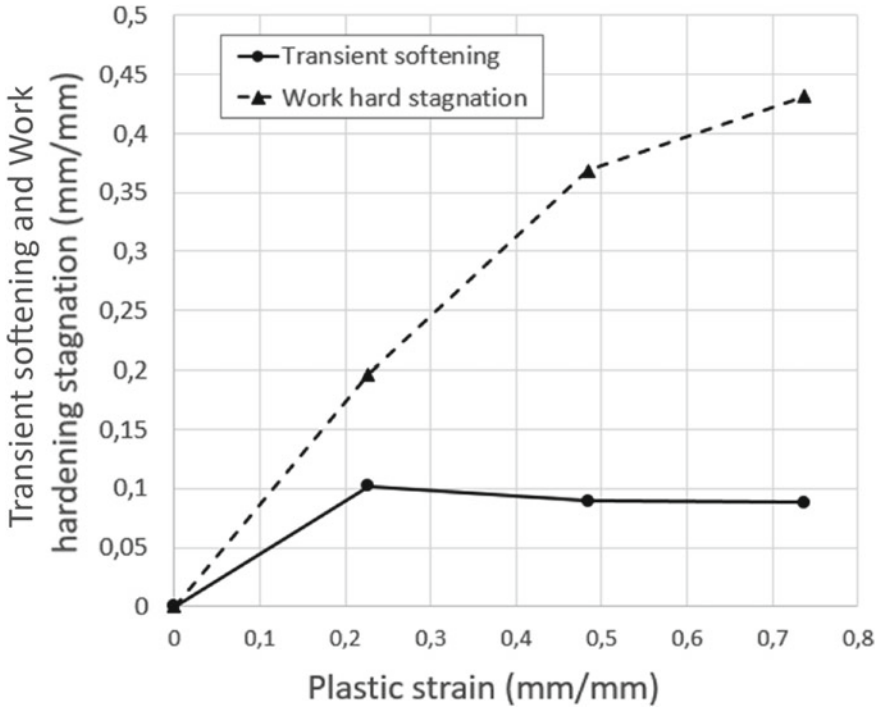

Fig. 6 Evolution of transient softening and stagnation behaviour

Note that σ_0^C is negative in the formulae, as it is the compression yield stress of the material after loading. σ_0^A and σ_0^B are positive being the initial yield stress and yield stress after uniaxial pre-straining.. The evolution of isotropic hardening (R) and the kinematic hardening (X) for the different cyclic tests is shown in Fig. 8. As it is observed, the R follows a linear evolution while X tends to stabilize at a plastic strain of approximately 0.8.

3 Parameter Identification of Mixed Chaboche and Lemaitre Model

The Chaboche and Lemaitre hardening model (1990) [26] was combined with the Von Mises yield criteria, as these are recommended for cyclic plasticity analyses and widely distributed in commercial FE-codes. The Von Mises yield criteria can be expressed.

The Chaboche and Lemaitre hardening model (1990) [25] was combined with the Von Mises yield criteria, as these are recommended for cyclic plasticity analyses and widely distributed in commercial FE-codes. The Von Mises yield criteria can be expressed:

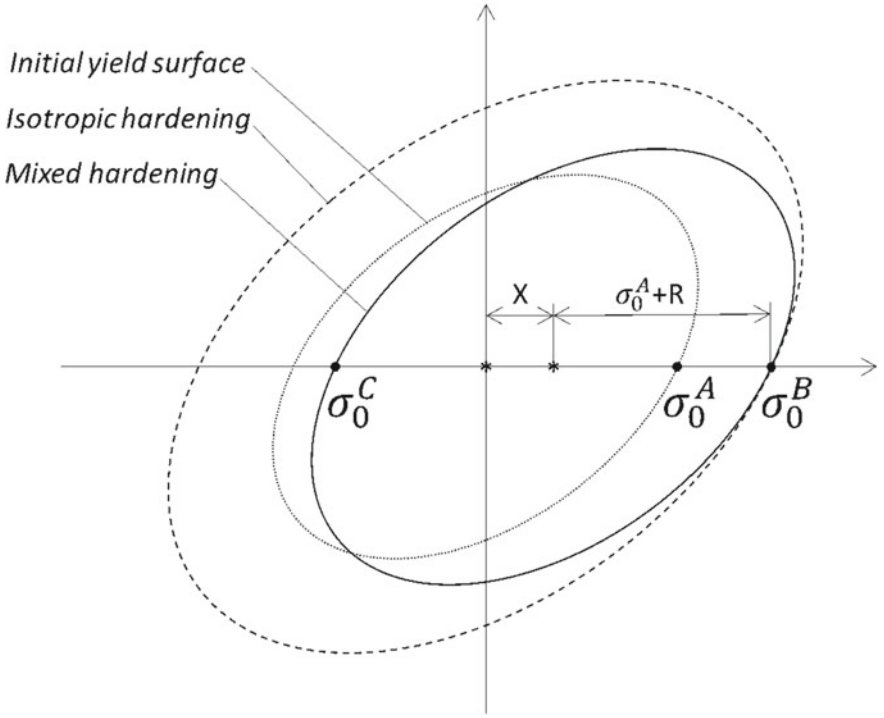

Fig. 7 Representation of isotropic and kinematic hardening

$$\phi(\boldsymbol{\sigma}, \boldsymbol{X}, \sigma y) = \sqrt{3/2(\boldsymbol{\sigma} - \boldsymbol{X}) : (\boldsymbol{\sigma} - \boldsymbol{X})} - \sigma y - R \tag{3}$$

where $\boldsymbol{\sigma}$ denotes the deviatoric stress tensor, $\boldsymbol{X}$ is the deviatoric backstress tensor, σ_y is the initial yield stress and R is the isotropic hardening. An associated flow rule has been considered to define the plastic strain increment.

The Chaboche and Lemaitre hardening model is a mixed isotropic-kinematic hardening formulation. The nonlinear kinematic hardening describes the movement of the yield surface by means of the evolution of the backstress. The change in the size of the yield surface, is related to the isotropic hardening and is introduced by means of the initial value of the yield strength σ_y and the isotropic variable R. In the proposed model, the evolution of the isotropic hardening is defined in function of the accumulated plastic strain $\mathrm{d}\bar{\varepsilon}_p$ by the following law:

$$\mathrm{d}R = b \cdot (Q - R) \cdot \mathrm{d}\bar{\varepsilon}_p \tag{4}$$

where and are material parameters of the model. The kinematic evolution of the yield surface, proposed by Chaboche et al. is presented in Eq. (5). This model is based on a decomposition of the non-linear kinematic hardening rule proposed by Armstrong and Frederik (1966). Chaboche decomposed a stable hysteresis curve in several parts

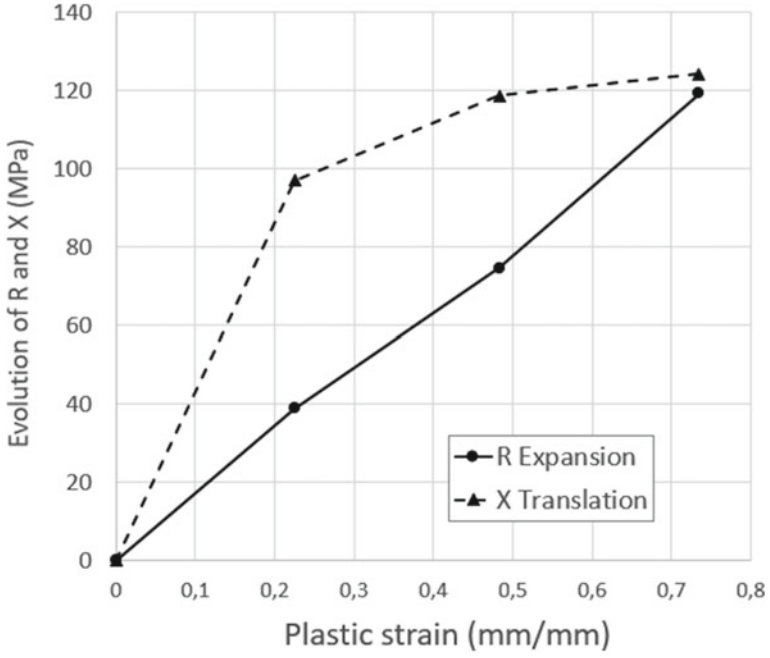

Fig. 8 Evolution of isotropic and kinematic hardening

and it was observed that increasing the material parameters of the hardening rule by the superposition of backstresses, a more accurate model was obtained [16]. However, in this work only one backstress has been considered in the model definition.

$$d\,\boldsymbol{X} = \frac{2}{3} C d\varepsilon_p - \gamma \boldsymbol{X} d\bar{\varepsilon}_p \tag{5}$$

where C and γ are the material parameters to be fitted.

The parameter identification method consisted of an unconstrained non-linear optimization proposed by Nelder and Mead [51] available at Matlab®. First, initial values of Q, b, C and γ where found using the data of Fig. 8. After these first calculation the error function shown in Eq. (6) was minimized using all the experimental data of the three cyclic tests.

$$f_{obj} = \frac{1}{n} \sum_{i=1}^{n} \left| \sigma_i^{exp} - \sigma_i^{model} \right| \tag{6}$$

The results of the fitting are presented in Fig. 9. The model taking into account only the isotropic hardening was labelled as IH while the mixed isotropic and kinematic model with one backstress is labelled as KH. As can be observed, the model was able to predict the cyclic hardening of the material. The model predicted the Bauschinger

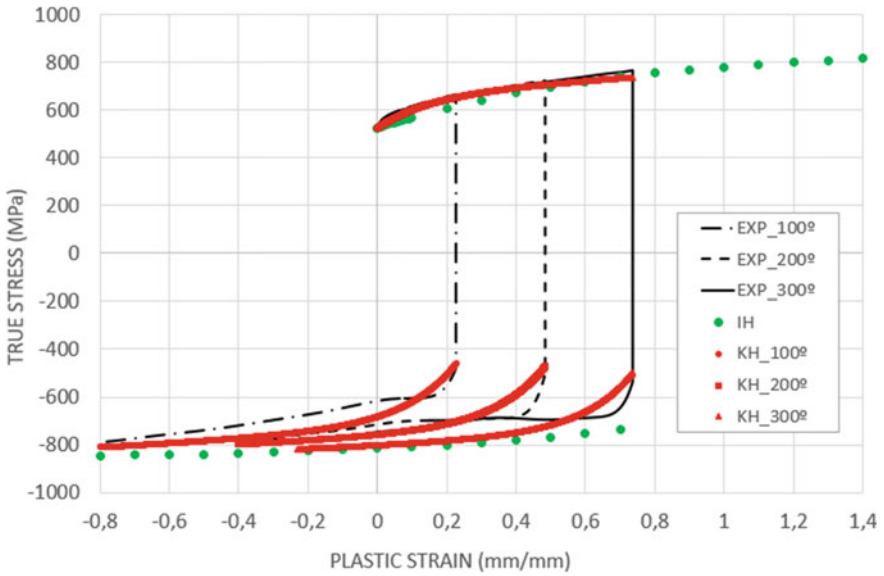

Fig. 9 Fitting of Chaboche and Lemaitre model to experimental curves. (Color figure online)

Table 2 Material parameters of the mixed Chaboche and Lemaitre hardening model

Isoropic model IH			Mixed hardening model IK			
σ_0	Q	b	Q	b	C	γ
525 MPa	335 MPa	1.45	300 MPa	0.5	850	7.0

Effect observed in the experimental results. However, was not able to accurately predict the transient behavior and work hardening stagnation. This can be explained because only one backstress tensor was used in this study and at least two are needed for capturing the transient behavior. The four material parameters involved in the model obtained by means of the explained optimization method are presented in Table 2.

4 Finite Element Modelling of a Ball Pin Cold Forging

In order to quantify the influence the hardening model has on the numerical results, a real cold forging process of a ball pin was simulated. For confidential issues, only the first three operations were simulated; one upsetting, one extrusion operation and the forging of the ball.

FORGE® NxT was used for the process modelling. A full 3D model was used although the model is asymmetric because the material model was coded for a 3D general case. One twelfth of the billet was simulated using two symmetry planes to

avoid excessive computing time. The mesh sensitivity analysis suggested the use of 0.5 mm mesh size in the most strained areas, the transition and rounded zones. For this reason, the billet was meshed using tetrahedral elements with a general mesh size of 1.5 mm and remeshing boxes of 0.5 mm in the transition zones. A friction value of $\mu = 0.05$ was used in the simulations as suggested in [7]. Simulations were run with the two material models, a pure isotropic model and a mixed kinematic hardening model as explained before. For the numerical comparison the material flow, the equivalent Von Mises stress after each process step, the residual stresses after punch-die release and the punch forces were compared.

The material flow analysis, displacement in Z direction, (see Fig. 10) demonstrates that material flow is similar in both material models. The equivalent strain analysis shows similar results and strain levels are similar for both material models. This can be explained because the closed die forging is driven by the die and punch geometries. The material displacement after punch release is higher for the isotropic model. This can be explained because higher residual stresses result when using a isotropic model in the lower part of the ball pin.

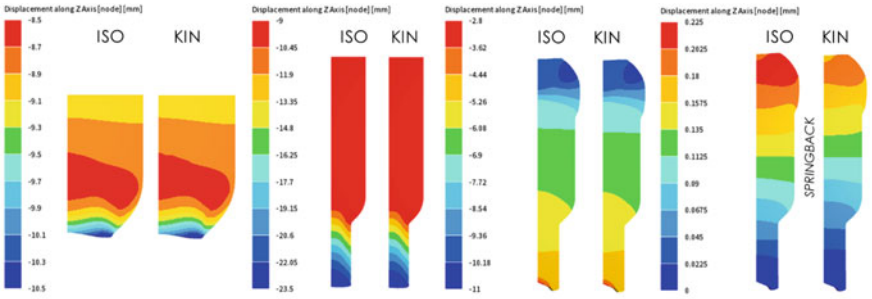

Fig. 10 Material flow results (displacement in Z direction). Upsetting, Extrusion and Ball forging operations together with the final springback. (Color figure online)

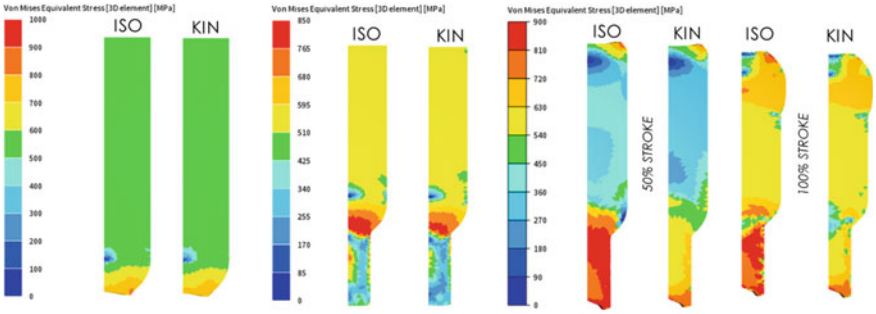

Fig. 11 Material flow results (displacement in Z direction). Upsetting, Extrusion and Ball forging operations together with the final springback. (Color figure online)

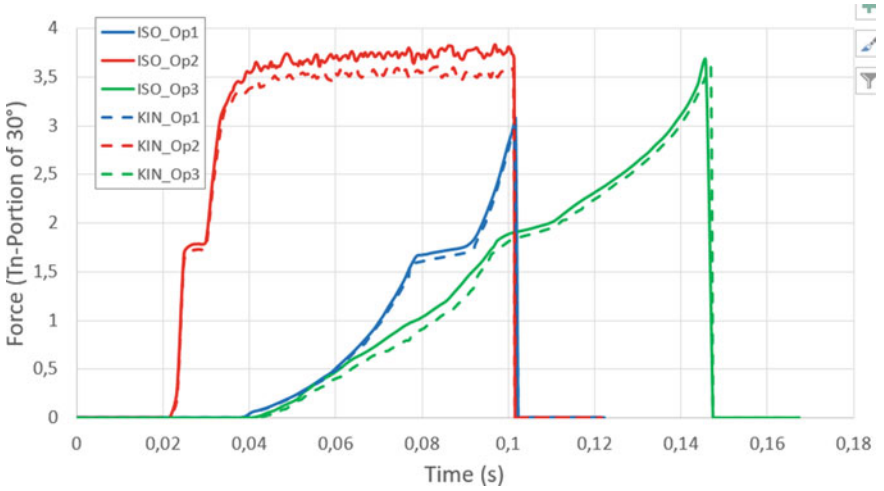

Fig. 12 Punch forces for the different hardening models and operations. (Color figure online)

The equivalent Von Mises stresses after each process step are shown in Fig. 11. The Upsetting and Extrusion operations show similar stress levels for both models. However, the third operation clearly shows that the compression of the lower part after the extrusion operation is highly affected by the hardening model. AT 50% of the punch stroke, when the bottom part of the ball pin is forged, shows significantly higher stress levels for the isotropic model than the kinematic one. This is also observed after the punch reaches the 100% of the stroke at this operation and this explains the higher springback observed after this forging operation in the material flow results.

Finally, punch forces for the different hardening models and operations are shown in Fig. 12. Kinematic model forces are lower than the isotropic model. This is observed principally in the extrusion operation. The difference is not remarkable in the last operation where the kinematic hardening model predicts the biggest differences in terms of stresses. However cam be explained because the biggest amount of work is used for the ball forging where the kinematic hardening effect is not important.

5 Conclusions

The 42CrMoS4Al case hardening steel used to produce automotive ball pins was characterized using torsion cyclic tests. The methodology showed the test is suitable for reaching high strain levels and studying the transient softening and work hardening stagnation phenomena. These two effects could be important for the cold forging process modeling because equivalent strains reached in this process are very high.

The experimental results were fitted to the well-known the Chaboche and Lemaitre hardening model. The mixed hardening model was able to capture the Bauschinger effect but the transient softening and work hardening stagnation were not properly captured. The superposition of more backstress tensors needs to be evaluated to enhance the model accuracy. On the other hand the influence of the temperature needs to be also introduced in the model. This is currently being analyzed by the authors.

Different material flow was observed for the kinematic and isotropic models principally in the final springback of the component. Von Mises stresses are different for the two laws during the forging but the biggest influence was observed during the compression after an extrusion operation, where the path change is important. Although the kinematic hardening showed slightly lower punch forces the difference seems to be not relevant for the analyzed component.

Acknowledgments The authors would like to thank the Gipuzkoa Provincial Council for the funding of the RELASHEET research project (Desarrollo de distintos métodos de alivio de tensiones residuales en chapas metálicas) and the Ecenarro S. Coop. cold forging company for their technical support.

Analysis of the Thermomechanical Flow Behavior of Carburized Sheet Metal in Hot Stamping

Alexander Horn and Marion Merklein

Abstract The reduction of fuel consumption due to restrictions regarding CO_2 emissions is one of the major driving forces for lightweight design in the automotive industry. In this context, hot stamping of ultra-high-strength steels has developed to a state of the art process for manufacturing safety-relevant components. With regard to passenger safety and weight reduction, further potential lies in the functional optimization of the parts. Prior local carburization followed by hot-stamping is a new process variant for tailored properties, which overcomes the limitations of established processes. Due to the varying carbon content after carburization, the sheets have graded mechanical properties. Within this contribution, the influence of temperature, strain rate and carburization on the flow behavior will be investigated. For this purpose, tensile tests at elevated temperatures are carried out in a physical simulator of type Gleeble. The resulting flow curves of the carburized complex phase steel are modeled with a modified Norton-Hoff hardening law and the influence of the carburization process is analyzed by means of the initial yield stress. Furthermore, the results from tensile tests are correlated with the phase transformation behavior obtained by a laser ultrasonic sensor.

Keywords Hot stamping · Quenching · Carburization

1 Introduction

One of the biggest challenges in today's automotive industry is the reduction of car body weight. This is especially apparent against the background of increasing demands regarding safety standards and expectations of comfort. As a result, the average vehicle weight significantly increased within recent years [1]. To fulfill

the contradictory request of low fuel consumption and governmental requirements concerning CO_2 emissions, lightweight design is of the highest importance. Besides the application of lightweight materials, for instance, aluminum or titanium, the usage of ultra-high-strength steels is a successful strategy. In terms of safety-relevant components, such as b-pillars or bumper plates, hot stamping has developed to a state of the art process for manufacturing [2]. In this process, steel sheets are fully austenitized above their AC_3 temperature for several minutes. Afterward, the sheets are transferred to a press and subsequently formed and in-die quenched [3]. With the conventionally used boron-manganese steel alloy 22MnB5, an ultimate tensile strength of 1500 MPa can be achieved as long as the cooling rate during quenching exceeds the critical value of 27 K/s. Further development of hot stamping steels, for example by increasing carbon content, has led to tensile strengths of up to 2000 MPa [4].

The application of functional optimized components offers further potential regarding passenger safety and weight reduction [5]. The process variants for manufacturing parts with tailored properties can be divided into two groups. One aims to improve the ductility of the parts, while the other strategies locally increase strength. The enhancement of ductility, which is beneficial during crashes, since impact energy can be absorbed, can be realized by means of controlling the microstructure during the process. To prevent the martensitic transformation, which would result in high strength, but low ductility, either the austenitization process [6] or the in-die quenching step can be adapted [7]. Furthermore, it is possible to perform additional heat treatment after hot stamping to receive an annealed microstructure [8]. A fourth strategy to improve ductility are tailor welded blanks, where the joining partner is selected with regard to a high residual elongation after quenching [9]. The second approach for functional optimized components is to locally increase strength, which improves structural integrity. State of the art processes are the application patchwork blanks [10] and tailor rolled [11], or rather tailor forged blanks [12]. A novel process is to locally increase carbon content by carburization. For this purpose, the sheets of a complex phase steel are coated with carbonic material such as graphite prior to a heat treatment [13]. Another approach is to expose the sheets to a carbonic atmosphere, while some areas are masked [14]. It was found, that it is possible to significantly enhance the ultimate tensile strength in carburized areas compared to non-carburized zones with only a small transition zone. After carburization, the semi-finished parts are hot stamped. As with all manufacturing processes, especially thermally assisted ones, a suitable material model is necessary for the numerical process design. Therefore, the thermomechanical flow behavior of a carburized sheet is investigated within this study. In this context, the initial yield stress is compared to samples being hot stamped from as-delivered condition. Furthermore, the flow behavior is modeled using Norton-Hoff hardening law. In addition, the results from tensile tests are correlated with phase transformation obtained by a laser ultrasonic sensor.

2 Methodology

2.1 Investigated Material

The investigated sheet material is a complex-phase steel CP-W® 800 with a sheet thickness of 1.6 mm. This steel alloy can be related to the advanced high strength steels. In the as-delivered condition, it is typically used for safety-relevant car body parts. The initial fine-grained microstructure consists out of ferrite, bainite and martensite. Although CP-W® 800 is usually processed via cold-forming, hot stamping is also applicable. Due to an improved strength after hot stamping, the application potential of this alloy is extended. Since the carbon content in the as-delivered condition amounts to 0.14 wt% [15], a further increase in strength by carburization is possible. As a comparison, the conventionally used hot stamping steel 22MnB5 has a carbon content of 0.25 wt% [16]. For this reason, the CP-W® 800 is particularly suitable for the process combination of carburization followed by hot stamping. Table 1 shows the ultimate tensile strength as a result of various process routes. In this context, it is noteworthy, that the hot stamping process consists of four minutes dwell time at 900 °C for austenitization followed by water quenching. The carburization parameters are three hours of holding time and a carburization temperature of 900 °C as well.

2.2 Uniaxial Tensile Tests at Elevated Temperatures

Within this study, carburized samples, as well as samples being hot stamped from as-delivered condition, are investigated. While the specimens being hot stamped from the as-delivered material do not need additional treatment, carburized samples are coated with graphite and heat-treated for three hours at 900 °C prior to uniaxial tensile tests. The tests are carried out in a physical simulator of type Gleeble 3500® (Dynamic Systems Inc., Poestenkill, NY, USA) with digital image correlation GOM Aramis for optical strain measurement. The samples are heated by an electrical current and temperature is controlled with thermocouples. The evaluation of the strain is done in the center of the samples, where the temperature is homogeneous. For both, carburized samples and samples being hot stamped from as-delivered condition, the

Table 1 Ultimate tensile strength of CP-W® 800 depending on the process route

	Ultimate tensile strength
As delivered	780 MPa [15]
Hot stamped from as-delivered condition	1128 MPa
Carburized and hot stamped	1400 MPa [13]

Table 2 Experimental parameters for uniaxial tensile tests at elevated temperatures

		Temperature				
		500 °C	600 °C	700 °C	800 °C	
Strain rate	0.01 s^{-1}	x	x	xo	x	x Carburized o Hot stamped from as-delivered condition
	0.1 s^{-1}	xo	xo	xo	xo	
	0.5 s^{-1}	x	x	xo	x	

same time-temperature profile is applied. It consists of heating up to the austenitization temperature of 900 °C with a rate of 15 K/s followed by four minutes of holding time. Afterward, a quenching rate of 50 K/s is applied to cool the samples to the testing temperature. Compressed air is used as quenchant. The testing temperatures are 500 °C, 600 °C, 700°C and 800 °C, which corresponds to the temperature range for forming in hot stamping. Furthermore, three different strain rates are applied to investigate the influence of the deformation rate. In the case of carburized samples, a full factorial design is chosen, while samples being hot stamped from as-delivered material are only investigated at selected parameter combinations. The experimental parameters are shown in Table 2.

In the first step, the influence of the carburization process is analyzed. While the ultimate tensile strength is appropriate to investigate the different mechanical properties after carburization and hot stamping, the initial yield surface is more suitable in terms of the thermomechanical flow behavior. Moreover, the temperature and strain rate dependency of the carburized samples are evaluated. Finally, the flow behavior will be modeled using a modified Norton-Hoff hardening law [17].

2.3 Phase Transformation

Besides uniaxial tensile tests at elevated temperatures, also the phase transformation behavior is analyzed to support the findings from tensile testing. This will be done using a laser-ultrasonic sensor. The measuring principle is rested upon the interaction of a laser pulse generated ultrasonic signal with the microstructure of the base material [18]. While conventional dilatation is premised on the temperature and phase-dependent thermal expansion, the principle of laser-generated ultrasound is based on the variation of ultrasonic propagation speed [19]. A generation laser pulse causes ablation on the surface of the samples. Due to the vaporization of the material, the ultrasonic pulse is induced. The ultrasound signal propagates through the sample and gets reflected at the specimen's bottom side. The respective echo is detected by means of an interferometer with the detection laser. By analyzing the variation of the delay between consecutive echoes, phase transformation can be monitored [20]. Besides phase transformation, evaluation of the ultrasonic attenuation allows the in-situ investigation of austenite grain growth [21]. The determined measurands refer to an average of the measured volume, consisting out of a cylinder with the height of

the samples' thickness and the laser spot as base area. Within this study, a sensor of type LUMet® is used. The generation laser is a frequency-doubled Nd:YAG pulse laser with a pulse duration of approximately 6 ns and maximum pulse energy of 72 mJ, while the detection laser is a frequency stabilized Nd: YAG laser with a pulse duration of 90 µs. To verify the findings from the laser-ultrasonic sensor, the transformed fraction is compared to measurement data obtained with an extensometer of type Keyence LS7600. To enable a correlation between the results from the uniaxial tensile tests at elevated temperatures and the phase transformation, the same thermal cycle is applied. The samples are heated to a temperature of 900 °C with 15 K/s, held for four minutes and quenched to room temperature with a quenching rate of 50 K/s.

3 Results

3.1 Uniaxial Tensile Tests at Elevated Temperatures

Contrary to the experimental design shown in Table 2, the evaluation of neither the true stress-strain curve nor the initial yield strength was possible for strain rates of 0.1 s^{-1} and 0.5 s^{-1} at 500 °C, since eccentric failure occurred. Due to the conductive heating, the temperature distribution is inhomogeneous along the sample. Therefore, the applied temperature cycle is only valid for the middle area of the specimens. If the quenching rate is sufficient, phase transformation leads to a gradient in strength at lower temperatures. As a result, the softer eccentric areas fail during testing. As the first part of the results, the initial yield stresses of carburized samples and samples being hot stamped from as-delivered material are presented. Figure 1 shows the respective values.

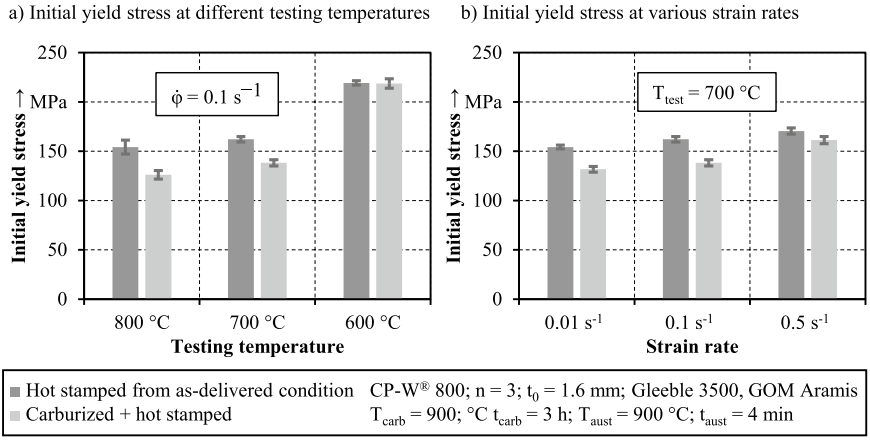

Fig. 1 Initial yield strength of carburized and non-carburized samples at various temperatures and strain rates

It can be seen, that there are temperature and strain rate dependent differences in the initial yield stress. For all tested parameter combinations, the initial yield stress of samples being hot stamped from as-delivered condition is higher compared to carburized specimens. In the case of a testing temperature of 800 °C and 0.1 s^{-1}, the difference amounts to approximately 28 MPa. Lowering the testing temperature, the gap decreases to 14 MPa at 700 °C and nearly 0 MPa at 600 °C. A contrary trend can be seen for the strain rate, which is illustrated in Fig. 1b. Increasing the strain rate from 0.01 s^{-1} to 0.5 s^{-1} leads to a decreasing difference in the initial yield strength between carburized specimens and samples being hot stamped from as-delivered material from 23 MPa to 9 MPa.

Besides the initial yield strength, also the true stress-strain curves of carburized samples are analyzed. During the tensile tests, a degree of deformation of up to 0.9 was achieved. For better comparison, the data is only shown up to a value of 0.3. Moreover, due to the temperature distribution, necking occurs already at low degrees of deformation, which results in an exponential rise of strain rate.

Figure 2a shows the results for testing temperatures of 800, 700, 600 and 500 °C at a strain rate of 0.01 s^{-1}. It can be seen, that not only the initial yield strength increases with decreasing temperature, which was already seen in Fig. 1, but also strain hardening. The rise of both, strain hardening and initial yield strength is especially apparent between 700 °C and 600 °C and between 600 °C and 500 °C. The influence of forming speed can be seen by means of the strain rate, illustrated in Fig. 2b. At a temperature of 800 °C, the initial yield stress of various strain rates is within the range of ±5 MPa, whereas the strain hardening increases with a rising strain rate. For a testing temperature of 600 °C, contrary behavior can be seen. The initial yield stresses are between 168 and 235 MPa. However, the difference in flow

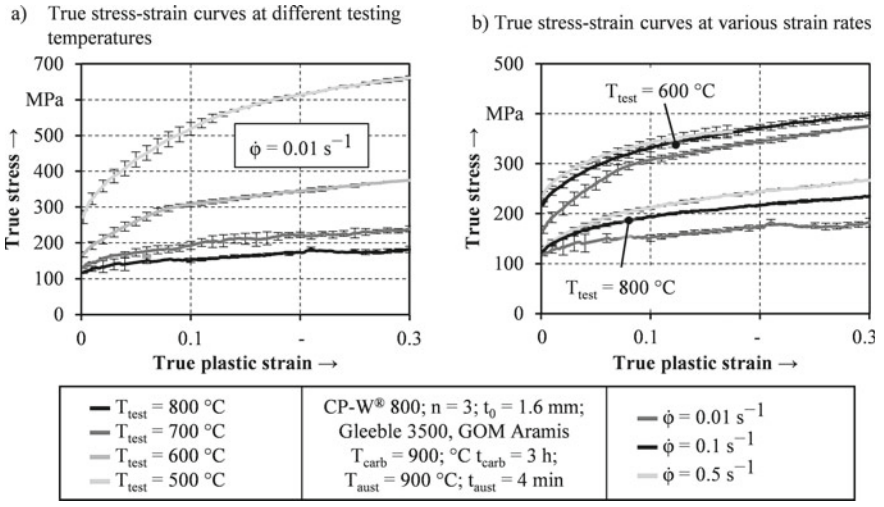

Fig. 2 Flow curves of carburized and non-carburized samples at temperatures between 800 and 500 °C and three different strain rates

stress decreases at higher deformation rates. This is especially apparent for a strain rate of 0.1 s^{-1} and 0.5 s^{-1}, where the flow stress is within the standard deviation for degrees of deformation higher than 0.1.

After analyzing the true stress-strain curves of carburized samples, the flow behavior is interpolated and extrapolated using a modified Norton-Hoff model [17]. According to this approach, the relationship between flow stress σf and degree of deformation φ, strain rate $\dot{\varphi}$ and temperature T can be expressed as

$$\sigma_f(\varphi, \dot{\varphi}, T) = K \cdot e^{\beta/T} \cdot (c + \varphi)^n \cdot \dot{\varphi}^m \tag{1}$$

with K, β, n, m and c as model parameters that have to be fitted to match the experimental data. Besides modeling the flow behavior with fixed model parameters from Eq. 1, two further approaches are pursued. To improve accuracy, the parameters K, β, n and m are also expressed as a function of temperature. Besides an exponential correlation, which was already used by Lechler and Merklein [17] for modeling of the flow behavior of 22MnB5, also a linear relationship is used. The respective equations are presented in Eqs. 2 and 3.

$$\text{Linear correlation}: \; K, \beta, n \text{ and } m \rightarrow f(T) = x_0 + c_x \cdot T \tag{2}$$

$$\text{Exponential correlation}: \; K, \beta, n \text{ and } m \rightarrow f(T) = x_0 \cdot e^{c_x \cdot T} \tag{3}$$

For fitting the parameters to the experimental data, the least square method is applied. To ensure a constant strain rate, input data is limited to a degree of deformation of up to $\varphi = 0.2$. The evaluation of the three different modeling approaches is done by means of the root mean square error, displayed in Fig. 3a. The RMSE relates to all tested temperatures and strain rates. While the average deviation between experimental and analytical data amounts to around 15 MPa in the case of fixed model parameters, it is reduced to 8.4 MPa for temperature-dependent coefficients. The difference of the RMSE between a linear and an exponential correlation is below 0.1 MPa. Therefore, both approaches can be seen as equivalent with regard to the interpolation and extrapolation of true stress-strain curves of a carburized complex phase steel at elevated temperatures. The respective model parameters for all three approaches are listed in Table 3.

In Fig. 3b, the comparison between the experimental data and the analytical approximation using a linear correlation between temperature and the model coefficients, is displayed. The results are exemplarily shown for a temperature of 500 °C and 700 °C and in the case of 700 °C for three different strain rates. It can be seen, that there is a good agreement between experimental and analytical data.

3.2 Phase Transformation

Besides the flow behavior, also the occurring phase transformations are investigated by means of a laser ultrasonic sensor. The resulting measurement data is similar to conventional dilatometry curves. A direct comparison of the curves obtained by both measurement principles is not possible, due to different physical quantities determined. While conventional dilatometry refers to longitudinal expansion, the laser ultrasonic sensor measures ultrasonic velocity. Therefore, the transformed fraction is presented in dependence on the temperature during cooling. The transformed fraction is calculated according to Fig. 4a. The phase transformation occurs as a discontinuity in the ultrasonic velocity or rather dilatation curve. With the help of two constructed tangents, the transformed fraction is calculated. The respective results are shown in Fig. 4b. It can be seen, that phase transformation begins between 620 °C and 640 °C. The end of the transformation is approximately between 460 °C and 480 °C. The measurement data obtained by the laser ultrasonic sensor show good repeatability. Compared to the extensometer, the progress of phase transformation

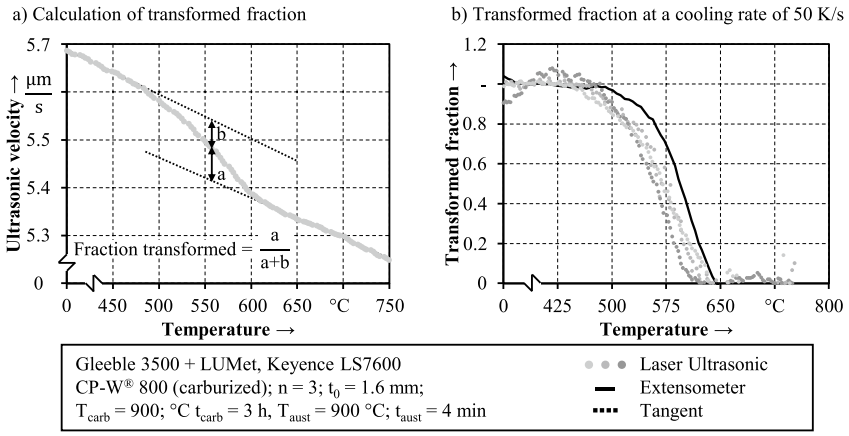

Fig. 4 **a** Procedure for the calculation of transformed phase fraction from measurement data. **b** Comparison of transformed fraction of experimental data measured with laser-ultrasonic and extensometer at a quenching rate of 50 K/s

is of good accordance, especially with regard to the start and end temperatures. Therefore, the applicability of this measurement principle for the determination of phase transformation during hot stamping can be confirmed.

4 Discussion

In the results section, it was illustrated, that the initial yield stress of carburized samples was lower in comparison with specimens being hot stamped from as-delivered condition. These findings indicate a contrary behavior compared to tensile tests at room temperature, where strength is increased due to the carburization process as listed in Table 1. During the carburization process, the carbon content increases. Various authors already investigated the influence of carbon on the stress-strain behavior at elevated temperatures. Wray [22] showed, that carbon content reduces work hardening at temperatures between 850 and 1300 °C. This effect was explained with enhanced dynamic recovery, probably due to an expansion of the austenite lattice. Kong et al. [23] analyzed the flow stress of several austenitic steels with a varying carbon content of up to 0.79 wt%. The results indicated that increasing carbon content leads to an increase in flow stress at low temperatures and high strain rates, while it decreases flow stress at high temperatures and low strain rates. Serajzadeh and Taheri [24] stated that the rate of dynamic recrystallization increases with rising carbon content, while dynamic recovery decreases. As a result, under conditions with dominating dynamic recrystallization such as high temperatures and low strain rates, flow stress is decreased, while a contrary effect can be seen when dynamic recovery is dominating, hence at low temperatures and high strain rates.

These findings are in good accordance with the results from Sect. 3, where the difference in initial yield stress between carburized specimens and samples being hot stamped from as-delivered material decreased at lower temperatures and high strain rates.

Besides the influence of carburization on the initial yield stress, the temperature and strain rate dependent flow behavior was analyzed as well. As expected, flow stress was reduced with rising temperatures and decreasing strain rate, which is an already well know behavior [25]. However, it was depicted in Fig. 2a, that the temperature-dependent rate of increase in flow stress was higher at temperatures below 700 °C. This can be explained with the decomposition of austenite. The experiments with the laser ultrasonic sensors revealed a start temperature for the phase transformation of approximately 620 °C to 640 °C. Since the transformed fraction increases with decreasing temperature, as shown in Fig. 4b, the rate of increase in stress further goes up. In addition, it was shown, that the effect of strain rate decreased at lower temperatures. In the case of 0.1 s^{-1} at 600 °C strain hardening was higher compared to a strain rate of 0.5 s^{-1}. An explanation for this is an ongoing phase transformation. As shown in Fig. 4b, only a small fraction of austenite is already transformed at 600 °C. Since a lower strain rate equals a longer test duration, phase transformation further proceeds, which results in increased strain hardening during deformation.

5 Summary and Outlook

Within this study, the thermomechanical flow behavior of a carburized complex-phase steel at elevated temperatures was investigated. It was shown, that the initial yield stress was reduced due to the carburization process. The influence depends on the respective strain rate and temperature. Furthermore, the flow behavior was analyzed and modeled using a modified Norton-Hoff approach. As expected, the experiments revealed a temperature and strain rate dependent material behavior. By using a linear and exponential dependence of the Norton-Hoff parameters on temperature, accordance between experimental and analytical data was significantly improved. To support the findings from uniaxial tensile tests at elevated temperatures, phase transformation was investigated by means of a laser ultrasonic sensor and correlated with the stress-strain curves.

Within this work, carburized samples were compared to specimens being hot stamped from as-delivered material. To enable a holistic process design of the tailored carburization process by numerical simulation, the flow behavior of non-carburized samples under process conditions, more precisely after a heat treatment of several hours, has to be investigated as well. Furthermore, the phase transformation under various quenching conditions is of high interest.

Acknowledgments The authors would like to thank the German Research Foundation (DFG) for funding the project “Tailored Carburization: Gradierung mechanischer Eigenschaften in der Blechebene und über die Blechdicke” (DFG ME 2043/51-1).

The authors would also like to show their gratitude to Mr. Yaowu Jiang, who participated in this experimental study within the scope of his master thesis.

Effect of Short Pulsed-Current on Stress Relaxation in Uniaxial Tensile Test

Ichsan Indhiarto, Qiu Zheng, Tetsuhide Shimizu, Tsuyoshi Furushima, and Ming Yang

Abstract Electricity-assisted metal forming, especially using pulsed-current, was demonstrated to promote a drop in flow stress and improving formability. To investigate the effect of pulsed-current on stress relaxation, a uniaxial tensile test was conducted with different pulsed-current parameters by changing its pulse-width and frequency. Short pulse-width was used in the range of microseconds, while the frequency was arranged under 1 kHz. Different level of temperature was used to consider the effect from joule heating. Stress relaxation in the tensile test was repeated at constant strain interval at 3% strain. This research presents an analysis of stress relaxation influenced by the time-dependent parameter of short pulsed-current.

Keywords Electropulse · Electroplasticity · AZ31B · Stress relaxation

1 Introduction

In recent years, interest in applying pulsed-current to the manufacturing process of metals was increasing. The effect of pulsed-current on reducing the flow stress and promoting metal deformation was reported in many studies. It has been found that on exposure to pulsed DC current, AZ31 plastic behavior was mainly dictated by its current density in its root mean square value, while the peak current can increase its potency [1]. It is also shown that the influence of pulsed-current can reduce flow stress and increase elongation in Al–Mg–Si alloy [2]. Another research shows that pulsed-current did induce dynamic recrystallization at a lower temperature which affects flow stress [3]. Another observation found that the non-deformation test with

pulsed-current can affect dislocation density, thus affecting its formability properties [4]. Meanwhile, the effect of pulsed-current on stress relaxation conditions was still not properly investigated.

In this study, the effect of electricity on stress relaxation of AZ31 sheet material of thickness 100 μm was investigated. By distinguishing between the thermal and non-thermal effects by regulating the temperature, the effect of electricity can be further analyzed. The relationship between temperature, type of current flow, current density, and frequency can be investigated.

2 Experiment and Methods

2.1 Material and Specimen Preparation

JIS AZ31B with chemical composition as stated in Table 1 was acquired directly from the manufacturer. A workpiece of 100 μm thickness was used in this experiment. The raw material was acquired from Nippon Kinzoku Co., Ltd Itabashi in rolled thin foils. The specimen was manufactured to become dog bone shape, as can be observed in Fig. 1 according to DIN 50125:2009-07 Type H test pieces. All the manufactured specimens were cut at 0° in the rolling direction. The specimen was cleaned with ethanol to remove any oil residue after the manufacturing process. After cleaning, all the specimens were dried, then annealed to remove any residual stress, and normalized then to their conditions. The annealing parameter was 200 °C and

Table 1 Chemical composition of AZ31B

Chemical composition (wt%)

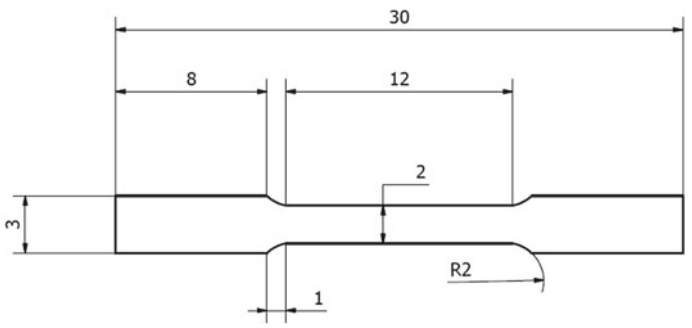

Fig. 1 Shape and dimension of specimen

cooling inside for 1 h until room temperature was also done in a vacuum. To provide constant emissivity, one side of the specimen was sprayed using thermographic spray paint with an emissivity index 0.94.

2.2 Experimental Methods

Uniaxial tensile test was conducted using universal test machine from Zwick Roell Z005 equipped with Zwick Roel LaserXtens as extensometer and Zwick Roell 5 kN load cell. The strain rate was 0.001 s^{-1} for all conditions. Optris infrared thermography camera was used to measure and record the surface temperature of workpiece. The temperature reading was measured by OMRON digital controller in PID mode. This temperature control system was responsible for maintaining the temperature of the specimen during the test. The pulsed-current was generated from PEKURIS PVP 2KV1KA pulse power supply with maximum voltage and current 2 kV and 1 kA, respectively. Schematic and real views of the experimental setup are given in Fig. 2a, b, respectively. Each test was started 1 min after the specimen reaches the desired temperature. The stress relaxation test was started from 3% nominal strain and kept at that level for 20 s. That treatment was repeated every 3% nominal strain increment until break.

Different temperature conditions are used for each electrical condition, as can be observed in Table 2. The temperature was regulated for different electrical conditions to distinguish between thermal and non-thermal effects. The non-thermal effect is commonly referred to as Electroplasticity. Due to Joule heating, the workpiece temperature will increase proportionately with current density. In the case of pulsed-current, there are two types of current density, which is peak current density and root mean square of the peak current density. The root mean square current density is equivalent to the DC current density at the same temperature. In this way, the peak current density at pulsed condition can be applied at a higher magnitude but still

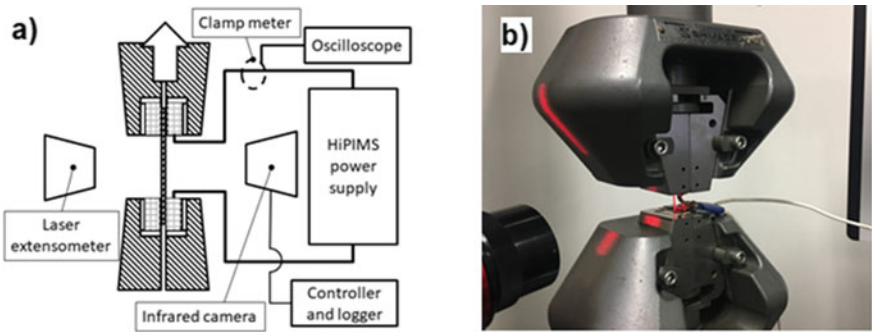

Fig. 2 View of experimental setup **a** schematic and **b** real view. (Color figure online)

Table 2 Experimental conditions

Electrical conditions	Frequency (kHz)	Pulse width (μs)	Temperature (°C)

resulting in the same temperature as the DC condition. For comparison purposes, we use the current density from the DC condition and peak current density from the pulsed condition.

3 Results and Discussion

3.1 Finding Stress Relaxation Limit

Due to short time nature of this experiment, the stress relaxation limit was unknown. But, since the initial stress was well recorded, the stress relaxation limit can be predicted using some fitting parameter. Luo et al. [5] provide an equation for parameter fitting with good agreement with their experimental results, as can be seen below.

$$\sigma_t = \sigma_r + \sum_{i=1}^{j} A_i \exp\left(-\frac{t^m}{B_i}\right) \tag{1}$$

σ_t, σ_r, and t are stress at a given time, stress relaxation limit, and time, respectively. A_i, B_i, and m are fitting parameters related to material nature and relaxation conditions. At the beginning of relaxation stage where t is 0,

$$\sigma_t = \sigma_r + \sum_{i=1}^{j} A_i = \sigma_0 \tag{2}$$

where σ_0 is initial stress, then the equation can become

$$\sigma_t = \sigma_0 + \sum_{i=1}^{j} A_i \left(\exp\left(-\frac{t^m}{B_i} \right) - 1 \right) \tag{3}$$

From (3) the fitting parameter can be acquired, as shown in Table 3. The fitting curve and its experimental value are given in Fig. 3. After acquiring the fitting parameter, (1) was used to find the stress relaxation limit. The value of stress relaxation limit is provided in Table 4.

Table 3 Fitting parameter to find stress relaxation limit

Electrical conditions	Frequency (kHz)	Temperature (°C)	A	B	m
Pulsed-current	0.5	50	38.8	3.74	0.65
		100	50.71	4.1	0.6
		200	35.77	4.09	0.78
	1	50	42.35	3.51	0.62
		100	54.22	4.16	0.64
		200	41.07	4.1	0.67
Direct current	–	50	41.91	4.02	0.6
		100	47.87	4.05	0.6
		200	44.92	4.1	0.67

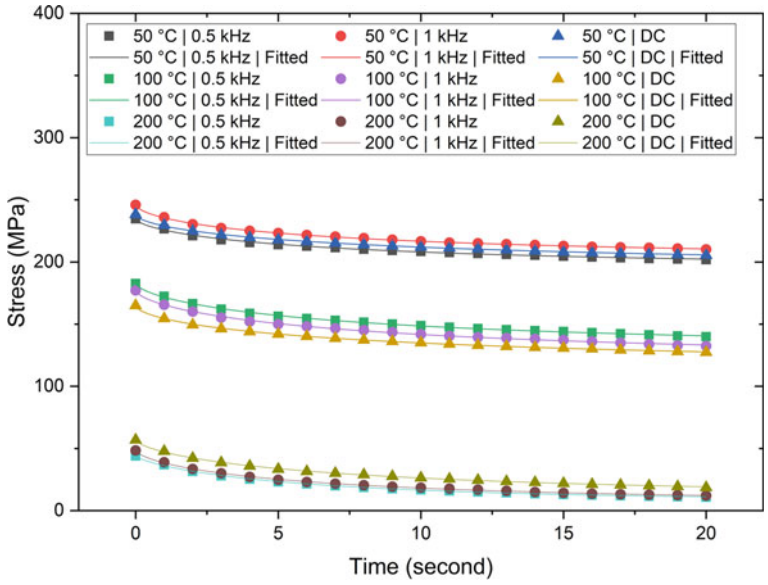

Fig. 3 Time versus nominal stress curve with fitted curve from (3). (Color figure online)

Table 4 Stress relaxation limit and stress exponent

Temperature	σ_r (MPa)			n		
(°C)	0.5 kHz	1 kHz	DC	0.5 kHz	1 kHz	DC
50	198.07	200.78	199.41	29.49	31.44	32.72
100	129.04	128.69	130.35	16.5	16.12	17.67
200	6.28	5.87	11.42	4.29	4.13	4.6

Stress relaxation limit at 50 °C and 100 °C shows no difference despite having different electrical conditions. But, at 200 °C, it is apparent that the stress relaxation limit for DC is slightly higher than the other two. This result agrees with the previous result, which stated that with a high-enough temperature, pulsed-current can produce lower flow stress than DC, given the same operating temperature environment [6]. The stress relaxation limit and initial stress were given in Fig. 4 to produce modified stress–strain curve from each experiment. Disregarding the electrical conditions, the stress–strain curve shows a pattern typical for each temperature group. At 50 °C it shows strain hardening. With increasing temperature, the strain hardening slowly diminishes and at 200 °C it shows thermal softening phenomenon.

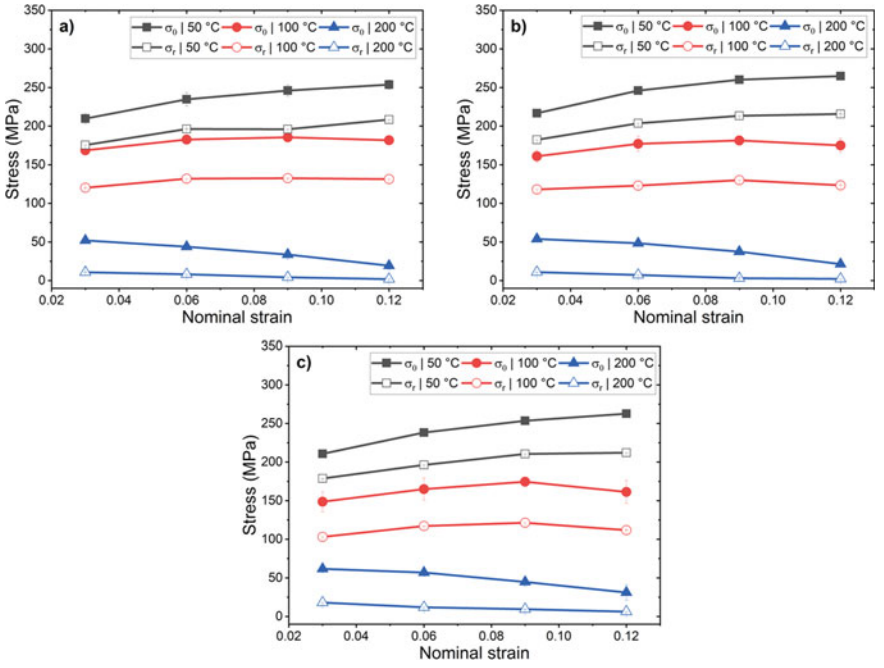

Fig. 4 Modified stress–strain curve with initial stress (σ_0) and stress relaxation limit (σ_r) for **a** 0.5 kHz, **b** 1 kHz, and **c** DC. (Color figure online)

3.2 Stress Exponent

Stress relaxation is regarded as somewhat a kind of plastic deformation where it can be expressed with

$$\varepsilon_0 = \varepsilon_e + \varepsilon_p = constant \tag{4}$$

where ε_0, ε_e, and ε_p represent total strain, elastic strain, and plastic strain, respectively. Considering (4) stress relaxation can also be expressed using creep strain with

$$\dot{\varepsilon}_c = \frac{d\sigma}{dt}\left(-\frac{1}{E}\right) \tag{5}$$

where $\dot{\varepsilon}_c$ is the creep strain rate and E is its elastic modulus. To determine the creep mode at each condition, the stress exponent needs to be calculated. The stress exponent (n) was acquired from the gradient of $\log \dot{\varepsilon}_c / \log \sigma$ [5, 7, 8]. The stress exponent can be seen in Table 4.

The stress exponent did not show a significant difference at the same temperature. It has been stated that the creep mode was mainly regulated by the temperature. At stress exponent n = 1, the creep mechanism is purely diffusive. Grain elongates in the direction of stress due to the diffusion of vacancies through the grain. Vacancies diffusion along grain boundary also contributes to grain elongation. At stress exponent 4–5, climb and annihilation of dislocation mainly control the creep mode. Dislocation climb enhanced by extensive number of vacancies diffusion occurs during stress relaxation [9]. At high stress exponent, it is called power law creep. The power law creep happens at temperature below 50% of its material melting point. In this study, from its low temperature nature, it is apparent that the main mechanism in stress relaxation will be mainly related to dislocation creep. Another consideration is that this study used short time relaxation, meaning it only stays in the first stage of relaxation where most of the diffusion happens rather than in the next stage of relaxation [10]. Also due to this short time nature, the static recovery barely happens and thus grain refining can be avoided [8, 11].

As can be observed from Table 4, this experimental result agrees with the previous law. The stress relaxation at all conditions never goes lower than 4. This means all conditions were subjected to power law creep as its relaxation mechanism. But, as temperature increases, the stress exponent value steadily decreases and approaches 1. At higher temperatures the diffusion rate increases, which also contributes to increased activity of diffusion creep where the dislocation climbs in part due to vacancies diffusion. It is also demonstrated that the stress exponent barely changes with the different electrical conditions at a constant temperature. But it is also worth noting that, despite its minuscule value, DC condition always has higher stress exponent value than the pulsed-current condition.

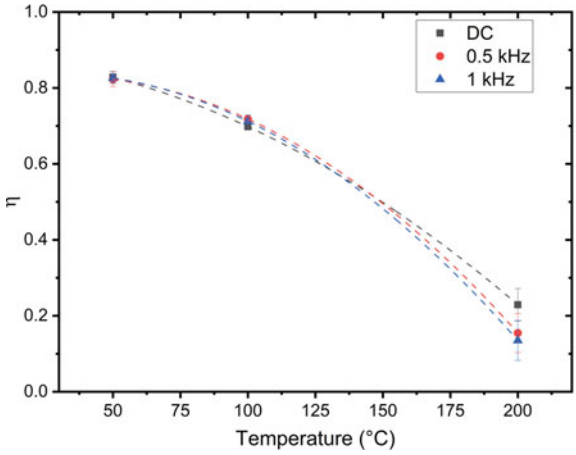

Fig. 5 Relationship between temperature and relaxation resistance at different electricity conditions. (Color figure online)

3.3 Relaxation Resistance

Relaxation resistance (η) can be determined using the ratio between relaxation limit to initial stress. Higher relaxation resistance means it is harder for stress to go down during stress relaxation process [10]. Figure 5 demonstrates the relationship between temperature and relaxation resistance. At 50 °C and 100 °C, the relaxation resistance shows no difference for 0.5 kHz, 1 kHz, and DC. But, at 200 °C the relaxation resistance of DC becomes higher than the other two. From the previous section, it is noted that the relaxation mechanism was mainly dislocation creep. It has been suggested that the movement of dislocation in stress relaxation test was not affected by the flow of current. At 50 °C and 100 °C the thermal effect is the main contributor of movement of dislocation.

At 200 °C, relaxation resistance for DC has a higher value than 0.5 and 1 kHz. As already mentioned before, at higher temperature the value of the stress exponent decreases and becomes closer to 1. It can be said that more diffusion creep mechanisms take effect compared to lower temperature. This result shows that the vacancy diffusion rate is more sensitive to current flow, especially pulsed-current, than dislocation movement, thus promoting dislocation climb. While the DC condition shows higher relaxation resistance, pulsed-current conditions, namely 0.5 kHz and 1 kHz, show no difference in its value.

Several studies state that electropulse can promote dynamic recrystallization and induce grain boundary sliding to take action under relatively poor conditions for AZ31 magnesium alloy [1, 6, 12–16]. It is worth noting that this effect mainly acts near the recrystallization temperature of AZ31, which is around 250 °C. Several prior studies also show that non-basal slip system can be activated at lower temperature, thus further promote the moving of dislocations. Since below 200 °C the main mechanism of relaxation is dislocation creep, the promotion of grain boundary sliding and non-basal slip system at a lower temperature is beneficial to reduce the relaxation resistance.

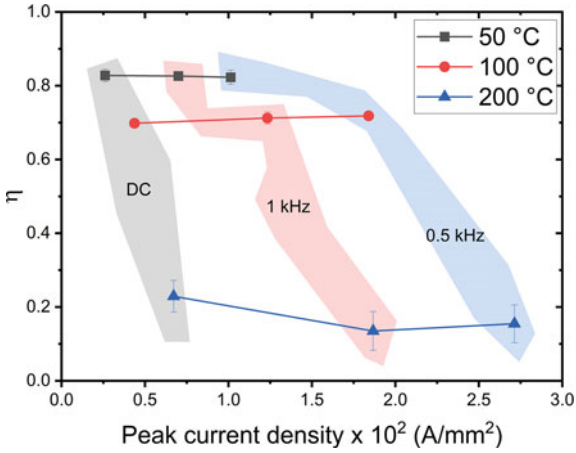

Fig. 6 Relationship between current density and relaxation resistance. (Color figure online)

Figure 6 shows the relationship between current density and relaxation limit. At 50 °C and 100 °C the current density has no effect on the relaxation limit, as already discussed earlier. At 200 °C the current density of 0.5 kHz, 1 kHz, and DC is 271.33 A/mm^2, 186.67 A/mm^2, and 67.18 A/mm^2, respectively. The difference from DC to 1 kHz is nearly three times, while DC to 0.5 kHz is four times. The large distance between the DC and pulsed-current can also be attributed to why the vacancy diffusion rate becomes more active with different electricity conditions. Thus, the relationship between the current density and relaxation mechanism is worth to be discussed as a future study.

4 Conclusions

In this paper, the stress relaxation of AZ31 at different electrical conditions was performed. The mechanism of relaxation at different working temperatures was demonstrated. The stress relaxation mechanism in this study was observed to be mainly law power dislocation at low temperature. The mechanism shifts to corporate more diffusion creep with increasing temperature. Only at 200 °C that the relaxation resistance was found to be different for DC and pulsed-current. But, in pulsed-current, different frequencies did not result in different relaxation limits.

Lower relaxation limit in pulsed-current can be attributed to several mechanisms. First is the promotion of grain boundary sliding induced by dynamic recrystallization which contributes to dislocation creep. The other is increasing the rate of vacancy diffusion, thus enhancing dislocation climb to avoid dislocation to entangle.

Experimental Study on Mechanical Response of Q235 Steel Under Cyclic Stress Loading

Qingling Zhang, Miao Jin, Baofeng Guo, and Qun Li

Abstract The cyclic softening/hardening, ratcheting effect, and Bauschinger effect usually occur in the body structure of large mechanical equipment under cyclic loading. This manuscript focuses on Q235 steel commonly used in the welded frame of large mechanical equipment. The experiments were carried out with mean stress varying from −60 to 60 MPa and stress amplitude varying from 300 to 340 MPa, respectively, and the mechanical responses were analyzed comprehensively. The experimental results show that Q235 steel exhibits cyclic softening characteristics at positive mean stress and cyclic hardening characteristics at negative mean stress. The larger the stress amplitude or the absolute value of the mean stress, the greater the absolute value of ratcheting strain. At the same stress amplitude, when the absolute value of the mean stress is equal, the Bauschinger coefficient is almost equal. Based on the experimental results, the evolution formula of ratcheting strain is established by a phenomenological method.

Keywords Cyclic stress loading · Cyclic softening/hardening · Ratcheting · Bauschinger effect

1 Introduction

Q235 steel is usually used as the raw material of the hydraulic press beam and other structural parts, due to its plasticity, toughness, good weldability, strength, and high-cost performance. In engineering applications, the hydraulic press beam is often subject to cyclic loading in the process of work. Because of its complexity in

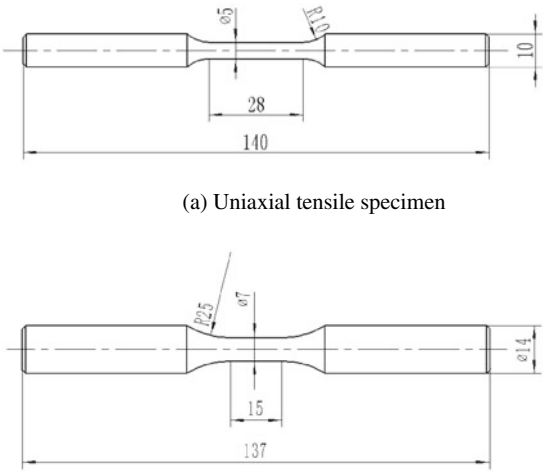
the structure, it is easy to produce stress concentration phenomena and even plastic deformation in the local area. Therefore, to study the deformation behavior of Q235 steel under cyclic loading after plastic deformation is very meaningful.

After plastic deformation of the structure, ratcheting effect, Bauschinger effect, and cyclic softening/hardening behavior will occur under cyclic loading. These cyclic deformation behaviors directly affect the design and safety evaluation of the beam structure of the hydraulic press.

Scholars at home and abroad have done a lot of research on the mechanical response of different materials under cyclic loading [1–6]. They also analyzed the influence of loading rate, stress amplitude, maximum stress, mean stress, and loading history on the cyclic softening/hardening and ratcheting effect about 316L stainless steel, 16Mn, SUS301L stainless steel, and 2024-T3 aluminum alloy. Lee [7] simulated the deformation behavior of two-phase stainless steel S32750 with the new constitutive model, and further verified the influence of positive mean stress, stress amplitude, and loading history on the behavior of uniaxial ratcheting. Segle et al. [8] conducted combined loading tests of the main loading and side loading on ferrite steel P265 and austenite steel 316L simultaneously, and concluded that ratcheting effect increases with the increase of loading level. Zhifeng [9] studied the relationship between ratcheting effect and microstructure of hot-rolled AZ31B magnesium alloy under asymmetric stress cyclic loading. Kang [10–12] explored the influence of mean stress, stress amplitude, and stress ratio on ratcheting strain of SS304 stainless steel at room temperature, and revealed cyclic soft/hardening characteristics and ratcheting deformation behavior of SS304 stainless steel under different loading rates, different holding time, and non-proportional loading paths. Zhang et al. [13] obtained the conditions for ratcheting effect of Q235 steel when the average stress was positive, through cyclic loading tests under different stress combinations.

Mingsen [14] carried out an axial tension-compression cyclic loading test on 7A04 aluminum alloy with four different strain values to explore the Bauschinger effect generated in the plastic deformation process after small pre-stress. Qingling et al. [15] found that under small symmetric strain cyclic loading, the cyclic hardening rate and the change rate of Bauschinger energy parameters of Q235 would eventually reach a stable value with the increase of cycle numbers. Chao [16] found that both QP980 and QP1180 show the Bauschinger effect through the tension-compression cyclic loading test. The authors of [17–19] studied the Bauschinger effect of as-cast A356-T6 aluminum alloy, rolled 7075 aluminum alloy, carbon steel, and X80 steel under different pre-strain, different heat treatment processes, microstructure, and yield ratio. Han [20] carried out the tension-compression loading experiment on low carbon steel, low alloy steel, and duplex steel, and found that the Bauschinger effect on the three materials is related to the pre-strain but not to the strain rate.

Although many researchers have studied the cyclic deformation behaviors of different metal materials in many aspects, studies on Q235 steel in this area are rare, especially under the conditions of zero and negative mean stress. Therefore, the plastic deformation response of Q235 steel was analyzed in this work at positive, zero, and negative mean stress, which can provide more comprehensive experimental data and theoretical basis for the engineering application of Q235 steel.



2 Experimental Procedure

All the experimental specimens are solid bars cut from Q235 steel plate in the rolling direction. The thickness of the steel plate is 20 mm. The specimens have a circular section and are processed according to the national standard GB228.1-2010 and GBT 3075-2008. The basic sizes of the uniaxial tensile specimen and cyclic loading specimen are shown in Fig. 1.

All experiments were carried out on Instron 8801 electro-hydraulic servo fatigue testing machine, which was equipped with contact extensometers. The extensometer with a 25 mm gauge was used for uniaxial tensile experiments, and the extensometer with a 12.5 mm gauge was used for cyclic loading experiments. The measurement accuracy of the two extensometers is 0.1 um.

Uniaxial tensile experiments were controlled by strain, and the strain rate was 0.1%. The basic mechanical properties of Q235 steel at room temperature were obtained through three repeated tests, which are shown in Table 1.

According to the properties of Q235 steel obtained from uniaxial tensile and uniaxial compressive experiments, the loading conditions of cyclic stress loading experiments were determined. The specific experimental scheme is listed in Table 2.

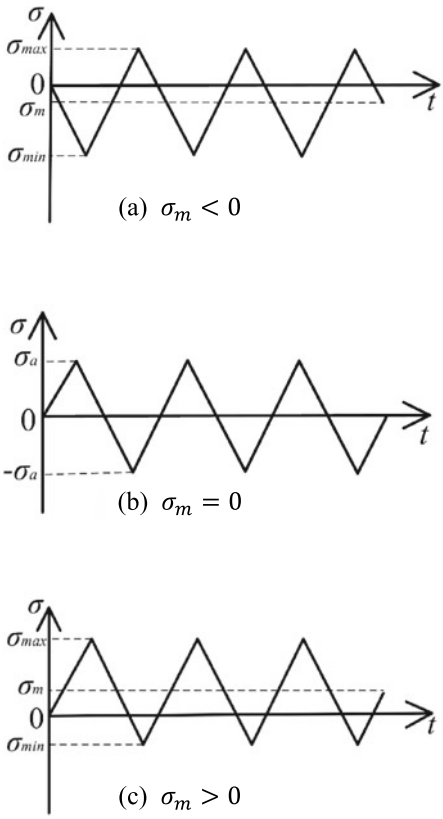
In order to keep the loading rate consistent during each cyclic loading process, triangular wave loading was adopted. The loading waveforms under different stress conditions are shown in Fig. 2. The loading rate was set to 40 MPa/s.

3 Results and Discussion

3.1 Analysis of Ratcheting Effect



The traditional ratcheting effect is defined as the cyclic accumulation of plastic strain under asymmetric stress loading. However, this phenomenon is also found under symmetric stress loading. In this manuscript, the ratcheting strain $_{\mathrm{r}}$ is calculated by formula 1.

$$\varepsilon_{\mathrm{r}} = \left(\varepsilon^{\mathrm{T}}_{\max} + \varepsilon^{\mathrm{T}}_{\min}\right)/2 \tag{1}$$

where $\varepsilon^{T}_{\max}$, $\varepsilon^{T}_{\min}$, respectively, represent the maximum and minimum true strains in a cycle. The increment of ratcheting strain in each cycle is called the ratcheting strain rate, in terms of $\mathrm{d}_{\mathrm{r}}/\mathrm{d}N$, where N is the cyclic numbers.

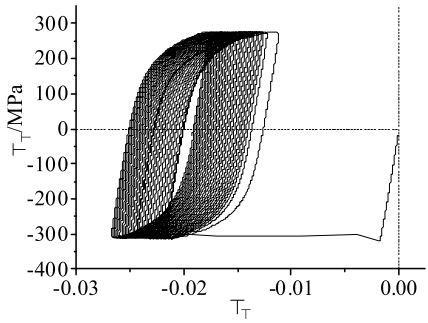


Figure 3 shows the stress–strain hysteretic curve of Q235 steel during cyclic loading with stress amplitude of 300 MPa and mean stress of −20 MPa, 0 MPa, and 20 MPa. In this figure, $_{\mathrm{T}}$ represents the true strain and $_{\mathrm{T}}$ represents the true stress. Since there is yield platform in the hysteretic curve of Q235, the strain in the first

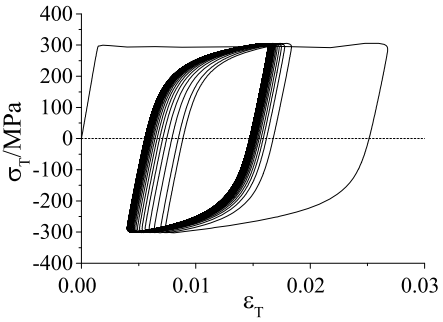
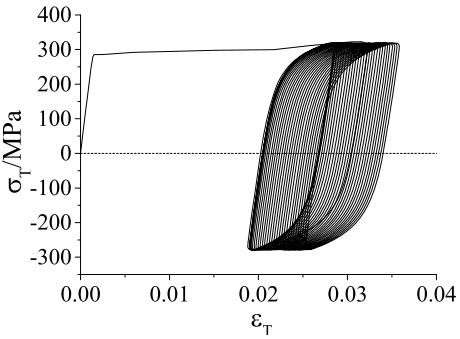
Fig. 2 The loading curves



cycle is large. As shown in Fig. 3, no matter the mean stress is positive, negative, or zero, the hysteretic curves of Q235 do not close, which means the ratcheting phenomenon has occurred. When the mean stress is negative, the hysteretic curve moves toward the negative direction of the strain. When the mean stress is zero, the hysteretic curve first moves toward the negative direction of the strain for several cycles and then turns to the positive direction. When the mean stress is positive, the hysteretic curve always moves toward the positive direction of the strain.



The ratcheting strain under various loading conditions was calculated according to formula (1). Due to the influence of the yield platform, the ratcheting strain in the first cycle should be discarded. The calculation of ratcheting strain starts from the second cycle in this manuscript. The variation curve of ratcheting strain with cyclic numbers under different mean stress at the same stress amplitude of 300 MPa is illustrated in Fig. 4. The ratcheting strain is positive when the mean stress is positive, and the ratcheting strain is negative when the mean stress is negative. The greater the absolute value of average stress, the greater is the absolute value of ratchet strain. The absolute value of ratcheting strain increases as the cycle numbers

（a）-20±300MPa

（b）0±300MPa

（c）20±300MPa

Fig. 3 Cyclic stress–strain curve

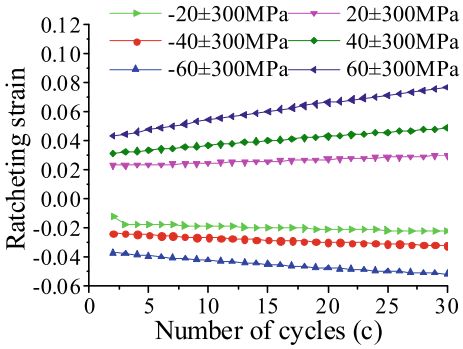


Fig. 4 The ratcheting strain versus cycle numbers at the stress amplitude of 300 MPa. (Color figure online)

increase. Although the variation trend of ratcheting strain under different mean stress is similar, ratcheting strain rate is different. With the increase of cyclic numbers, ratcheting strain rate becomes stable gradually. If the stable value of ratcheting strain rate is higher than the mean stress is, the greater is the ratcheting strain rate. When the mean stress is negative, the ratcheting strain rate increases with the increase of the absolute value of the mean stress also, but it is not as significant as the positive mean stress.

Figure 5 presents the ratcheting strain under different stress amplitudes when the mean stress is positive, zero, and negative. It can be observed that the ratcheting strain and ratcheting strain rate all increase with the increase of stress amplitude, no matter the mean stress value is positive or negative. Under the control of symmetrical cyclic stress loading, the ratcheting strain decreases rapidly in the first ten cycles and then increases gradually. The ratcheting strain rate also increases with the increase of stress amplitude (Table 3).

According to the above analysis, the ratcheting strain of Q235 steel relates to the mean stress, stress amplitude, and cyclic numbers. Based on the phenomenological theory, the following calculation formula of the ratcheting strain is established.

$$\varepsilon_r = \begin{cases} \dfrac{\lambda\eta\sigma_m}{\sigma_s{}'-\sigma_s}\exp(\eta)N + \dfrac{\varepsilon'}{\eta}\sigma_m > 0 \\ \dfrac{\lambda\eta^3}{\sigma_s{}'-\sigma_s}\exp(\eta)N + \dfrac{\varepsilon'}{\eta^2}\sigma_m = 0 \\ \dfrac{\lambda\sigma_m}{(\sigma_s{}'-\sigma_s)\eta}\exp(\eta)N - \dfrac{\varepsilon'}{\eta}\sigma_m < 0 \end{cases} \tag{2}$$

where λ is the material parameter, and it is 3.5 for Q235 which can be obtained by fitting the ratcheting strain with cyclic numbers under stress loading; ε' is the strain in uniaxial tensile stress–strain curve corresponding to the peak stress of applied loading in cyclic stress experiment; $\eta = \sigma_a/\sigma_s$.

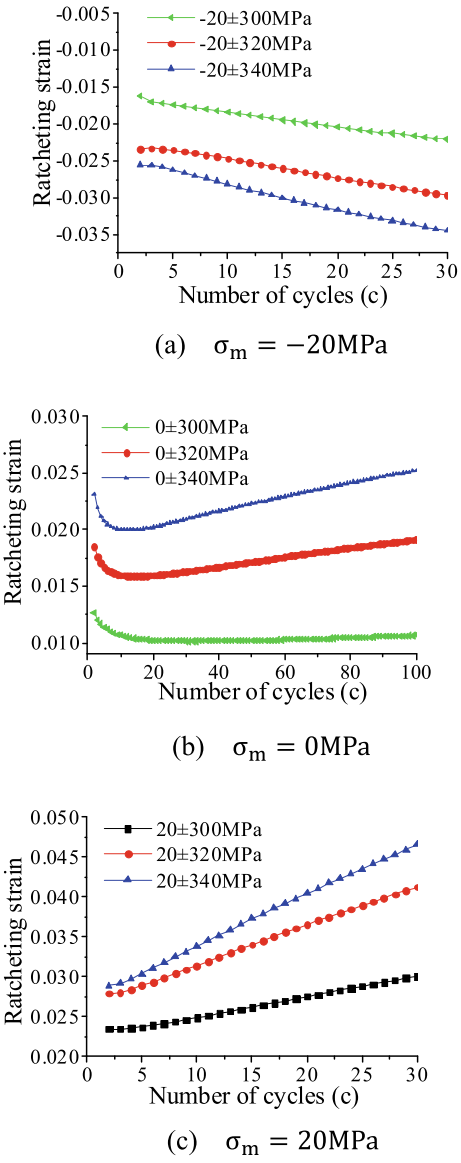

Fig. 5 The ratcheting strain versus cycle numbers at different stress level. (Color figure online)

As shown in Fig. 6, the ratcheting strain calculated by the formula (2) and the data obtained from the test are in good agreement. Therefore, this formula can characterize the ratcheting effect of Q235 steel very well.

Table 3 The ratcheting strain rate at the stress amplitude of 300 MPa

Stress level (MPa)		Ratcheting strain rate (10^{-3}%/c)

	40	0.56
	60	1.04

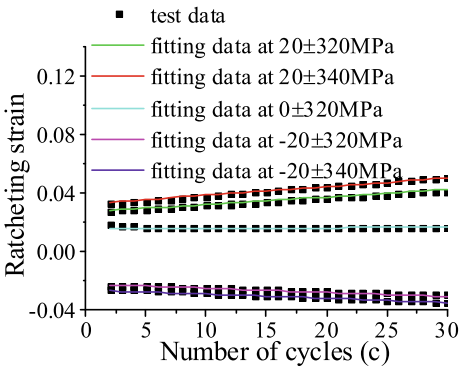

Fig. 6 Comparison of the test data and fitting data. (Color figure online)

3.2 Analysis of Cyclic Softening/Hardening

Q235 steel shows different cyclic softening and hardening behaviors under different stress loading conditions. Figure 7 shows the evolution of strain amplitude with cyclic numbers under the same stress amplitude of 300 MPa and different mean stress. The corresponding cyclic softening and hardening rates are shown in Table 4. Figure 7a and Table 4 illustrate that when the mean stress is negative, Q235 steel presents hardening characteristics with the increase of cyclic numbers eventually, and the smaller the absolute value of the average stress, the greater is the absolute value of the cyclic hardening rate. It can also be observed that when the mean stress is positive, the cyclic softening phenomenon appears, and the greater the mean stress, the higher is the cyclic softening rate.

Figure 8 presents the change of strain amplitude with cyclic numbers under different stress amplitudes, when the mean stress is −20 MPa, 0 MPa, and 20 MPa. As shown in Fig. 8a, when the mean stress is −20 MPa, cyclic hardening occurs after ten cycles of softening. It can be seen from Fig. 8b, when the mean stress is 0 MPa, the strain response is similar to the negative mean stress, which is softening

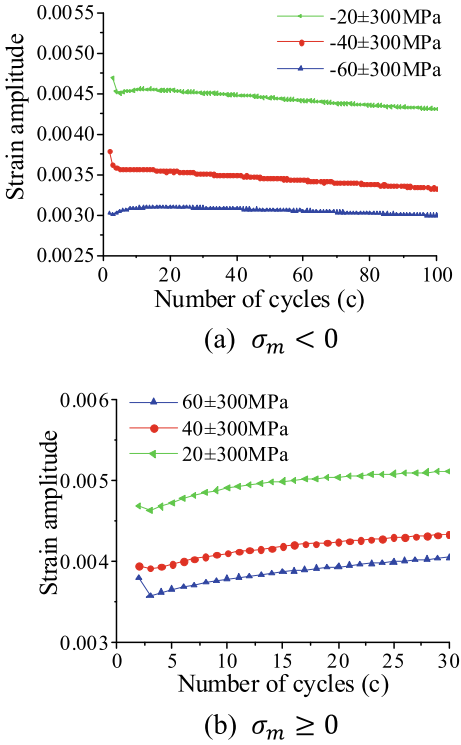

Fig. 7 The strain amplitude versus cycle numbers at the stress amplitude of 300 MPa. (Color figure online)

Table 4 The cycling hardening/softening rate at the stress amplitude of 300 MPa

Stress level (MPa)		Cycling hardening rate (10^{-5}%/c)	Cycling softening rate (10^{-5}%/c)
Stress amplitude	Mean stress		
300	−60	−0.132	–
	−40	−0.263	–
	−20	−0.295	–
	20	–	0.732
	40	–	0.973
	60	–	1.174

before hardening. When the mean stress is 20 MPa, Q235 presents the cyclic softening characteristic. These conclusions are consistent with the foregoing analysis of Fig. 7.

Under these three kinds of loading conditions, there is no cycle hardening saturation in the test cycle. The cyclic softening and hardening rate tends to stabilize to a non-zero constant with the increase of the cycle numbers. The steady rates of cyclic

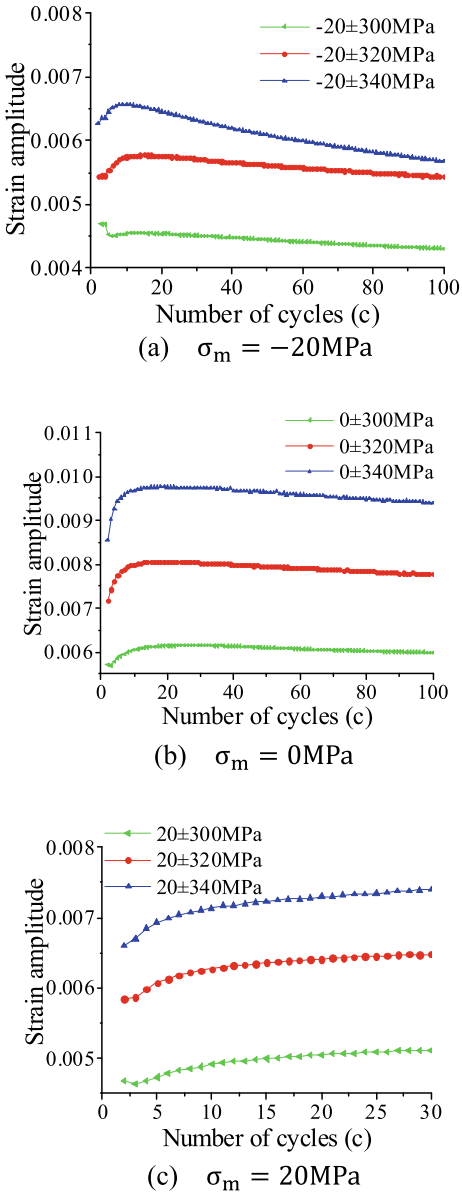

Fig. 8 The strain amplitude versus cycle numbers. (Color figure online)

softening and hardening are listed in Table 5. It is obvious that under the same mean stress condition, the higher the stress amplitude, the higher is the absolute value of cyclic softening or cyclic hardening rate.

Combined with Figs. 7 and 8, when the mean stress is negative, the smaller the absolute value of the mean stress or the larger the stress amplitude, the more

Table 5 The cycling hardening/softening rate at the mean stress of −20 MPa, 0 MPa, and 20 MPa

Stress level (MPa)		Cycling hardening rate (10^{-5}%/c)	Cycling softening rate (10^{-5}%/c)
Mean stress	Stress amplitude		
−20	300	−0.295	–
	320	−0.405	–
	340	−0.947	–
0	300	−0.239	–
	320	−0.378	–
	340	−0.481	–
20	300	–	0.732
	320	–	0.786
	340	–	1.071

obvious is the cyclic hardening. When the mean stress is positive, the cyclic softening phenomenon slightly intensifies with the increase of the mean stress and stress amplitude. When the mean stress is zero, the cyclic softening behavior increases with the increase of stress amplitude.

3.3 Analysis of Bauschinger Effect

Bauschinger effect means that the yield strength decreases obviously compared with the performance of the original pre-deformation direction when the metal deformed in a certain direction in advance and then deformed in the opposite direction. The yield stress in this manuscript is calculated when 0.2% elongation occurs in the material, i.e. $\sigma_{0.2}$, as shown in Fig. 9.

The variation curves of yield stress under different mean stress at the stress amplitude of 300 MPa are illustrated in Fig. 10. As shown in the figure, when the mean stress is negative, the compressive yield stress is greater than the tensile yield stress, and with the increase of the absolute value of the mean stress, the compressive yield

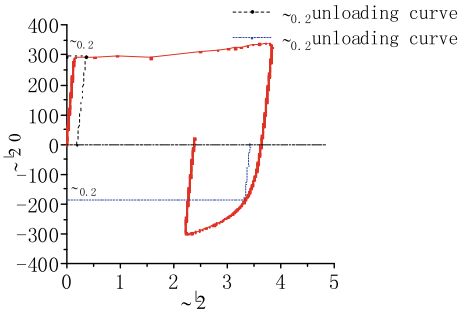

Fig. 9 Method to obtain yield stress $\sigma_{0.2}$. (Color figure online)

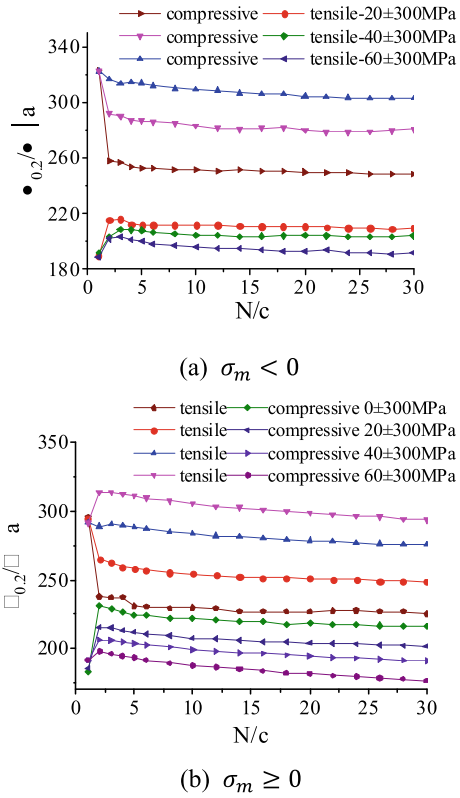

Fig. 10 Yield stress with different mean stress at the stress amplitude of 300 MPa. (Color figure online)

stress increases, while the tensile yield stress decreases. When the mean stress is positive, the tensile yield stress is greater than the compressive yield stress, and with the increase of the mean stress, the tensile yield stress increases, while the compressive yield stress decreases. When the mean stress is zero, the tensile and compressive yield stresses still differ by about 10 MPa due to asymmetrical tensile and compressive properties.

The yield stresses of each cycle under the same mean stress and different amplitude are presented in Fig. 11. It is consistent with the conclusion drawn in Fig. 10 that under the stress loading, the higher the tensile loading or the compressive loading, the higher is the yield stress in the corresponding direction. As the stress loading is symmetrical, the yield stress is not equal due to the asymmetry of tensile and compressive properties. When the mean stress is constant, the yield stress changes slightly with the increase of the stress amplitude. By comparing Figs. 10 and 11, it can be observed that under the same peak stress, the mean stress has a more significant influence on the yield stress than the stress amplitude.

In order to describe the Bauschinger effect more intuitively, the Bauschinger coefficient is introduced. The Bauschinger coefficient relates directly to the change of yield stress after pretension/precompression deformation under cyclic loading.

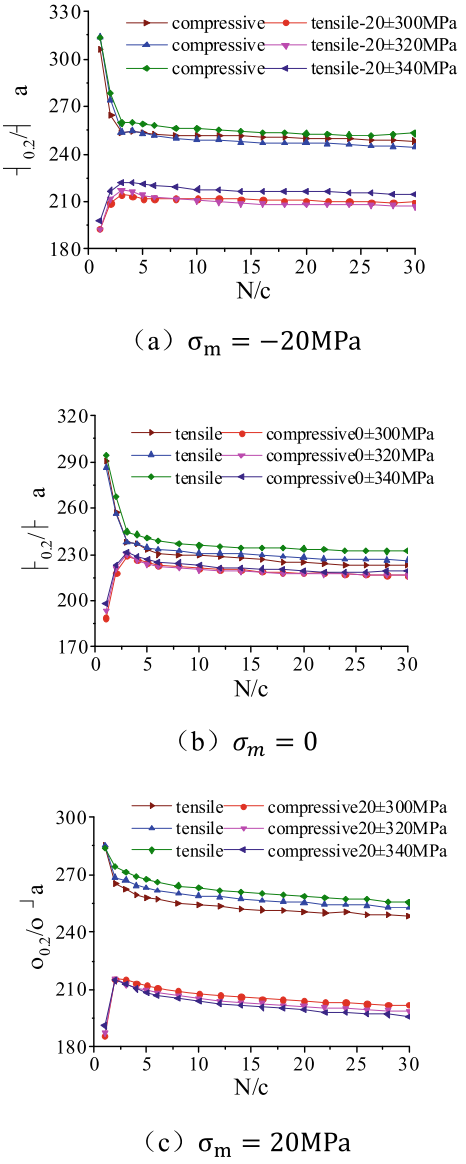

Fig. 11 Yield stress with different stress amplitudes at the same mean stress. (Color figure online)

The more the yield strength decreases, the higher is the Bauschinger coefficient, and the more obvious is the Bauschinger effect. The Bauschinger coefficient is expressed as follows:

$$B = \begin{cases} \frac{\sigma_{0.2}^{+} - \sigma_{0.2}^{-}}{\sigma_{0.2}^{+}} & \sigma_m > 0 \\ \frac{\sigma_{0.2}^{-} - \sigma_{0.2}^{+}}{\sigma_{0.2}^{-}} & \sigma_m \leq 0 \end{cases} \tag{3}$$

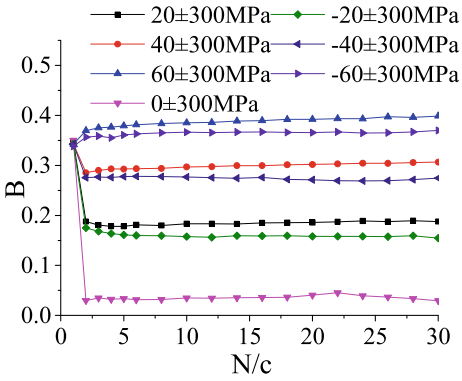

Fig. 12 The variation of Bauschinger coefficient with cyclic numbers at the stress amplitude of 300 MPa. (Color figure online)

where $\sigma_{0.2}^{+}$ is for the tensile yield stress, and $\sigma_{0.2}^{-}$ is for the compressive yield stress.

The variation trend of the Bauschinger coefficient with the cyclic numbers at different mean stress is drawn in Fig. 12, when the stress amplitude is 300 MPa. As can be seen from the figure, the Bauschinger coefficients in the first cycle are nearly equal under different stress loading, but it is greatly different from the second cycle. The larger the mean stress, the larger is the Bauschinger coefficient, which means more obvious the Bauschinger effect. The values of the Bauschinger coefficient in the second cycle under various loading conditions and the change rates in the subsequent cycles are given in Table 6. It can be concluded that if the absolute value of the mean stress is equal, the Bauschinger coefficient is very close, and the Bauschinger coefficient changes little after the second cycle. It is feasible to use the Bauschinger coefficient in the second cycle to describe the influence of Bauschinger effect on the mechanical properties of Q235 steel.

Table 6 Change rates of Bauschinger coefficient with cyclic numbers at different stress levels

Stress level (MPa)		B at the second cycle	Growth rate (10^{-4})
Stress amplitude	Mean stress

4 Conclusions

(1) Ratcheting effect will occur when Q235 is subjected to both symmetric and asymmetric cyclic stress loading.
(2) When the mean stress is the same, the greater the stress amplitude is, the greater the absolute value of ratcheting strain and the ratcheting strain rate; when the stress amplitude is the same, the greater the mean stress is, the greater the absolute value of ratcheting strain and the ratcheting strain rate is.
(3) Q235 steel shows cyclic softening properties, which become more obvious with the increase of the mean stress and the stress amplitude when the mean stress is positive. Q235 steel shows cyclic hardening properties, which become more obvious with the decrease of the absolute value of the mean stress and the increase of the stress amplitude when the mean stress is non-positive.
(4) The Bauschinger coefficient of Q235 steel is nearly equal, when the absolute value of the mean stress is the same, and the Bauschinger coefficient of the second cycle can be used to characterize the Bauschinger effect of the material.

The Effect of Trace Nitrogen on Microstructure and Property of Cr-Mo-V Hot-Working Die Steel

Jinbo Gu, Jingyuan Li, and Lihao Li

Abstract The effect of trace nitrogen on microstructure, hardness, toughness, and tempering stability of Cr-Mo-V hot-working die steel was investigated in this study. Results show that trace nitrogen promotes the precipitation of V(C, N), increasing the amounts of undissolved carbides in tempered steel. The undissolved carbides exert a stronger pinning effect on refining austenitic grains during the quenching process and refine the final tempered microstructure. The solid solubility of alloying elements and lattice distortion of matrix decreased obviously by trace nitrogen. Trace nitrogen could increase the hardness and toughness of hot-working die steel by refining the microstructure. However, the tempering stability would be decreased obviously due to the decrease of solid solubility of alloy elements, especially V. The results of this research can be used to provide a scientific basis for applications of nitrogen in hot-working die steel.

Keywords Nitrogen · Die steel · Hardness · Toughness · Tempering stability

1 Introduction

Due to its high hot hardness and toughness, Cr-Mo-V die steel is commonly used in forging, hot-extrusion, and die-casting [1, 2]. There have been many studies on the development of hot-working die steel, including composition adjustment and process improvement. The effect of different alloy elements such as Nb [3, 4] and Re [5] on die steel has been widely investigated. However, there are few reports about the application of nitrogen on this type of steel. On the other hand, it has been widely recognized that nitrogen can be used as a useful alloy element, especially in austenitic stainless steel. Trace nitrogen could enlarge the austenite phase region,

enhance the solution strengthening effect, and improve the corrosion resistance [6, 7]. Especially, trace nitrogen plays an important role in delaying precipitation and coarsening of carbide which is a benefit to improve the structural stability of steel [8]. Therefore, there is an application prospect of nitrogen on hot-working die steel, according to its strengthening mechanism.

The purpose of the present research is to study the effect of trace nitrogen on microstructure, hardness, toughness. and tempering stability of Dievar (4Cr5Mo2V) hot-working die steel. The results of this research can be used to provide a scientific basis for applications of nitrogen in hot-working die steel.

2 Experimental

Two 50 kg ingots of Dievar steel were prepared in a vacuum induction melting furnace with the measured composition as listed in Table 1. The nitrogen-alloyed steel was melted under the protection of the nitrogen atmosphere. The ingots were heated to 1250 °C and held at that temperature for 3 h for sufficient multi-directional forging between 850 and 1150 °C. After forging, 850–650 °C annealing process at a rate of 10 °C/h was adopted to the ingots, and then air-cooled. Subsequently, the samples were austenitized at 1030 °C for 30 min, quenched in oil to attain martensite, and then tempered at 600 °C for 4 h to produce tempered martensite. A Rockwell hardness tester (TH320, Beijing TIME Group Co., Ltd, China) and impact testing machine (JB-30B, Jinan Hensgrand Instrument Co., Ltd., China) were used to measure the HRC hardness and impact toughness using the Charpy V-notch test method (ASTM A370). The tempered microstructure was observed using scanning electron microscopy (SEM; S-360, CAMBRIDGE, England) equipped with energy-dispersive X-ray spectroscopy (EDS). The effect of nitrogen on precipitates and solid solubility of alloying elements was analyzed by Thermo-Calc software and X-ray diffraction (XRD; DMAX-RB, Rigaku, Japan).

Samples	C	Si	Mn	Cr	Mo	V	P	S	N	Fe
Dievar	0.39	0.48	0.38	5.3	2.4	0.68	0.0076	0.0038	0.004	Bal.
Dievar(N)	0.39	0.48	0.40	5.26	2.4	0.70	0.064	0.0032	0.042	Bal.

3 Results and Discussion

3.1 Microstructure

The final tempering microstructure of the two steels consists of tempered martensite, undissolved carbide, and a small amount of residual austenite, as shown in Fig. 1. It is observed that the martensite is uniformly distributed in the original austenite matrix. The major difference between the two steels is that the undissolved carbides measured 100 nm of Dievar(N) steel, which is much more than that of Dievar steel. Further, EDS map (Fig. 2) confirms that the undissolved carbides were enriched with V and little Cr or Mo, indicating that nitrogen addition increased the V-rich carbides. Moreover, the original austenite size of Dievar(N) is 10 μm, much smaller than that of Dievar steel.

To investigate the crystal structure of martensite lath, electron back-scattered diffraction (EBSD) was subjected to tempered samples. As shown in Fig. 3, the tempered martensite slab structure of two steels is clearly visible. The original austenite grain is composed of several slat bundles with different orientations, and each slat bundle includes several slat blocks. The orientation difference of the strip bundles on both sides of the original austenitic grain boundary is obvious, which is attributed to that the martensite strip first grows in the nucleus of the original austenitic grain boundary and then grows on both sides during the quenching process [9, 10]. Further grain size statistics show that the sub-grain of Dievar(N) steel is obviously small, which proves that the grain of the original austenite is small and the degree of martensite strip coarsening is relatively small during the tempering process.

3.2 Mechanical Properties and Tempering Stability

The mechanical properties of steel were as shown in Fig. 4a. As can be seen, the hardness and toughness of Dievar steel are 49HRC and 18 J cm^{-2}, respectively, while those are 51.5HRC and 21 J · cm^{-2} for Dievar(N) steel. Obviously, trace nitrogen has the benefit of increasing the hardness and toughness of steel. In general, the increase of hardness is easy to result in a decrease of toughness. Obviously, the reason for the above phenomenon was ascribed to the refinement of microstructure, as shown in Fig. 2.

As known to all, tempering stability is another important performance, which is closely related to the service life of die steel. In this study, Dievar steel and Dievar(N) steel exhibited different tempering stability, as shown in Fig. 4b. The initial hardness of the samples at quenched state was 53HRC and 55.5HRC for Dievar and Dievar(N) steel, respectively. The hardness of both steels decreased continuously with the increase of tempering time. The hardness of Dievar(N) steel is higher than that of Dievar steel between 0 and 24 h. But when tempered time increase to 48 h, the hardness of Dievar(N) begins to fall below that of Dievar steel, exhibiting poor tempering stability. Figure 5 shows the microstructure of samples tempered for 24 and 48 h. As can be seen from Fig. 5a and b, the martensite characteristics of the lath are no longer obvious, indicating the recovery of matrix [11]. However, the amount of carbides is not so much different from the samples tempered for 4 h, which means

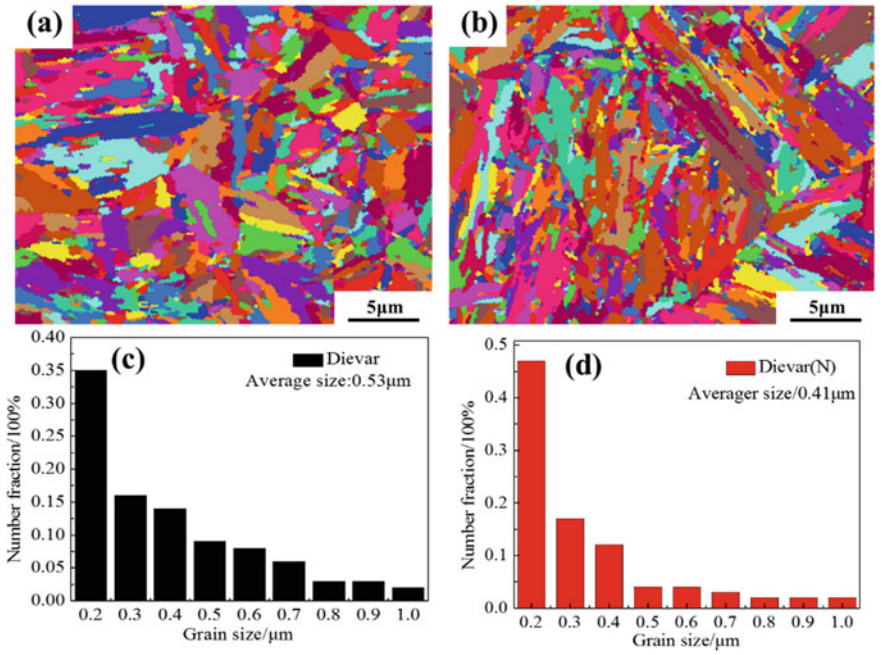

Fig. 3 The crystal structure and grain size distribution. **a** Morphology of Dievar; **b** Morphology of Dievar(N); **c** Grain size distribution of Dievar; **d** Grain size distribution of Dievar(N). (Color figure online)

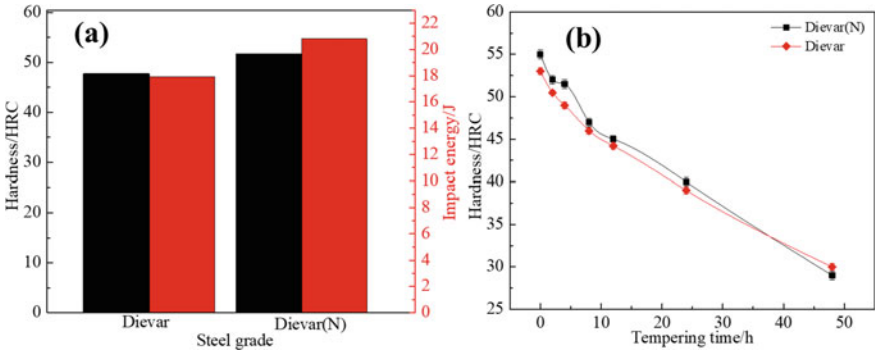

Fig. 4 Mechanical properties and tempering stability of samples: **a** Mechanical properties. **b** Tempering stability. (Color figure online)

that the carbides did not grow significantly during long-term tempering. Further, the morphology exhibits a big difference when the tempering time extended to 48 h, as shown in Fig. 5c and d. A large amount of carbides begin to precipitate in both samples. However, the amount of carbides in Dievar(N) steel is much more than

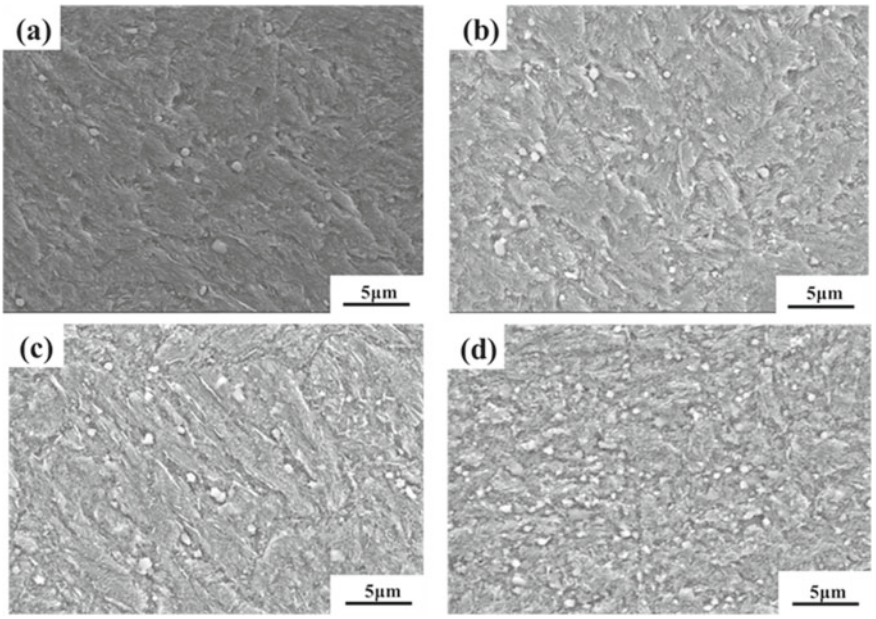

Fig. 5 SEM micrographs of tempered samples: **a** Dievar (24 h); **b** Dievar(N) (24 h); **c** Dievar (48 h); **d** Dievar(N) (48 h)

that of Dievar steel, indicating poor tempering stability, which is consistent with the tempering stability curve. Further, EDS confirms that large Cr-rich carbides begin to precipitate in Dievar(N) steel as shown in Fig. 6. Therefore, the tempering stability of Dievar(N) steel was deteriorated by precipitation of Cr-rich carbides.

3.3 Influence Mechanism

Figure 7 shows the binary phase diagrams of Dievar steel calculated by Thermo-calc software (database TCFE7). As can be observed, the most significant effect of trace nitrogen on phase diagram is the solution temperature change of M(C, N). With the increase of nitrogen content in steel, the solution temperature of M(C, N) increase from 1300 to 1600 K. In other words, trace nitrogen increase the stability of M(C, N) significantly, resulting in that M(C, N) can exist at higher quenching temperatures. It is worth noting that the gas phase will generate when nitrogen increases to 0.07% because of supersolubility. Further, equilibrium precipitation diagrams [12, 13], Figure 8, show that trace nitrogen mainly precipitates as V(C, N) and not only increase the precipitation temperature but also increase the amount of precipitation significantly. These highly stable precipitates were insoluble during austenitization before quenching and then remain in the tempering samples, which is consistent with the SEM observation in Fig. 1.

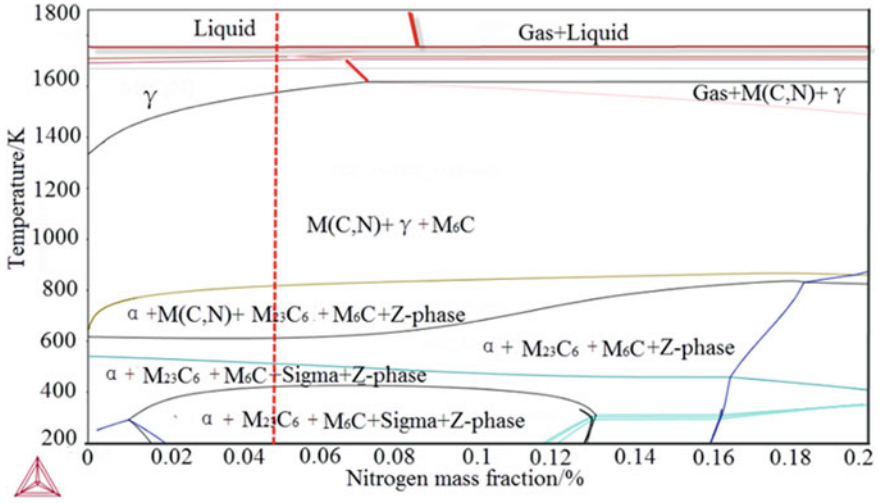

Fig. 7 Binary phase diagrams by Thermo-Calc software. (Color figure online)

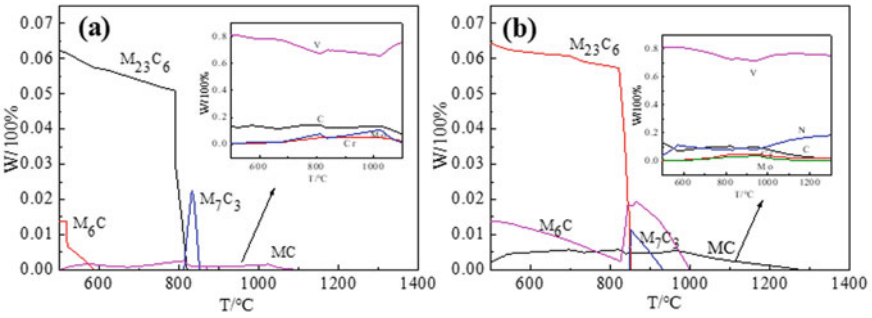

Fig. 8 Equilibrium precipitation calculated by Thermo-Calc software. (Color figure online)

In fact, all performance changes of die steel are attributed to the precipitation of these V(C, N). On the one hand, the precipitation of V(C, N) benefits in inhibiting the growth of original austenitic grains during the quenching process, while refining the final tempered microstructure, as shown in Fig. 2 provide the benefit of increasing the hardness and toughness of steel. On the other hand, these nano-sized carbides cause less loss to toughness because of their small size, guaranteeing high toughness [14]. However, large amounts of undissolved carbides are sure to take up a lot of alloying elements, especially V, thus resulting in that the alloying element could not be fully soluted into matrix, which can be proved by XRD as shown in Fig. 9. As can be observed, the diffraction angles of Dievar steel are shifted toward smaller diffraction angles compared to Dievar(N) steel, indicating a more severe lattice distortion. In other words, trace nitrogen decreases the solid solubility of alloying elements, especially V, which is an important carbide stabilizing element [15]. Reduction of vanadium in quenching matrix leads to decrease of vanadium in tempering metastable precipitates. These metastable precipitates are easy to transform to Cr-rich carbides and coarsening during long temper time due to lack of V, resulting in lower tempering

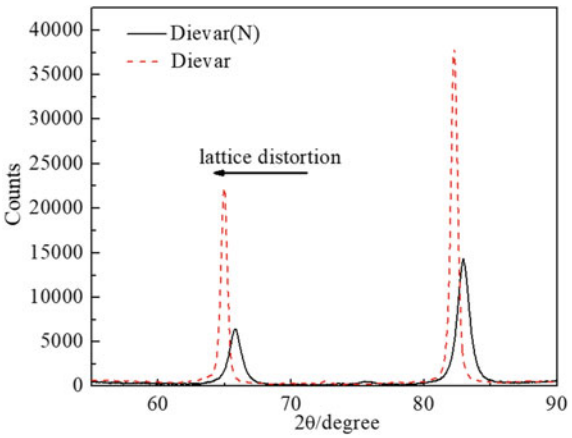

Fig. 9 X-ray diffraction pattern curves of tested steels quenched at 1030 °C. (Color figure online)

stability of steel. Therefore, trace nitrogen decreases the tempering stability of steel through decreasing of vanadium element in the matrix.

4 Conclusions

The effect of trace nitrogen on microstructure and the property of Cr-Mo-V hot-working die steel were studied in this work. The main conclusions are drawn as follows:

(1) Trace nitrogen promotes the precipitation of nano-sized V(C, N), increasing the undissolved carbides in tempered steel.
(2) The undissolved V(C, N) carbides in nitrogen-alloyed steel exert a stronger pinning effect on refining austenitic grains during the quenching process and refine the final tempered microstructure. However, the solid solubility of alloying elements and lattice distortion of matrix decreased obviously.
(3) Trace nitrogen could increase the hardness and toughness of Cr-Mo-V steel by refining the microstructure. However, the tempering stability would be decreased obviously due to the decrease of solid solubility of alloy elements such as V.

Rate-Dependent Hardening Behavior of Autobody Sheet Metals in Tension and Compression

H. Huh, G. Joo, and M. K. Kim

Abstract This paper is concerned with the evaluation of rate-dependent hardening behaviors of autobody metal sheets with novel tension and compression testing devices. Hardening behaviors in tension and compression are indispensable for accurate numerical simulation of sheet metal forming and subsequent spring-back as well as crashworthiness. In addition, it is important to consider the strain rate effect for hardening behaviors in tension and compression because sheet metal deformation prevails at intermediate strain rates up to hundreds per second in press shops of the automotive industry as well as in car crash. Novel in-plane tension and compression testing devices are developed with a servo-hydraulic testing machine to obtain tension–compression hardening curves of autobody metal sheets at intermediate strain rates ranging from 0.001 s^{-1} to 100 s^{-1}. With the testing devices specially developed, hardening behaviors are evaluated in tension–compression for mild steel sheets, TRIP980, TWIP980 steel sheets, and magnesium alloy at various strain rates ranging from 0.001 to 100 s^{-1} in terms of the flow stress considering the Bauschinger effect and the permanent softening. It is observed that the stress offset is dependent on the inherent characteristics of metal sheets as well as the strain rates. It is confirmed from the experiments that the Bauschinger effect decreases as the strain rate increases. The permanent softening defines the stress offset between flow stress curves in tension–compression and monotonic tension with large deformation after loading reversal.

Keywords Hardening behavior · Tension and compression · Rate dependency · Autobody sheet metal · Permanent softening

1 Introduction

In practical sheet metal forming, hardening behaviors of AHSS sheets are subjected to both complicated loading paths and strain rate effects simultaneously. With regards

to loading path, it is necessary to characterize the material properties for tension and compression because of loading reversal due to bending–unbending process in sheet metal forming. Consideration of the strain rate effect is also necessary to measure the material properties which alter at intermediate strain rates higher than tens per second in automotive sheet metal forming.

In order to observe hardening behaviors of sheet metals under loading reversal, in-plane uniaxial tension–compression tests are preferable because of uniform deformation in the gauge section of a specimen. To realize the in-plane compression test, however, a sheet specimen should be prevented from buckling in accordance with an eccentric load. Many researchers have developed various methods to suppress the buckling of a specimen under the in-plane compression test [2, 4, 5, 9, 13, 14]. The most promising clamping method to prevent buckling is a hydraulic clamping system proposed by many researchers [1, 3, 9–12]. In contrast to the previous work performed at the quasi-static state, in-plane tension and compression material properties have been investigated at intermediate strain rates with servo-hydraulic material testing machines, which can control a constant high velocity during experiments. Joo et al. [7] have developed a novel device for a servo-hydraulic testing machine to obtain tension–compression hardening curves of auto-body metal sheets at intermediate strain rates without fluctuation of the measured force.

This paper proposes novel tension and compression test devices that avoid the fluctuation of the measured force at intermediate strain rates of up to 100 s^{-1}. Hardening behaviors are evaluated with experimental results in tension–compression for various metal sheets such as DQ steel, DP steel, TRIP980, TWIP980 steel sheets, and magnesium alloy at various strain rates ranging from 0.001 to 100 s^{-1} considering the Bauschinger effect and the permanent softening. It is confirmed from the experiments that the Bauschinger effect decreases as the strain rate increases. It is also noted that the permanent softening is observed in the hardening behavior of TWIP980 and DP590, not of DQ steel and TRIP980.

2 Experimental Setup

A novel compression device has been suggested to measure an actual force of a specimen during deformation from a load cell at intermediate strain rates up to 100 s^{-1}. The main concept of a new device is to install a load cell close to a specimen inside the novel devices to measure the actual force during specimen deformation regardless of the vibration mode of a jig system [6, 8]. Figure 1 illustrates schematic diagrams of compression test devices before and after modification. The most important difference between the two test devices is the location of a load cell for the force measurement. Before modification, a load cell was not included inside the test device, whereas it was installed between the jig mount and the fixed block of the HSMTM. After modification, on the other hand, a load cell is installed between the specimen mount and the fixed jig of the test device. According to this modification, the movement of the load cell can be independent of the jig vibration so that the

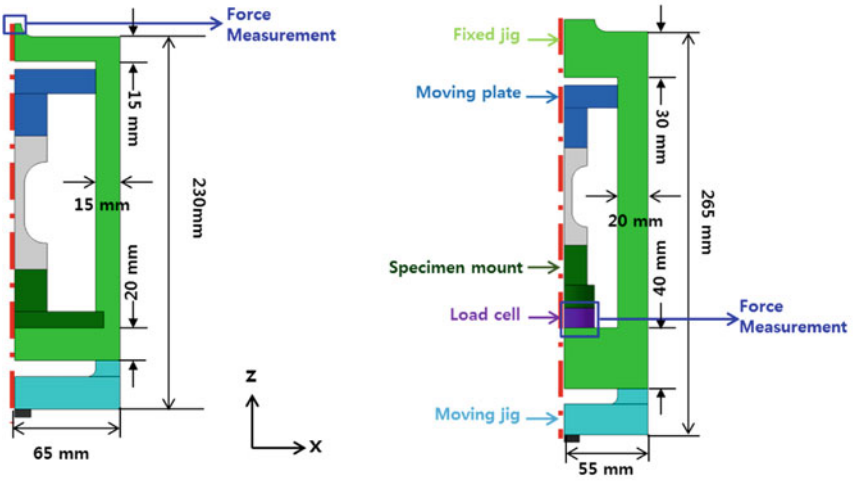

Fig. 1 Schematic diagrams of compression test devices: **a** before modification; **b** after modification. (Color figure online)

measured force can be less vulnerable to the jig vibration. Consequently, the actual force of a specimen during deformation can be measured from the load cell inside the novel test device.

3 Rate-Dependent Tension–Compression Hardening Behaviors of Sheet Metals

3.1 AHSS Steels of TRIP980 and TWIP980

Stress−strain curves of TRIP980 and TWIP980 steel sheets are obtained in tension and subsequent compression with a variation of the strain rate from 0.001 to 100 s^{-1} as shown in Fig. 2. The stress–strain curves confirm the positive strain rate hardening effect of both the materials in tension and subsequent compression. It is not easy to identify the tension–compression hardening characteristics from the obtained result of Fig. 2. Tension–compression hardening, however, can be investigated from a comparison of stress–strain curves in tension–compression and monotonic tension as shown in Fig. 3.

Figure 3 shows true stress–true strain curves in tension and those in subsequent compression at the strain rate of 100 s^{-1}. Solid lines with square and circle symbols indicate tension and subsequent compression test results, respectively, while dotted lines represent monotonic tension test results. It is noted from the comparison that the subsequent compressive yield stress becomes smaller than the flow stress in

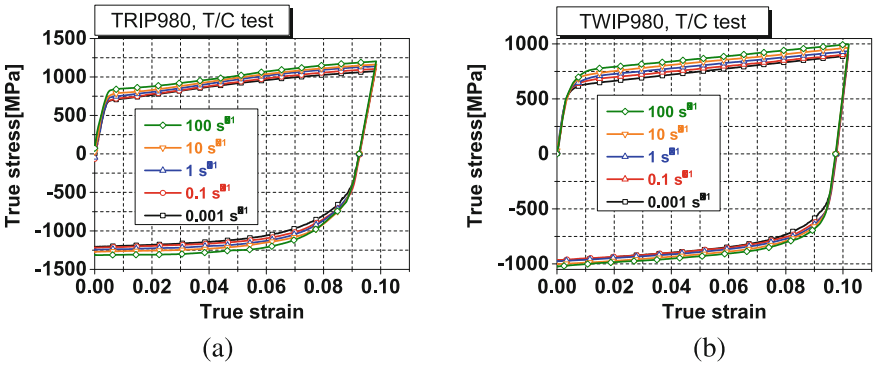

Fig. 2 Rate-dependent hardening curves of AHSS sheets in tension and subsequent compression: **a** TRIP980; **b** TWIP980. (Color figure online)

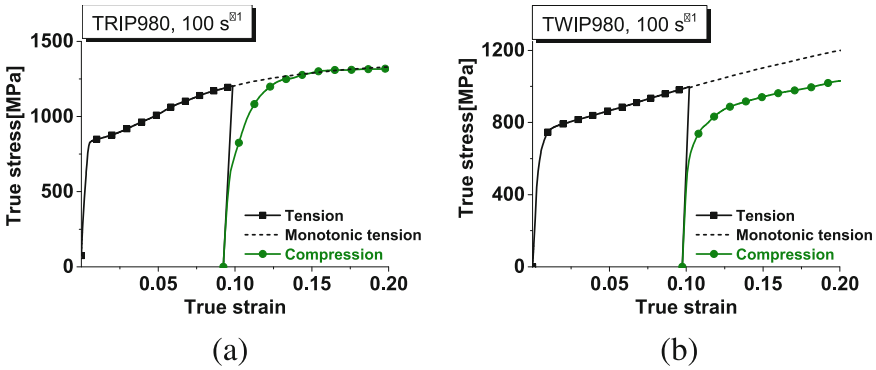

Fig. 3 Comparison of hardening curves of the TRIP980 and TWIP980 steel sheet in tension–compression and monotonic tension at a strain rate 100 s^{-1}: **a** TRIP980; **b** TWIP980. (Color figure online)

monotonic tension because of the Bauschinger effect. After the early re-yielding, in addition, the subsequent compressive curves of the two AHSS sheets exhibit a rapid change of the hardening rate for the transient behavior. The two types of AHSS sheets, however, show distinct hardening behavior at large deformation after the transient behavior. The TRIP980 steel sheet shows a convergence to the monotonic tensile curve, while the TWIP980 steel sheet maintains a constant stress offset showing that its curve remains smaller than that in monotonic tension as found in Fig. 3b, which is explained as the permanent softening.

3.2 AHSS Steels of DQ Steel and DP590

Stress−strain curves of DQ and DP590 steel sheets are obtained in tension and subsequent compression with the variation of the strain rate from 0.001 to 50 s^{-1} as shown in Fig. 4. The stress–strain curves show even more remarkable positive strain rate hardening of the both materials in tension and subsequent compression than the previous TRIP980 and TWIP980 steel.

Tension–compression hardening can be investigated from comparison of stress–strain curves in tension–compression and monotonic tension as shown in Fig. 5. Figure 5 shows true stress–true strain curves in tension and those in subsequent compression at the strain rate of 50 s^{-1}. Solid lines with hollow square and circle symbols indicate tension and subsequent compression test results, respectively, while dotted lines represent monotonic tension test results. The two types of steel sheets show distinct hardening behavior at large deformation after the transient behavior

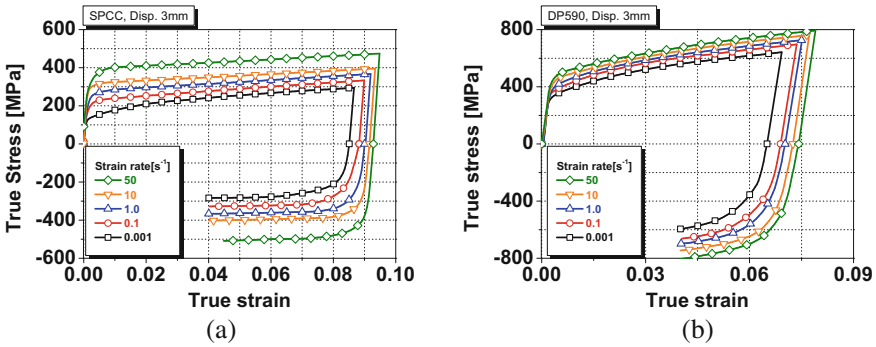

Fig. 4 Rate-dependent hardening curves of steel sheets in tension and subsequent compression: **a** DQ steel; **b** DP590. (Color figure online)

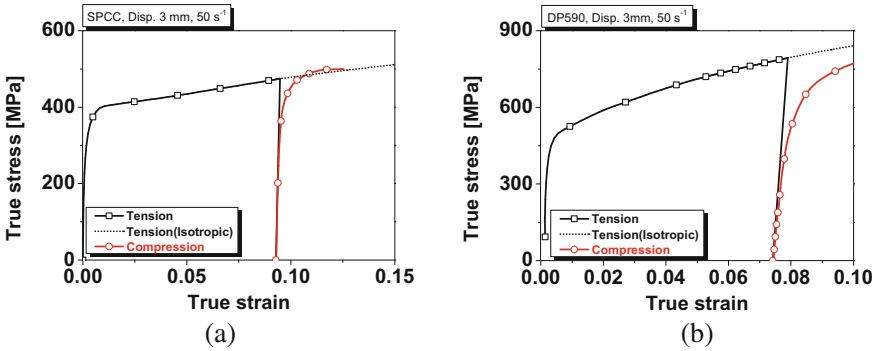

Fig. 5 Comparison of hardening curves of the DQ and DP590 steel sheet in tension–compression and monotonic tension at a strain rate 50 s^{-1}: **a** DQ steel; **b** DP590. (Color figure online)

explained in the previous section. The DQ steel sheet shows a convergence to the monotonic tensile curve while the DP590 steel sheet maintains a constant stress offset showing that its curve remains smaller than that in monotonic tension as found in Fig. 5b, which is explained as the permanent softening. Although the whole curves at various strain rates are not presented in Fig. 5, the hardening behavior of DQ steel in subsequent compression is interesting because they show the permanent softening at low strain rate and gradual convergence to the monotonic tension hardening as the strain rate increases. As a result, the hardening curve at the strain rate of 50 s^{-1} shows a convergence to the monotonic tensile curve in Fig. 5a.

3.3 Magnesium Alloy of AZ31B

Stress−strain curves of a magnesium alloy of AZ31B are obtained in tension and compression with the variation of the strain rate from 0.001 to 100 s^{-1} as shown in Fig. 6. The stress–strain curves are depicted for tension and compression separately because the hardening behavior in compression is exotic and entirely different from that in tension as shown in Fig. 6. The stress–strain curves in subsequent compression show very low compressive yield stress compared to the monotonic tensile curves, which is even different from the Bauschinger effect. After the early re-yielding, the subsequent compressive curves of AZ31B retain their slow hardening rate until a certain amount of deformation regardless of the strain rate showing independence of the strain rate. After some amount of deformation, the hardening rate increases rapidly and then slows down until the deformation reaches a limit strain at fracture. It should be noted that the hardening behavior continues until fracture which takes place even in the compression loading with the side-guide plates. The compressive yield stress is very low and almost half of the expected monotonic tensile flow stress. After the early yielding, the flow stress in compression reaches a very large value

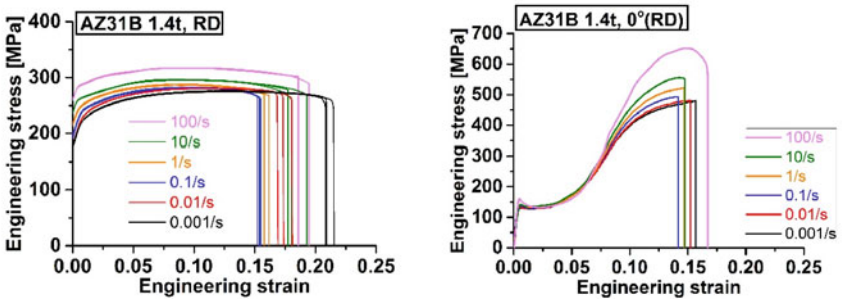

Fig. 6 Rate-dependent hardening curves of AZ31B sheets in tension and subsequent compression: **a** Tension; **b** Compression. (Color figure online)

which is almost four times higher than the compressive yield stress. This phenomenon explains the reason why an experimental result of the hardening curve has not been reported up to now. It is very tricky to conduct the compression test because of the exotic hardening behavior of AZ31B.

4 Conclusion

Rate-dependent hardening behavior of steel sheets and magnesium alloy sheets is evaluated at a wide range of the strain rate with novel tension and compression test devices [6, 8]. Tension–compression hardening behaviors are investigated in terms of the Bauschinger effect and the permanent softening with respect to the strain rate. In addition, asymmetric hardening behaviors are investigated from simple tension and simple compression test results. The main conclusion is summarized as follows:

(1) Novel tension and compression test devices are proposed to measure an actual force of a specimen during deformation at strain rates up to 100 s^{-1}. In the novel test devices, a load cell is installed between the specimen mount and the fixed jig of the novel devices.
(2) Tension–compression hardening behavior of steel sheets is evaluated with the variation of the strain rate in terms of the Bauschinger effect and the permanent softening. As the strain rate becomes higher, the Bauschinger ratio becomes larger with the decrease of the Bauschingher effect. The TWIP980 and DP590 show constant stress offset of the permanent softening at large reverse deformation, which increases as the strain rate increases.
(3) Tension–compression hardening behaviors of magnesium alloy sheet is evaluated with the variation of the strain rate. The hardening behavior of AZ31B shows very exotic and entirely different tendency from that of steel sheets. After the early yielding, the flow stress in compression reaches a very large value which is almost four times higher than the compressive yield stress.

Analysis of Creep Behavior of Magnesium Alloy Sheet (AZ31B) in Warm Forming

JaeHyeong Yu and Chang-Whan Lee

Abstract In this study, creep behavior characteristics of magnesium alloy sheet (AZ31B) according to pre-strain during warm forming were analyzed through experiments. In addition, stress relaxation process was analyzed by applying the creep behavior of magnesium alloy sheet to analytical simulation. In the creep test, the strain due to the creep phenomenon of magnesium alloy at room temperature was 0.001 at 1000 s of constant load holding time, whereas it was broken at 8 s at 250 °C. The stress exponent of magnesium alloy at room temperature is 10.60 and the stress exponent is 4.8 at 250 °C. Similarly, in the case of stress relaxation experiments at room temperature, the amount of load reduction was 74 N at 1000 s while the amount of load reduction was reduced by 522 N at 250 °C. The stress exponent and parameters obtained from the experiments were applied to the analysis simulation, and the creep and stress relaxation processes were compared with the experimental results.

Keywords Magnesium alloy sheet (AZ31B) · Warm forming · Uniaxial tensile creep · Stress relaxation · Finite element method · V-bending process

1 Introduction

Magnesium alloys are expected to be used in many applications such as semiconductors, displays, aerospace, and automotive parts due to their superior specific strength [1]. However, when forming at room temperature, it is easy to break due to low elongation and large springback occurs due to high flow stress. Owing to the tensile behavior of magnesium alloy at room temperature work hardening mainly occurs, whereas work softening occurs due to recrystallization and potential rise from 150 °C [2]. For this reason, magnesium alloys are mainly formed in a warm form. Sufficient

creep strength is also essential for the application of magnesium alloys in automotive power trains, which are conventionally used in materials such as aluminum and steel. Previous studies on the creep behavior and warm forming of magnesium alloys are as follows.

Reddy et al. [3] performed a deep-drawing process on the various forming temperature of magnesium alloy by analysis simulation and experimental methods. Through this, the LDR value increases with increasing forming temperature in both simulation and experiment, but after 300 °C, the LDR value decreases due to the reduction of a local cross-section of the material. Wang et al. [4] measured the springback of the magnesium alloy sheet as a function of the punch radius and forming temperature in V bending forming. As a result, it was confirmed that the spring back of the magnesium alloy decreases as the forming temperature increases and the punch radius decreases. Also, the springback behavior was analyzed by observing the microstructures of the tension and compression parts with respect to the neutral axis of the specimen. Kim and Kim [5] measured the creep behavior of a magnesium alloy sheet at a temperature of 0.5 T_m or less. As a result, magnesium alloys exhibited different behaviors such as primary creep behavior under low stress and secondary creep behavior under high stress, and each behavior was predicted by the creep model. Kim et al. [6] conducted a three-point bending test in a warm state using a magnesium alloy sheet to investigate the effect of stress relaxation on springback. This shows that the springback decreases as the holding time of the material in the die increases. Kang et al. [7] used an AZ31 magnesium alloy to predict the short-term creep rupture life by the initial strain method (ISM) and a deformation mechanism that led to creep deformation at or below 0.5 times the melting temperature of pure magnesium. Creep experiments were performed at 443 K and stress conditions 109–141 MPa. This confirmed that the creep deformation mechanism of AZ31 is cross slip in the temperature range 423–443 K.

In this study, creep and stress relaxation tests were conducted to analyze the creep characteristics of magnesium alloy sheet (AZ31B) as a function of forming temperature and pre-strain. Creep behavior was analyzed and stress exponent was measured on the various forming temperature and pre-strain. Analytical simulations were performed using the stress exponent and parameters obtained from the experiments, and the results were compared and analyzed. Using the same stress exponent and parameters, the stress relaxation process was analyzed by analytical simulation and compared with the experimental results.

2 Experiment and Simulation Procedure

2.1 Material

In this study, Table 1 shows the chemical composition of magnesium alloy sheets that are used. The flow stress on the various forming temperature of the magnesium

Table 1 The chemical composition of magnesium alloy

Element	Mg	Al	Zn	Mn	Sl	Cu	Ca	Fe	Ni
Content(%)	97	2.5–3.5	0.6–1.4	0.2	0.1	0.050	0.040	0.0050	0.0050

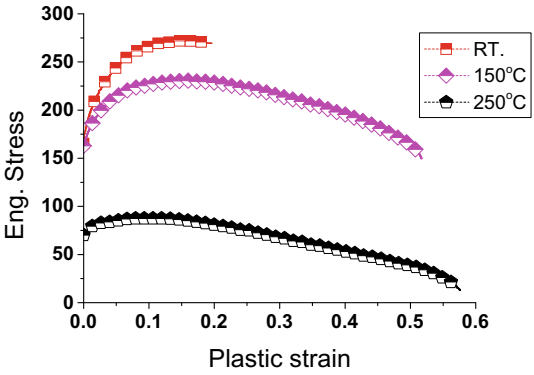

Fig. 1 The stress–strain of magnesium alloy sheet (AZ31B) . (Color figure online)

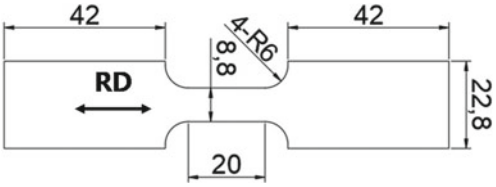

Fig. 2 The specimen of uniaxial tensile creep test

alloy sheet (AZ31B) is shown in Fig. 1. For this flow stress, the specimen shown in Fig. 2 was measured through a tensile test using the material tester INSTRON8516.

Creep test specimens were made in the rolling direction of the sheet (R.D.) and the schematics of the specimens are shown in Fig. 2 [8]. The gauge length of the specimen was 20, 8.8 mm wide and 1 mm thick.

2.2 Uniaxial Tensile Creep Test

In this study, the uniaxial tensile creep test was conducted to analyze the creep behavior of magnesium alloy sheet (AZ31B) according to temperature and pre-strain. Forming temperature is room temperature, 50, 100, 150, 200, and 250 °C. In the case of pre-strain, 50, 75, 90, and 100% of the ultimate tensile strength of the magnesium alloy sheet was defined as the strain when stress was applied. In the case of creep strain measurement, the specimen was tensiled to the target pre-strain, and then the measured strain changes due to constant load. The speed of the crosshead during the pre-strain was set to 12 mm/min and the constant load time was set to 0–1000 s.

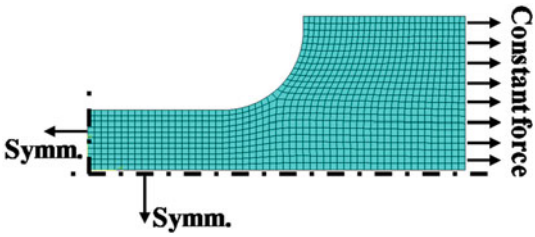

Fig. 3 The FEM model of uniaxial tensile creep process. (Color figure online)

2.3 Simulation

In this study, the creep and stress relaxation processes of magnesium alloy sheets were analyzed using ABAQUS v2016, a commercial finite element analysis program. The schematic of the creep process for the analysis is shown in Fig. 3. To analyze the creep process, *ABAQUS* Visco code was used and the material was modeled using solid elements. In this study, the secondary creep stage was considered and assumed as plane stress. For material properties, plastic strain and yield stress were used at 250 °C using the reference of benchmark # 2 provided by *NUMISHEET* [9]. In the case of creep properties, the parameters obtained from creep experiments were used in this study.

3 Results

3.1 Uniaxial Tensile Creep Test According to Temperature and Pre-strain

In this experiment, the creep test was conducted under constant load conditions to analyze the creep behavior of the magnesium alloy sheet. The creep behavior of magnesium alloy sheet (AZ31B) with pre-strain at forming temperature of 250 °C is shown in Fig. 4. The third creep entry time is 120 s when the pre-strain of the magnesium alloy sheet (AZ31B) is 50% at 250 °C and 8 s when it is 90%. Through this, it can be seen that the larger the pre-strain, the faster the tertiary creep stage and the shorter the rupture time. Also, it can be seen that the creep rupture is abruptly reduced between 50 and 75% of the pre-strain. For this reason, it can be seen that as the pre-strain progresses to the plastic region, the vertical cross-section in the tensile direction decreases and the creep rupture time occurs quickly.

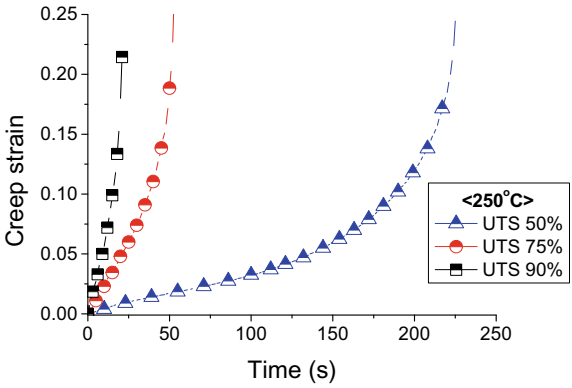

Fig. 4 The creep behavior of AZ31B according to pre-strain at 250 °C. (Color figure online)

3.2 Stress Exponent of Creep Strain

In this study, the creep behavior of magnesium alloy sheet was analyzed according to forming temperature and constant load time. From these results, the stress exponent for creep strain was obtained by the following method. The primary creep stage is characterized by a monotonous decrease in the creep strain rate, and the creep strain rate is constant for the secondary creep stage. In the case of tertiary creep, the creep strain rate increases rapidly. The creep strain can be represented by the simple power law formula

$$\varepsilon_c = A\sigma^n t^m \tag{1}$$

where A, n, m are the temperature-dependent parameters. In this study, the primary and secondary creep stage was considered and the third creep was not considered. In this study, it was found that the primary creep stage is shorter than the secondary creep stage in the magnesium alloy sheet (AZ31B). Especially, the larger the pre-strain, the shorter is the primary creep section and then it immediately enters the secondary creep section. Therefore, the creep strain rate (the slope of the creep strain diagram) in the primary and secondary creep stages is constant. At this time, the empirical formula for expressing the creep strain rate as a function of stress and temperature can be expressed as Eq. (2). Equation (2) shows the dependence on the stress of the normal creep rate (secondary creep).

$$\dot{\varepsilon}_c = A\sigma^n \tag{2}$$

To find the parameters A and n, take the logarithm in Eq. (2) and make it a linear equation.

$$ln(\dot{\varepsilon}_c) = lnA + nln\sigma \tag{3}$$

Table 2 The stress exponent parameter of AZ31B according to forming temperature

	100 °C	150 °C	200 °C	250 °C
Stress exponent (n)	10.60	9.30	7.65	4.80
Parameter A	2.97E-30	8.59E-25	6.08E-20	9.13E-13

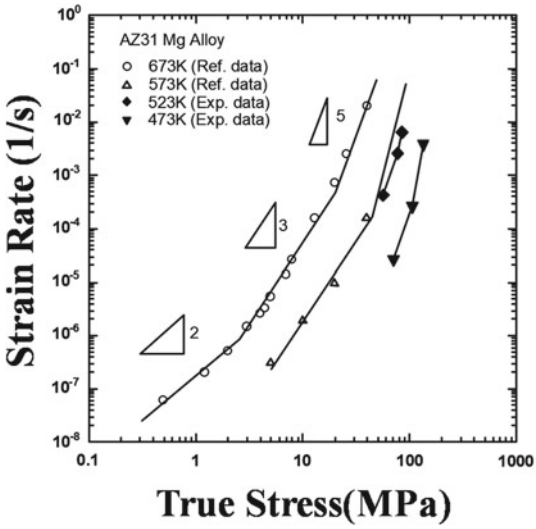

Fig. 5 Steady-state strain rate against stress for specimens tested from 573 to 673 K [10]

The parameters A and n were obtained through Eq. (3) and the experiment. The stress exponent at each forming temperature is shown in Table 2.

The stress exponent obtained in this study is shown in the results of previous studies representing the stress exponent of steady-state creep strain and true stress (Fig. 5) [10]. Figure 5 represents the creep rate for the secondary creep strain corresponding to each temperature when the material is stressed. As can be observed from Fig. 5, the speed of creep test in this study was performed in a range similar to the speed used in the previous study.

3.3 Simulation Results of Creep

At the forming temperature of 250 °C and the 75% of pre-strain of the ultimate tensile strength, the results of the creep strain simulation and the experimental are shown in Fig. 6.

In the case of the experiment at the pre-strain $\varepsilon_{75\%}$, the time to enter the tertiary creep stage from the secondary creep stage is about 40 s. In the case of the analytical simulation, the time taken from the secondary creep stage to the tertiary creep stage is about 39 s, showing a 2% error based on the experimental result. At $\varepsilon_{90\%}$ pre-strain,

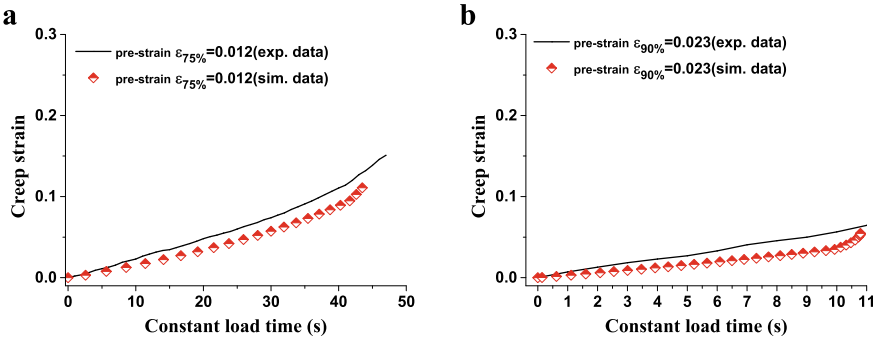

Fig. 6 Creep strain for experimental and simulation under constant load at **a** 75% and **b** 90% of pre-strain. (Color figure online)

the entry time of the tertiary creep section is 10 s for the experiment, and the entry time of the third creep section for the analysis is 11 s, showing a 10% error based on the experimental results. In addition, both experimental and analytical simulations show that the higher the pre-strain, the shorter the tertiary creep entry time and the higher the creep rate in the secondary creep stage. In this study, creep modeling was performed without considering the tertiary creep stage. Therefore, the experimental and the analysis simulation results tend to be different from the tertiary creep.

3.4 Simulation Results of Stress Relaxation

As a result of analytical simulations using the parameters obtained in the previous section of this study, it can be seen that there is a similar trend up to the secondary creep stage considered. In addition, materials having creep characteristics generate stress relaxation characteristics similar to the creep characteristics. In this study, therefore, the stress relaxation process was compared with the experimental and simulations. Figure 7 is the result of the stress relaxation under constant displacement time in the experimental and analytical simulations.

As can be observed from the experimental and analytical simulation results for all pre-strains, the load decreased and converged from about 30 s as the constant displacement holding time increased. At the pre-strain $\varepsilon_{75\%}$, the load reduction amount is 524 N for the experiment, and the load reduction amount is 478 N for the analysis simulation when the constant displacement time is 30 s. This shows an 8% error based on the experimental results. At the pre-strain $\varepsilon_{90\%}$, the load reduction amount is 553 N for the experiment, and the load reduction amount is 496 N for the analysis simulation when the constant displacement time is 30 s. This shows a 10% error based on the experimental results. At pre-strain $\varepsilon_{75\%}$, it takes 14 s for the load relaxation time (time to reach initial load $(F_0) \times 0.37$) for the experiment and 15 s for the analytical simulation. The two results show a difference of about 1 s. At the pre-strain

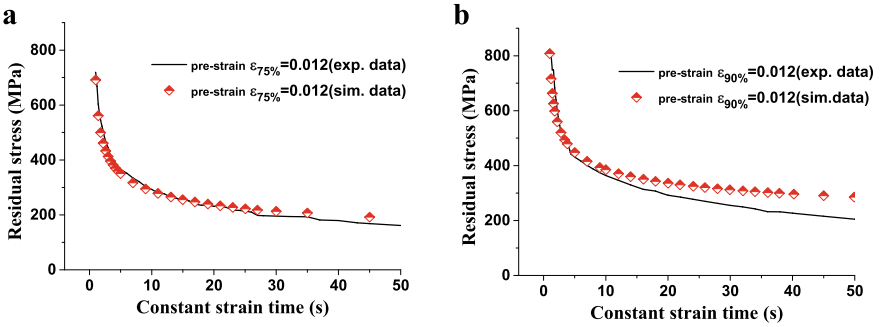

Fig. 7 Residual stress for experimental and simulation under constant strain at **a** 75% and **b** 90% of pre-strain. (Color figure online)

$\varepsilon_{90\%}$, there is a difference of about 7, 19 s for the load relaxation time for the experimental and 12 s for the analysis simulation. When the stress relaxation behavior is applied to the V-bending process, the springback change is shown in Fig. 8.

The springback tended to decrease as material holding time increases in the die at all forming temperatures. This is because the springback decreases due to the stress caused by the deformation of the material relaxation. The springback tends to rapidly decrease the holding time of the material in the die to about 250 s, and then tends to converge. As the forming temperature increased, the amount of springback reduction also increased. This trend is similar to that of the stress relaxation test on the forming temperature in the previous section. In addition, the amount of springback decreased according to the forming temperature is 16.65° and the amount of springback decreased is 19.25° as the holding time of the material in the die increases at 200 °C [11]. As a result, it can be noticed that the amount of springback decrease with increasing material holding time in the die is larger than the amount of springback decrease with increasing forming temperature.

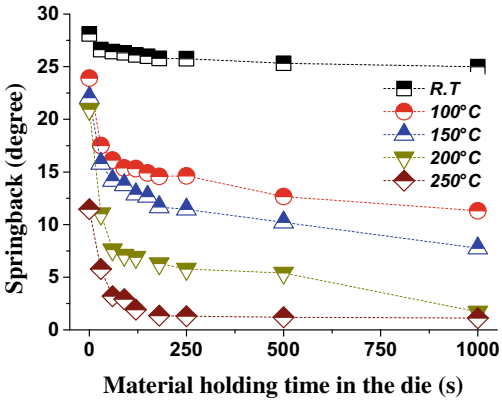

Fig. 8 The springback of V-bending process according to material holding time and forming temperature [11]. (Color figure online)

4 Conclusion

In this study, the creep and stress relaxation behaviors of magnesium alloy sheet (AZ31B) according to temperature and pre-strain were analyzed through experimental and analytical simulations. The research results are as follows.

The stress exponent obtained through the uniaxial tensile creep test was 4.8 at 250 °C and decreased with increasing forming temperature.

Both creep experiments and analytical simulations tended to reduce the time to enter the tertiary creep as the pre-strain increased. In addition, the error in experimental and analytical simulations according to each pre-strain was measured to be <10%.

As a result of stress relaxation simulation after applying the same parameters as the creep simulation, the load tended to converge from about 30 s.

The Effect of Electroplasticity on the Flow Behavior of AA7075 in T6 Temper

Dong Hongrui, Li Xiaoqiang, Wang Haibo, Li Dongsheng, and Yang Yanfeng

Abstract Warming forming, or the combination of cold forming, and multiple heat treatment processes are usually used to obtain AA7075 parts in T6 temper. However, the above-mentioned methods increase the forming cycle and cost, and lead easily to change in the microstructure. In this paper, a new forming process is proposed, namely pure electroplastic-assisted thermal forming (PEPATF) process, which can reduce the forming temperature by using pure electroplastic/non-thermal effect to compensate plasticity loss caused by the decrease of temperature. In order to research the mechanism of electroplastic effect, oven-heating uniaxial tension at different temperatures and electrically assisted uniaxial tension test at different temperatures and current densities are performed for AA7075-T6. On the one hand, the results show that at the same temperature, the flow stress obtained by electrically assisted heating is lower than that obtained by oven-heating, indicating that pure electroplasticity exists and is more obvious with the increase of temperature. Moreover, at the same temperature, the flow stress decreases with the increase of current density at the same temperature. On the other hand, the elongation obtained by electrically assisted uniaxial tension is higher than that obtained by oven-heating uniaxial tension. For electrically assisted uniaxial tension, the largest elongation is at 150 °C.

1 Introduction

Modern aerospace equipment is developing toward lightweight, long life, and high reliability, and its service performance tends to be extreme, which requires that its material must have super high strength and low weight correspondingly. AA7075 is widely used in aerospace field because of excellent combination of properties such as high strength to density ratio, fracture toughness, and resistance to stress corrosion cracking [1, 2]. When in T6 temper, its tensile strength can reach 550 MPa, which can be used to manufacture aircraft structures and other parts with high strength. However, poor formability at room temperature limits its application [3].

In order to obtain AA7075 part in T6 temper, the combination of cold forming and multiple heat treatment processes are usually used to form the part, and heat treatment is used to make the part in T6 temper. However, the following problems exist: (1) long process route, long manufacturing cycle, and high cost; (2) large deformation due to heat treatment; (3) large force, large springback, and low forming accuracy. Based on the above problems, Sotirov et al. [4] proposed the warm forming of AA7075 in T6 temper directly, which avoids intermediate heat treatment, significantly reduces the forming cycle, and improves the forming accuracy. In order to improve the formability of AA7075 in T6 temper, it is necessary to make its forming temperature reach 200–230 °C. However, the forming temperature of 200–230 °C will induce the change of microstructure during the forming process, which will decrease the yield strength of the part after forming and affect its service performance. If the forming temperature is decreased, the plasticity of AA7075 will decrease. Therefore, the new forming methods are needed to solve these problems.

Researchers have found that the formability of metal has changed significantly when the current is applied during forming, such as the increase of plasticity and the decrease of deformation resistance [5]. This phenomenon is called electroplastic effect. It has been found that on the one hand, electric current can increase the temperature of the material through the Joule heating effect, which makes the material soften (thermoplasticity/thermal effect). On the other hand, electric current can directly reduce the flow stress of the material (pure electroplasticity/non-thermal effect). Therefore, pure electroplasticity can be used to reduce the forming temperature and make up for the decrease of the plasticity caused by the decrease of the temperature. A novel process is put forward, namely pure electroplastic-assisted thermal forming (PEPATF) process, which can reduce the forming temperature by using pure electroplastic/non-thermal effect to compensate plasticity. It is expected to greatly improve the forming limit and the forming quality of the materials. It is a promising technology to realize the precise forming and manufacturing of the difficult-to-form materials and structures.

In order to use PEPATF process, it is necessary to research the mechanism of electroplastic effect. In this paper, oven-heating uniaxial tension at different temperatures and electrically assisted uniaxial tension test at different temperatures and different current densities are performed for AA7075 in T6 temper and the thermal effect and electroplastic effect are studied.

2 Material and Experiment

2.1 Material and Specimen

The material used in the test is AA7075 with T6 temper, whose chemical composition is shown in Table 1. The size of specimen used in oven-heating uniaxial tension is shown in Fig. 1. During electrically assisted uniaxial tension, the non-uniform temperature distribution on the specimen is mainly caused by the heat conduction between specimen and clamp. Therefore, in order to improve the uniformity of temperature distribution, the contact area between specimen and clamp should be decreased to increase the contact resistance. Therefore, the size of the designed specimen used in electrically assisted uniaxial tension is shown in Fig. 2.

2.2 Oven-Heating Uniaxial Tension

In order to study the influence of electroplasticity and pure electroplasticity on the flow behavior of AA7075-T6, it is first necessary to study the influence of thermal effect on the flow behavior. Therefore, oven-heating uniaxial tensions are carried out at different temperatures (25, 50, 100, 150, and 200 °C) with a strain rate of 0.005/s and each test is repeated three times. During the test, three thermocouples are used to measure the temperature of the upper, middle, and lower area of the specimen, and the strain is measured with a ceramic extensometer. The test equipment is shown in Fig. 3.

Table 1 Chemical composition of AA7075-T6 (wt%)

Zn	Mg	Cu	Si	Fe	Mn	Ti	Cr	Others	Al
05.1–6.1	2.1–2.9	1.2–2	≤0.4	≤0.5	≤0.3	≤0.2	0.18–0.28	0.05–0.15	Balance

2.3 Electrically Assisted Uniaxial Tension

In order to study the influence of electrical parameters on the flow behavior of AA7075-T6, electrically assisted uniaxial tensions are carried out with different temperatures and current densities. The test matrix is shown in Table 2 and each test is repeated 3–5 times. The test equipment is shown in Fig. 4. During the test, clampers are insulated with an insulating electrical board. Digital image correlation (DIC) is used to measure the strain, an infrared thermal imaging camera is used to

Table 2 Test matrix for electrically assisted uniaxial tension

measure the temperature, and a blower is used to control the temperature distribution on the specimen. A ceramic heating plate is used to compensate for the lost heat due to the heat conduction between specimen and clamper. In order to stabilize the emissivity of temperature measurement, the specimen is coated with a thin layer of black paint and the emissivity is set to 0.9 [6].

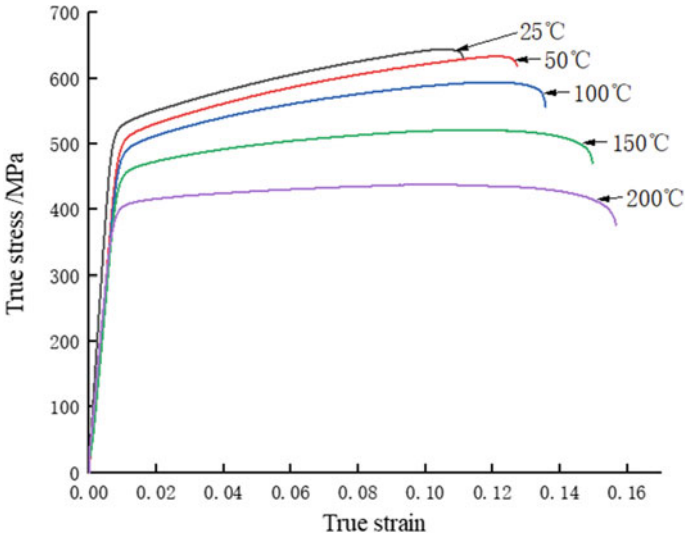

Fig. 5 Flow stress curves at different temperatures (oven-heating). (Color figure online)

3 Results and Discussion

3.1 Results

The flow stress curves for oven-heating uniaxial tension at different temperatures are shown in Fig. 5. The flow stress decreases (600–410 MPa) and the elongation increases with the increase of temperature (25–200 °C). In addition, at the same temperature increment, the higher the temperature, the greater is the decrease of flow stress. The flow stress curves obtained by electrically assisted uniaxial tension are shown in Fig. 6. As observed from Fig. 6, the flow stress decreases with the increase of temperature; at the same temperature, the flow stress slightly decreases with the increase of current density.

3.2 Discussion

In terms of flow stress and yield ratio, the difference ($\Delta\sigma$) of flow stress between oven-heating and electrically assisted heating at the same temperature is shown in Fig. 7, which is expressed as Eq. (1), where σ_O is the stress value obtained with oven-heating and σ_E is the stress value obtained with electrically assisted heating. Because the flow stress values with different current densities are very close at the same temperature, the stress value of one current density is selected to calculate the stress difference at a certain temperature. As observed from Fig. 7, when the temperature

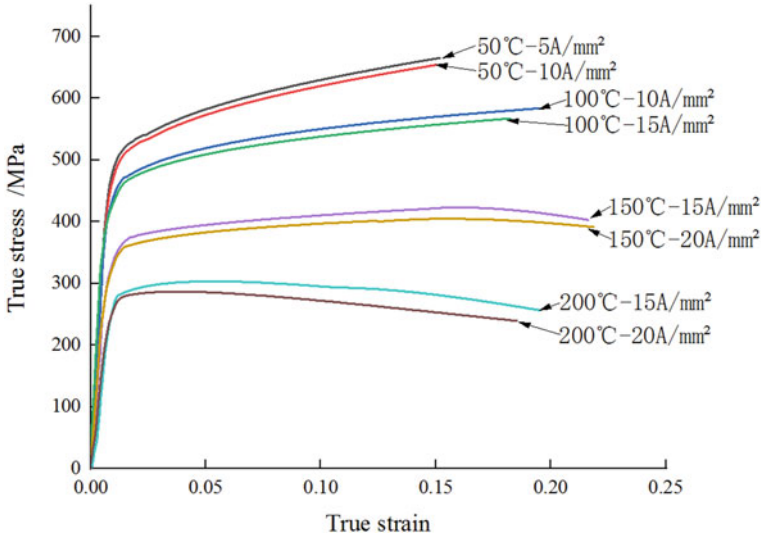

Fig. 6 Flow stress curves at different temperatures and current densities (electrically-assisted). (Color figure online)

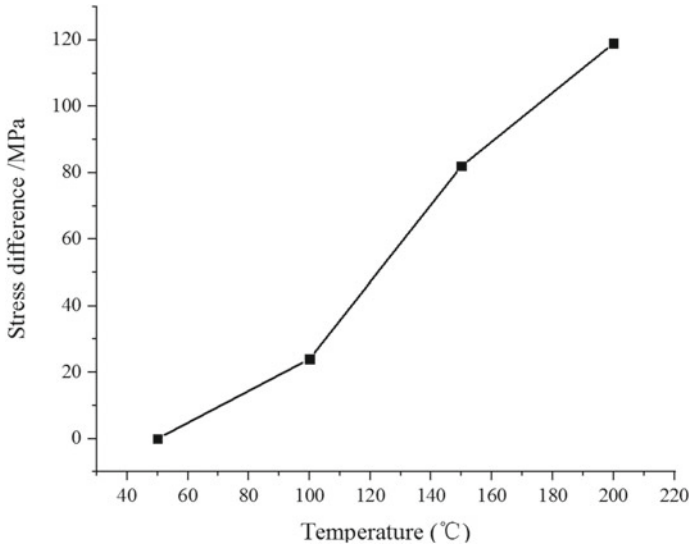

Fig. 7 The difference curves of flow stress for different heating methods at the same temperature

is 50 °C, the $\Delta\sigma$ is close to 0. With the increase of temperature, the $\Delta\sigma$ increases, which shows that pure electroplasticity becomes more obvious with the increase of temperature. In addition, the stress level at 150 °C for electrically assisted heating

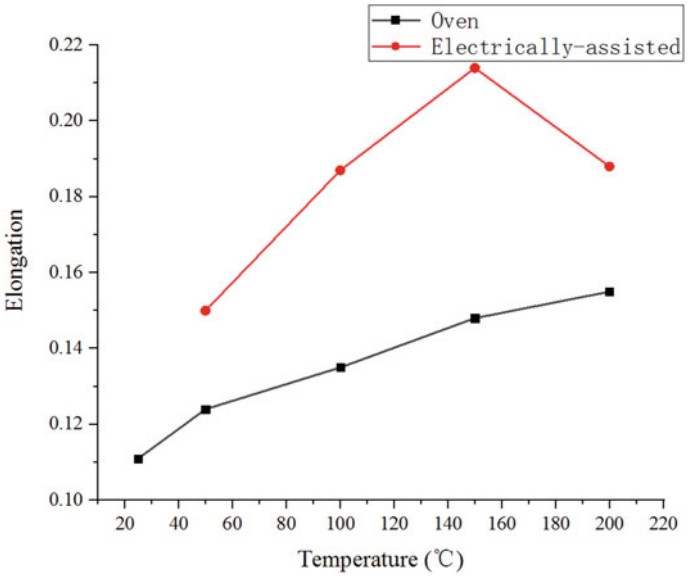

Fig. 8 Change curves of elongation with temperature for different heating methods. (Color figure online)

is close to that at 200 °C for oven heating, and the yield ratio of electrically assisted heating is obviously lower than that for oven heating, which shows that AA7075-T6 has better plastic formability with electrically assisted forming. In addition, for electrically assisted uniaxial tension, the difference of stress obtained by different current densities at the same temperature is very small, which is mainly because the difference of current density at the same temperature is only 5 A/mm^2.

$$\Delta\sigma = \sigma_{\mathrm{O}} - \sigma_{\mathrm{E}} \tag{1}$$

In terms of elongation, the change curves of elongation with temperature for different heating methods are shown in Fig. 8. Attentively, the elongation corresponding to different current densities at the same temperature for electrically assisted uniaxial tension is close, so the elongation under a certain current density at the same temperature is selected when the elongation is compared. As observed from Fig. 8, larger elongation can be obtained with electrically assisted heating. For oven-heating uniaxial tension, the elongation increases with the increase of temperature; for electrically assisted uniaxial tension, the elongation increases with the increase of temperature/current density on the whole. However, the elongation at 200 °C is lower than that at 150 °C, which is because of the obvious high temperature softening effect and non-uniform temperature distribution.

4 Conclusion

1. For AA7075-T6, there is pure electroplasticity. The higher the temperature, the more obvious is the pure electroplasticity.
2. The flow stress level at 150 °C for electrically assisted uniaxial tension is the same as that at 200 °C for oven-heating uniaxial tension. However, the corresponding yield strength ratio of electrically assisted uniaxial tension is lower than that of oven-heating uniaxial tension.
3. The elongation obtained by electrically assisted uniaxial tension is higher than that obtained by oven-heating uniaxial tension. For electrically assisted uniaxial tension within the temperature range of 50–200 °C in this paper, the largest elongation is obtained at 150 °C.

Effect of Pulse Current on Mechanical Properties and Microstructure of Ultrahigh-Strength Steel

Xin Chen, Dongkai Xu, Lei Shi, Hua Xiao, Xifeng Li, and Jun Chen

Abstract The effects of pulse current on the microstructure and mechanical properties of two kinds of ultrahigh-strength steels (UHSS) were studied by electrically assisted tension tests. The elongation of the two UHSS (MS1300 and QP980) moderately increases at relatively low current density, while their microstructures keep almost unchanged. For MS1300 steel, the elongation can be increased from 8.3% at room temperature to 12.4% at the current density of 6.58 A/mm^2. The peak stress of QP980 is reduced to 900 MPa at the current density of 7.46 A/mm^2, and the elongation is increased from 22.3% at room temperature to 38.4%. If the current density is further increased, the tensile strengths of UHSS are greatly reduced. Meanwhile, their microstructures are also obviously varied. Therefore, the appropriate current density should be selected in order to maintain the UHSS grades.

1 Introduction

Ultrahigh-strength steels can reduce automobile sheet thickness under the premise of ensuring the safety requirements. They are important materials for realizing the automobile lightweight [1]. Ultrahigh-strength steels have some disadvantages, i.e., high yield limit, low elongation, easy cracking during forming, large residual stress after forming, and large springback amount. These drawbacks make them difficult to form complex structures, which limit their application. The hot stamping forming

process for high-strength steels is relatively mature now, but it has disadvantages such as high energy consumption, long forming cycle, and high cost [2, 3].

At the same time, some studies show that the pulse current has a significant effect on the regulation of the material microstructure. Pulse current treatment is a processing method of instantaneous high energy input. It has the merits of short time, high energy effect, convenient operation, and efficiency [4]. Additionally, the action of pulse current on various metals is different from the ordinary heating effect. The pulse current is helpful for the metal forming process as follows: (1) reducing the flow stress during plastic forming; (2) improving the forming limit of materials and increasing plasticity; (3) decreasing or eliminating the workpiece springback after forming; and (4) achieving the microstructure regulation and optimization during the forming process [5].

Electrically assisted forming (EAF) is a metal forming technique where the metal workpiece formability is improved owing to the application of electricity that is applied concurrently during plastic deformation [6–8]. Nowadays, it is mainly used in light alloy materials and has achieved remarkable usage effects. However, there are few forming applications for UHSS. Therefore, two kinds of UHSS (MS1300 and QP980) provided by BaoSteel that were chosen for this study. Both have a tensile strength of about 1000 MPa. The electrically assisted tension and microscopic analysis were performed to study the effect of pulse current on their deformation behavior and microstructural evolution.

2 Experimental Methods

The chemical compositions of two AHSS are shown in Table 1. The thicknesses of MS1300 and QP980 steel sheets are 1.4 and 1.2 mm, respectively. The sheet was wire cut to obtain tensile specimens with a gauge length of 35 mm × 6 mm. The electrically assisted tension and pulse current treatment without stretching were carried out on a SANS testing machine. The initial strain rate was 10^{-3} s^{-1}. The pulse current was supplied by TSGZ-2.0KVA capacitor banks. The amount of pulse current was measured by a Tektronix oscilloscope. FLIR-A651 thermal imager was used to record the specimen temperature variation. Each tension under the same condition was repeated with a minimum of three samples to ensure repeatability and reproducibility.

In the microscopic analysis experiment, the microstructure of UHSS was observed by Zeiss optical microscope. The phase analysis of the specimen was performed on

Table 1 Chemical compositions of MS1300 and QP980 sheet (wt%)

Material	C	Si	Mn	P	S	Fe
MS1300	0.18	0.37	1.55	0.011	0.002	Balance
QP980	0.20	1.49	1.80	0.017	0.0043	Balance

the D8 Advance X-ray diffractometer. The XRD measurements were carried out between 30° and 95° at room temperature by using a diffractometer with Cu target and a step size of 0.02°. The fracture morphology was observed by TESCAN Mira3 scanning electron microscope.

3 Results and Discussion

The microstructure of UHSS needs to be finely regulated since the phase transformation easily occurs at high temperatures [9]. Therefore, excessive current should not be introduced into EAF to avoid changing their microstructure. In the following experiment, the output voltage was fixed to 30 V. The current density was changed by adjusting the pulse current frequency to study the influence of pulse current on the tensile behavior of MS1300 steel.

As shown in Table 2, the current density has a significant effect on the tensile properties of MS1300 steel. The elongation under the current density of 5.60– 7.49 A/mm^2 has an increase compared to that tested at room temperature. Under the current density of 6.58 A/mm^2, the elongation can be increased to 12.4%. The result is similar to the conclusions of Xie et al. [10]. The pulse current helps to increase the elongation within a certain range. But when the current density is too large, it generates a higher temperature in the necking region to accelerate the specimen fracture. The elongation declines instead.

As shown in Fig. 1 and Table 2, when the specimen temperature increases the elastic modulus gradually decreases, and the flow stress slightly rises. The peak stress during the tensile process first increases and then decreases in the current density range of 4.99–6.58 A/mm^2. The peak stress of MS1300 steel exceeds that tested at room temperature. Lin and Zhang [11] have carried out high temperature tension tests on MS1400 steel of Baosteel by using Gleeble1500 thermal simulation testing machine. The results showed that the flow stress of martensitic steel monotonously decreased with the increase of temperature. Therefore, the non-thermal effect of pulse current makes the flow stress of MS1300 steel increase. The current density

Table 2 Electrically assisted tension results of MS1300 steel at different current densities

Current density (A/mm^2)	Temperature (°C)	Peak stress (MPa)	Elongation (%)
0	20	1357.7	8.3
4.99	145	1410.1	6.5
5.60	178	1458.5	8.5
6.02	212	1442.3	12.2
6.58	240	1461.2	12.4
7.03	279	1342.6	11.6
7.49	310	1298.8	11.2

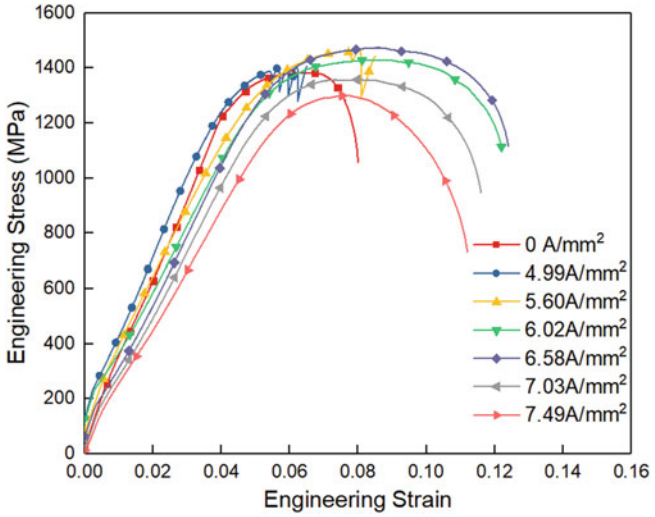

Fig. 1 Engineering stress–strain curves of MS1300 at different current densities. (Color figure online)

is further increased to 7.49 A/mm^2, and the flow stress of MS1300 steel decreases. The joule heating effect dominates, and it increases the temperature and softens the specimens. In addition, when the current density is 4.99 A/mm^2, the temperature of MS1300 specimen only reaches 145 °C. But the elongation is abnormally decreased. It shows that pulse current causes low-temperature temper embrittlement of MS1300 steel [12].

A similar experimental method was selected for QP980 steel, and the output voltage was fixed to 20 V. The testing results are listed in Table 3. The tensile deformation behavior of QP980 steel significantly varies at different current densities. The tensile strength of QP980 in the electrically assisted tension process is lower

Table 3 Electrically assisted tension results of QP980 steel at different current densities

Current density (A/mm^2)	Temperature (°C)	Peak stress (MPa)	Elongation (%)
0	20	1041.7	22.3
3.31	67	970	23.15
5.39	165	890	25.8
6.47	230	890	30.3
7.46	295	900	38.4
8.37	355	923	35.5
9.86	510	1020	23.3
10.78	600	790	15.3

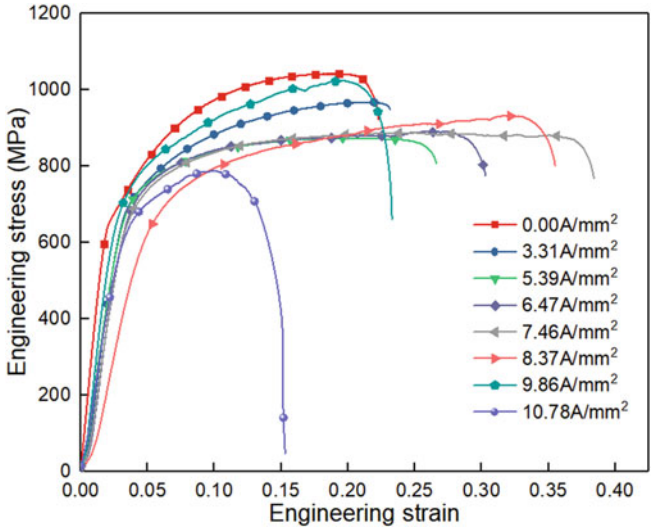

Fig. 2 Engineering stress–strain curves of QP980 at different current densities. (Color figure online)

than that tested at room temperature. But it does not show obvious regularity. It indicates that the effect of pulse current on the deformation behavior of QP980 is not solely caused by the joule heating effect. On the one hand, the temperature increase reduces the strength of QP980 steel. On the other hand, the non-thermal effect of pulse current may increase the flow stress of QP980 steel. Under the pulse current of 9.86 A/mm^2, the peak stress reaches 1020 MPa and it is close to that tested at room temperature. Further increasing the current density, the thermal effect may play a leading role, and the flow stress of QP980 steel decreases rapidly (Fig. 2).

With the increase of pulse current density, the elongation of QP980 steel after electrically assisted tension first increases and then decreases. It rises from 22.3% at room temperature to 38.4% at current density of 7.46 A/mm^2. When the current density is further increased, the elongation decreases instead. The thermal effect of pulse current gradually dominates. The higher current density in necking section results in a local temperature increase that accelerates the fracture process.

The microstructure near the fracture zone of the stretched specimens is shown in Fig. 3. The original microstructure of MS1300 steel is composed of acicular martensite and ferrite. The martensite is the main phase. The ferrite is distributed in the martensite matrix. After electrically assisted tensions with a current density of 4.99–7.49 A/mm^2, the basic phase compositions of the stretched specimen have no significant change. When the current density is controlled in relatively low value ranges, the elongation of MS1300 steel can be increased without destroying its microstructure or reducing its strength. Nevertheless, the elongation variation may result from the direct effect of the drift electrons on dislocation motion [13, 14]. Dislocation pile-ups and tangles are overcome and the plasticity is differently improved by pulse current with various densities.

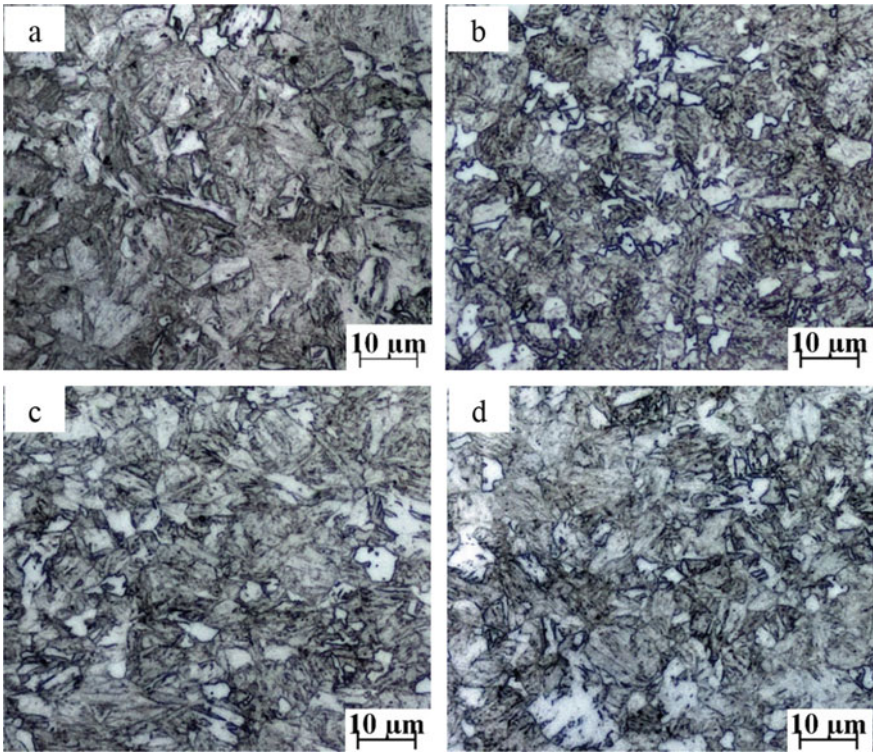

Fig. 3 Microstructure of MS1300 specimens after stretching at different current densities: **a** 0, **b** 4.99 A/mm^2, **c** 6.58 A/mm^2, **d** 7.49 A/mm^2. (Color figure online)

Further increasing the current density to 9.21 and 12.03 A/mm^2, the pulse current treatments were performed on the specimens without stretching for 100 s. Their temperatures reached 427 °C and 706 °C, respectively. As indicated in Fig. 4, there is a significant microstructural change. Figure 4a shows that the boundaries between ferrite and martensite are blurred. The carbide in the martensite matrix precipitates and diffuses into ferrite to form an intermediate phase. Figure 4b shows that the decomposition of martensite and the diffusion rate of carbide increases greatly after the high temperature and electron wind effect produced by pulse current. After 100 s treatment at relatively high current density, the martensite almost disappears. The recrystallization occurs and the new grains tend to be equiaxed.

The microstructure near fracture zones of electrically assisted tension specimens of QP980 was observed in Fig. 5. Figure 5a shows the optical microstructure of QP980 after stretching at room temperature. It contains a large amount of martensite, and the rest is mainly ferrite. The temperature reaches 67 °C at 3.31 A/mm^2. The microstructure is nearly the same as that stretched at room temperature. This indicates that the low-density current can reduce the flow stress without changing the microstructure of QP980 steel. When the pulse current density of 6.47 A/mm^2

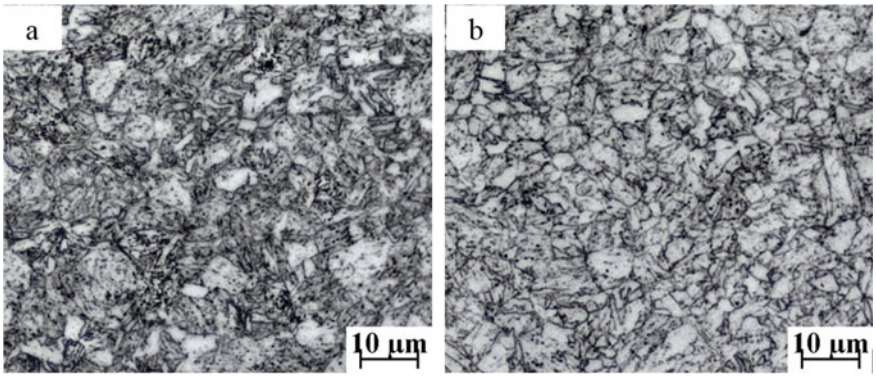

Fig. 4 Microstructure of MS1300 steel after 100 s pulse current treatment without stretching: **a** 9.21 A/mm^2, **b** 12.03 A/mm^2. (Color figure online)

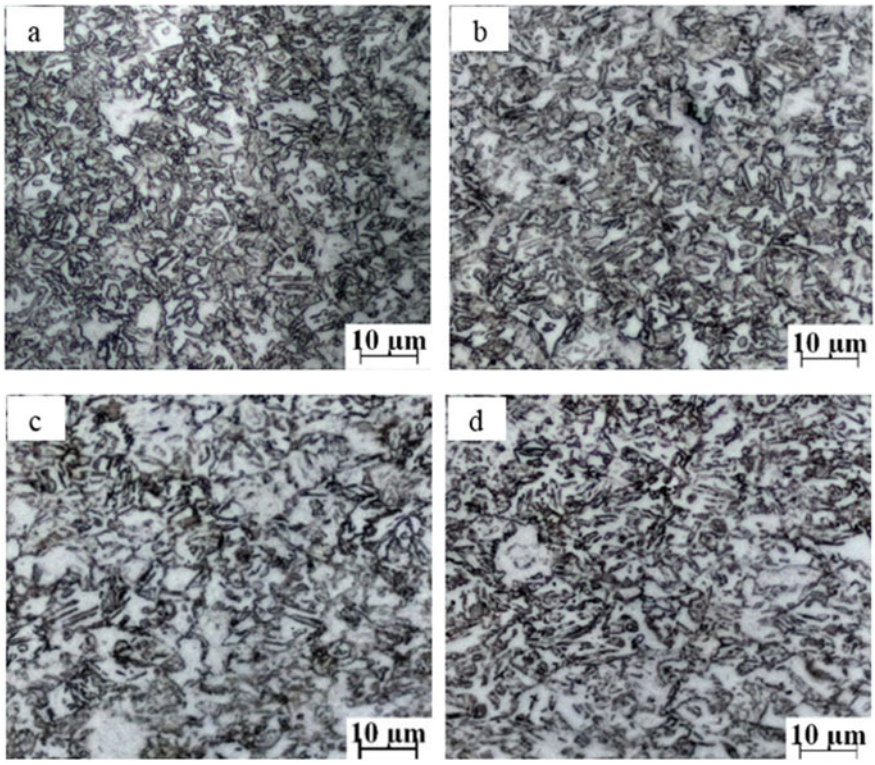

Fig. 5 Microstructure of QP980 specimens after stretching at different current densities: **a** 0, **b** 3.31 A/mm^2, **c** 6.47 A/mm^2, **d** 9.86 A/mm^2. (Color figure online)

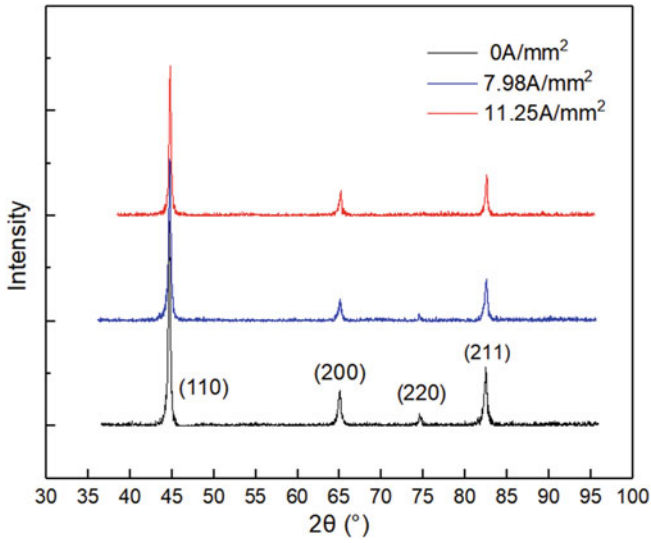

Fig. 6 Diffraction pattern of QP980 steel after pulse current treatment without stretching at different current densities. (Color figure online)

is applied, the temperature reaches 230 °C. Figure 5c shows that its microstructure is changed significantly. The martensite content is obviously reduced, and the ferrite fraction is increased. The deformation process is accompanied by the martensite decomposition, which partly reduces the tensile strength of QP980 steel. A similar transformation appears at 9.86 A/mm^2 as indicated in Fig. 5d.

The retained austenite in QP980 steel can be transformed into martensite during the plastic deformation. Therefore, in order to study the effect of pulse current on the retained austenite of QP980, the undeformed QP980 sheet was treated by pulse current for 100 s. The XRD analysis was carried out to obtain the diffraction patterns as shown in Fig. 6. It can be seen that the XRD diffraction patterns of original QP980 steel mainly consist of four peaks of (110), (200), (220), and (211). The (220) peak corresponds to the austenite. When the current density is 7.98 A/mm^2, the peak intensity of (200) weakens. It indicates that the austenite content is reduced due to the effect of pulse current. When the current density increases to 11.25 A/mm^2, the (200) peak disappears, which indicates that excessive current can cause the decomposition of retained austenite.

Figure 7 shows fracture morphologies of QP980 specimens after stretching at different current densities. For the as-received QP980 steel, large quantities of small voids distribute on the fracture surface, indicating the ductile fracture characteristics. When the current density of 7.46 A/mm^2 is applied, the voids become larger and deeper, which demonstrate better plasticity. Actually, the highest elongation of 38.4% is obtained at 7.46 A/mm^2 as shown in Table 3. Therefore, the fracture morphology observation accords to the electrically assisted tension results.

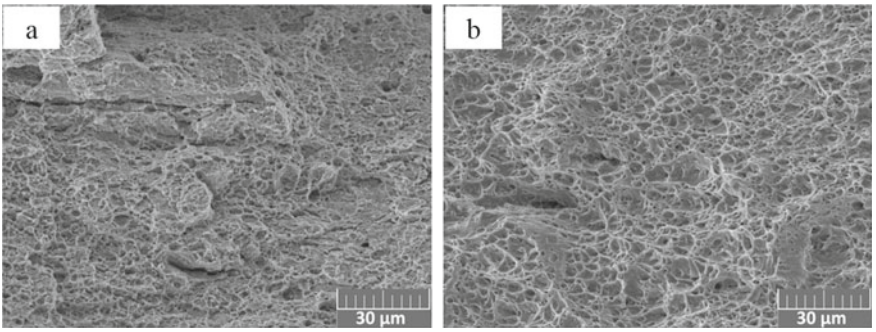

Fig. 7 Fracture morphologies of QP980 specimens after stretching at different current densities: **a** 0, **b** 7.46 A/mm^2

4 Conclusions

(1) Pulse current can improve the tensile deformation behavior of ultrahigh-strength steel. For MS1300 steel, the elongation can be increased from 8.3% at room temperature to 12.4% at a current density of 6.58 A/mm^2. The peak stress of QP980 is reduced to 900 MPa at a current density of 7.46 A/mm^2, and the elongation is increased from 22.3% at room temperature to 38.4%.

(2) The non-thermal effect of current may cause the abnormal rise of flow stress in ultrahigh-strength steel. For MS1300 steel, the peak stress of the electrically assisted tension in the current density range of 4.99–6.58 A/mm^2 exceeds that tested at room temperature. For QP980 steel, its peak stress obviously varies when the current density is increased from 3.31 to 10.78 A/mm^2.

Experimental Study and Modelling of Stress Relaxation Ageing Behaviour and Post-form Mechanical Properties in Creep Age Forming of Al-Zn-Mg Alloy

Yong Li, Fenggong Lyu, Zhusheng Shi, Yuansong Zeng, Xia Huang, and Jianguo Lin

Abstract The stress relaxation ageing behaviour and post-form mechanical properties of an Al-Zn-Mg alloy, AA7B04, have been experimentally investigated and modelled. The stress relaxation ageing tests were carried out under different initial stress levels and durations at 165 °C and subsequent tensile tests were performed at room temperature. The detailed effects of stress and time on stress relaxation and main post-form mechanical properties (yield strength, ultimate tensile strength, and uniform elongation) have been analysed and discussed. Based on the results and analysis, a set of unified constitutive equations has been developed for the first time to simultaneously predict stress relaxation ageing behaviour of the aluminium alloy during the creep age forming (CAF) process and the main mechanical properties of the products after CAF. The model comprises three sub-models, including microstructure, stress relaxation ageing and post-form mechanical properties, and has successfully predicted corresponding behaviour. The developed model provides an effective tool to not only predict the forming process but also support possible industrial applications for CAF products.

Keywords Stress relaxation · Ageing · Post-form mechanical property · Al-Zn-Mg alloy · Constitutive model

1 Introduction

Creep age forming (CAF) is an advanced sheet forming technology that combines creep/stress relaxation and artificial ageing processes to concurrently deform and strengthen heat-treatable aluminium alloys, making it an efficient and accurate

method to manufacture large panels in the aerospace industry, such as wing skins [1, 2]. The integrated creep ageing or stress relaxation ageing (SRA) behaviour of aluminium alloys is a key factor to determine both the final shape and post-form mechanical properties of creep age formed (CAFed) products. Hence, it is important to systematically understand and predict the relationship between creep/stress relaxation and key mechanical properties during and after CAF so as to provide useful guidance for not only accurate forming but also successful applications of the CAFed products.

The creep ageing or stress relaxation ageing behaviour, including both key microstructures and macro-properties, of various heat-treatable aluminium alloys, such as Al-Cu-Mg [3], Al-Zn-Mg [4], and Al-Cu-Li [5], has been widely investigated in the last few decades and based on which many constitutive models have been proposed to predict the evolutions of precipitation, dislocation, creep/stress relaxation and yield strength during creep ageing for CAF process simulation [3, 6]. Except for the yield strength, other post-form mechanical properties of the CAFed materials, such as tensile strength and elongation, which are also key factors concerned for industrial applications, however, have attracted less attention currently. Li et al. [7] and Chen et al. [8] have investigated the work hardening behaviour, tensile strength, and uniform elongation properties of AA2050 and AA7050 materials after CAF, respectively, and the relationship between the microstructures and post-form mechanical properties has been discussed. However, the corresponding modelling work is still unavailable.

Hence, this study tries to perform a systematic investigation of the SRA behaviour during CAF and key post-form mechanical properties after CAF in both experimental and modelling ways. SRA and tensile tests of an Al-Zn-Mg alloy, AA7B04, have been performed for detailed analysis and discussion, and based on which a unified constitutive model to simultaneously predict both stress relaxation and key post-form mechanical properties has been proposed and discussed.

2 Materials and Experiments

The material investigated is AA7B04, with the main chemical composition of Al-5.97Zn-2.48 Mg-1.51Cu (wt%). The material was prepared with a special initial temper, named AA7B04-P, which had undergone solution heat treatment (SHT), water-quenching, pre-stretching, and a single-step artificial ageing to an under-aged state.

A set of SRA tests at 165 °C was performed under different initial stress levels (200, 250, 300, and 350 MPa) at different durations (2, 4, 8, and 16 h) to get the stress relaxation behaviour of the material. In addition, tensile tests at room temperature were also carried out on specimens after SRA tests to investigate the evolutions of main post-form mechanical properties of the material during SRA. The dog-bone specimens were prepared for both SRA and tensile tests, with the key dimension of 8 mm in radius and 50 mm in gauge length. Both kinds of tests were carried out on an

Instron 5584 machine with a furnace to provide a high-temperature environment. In SRA tests, specimens were first heated to 165 °C, then loaded to the initial stress level, and held for designated durations for stress relaxation behaviour characterisation. The quasi-static tensile tests were performed with a strain rate of 10^{-4} s^{-1}. Further details of the material and corresponding test conditions can be found in a previous study [4].

3 Experimental Results and Discussion

Figure 1 shows the stress relaxation curves of AA7B04-P at 165 °C. Higher initial stress leads to a more prominent stress relaxation behaviour, due to the larger creep strains generated at higher initial stress levels [4]. The remained stress after 16 h tests is generally larger with a higher initial stress level from 200 to 300 MPa; however, the remained stress for the initial stress of 350 MPa is lower than that for 300 MPa. This is because 350 MPa already exceeds the 0.01% offset yield point of the material (325 MPa) and the phenomenon may be explained by the additional initial dislocations introduced when loaded to the plastic region [4, 9].

The room temperature flow stress curves of the material after SRA tests under different initial stress levels at different durations have been plotted in Fig. 2. All the flow stress curves of the SRAed materials show a fair level of work hardening behaviour, in which the highest level of work hardening exists in the as-received material. The flow stress level becomes lower with increasing SRA time under the initial stress of 200 MPa. In addition, Fig. 2 compares the flow stress of the material after 16 h SRA tests under 200 and 300 MPa, and the results show that with a higher initial stress, a lower flow stress is observed in the material after the SRA test for the same duration.

Figure 3a shows the detailed ultimate tensile strength (σ_{UTS}) and yield strength (σ_y) values of the materials SRAed under initial stresses of 200 and 300 MPa.

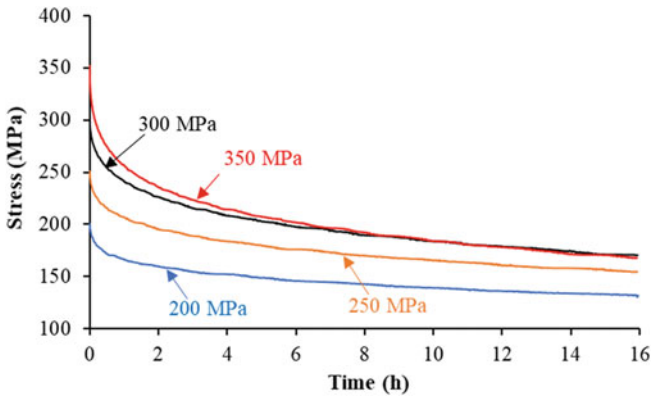

Fig. 1 Stress relaxation curves of AA7B04-P under different initial stress levels at 165 °C. (Color figure online)

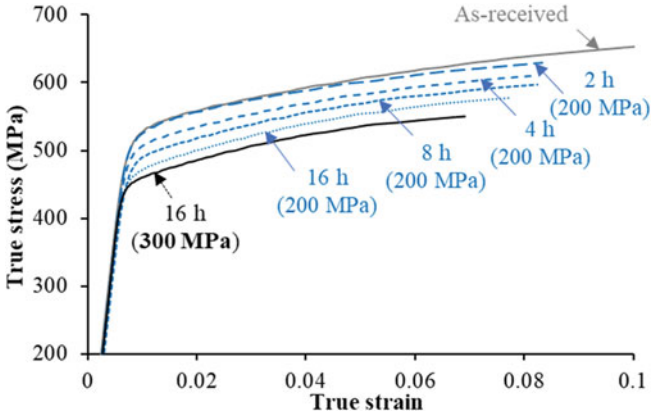

Fig. 2 The stress–strain curves of AA7B04-P after SRA tests at 165 °C for a different duration and under indicated initial stress levels. (Color figure online)

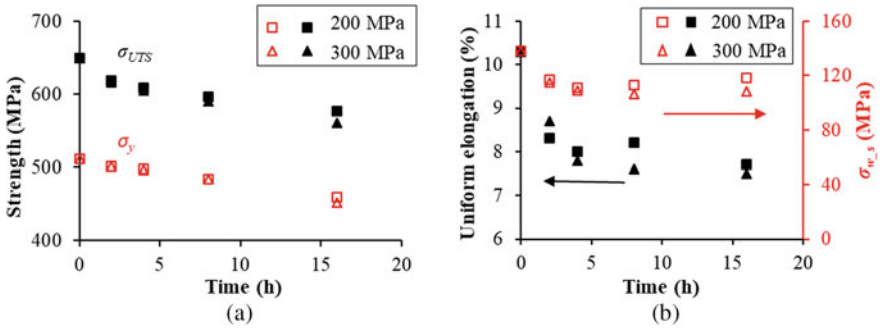

Fig. 3 Evolution of **a** ultimate tensile strength (σ_{UTS}) and yield strength (σ_y), and **b** uniform elongation and saturate work hardening stress (σ_{w_s}) versus SRA time for AA7B04-P at 165 °C. (Color figure online)

Although the as-received material is in an under-aged condition [4], yield strength of the material decreases after 2 h SRA tests and experiences a continuously decreasing trend afterwards, which indicate that over-ageing has already started after 2 h. With higher initial stress, slightly lower yield strength is observed in the SRAed materials under the same testing time and temperature, as higher initial stresses lead to larger stress relaxation/creep, which can accelerate the coarsening of precipitates in the material [10]. Meanwhile, σ_{UTS} shows the same trend with σ_y results.

The uniform elongation, as shown in Fig. 3b, decreases significantly at the first 2 h, which could be related to the depleted solutes in the material from under-ageing to over-ageing within the first 2 h [11]. Figure 3b also shows the saturate work hardening stress ($\sigma_{w_s} = \sigma_{UTS} - \sigma_y$) of the SRAed materials, which demonstrates a similar trend with the uniform elongation. It should be noted that a slight increase of

σ_{w_s} after 8 h SRA tests can be observed in Fig. 3b, which may be due to the size of non-shearable precipitates that grow to a high level after 8 h tests, and the geometrically necessary dislocations accumulated around these fine precipitates become high enough to facilitate the work hardening of the material [12].

4 Modelling

A unified constitutive model that utilises and modifies both the conventional creep-ageing and work hardening equations has been proposed in this study to simultaneously model and predict the stress relaxation behaviour during CAF and main post-form mechanical properties of the alloys after CAF. The developed model is divided into three sub-models, from microstructures to macro-properties, including microstructure, stress relaxation ageing, and post-form mechanical properties sub-models.

4.1 Microstructure Sub-model

The main microstructures related to the stress relaxation ageing behaviour of aluminium alloys include precipitates, solid solutes, and dislocations. The effect of precipitates on SRA behaviour has been generally characterised by its size (r) and volume fraction (f), while the effects from solid solutes and dislocations are represented by solute concentration (c) and dislocation density (ρ), respectively. All the microstructural variables are modelled as normalised values in this study to eliminate the high difficulties in obtaining the actual microstructure values. The evolutions of these main microstructural variables during SRA can be modelled by the following equations [6, 13]:

$$\dot{\overline{r}} = C_r(Q - \overline{r})^{m_1}\left(1 + \gamma_0\overline{\rho}^{m_2}\right) \tag{1}$$

$$\dot{\overline{c}} = -A_1(\overline{c} - \overline{c}_a)\left(1 + \gamma_0\overline{\rho}^{m_2}\right) \tag{2}$$

$$\dot{\overline{\rho}} = A_2(1 - \overline{\rho})|\dot{\varepsilon}_c|^{m_3} - C_p\overline{\rho}^{m_4} \tag{3}$$

$$\overline{f} = \frac{1 - \overline{c}}{1 - \overline{c}_a} \tag{4}$$

$\overline{r}$ in Eq. (1) is the normalised precipitate radius defined as $\overline{r} = r/r_c$, where r_c is the critical radius at peak-ageing state. $\overline{r}$ then evolves from 0 at SHT state to 1 at peak-ageing state, and $\overline{r} \geq 1$ indicates over-ageing states. Q represents the maximum size

of precipitates during SRA of the alloys. $\overline{c}$ in Eq. (2) is the normalised solute concentration defined as $\overline{c} = c/c_s$, in which c_s is the solute concentration at SHT temperature. $\overline{c}_a$ is the normalised value at the test temperature. $\overline{\rho} = (\rho - \rho_0)/(\rho_s - \rho_0)$ is the normalised dislocation density, in which ρ_0 and ρ_s are dislocation density of the material before SRA tests and its maximum level during SRA tests, and thus, $\overline{\rho}$ generally evolves from 0 to 1 during the SRA tests. The accumulation and dynamic recovery effects of dislocations during SRA are considered in the first term on the right-hand side of Eq. (3), while the second term represents the static recovery effect. In addition, the normalised volume fraction of precipitates $\overline{f} = f/f_s$, in which f_s is the final equilibrium value of f during ageing, can be directly modelled by corresponding solute concentrations according to Eq. (4). Other parameters in Eqs. (1) to (4) are material constants and will be determined in Sect. 5.1.

4.2 Stress Relaxation Ageing Sub-model

The stress relaxation ageing sub-model contains two parts, one for the modelling of stress relaxation curves and the other for yield strength evolutions during the SRA tests. It is generally believed that the stress relaxation during SRA comes from creep strains and can be directly modelled according to the evolutions of creep strains. The creep behaviour is determined by related microstructural variables and can be modelled by the following equations [6]:

$$\dot{\varepsilon}_c = A_4 \sinh[B_1(\sigma - \sigma_{th})(1 - H)]\text{sign}(\sigma) \tag{5}$$

$$H = k_1\overline{\rho} + k_2\overline{c} + k_3\overline{r} \tag{6}$$

$$\dot{\sigma} = -E\dot{\varepsilon}_c \tag{7}$$

$\dot{\varepsilon}_c$ is the creep strain rate, which is modelled by the sinh function of applied stress σ, creep threshold stress σ_{th} and a variable H representing the combined effect from key microstructural variables in Eq. (6). E is the Young's modulus of the material, and the stress relaxation rate can be directly related to creep strain rate by Eq. (7). A_4, B_1, k_1, k_2, and k_3 are material constants to be determined in Sect. 5.1.

However, for yield strength (σ_y), it is comprised of three strengthening components from different microstructures, including dislocation hardening (σ_{dis}), precipitation hardening (σ_p), and solid solution hardening (σ_{ss}), which can be modelled as [14]:

$$\sigma_{dis} = A_3\overline{\rho}^n \tag{8}$$

$$\sigma_p = \sigma_r\overline{f}^{m_5} \tag{9}$$

$$\dot{\sigma}_r = C_a \dot{\bar{r}}^{m_7} \left(1 - \bar{r}^{m_8}\right) \tag{10}$$

$$\sigma_{ss} = C_{SS} \bar{c}^{m_{10}} \tag{11}$$

$$\sigma_y = \sigma_{ss} + \sigma_a = \sigma_{ss} + \sqrt{\sigma_{dis}^2 + \sigma_p^2} \tag{12}$$

in which A_3, n, m_5, C_a, m_7, m_8, C_{SS}, and m_{10} are material constants to be determined. A classic law of mixtures is utilised to combine the strengthening components for yield strength in Eq. (12), in which σ_a represents the combined effect from dislocations and precipitates.

4.3 Post-form Mechanical Properties Sub-model

Work hardening behaviour determines the post-form mechanical properties of ultimate tensile strength and uniform elongation. It has been reported that work hardening behaviour of aluminium alloys during plastic deformation is generally attributed to dislocation hardening: the statistically stored dislocations (ρ_{ss}) from interactions with weak obstacles (shearable precipitates) and solid solutes, and the geometrically necessary dislocations (ρ_{gn}) stored around strong obstacles (non-shearable precipitates) [15]. Both parts of dislocations would contribute to the work hardening behaviour during SRA of AA7B04-P in this study according to the results in Sect. 3, and the following equations are utilised to model their evolutions and effects on work hardening [14, 16]:

$$\dot{\bar{\rho}}_{ss} = k_4 * \bar{c}^{n_1} * \left(1 - \bar{\rho}_{ss}\right) \dot{\varepsilon}_p^{n_2} \tag{13}$$

$$\bar{\rho}_{gn} = \frac{k_5}{\bar{r}^{n_3}} \left[1 - \exp\left(-\dot{\varepsilon}_p^{n_4}\right)\right] \tag{14}$$

$$\sigma_d = C_d \sqrt{\bar{\rho}_{ss} + \bar{\rho}_{gn}} \tag{15}$$

$$\sigma_f = \sigma_{ss} + \sqrt{\sigma_d^2 + \sigma_a^2} \tag{16}$$

$$\sigma_w = \sigma_f - \sigma_y \tag{17}$$

The normalised values of ρ_{ss} and ρ_{gn} are used for modelling in Eqs. (13) and (14), and their contributions to work hardening have been represented by σ_d with the classic law of mixtures in Eqs. (15) and (16). The actual work hardening stresses

shown in the stress–strain curves in Fig. 2 then are represented by σ_w in Eq. (17). In addition, k_4, n_1, n_2, k_5, n_3, and n_4 are material constants.

5 Modelling Results and Discussion

5.1 Calibration of the Model

The AA7B04-P material has been reported to achieve the peak-ageing state after artificial ageing at 165 °C for about 4 h, with an average precipitate radius of about 4.5 nm at the as-received state and 5 nm after 165 °C/4 h artificial ageing [4]; hence, the initial value of normalised precipitate radius $\overline{r}_0$ is determined as 0.9. A cell assumption was used to relate the volume fraction and radius of precipitate, as $\overline{f} = (r/r_c)^3$ [6], and the initial value of normalised volume fraction $\overline{f}_0$ was approximately 0.72. $\overline{c}_0$ was then determined by Eq. (4). The initial values of the strengthening components were approximately determined according to [17]. The initial values of all the variables are listed in Table 1.

Based on the initial values determined in Table 1, a combination of manual adjusting and computational curve fitting method was utilised to calibrate all the material constants in the developed constitutive model according to the experimental data in Sect. 3, as detailed in [6, 14]. The determined material constants are listed in Table 2.

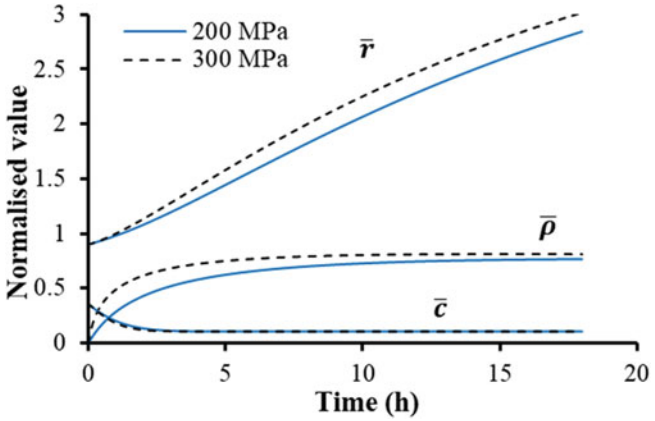

Fig. 4 Modelled evolution of normalised values of dislocation density ($\bar{\rho}$), precipitate radius ($\bar{r}$), and solid solution concentration ($\bar{c}$) in AA7B04-P during 16 h SRA tests at 165 °C under different initial stresses. (Color figure online)

5.2 Microstructural Evolutions

Figure 4 shows the evolution of normalised microstructural variables during SRA tests under 200 and 300 MPa from modelling results according to the material constants in Table 2. The normalised precipitate radius $\bar{r}$ increases continuously along the SRA time, and achieves to 1 (peak-ageing state) within 2 h, which shows the same trend with yield strength results obtained in Fig. 2, indicating the rationality of the modelling results [4]. The accelerated coarsening of precipitates at higher initial stress levels has also been successfully predicted in Fig. 4 [1]. Meanwhile, the normalised solute concentration $\bar{c}$ decreases to a stable level before 2 h, indicating an over-ageing behaviour after 2 h as well. The normalised dislocation density $\bar{\rho}$ increases significantly in the first couple of hours and gradually reaches a saturate level afterwards, which shows the same trend with many previous studies [1, 3]. In addition, more dislocations under higher initial stresses in SRA tests have also been well predicted by the developed model.

5.3 Stress Relaxation Behaviour

The stress relaxation curves under different initial stress levels from experiments and corresponding modelling results are compared in Fig. 5. A good correspondence between them has been achieved, especially for initial stress levels from 200 to 300 MPa, indicating the effectiveness of the model and determined material constants in modelling the stress relaxation behaviour of the alloys in the elastic region. When the initial stress increases to 350 MPa and exceeds the 0.01% offset yield stress, the

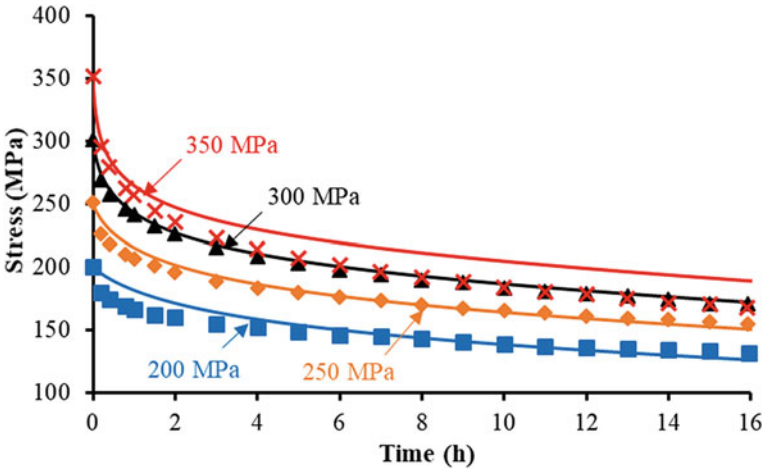

Fig. 5 Comparison of stress relaxation curves of AA7B04-P after 165 °C/16 h SRA tests under indicated initial stress levels from experiments (symbols) and modelling (solid lines). (Color figure online)

model predicts a larger remained stress compared with the experimental results; the reason could be attributed to the different stress relaxation mechanisms in the plastic region as reported in [5], which has not been considered in the model developed in this study.

5.4 Yield Strength Behaviour

Figure 6 compares the experimental and modelling results of the evolutions of yield strength and strengthening components during SRA tests. A good agreement between experiments and models in yield strength has been achieved, indicating the effectiveness of the developed model. A slight increase of yield strength σ_y has been well predicted within the first 2 h of SRA tests, due to the combined effect from precipitation hardening σ_p, dislocation hardening σ_{dis} and solid solution hardening σ_{ss}, as shown in Fig. 6. In addition, the effect of higher initial stress levels in accelerating the softening of the over-aged material has also been successfully modelled in Fig. 6.

5.5 Work Hardening Behaviour

The work hardening stress σ_w versus plastic strain ε_p curves from experiments and modelling results are compared in Fig. 7. Based on the predicted microstructures in Fig. 4 at different time states of SRA tests, the predicted work hardening results

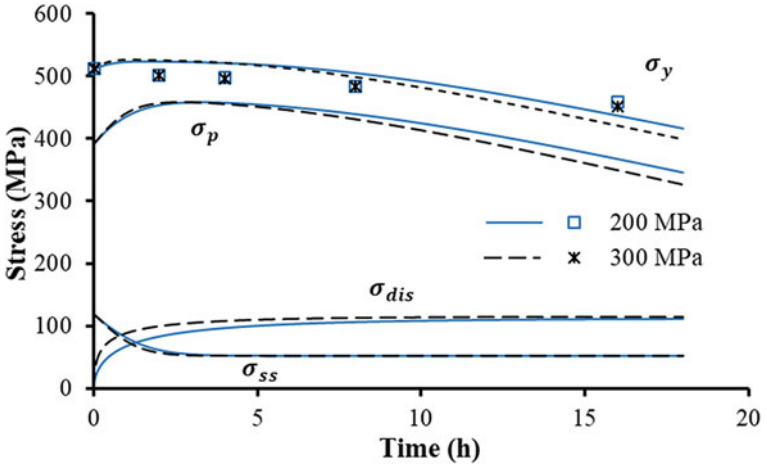

Fig. 6 Evolution of yield strength σ_y and strengthening components from precipitates σ_p, dislocations σ_{dis}, and solid solutes σ_{ss} of AA7B04-P during 16 h SRA tests at 165 °C from experiments (symbols) and modelling (lines). (Color figure online)

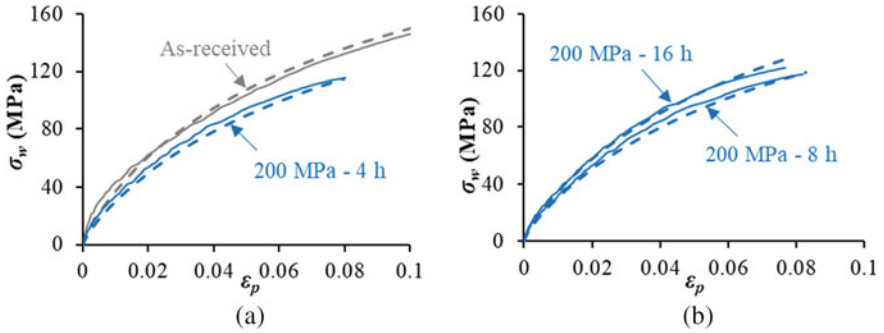

Fig. 7 Comparison of plastic stress versus plastic strain curves of AA7B04-P after SRA tests at 165 °C under initial stress of 200 MPa with indicated time durations from experiments (solid lines) and simulations (dashed lines). (Color figure online)

all correspond well with experimental results for the SRAed alloy with different durations in Fig. 7. In addition, the increase of work hardening stress after 8 h SRA tests has also been well predicted in Fig. 7b. All these results help to demonstrate the effectiveness of the developed model in predicting both microstructures and macro-properties of the alloys during and after SRA tests.

6 Conclusions

The stress relaxation ageing behaviour during CAF and post-form properties after CAF of AA7B04-P material at 165 °C have been experimentally investigated in this study. Higher initial stress leads to more apparent stress relaxation behaviour. Over-ageing occurs within the first 2 h of SRA tests, after which both lower yield strength and ultimate tensile strength can be observed with higher initial stressess. The uniform elongation and saturate work hardening stress show similar trends during SRA, decrease first, and experience a minor increasing trend after 8 h, which may be attributed to the accumulated geometrically necessary dislocations from the well-developed non-shearable precipitates.

A unified constitutive model, which is divided into three sub-models (microstructure, stress relaxation ageing, and post-form mechanical properties), has been developed in this study. The model, for the first time, simultaneously predict the stress relaxation ageing and key post-form mechanical properties in both micro and macro-sides during and after SRA tests, providing a solid and effective tool to predict the forming process and support potential industrial applications. It should be noted that the current model excellently predicts the SRA-related behaviour in the elastic region; however, more work needs to be done to accurately predict the SRA behaviour in both elastic and plastic regions.

Acknowledgments The research in this paper was funded by the National Natural Science Foundation of China (52005020) and Guangdong Basic and Applied Basic Research Foundation (2019A1515110851). The strong support from the Aviation Industry Corporation of China (AVIC) Manufacturing Technology Institute (MTI) for this funded research is much appreciated. The experiments in this study were performed at the AVIC Centre for Structural Design and Manufacture at Imperial College London.

Flow Behavior and Processing Map of a Nickel-Based Superalloy During Hot Plastic Deformation Process

Baoyun Zhang, Shuo Huang, Wenyun Zhang, Beijiang Zhang, and Yongquan Ning

Abstract Nickel-based superalloys have been widely used to produce high-performance components in advanced engines. In present research, isothermal compression tests of GH4065A nickel-based superalloy were conducted at deformation temperatures of 1020–1140 °C and strain rates of 0.001–1.0 s^{-1}. The deformation temperature and strain rate have a significant effect on the flow curves, from which the intrinsic connection between the flow stress and deformation behavior can be systematically investigated. The deformation activation energy of the studied alloy was calculated to be 521.65 kJ·mol^{-1} at the strain of 0.5 when the flow stress was steady. Meanwhile, the constitutive equation was constructed for modeling the hot plastic deformation, and the prediction accuracy of flow stress was well verified. Based on the combination of processing map and microstructural observation, two instability domains were delineated as follows: Domain #1: 1020–1065 °C/0.25–1.0 s^{-1}; Domain #2: 1130–1140 °C/0.001–0.002 s^{-1}. In addition, the instability mechanism of these two domains was deeply discussed. The results obtained in this research would provide effective theoretical guidance for manufacturing high-performance components in advanced engines.

material for critical rotating components in the range of 700–750 °C of high-performance aero-engines due to its outstanding microstructural stability and excellent mechanical properties. Generally, proper combination of hot deformation parameters such as strain rate and deformation temperature can improve the workability of novel superalloy effectively [1, 2]. However, obtainable information on the hot deformation behavior of GH4065A nickel-based superalloy can be hardly found in the present open literature. Thus, it is vital to investigate the flow behavior and microstructural evolution of the GH4065A nickel-based superalloy during hot plastic deformation.

In present research, uniaxial compression tests were carried out on the GH4065A nickel-based superalloy at different deformation temperatures and strain rates. On the basis of compression results, the flow behavior and constitutive model were deeply investigated. Moreover, processing map was also established to further study the hot workability of alloy GH4065A, and the domains of flow instability were identified.

2 Material and Experiments

The alloy GH4065A investigated in present work was supplied by Central Iron and Steel Research Institute, Beijing. Its chemical composition in weight percent is listed in Table 1. The initial microstructure of the as-received GH4065A nickel-based superalloy is illustrated in Fig. 1a. Small equiaxed recrystallized grains and large agglomerated non-recrystallized grains can be observed before hot deformation, showing a typical mixed grain structure. Figure 1b, c gives out the various morphologies of γ' precipitate in two different regions, respectively. It can be found that coarse γ' phases are mainly distributed at recrystallization regions, while a large number of fine γ' precipitates exist in non-recrystallization regions.

Cylindrical specimens of 8 mm in diameter and 12 mm in height were electro-discharge prepared from the GH4065A nickel-based superalloy experimental billet. With a heating rate of 10 °C/s, compression specimens were heated to deformation temperatures (1020, 1050, 1080, 1110, and 1140 °C) in the Gleeble-3800 thermo-mechanical simulator, held at deformation temperature for 5 min in order to eliminate thermal gradient. Subsequently, the specimens were compressed to 50% reduction in height accounting true strain of 0.69 at four different strain rates (0.001, 0.01, 0.1, and 1.0 s^{-1}). The deformed specimens were quenched immediately, using water, to preserve the microstructure formed during hot deformation. Eventually, the specimens were sliced along the compression axis, and the microstructural observation

was carried out by optical microscopy (OM) with the chemical etchant of $CuCl_2$ (20 g) + HCl (100 mL) + C_2H_5OH (100 mL).

3 Results and Discussion

3.1 Flow Behavior

The flow curves of the GH4065A nickel-based superalloy obtained via isothermal compression tests under different deformation conditions are illustrated in Fig. 2. Obviously, the effects of deformation temperature and strain rate on the flow behavior of the alloy GH4065A are remarkable. Generally, the curvilinear trend of flow curves is capable of reflecting the inherent relationship between the flow stress and thermal-dynamic behavior. At the beginning of deformation, the strain hardening, which is guided by the generation and multiplication of dislocations [3, 4], results in the sharply increase of the flow stress to a peak value. With the increase of strain, the

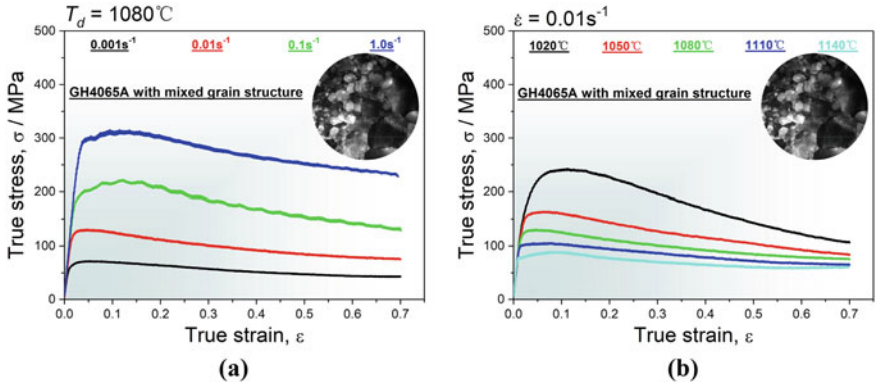

Fig. 2 Selected flow curves of the GH4065A nickel-based superalloy at different deformation conditions: **a** 1080 °C; **b** 0.01 s^{-1}. (Color figure online)

dynamic softening behavior induced by dislocation cross-slip and climb such as dynamic recovery and dynamic recrystallization begin to appear, and thus partially counterbalancing the effect of strain hardening [5, 6]. Consequently, the flow stress gradually reduces to a certain extent after the peak value. With the further increase of deformation degree, dynamic recrystallization becomes the dominant deformation mechanism. Finally, the platform of flow stress occurs at the high-strain zone due to the dynamic equilibrium between strain hardening and dynamic softening is achieved and the dislocation density maintains relatively constant [7].

In addition, it is noteworthy that peak flow stresses increase with the augment of strain rate, whereas they all decrease with deformation temperature increasing. Under relatively high strain rate, the reduction of deformation time increases the strain hardening effect and restrains the nucleation and growth of dynamic recrystallization grains [8]. The average kinetic energy of atoms increases with the augment of deformation temperature. Meanwhile, the elevated deformation temperature provides the higher movability of grain boundaries [9].

3.2 Constitutive Equation

The constitutive equations associated with various deformation parameters such as deformation temperature and strain rate are utilized to depict the flow behavior during hot plastic deformation. In this work, the Arrhenius constitutive equation proposed by Sellars and Mctegart [10] is employed to investigate the deformation behavior of the GH4065A nickel-based superalloy, as follows:

$$\dot{\varepsilon} = A_1 \sigma^{n_1} \exp\left(-\frac{Q}{RT}\right) \alpha\sigma < 0.8 \tag{1}$$

$$\dot{\varepsilon} = A_2 \exp(\beta\sigma) \exp\left(-\frac{Q}{RT}\right) \alpha\sigma > 1.2 \tag{2}$$

$$\dot{\varepsilon} = A[\sinh(\alpha\sigma)]^n \exp\left(-\frac{Q}{RT}\right) \text{ for all } \sigma \tag{3}$$

where $\dot{\varepsilon}$ is strain rate (s^{-1}); σ is flow stress (MPa); T is deformation temperature (K); Q is activation energy of hot deformation ($kJ \cdot mol^{-1}$); R is molar gas constant (8.314 $J \cdot mol^{-1} \cdot K^{-1}$). Moreover, A_1, A_2, A, β, n_1, n, and α ($\alpha = \beta/n_1$) are material constants.

Taking the natural logarithm on both sides of Eqs. (1)–(3), the following equations can be obtained:

$$\ln\dot{\varepsilon} = n_1 \ln\sigma + \left(\ln A_1 - \frac{Q}{RT}\right) \tag{4}$$

$$\ln\dot{\varepsilon} = \beta\sigma + \left(\ln A_2 - \frac{Q}{RT}\right) \tag{5}$$

$$\ln\dot{\varepsilon} = n \ln[\sinh(\alpha\sigma)] + \left(\ln A - \frac{Q}{RT}\right) \tag{6}$$

In this paper, the material constants were calculated at the strain of 0.5 when the flow stress was steady. Based on Eqs. (4) and (5), the values of n_1 and β can be obtained as 4.509 and 0.0369 from linear fitting between the lnσ–ln $\dot{\varepsilon}$ and σ–ln $\dot{\varepsilon}$, which were plotted as shown in Fig. 3a, b. Thus, the α value was calculated to be 0.00819.

Taking the partial derivative on both sides of Eq. (6), the n and Q can be expressed as:

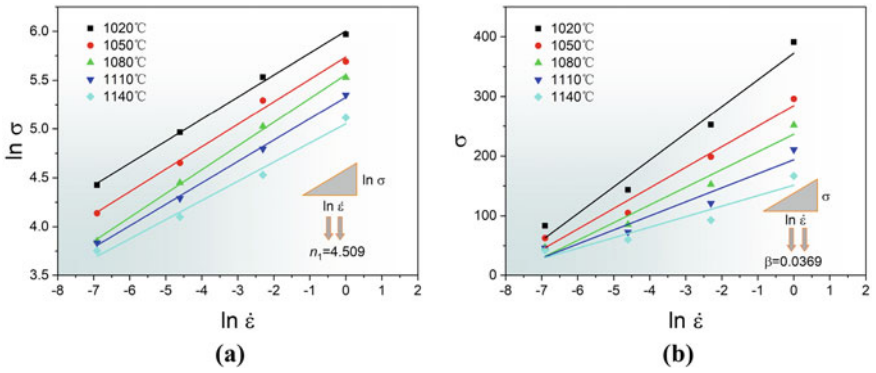

Fig. 3 Relationships between **a** lnσ–ln $\dot{\varepsilon}$; **b** σ–ln $\dot{\varepsilon}$. (Color figure online)

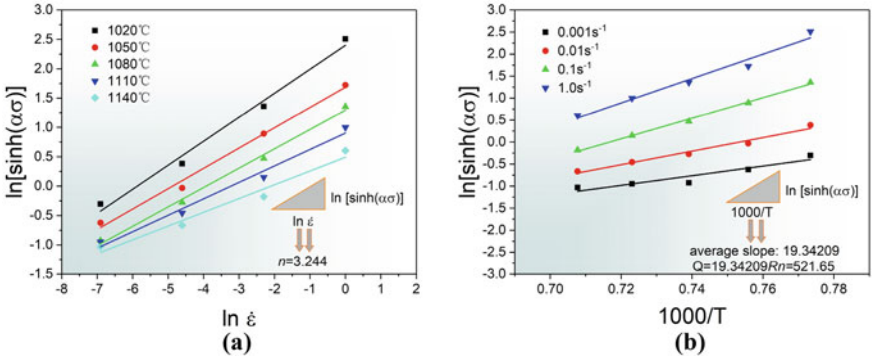

Fig. 4 Relationships between **a** ln[sinh(ασ)]–ln $\dot{\varepsilon}$; **b** ln[sinh(ασ)]–1000/T. (Color figure online)

$$n = \left.\frac{\partial \ln \dot{\varepsilon}}{\partial \ln[\sinh(\alpha\sigma)]}\right|_T \tag{7}$$

$$Q = Rn \left.\frac{\partial \ln[\sinh(\alpha\sigma)]}{\partial(1/T)}\right|_{\dot{\varepsilon}} \tag{8}$$

According to Eqs. (7) and (8), the linear relationships of ln[sinh(ασ)]–ln $\dot{\varepsilon}$ and ln[sinh(ασ)]–1000/T can be given, as shown in Fig. 4a, b, respectively. From Fig. 4, these data can be obtained: $n = 3.244$, $Q/Rn = 19.34209$. Therefore, the activation energy of the GH4065A nickel-based superalloy can be derived as 521.65 kJ·mol^{-1}.

Considering the effects of deformation temperature and strain rate, the Zener–Hollomon parameter is introduced [11]:

$$Z = \dot{\varepsilon} \exp\left(\frac{Q}{RT}\right) = A[\sinh(\alpha\sigma)]^n \tag{9}$$

Treating Eq. (9) by natural logarithm, the following equation can be obtained:

$$\ln Z = \ln A + n \ln[\sinh(\alpha\sigma)] \tag{10}$$

Figure 5 illustrates the linear relationship between ln$Z$ and ln[sinh(ασ)] with the correlation coefficient about 0.98. The intercept of the fitting curve signals the value of ln$A$. Thus A-value can be determined as 2.14×10^{18}.

Eventually, substituting the values of α, n, Q, and A into Eq. (3), the constitutive equation at the strain of 0.5 for the GH4065A nickel-based superalloy can be described by a hyperbolic sine equation as follows:

$$\dot{\varepsilon} = 2.14 \times 10^{18}[\sinh(0.00819\sigma)]^{3.244} \exp\left(-\frac{521650}{RT}\right)$$

In order to verify the credibility of the established constitutive equation, Fig. 6

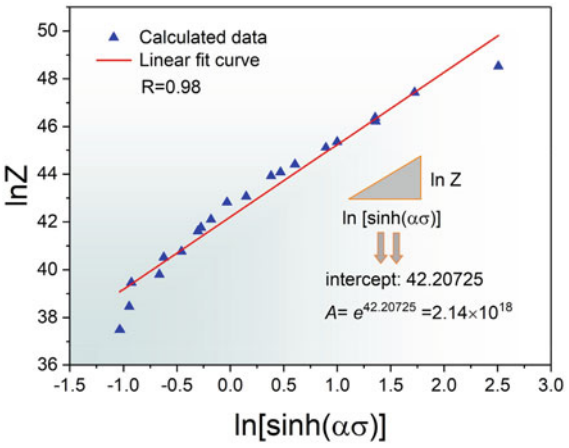

Fig. 5 Relationship between ln*Z*–ln[sinh(ασ)]. (Color figure online)

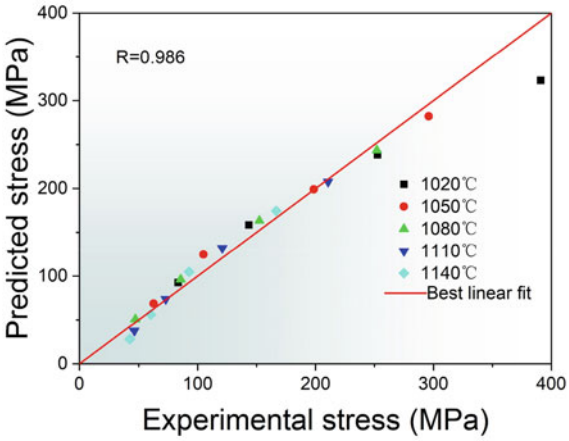

Fig. 6 Comparison between predicted data and experimental results. (Color figure online)

illustrates the comparison between predicted data and experimental results with *R*-value about 0.986. It can be observed that almost all data points are close to the line of best fit. Therefore, the established constitutive equation in this research has a good ability to predict the flow stress of the GH4065A nickel-based superalloy.

3.3 Processing Map

Processing map based on dynamic material model (DMM) has been proven as a powerful method to optimize hot working parameters and control microstructural evolution during the hot plastic deformation of metallic materials [12, 13]. The processing map can be established by the superimposition of instability map on

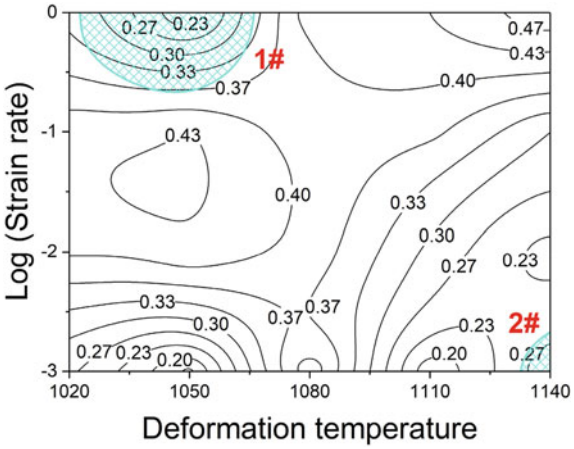

Fig. 7 The processing map of the GH4065A nickel-based superalloy processed at the strain of 0.69. (Color figure online)

power dissipation map, from which unstable region can be determined effectively. Moreover, microstructural observation is necessary to verify the instability mechanism related to the unstable region. With the huge advantages of time and cost saving, processing map is of great significance for practical industrial manufacturing.

The processing map obtained on GH4065A nickel-based superalloy at the strain of 0.69 is illustrated in Fig. 7. The contour numbers in processing map represent the value of power dissipation efficiency. The white and blue regions were identified as stable and unstable domains, respectively. It can be observed that two instability domains are delineated in processing map. The first occurs at the deformation temperature range of 1020–1065 °C and strain rate range of 0.25–1.0 s^{-1}, marked as Domain #1 in the processing map. The corresponding microstructure in this domain under the condition of 1050 °C/1.0 s^{-1} is shown in Fig. 8a. The adiabatic shear band can be

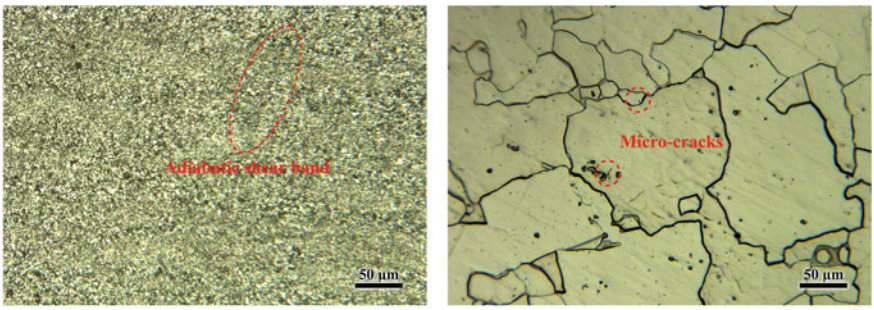

Fig. 8 Typical microstructures of the GH4065A nickel-based superalloy deformed at the condition of **a** 1#: 1050 °C/1.0 s^{-1}; **b** 2#: 1140 °C/0.001 s^{-1}. (Color figure online)

clearly seen under this condition, which is oriented to be about 45° off the compression axis. The second (Domain #2) locates at the deformation temperature about 1130–1140 °C and strain rate about 0.001–0.002 s^{-1}. Figure 8b gives the typical microstructure in this area under the condition of 1140 °C/0.001 s^{-1}. Obviously, the micro-cracks appear. Thus, these two instability domains should be prevented in hot working process of the GH4065A nickel-based superalloy.

4 Conclusions

Isothermal compression tests were carried out on the GH4065A nickel-based superalloy at the deformation temperature range of 1020–1140 °C and the strain rate range of 0.001–1.0 s^{-1} with the deformation degree of 50%. The following conclusions can be drawn from this research:

(1) The flow curves of the GH4065A nickel-based superalloy are sensitive to deformation temperature and strain rate. Flow stress decreases significantly with the increase of deformation temperature or the decrease of strain rate.

(2) The constitutive equation at the strain of 0.5 constructed for modeling the hot plastic deformation of the GH4065A nickel-based superalloy can be expressed as:

$$\dot{\varepsilon} = 2.14 \times 10^{18}[\sinh(0.00819\sigma)]^{3.244} \exp\left(-\frac{521650}{RT}\right)$$

(3) Based on processing map processed at the strain of 0.69, two instability domains can be identified as follows: Domain #1: 1020–1065 °C/0.25–1.0 s^{-1}; Domain #2: 1130–1140 °C/0.001–0.002 s^{-1}. The adiabatic shear band and micro-cracks are responsible for the above-mentioned domains, respectively.

Hot Deformation Behavior and Constitutive Modeling of a Novel Ni-Based Superalloy

Hao Yu, Hao Yang, Qi Liu, Baoyun Zhang, Bingchao Xie, and Yongquan Ning

Abstract Ni-based superalloys are widely used to manufacture the key components of a gas turbine engine because of their superior mechanical properties at elevated temperatures. In the present work, the hot deformation behavior of a novel Ni-based superalloy was investigated by compression test at temperatures of 1020–1140 °C and strain rates of 0.001–10 s^{-1}. At low temperature and high strain rates, the flow stress rapidly increased to a peak value due to work hardening. However, at high temperatures and low strain rates, the flow curves exhibited a typical dynamic softening stage. The hot deformation activation energy of the studied superalloy is determined to be 735.4961 kJ/mol, and a strain-compensated Arrhenius-type constitutive equation is obtained. On comparing the predicted and experimental values, the developed constitutive equation can accurately describe the deformation mechanism and the flow behavior. Meanwhile, the influence of hot processing parameters on microstructure has been deeply explored, which can optimize the process parameters for manufacturing key components in gas turbine engine.

Keywords Hot plastic deformation · Flow behavior · Constitutive modeling · Microstructure · Ni-based superalloy

1 Introduction

Owing to their excellent high-temperature rupture life, fatigue crack growth resistance, and creep strength, nickel-based superalloys are widely used in advanced turbine engines and other critical components [1–3]. The hot deformation behaviors of nickel-based superalloys were dependent on various factors, including the deformation temperature, strain rate, and strain; in addition, the initial microstructure also affects the hot deformation behaviors and final properties [4–6]. Thus, understanding the deformation behaviors of nickel-based superalloy at high temperatures could optimize the forming process and guide the practical application. In order to

simulate the hot deformation processes accurately, hot compression deformation had been well investigated and various constitutive models had been established [7–9].

In order to understand the hot deformation behavior of the novel nickel-based superalloy, in this paper the alloys were investigated by isothermal compression tests with the wide ranges of deformation temperature and strain rate. Based on the experimental results, the peak stress Arrhenius constitutive relationship of the alloy was established, through verification, and the model can accurately describe the relationship between the flow stress, strain rate, and deformation temperature.

2 Materials and Experiments

The material used in the present work was a disc with a diameter of 260 mm and a height of 25 mm after cogging. The chemical composition (wt.%) of this alloy was shown in Table 1, and the γ' solvus temperature was estimated to be about 1107 °C [10]. Cylindrical specimens with a diameter and height of 8 mm and 12 mm, respectively, were machined from the disc after cogging. Figure 1a presents the microstructure of the studied superalloy before the hot deformation, which is composed of fine equiaxed recrystallized grains and cluster-like non-recrystallized regions. Figure 1b shows the secondary γ' precipitates in the as-received superalloy, and it has been found that the secondary γ' precipitates were a mixture of irregular shape, small spherical, and cluster-like. The compression tests were performed using the Gleeble-1500D thermo-mechanical simulator at the deformation temperatures of 1020, 1050,

Table 1 Chemical composition of the studied alloy (wt.%)

Ni	Fe	Co	Cr	Mo	W	Al	Ti	Nb	B	C	Zr
Base	4	8.5	15.7	3.1	2.7	2.25	3.4	1.1	0.01	0.015	0.03

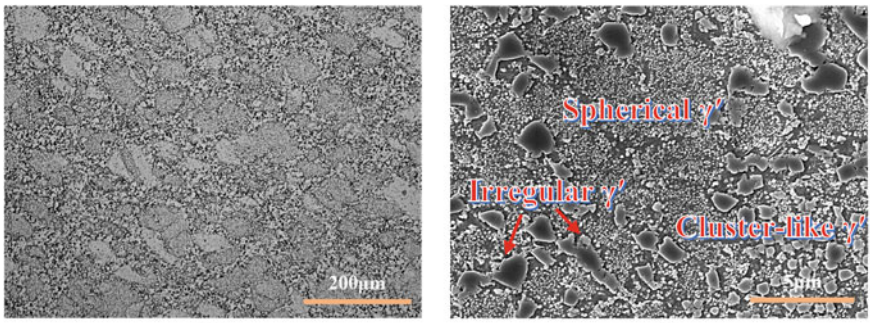

Fig. 1 **a** Microstructure of the studied alloy before the hot deformation, **b** γ' precipitates in the as-received superalloy. (Color figure online)

1080, 1110, and 1140 °C. The strain rates were 0.001, 0.01, 0.1, 1, and 10 s^{-1}, and the height reduction was 50%. Before the compression tests, the end faces of the specimen were coated with graphite lubricate to reduce the impact of contact friction on the stress state. All specimens were heated to the desired temperature at a heating rate of 10 K/s and then soaked for keeping the sample's temperature uniform before loading to eliminate the thermal gradient prior to deformation. The stress–strain data were automatically recorded by the testing system during the hot compression. The specimen after each compression was immediately quenched by the water. After deformation, the specimens were sectioned parallel to the compression axis through the centerline. Specimens for optical microscopy were mechanically polished and etched in a solution consisting of 10 mL HCl + 10 mL CH_3CH_2OH + 1 g $CuCl_2$ at room temperature for 1–3 min. Microstructure examination was performed by using OLYMPUS optical microscope. For scanning electron microscope (SEM), to reveal the morphology of γ' precipitate, the samples were mechanically polished and etched with a solution of 45%H_2SO_4 + 42%HNO_3 + 13%H_3PO_4, with electrolytic etching parameters as 3.5 V and 3–5 s. Morphology of the γ' precipitates was conducted using TESCAN SEM in the secondary electron (SE) or In-beam mode.

3 Results and Discussion

3.1 The True Stress–Strain Curves

Figure 2a–e shows the true stress–strain curves of hot compression of the studied alloy at various temperatures of 1020–1140 °C with strain rates of 0.001–10 s^{-1}. It can be seen that the flow behavior of the alloy is sensitive to deformation temperature and strain rate. The flow stress decreases with the increasing temperature and decreasing strain rate at a constant strain, and the true stress–strain curves exhibited completely different shapes depending on the deformation temperature and strain rate. When the strain was small, the flow stress increases quickly and rapidly increased to a peak value with increasing strain. In this process, the work hardening effect plays a dominant role, the dynamic softening is not enough to compensate for the work hardening caused by the dislocation proliferation. The deformation resistance reached the maximum and the corresponding stress and strain values, which were peak stress and peak strain, respectively. Both the peak stress and the peak strain were found to increase with decreasing deformation temperature or increasing strain rate. After exceeding the peak strain, the flow stress decreases gradually with the increase of strain. The flow curves exhibited an obvious phenomenon of flow softening, and the influence of dynamic softening was predominant. As the strain increases, the rates for the vacancy diffusion in the alloy increase, the ability of dislocations to overcome obstacles increases, and cross-slip of screw dislocations and climb of edge dislocations increase. Thus, dynamic recovery and recrystallization became easy to occur, making the density of dislocations decrease and overcome the work hardening

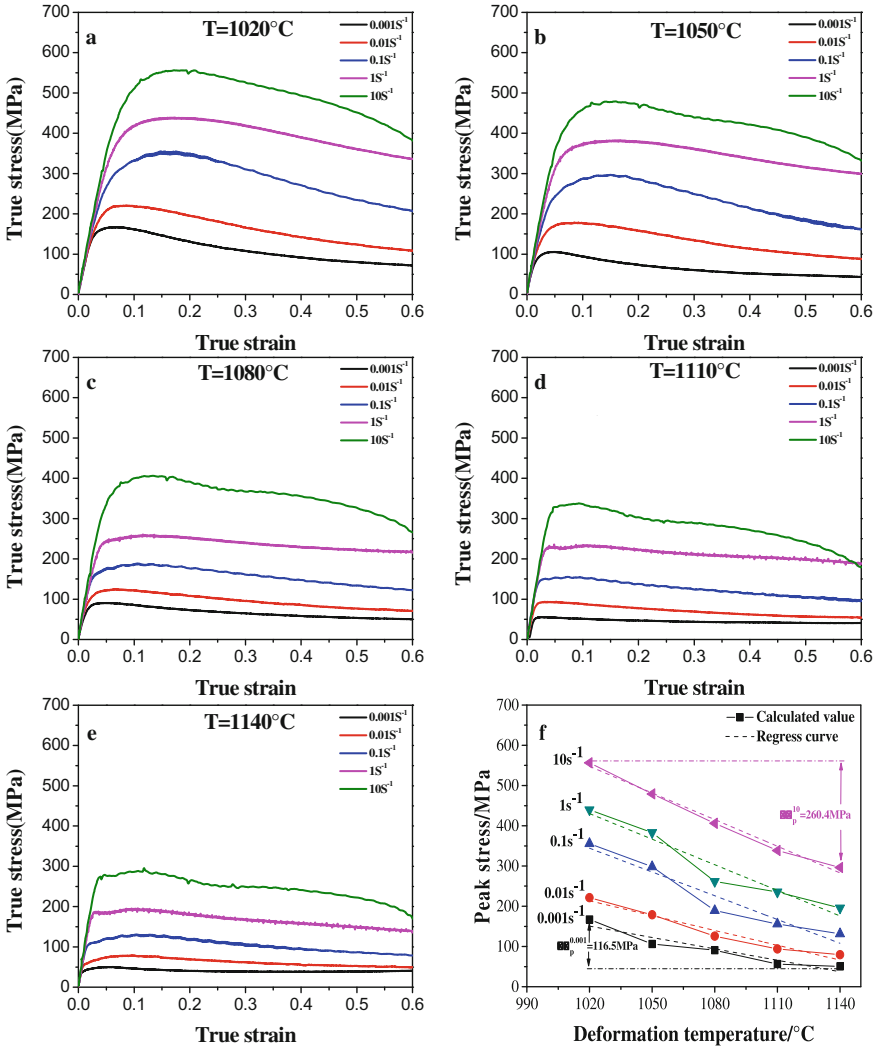

Fig. 2 True stress–true strain curves for the studied superalloy **a** T = 1020 °C **b** T = 1050 °C **c** T = 1080 °C **d** T = 1110 °C **e** T = 1140 °C **f** the peak stress of the studied superalloy. (Color figure online)

caused by the dislocation pile-up and tangling. Finally, the flow stress attains a relatively stable value under high strain, and the stress values were steady-state stress. The dynamic softening and the work hardening effects reach a dynamic balance.

Generally, the flow behavior of the alloy during the hot deformation is a result of the combined strain hardening and dynamic softening. The true stress–strain curves can be divided into three types: have an obvious peak, quasi-steady flow; have an obvious peak, continuous dynamic softening; and no obvious peak, steady flow. The flow softening was mainly associated with deformation heating and microstructure

evolution such as dynamic recrystallization. Figure 2f shows the peak stress gaps as a function of deformation temperature at various strain rates. It can be observed that when the strain rate is 10 s^{-1}, peak stress can be up to 550 MPa at 1020 °C, just 296 MPa at 1140 °C, and the peak stress gap is about 260.4 MPa. The peak stress is close to 170 MPa under the deformation temperature of 1020 °C, just 50 MPa at 1140 °C, and the peak stress gap is about 116.5 MPa. A similar pattern can be found under other strain rates, which shows that the peak stress decreases gradually with the increase of deformation temperature at a constant strain rate. It is because with the increase of deformation temperature, the atom's ability to move increases, the bonding force between atoms decreases, and the critical shear stress of the alloy decreases, which in turn reduces the construction of dislocation motion and crystal ship. In addition, the increase of deformation temperature is beneficial for the mobility of grain boundaries, which promote the nucleation and growth of dynamically recrystallized grains. Thus, the flow stress decrease.

3.2 Constitutive Modeling of Peak Stress

Researches on different materials show that high-temperature deformation of alloys is a process controlled by thermal activation. In order to accurately describe the relationship between the stress, strain rate, and the deformation temperature, the peak stress on deformation temperature and strain rate can be represented by hyperbolic sine-type Arrhenius equation proposed by Sellars and Tegart [11]:

$$\dot{\varepsilon} = A\left[\sinh\left(\alpha\sigma_p\right)\right]^n exp(-Q/RT) \tag{1}$$

In addition, the relationship between flow stress and strain rate can be described by the following models at low and high stress levels:

$$\dot{\varepsilon} = A_1\sigma^{n_1} \quad (\alpha\sigma < 0.8) \tag{2}$$

$$\dot{\varepsilon} = A_2 \exp(\beta\sigma) \quad (\alpha\sigma > 1.2) \tag{3}$$

where $\dot{\varepsilon}$ are the values of n1 (s^{-1}), σ_p is the peak stress (MPa), n is the stress exponent, Q is the apparent activation energy for deformation (J mol^{-1}), T is deformation temperature (K), R is the universal gas constant (8.3145 J mol^{-1} K^{-1}), and A_1, A_2, A, n_1, β, and α are materials constants. After taking the logarithm of Eqs. (1), (2), and (3):

$$\ln\dot{\varepsilon} = \ln A + n\ln[\sinh(\alpha\sigma)] \tag{4}$$

$$\ln\dot{\varepsilon} = \ln A_1 + n_1\ln\sigma \tag{5}$$

$$\ln \dot{\varepsilon} = \ln A_2 + \beta\sigma \tag{6}$$

The values of n_1 and β can be calculated by the linear statistical regression method. The peak stress and strain rate under different deformation temperatures are taken into Eqs. (5) and (6) to get the relationship between $\ln \sigma$ and $\ln \dot{\varepsilon}$ and the relationship between σ and $\ln \dot{\varepsilon}$, which are shown in Fig. 3a, b. It can be obtained that the average value of $n_1 = 5.8912$ and $\beta = 0.0286$. Therefore, $\alpha = \beta/n_1$=0.004852 is obtained. After the value of α was determined, from Eqs. (4) and (1) we get the relationship between $\ln[\sinh(\alpha\sigma)]$ and $\ln\dot{\varepsilon}$ and the relationship between $\ln[\sinh(\alpha\sigma)]$ and 1000/T, which are shown in Fig. 3c, d. Then, the values of n, A, and Q can be obtained by linear fitting of the experimental data and are found to be $n = 4.3098$, $A = 1.0124 \times 10^{27}$, and $Q = 735.4961$ kJ mol^{-1}. According to the values of α, A, n, and Q, the peak stress by hyperbolic sine-type Arrhenius constitutive relationship of the alloy can be expressed as:

$$\dot{\varepsilon} \cdot \exp(735496.1/RT) = 1.0124 \times 10^{27} \cdot [\sinh(0.004852\sigma)]^{4.3098} \tag{7}$$

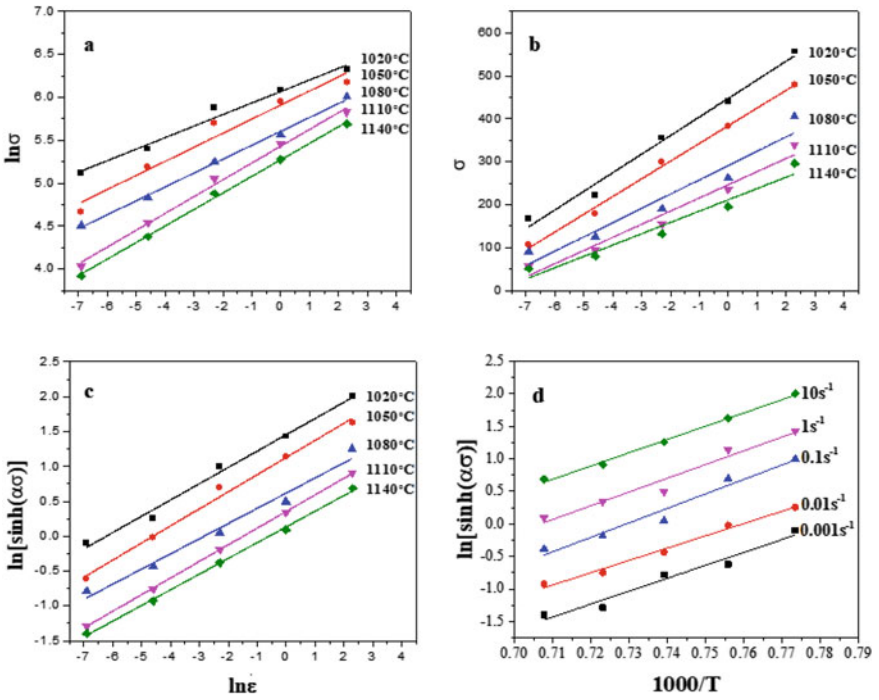

Fig. 3 The relationship between **a** $\ln \sigma$ and $\ln \dot{\varepsilon}$; **b** σ and $\ln \dot{\varepsilon}$; **c** $\ln[\sinh(\alpha\sigma)]$ and $\ln \dot{\varepsilon}$; **d** $\ln[\sinh(\alpha\sigma)]$ and 1000/T. (Color figure online)

Based on the regression analysis on the parameters of the hyperbolic sinusoidal Arrhenius equation, the functional relationship between parameters of the constitutive relationship and the true strain under different strains was established and the values of the parameters in the Arrhenius equation under different strains were calculated. The relationship between the parameters and the strain can be fit using a cubic function, and the third-order functions of each parameter with respect to ε can be obtained. Figure 4 shows the fitting curves, and it can be seen from the figure that the fit curves of each model are constant with respect to the strain variable is very well, and the linear correlation coefficients R are all above 0.99. The third-order functions can be expressed as:

$$\alpha = -4.1463 \times 10^{-4}\varepsilon^3 - 0.0030\varepsilon^2 + 0.0084\varepsilon + 0.0055 \tag{8}$$

$$\mathrm{n} = -10.7969\varepsilon^3 + 17.5480\varepsilon^2 - 8.8785\varepsilon + 4.6118 \tag{9}$$

$$\ln \mathrm{A} = 167.4583 - 182.3092\varepsilon^2 + 14.4139\varepsilon + 61.2625 \tag{10}$$

$$\mathrm{Q} = 1987.1757\varepsilon^3 - 2189.9876\varepsilon^2 + 207.6428\varepsilon + 735.0847 \tag{11}$$

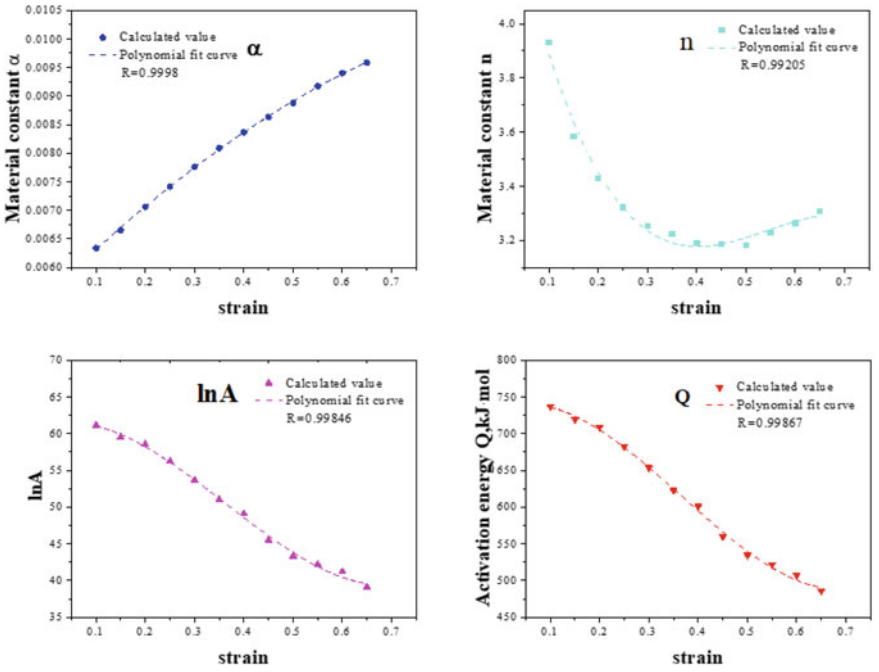

Fig. 4 Relationships between α, n, lnA, and Q and true strain. (Color figure online)

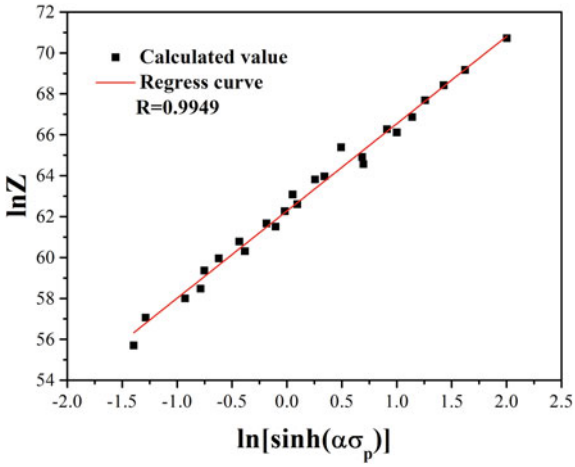

Fig. 5 Relationship between lnZ and $\ln[\sinh(\alpha\sigma_p)]$. (Color figure online)

Figure 5 shows the relationship between lnZ and $\ln[\sinh(\alpha\sigma_p)]$ according to the unary linear regression analysis. It can be seen that the fitting curve shows a good linear relationship, with a linear correlation coefficient of R = 0.9949, indicating that the hyperbolic sine-type Arrhenius constitutive relationship can accurately describe the relationship between the peak flow stress of the alloy and the deformation temperature and strain rate.

3.3 Microstructure and γ′ Precipitate

Figure 6 shows the microstructure of the studied alloy after the hot deformation. When the deformation temperature is 1020 °C, it can be seen that there are still a large number of non-recrystallized regions inside the alloy, the non-recrystallized regions that are elongated, and in the center of the deformation region, dynamic recrystallization has occurred, and the grain is fine, as shown in Fig. 6a. The influence of γ' precipitates on the microstructure evolution of the alloy was important. When the samples deformed at a sub-solvus temperature (1020 °C), the content and size of the γ' precipitates do not change greatly, as shown in Fig. 6b. The existence of the γ' precipitates not only promotes the nucleation of dynamic recrystallization but also inhibits the movement of the grain boundaries. Increasing deformation temperature promotes the occurrence of dynamic recrystallization of the alloy. Complete dynamic recrystallization occurred, and the uniform equiaxed recrystallized grains were obtained at the deformation temperature of 1140 °C (Fig. 6c). This is because at higher deformation temperature, the γ' precipitates are almost dissolved completely (Fig. 6d), and the pinning effect of grain boundaries migration and dislocations movement decreases.

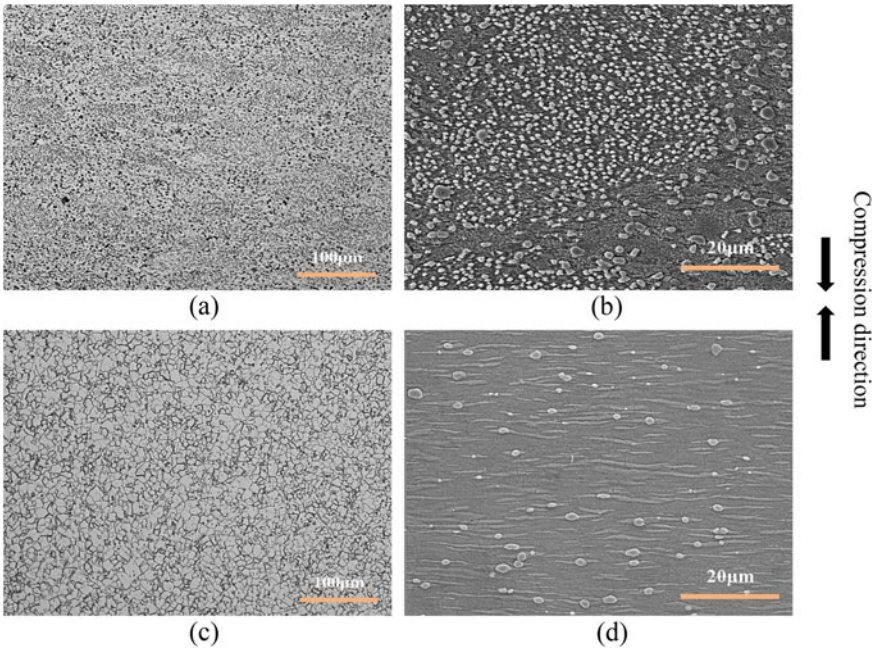

Fig. 6 Microstructure of the studied alloy after the hot deformation, **a** OM 1020 °C, 1 s^{-1}, **b** SEM 1020 °C, 1 s^{-1}, **c** OM 1140 °C, 1 s^{-1}, **d** SEM 1140 °C, 1 s^{-1}. (Color figure online)

4 Conclusions

Based on the hot compression tests of the novel Ni-based superalloy, flow behaviors under the conditions of various deformation parameters were obtained in this work. The main results are summarized as follows:

(1) The experimental data were analyzed, and the true stress–strain curves can be divided into three types: have an obvious peak, quasi-steady flow; have an obvious peak, continuous dynamic softening; and no obvious peak, steady flow.

(2) Based on the regression analysis, the peak stress hyperbolic sine-type Arrhenius equation of this studied alloy was established, the model can accurately describe the relationship between the strain rate, deformation temperature, and true strain of the alloy during high-temperature compressive deformation, and can well predict its hot deformation behavior.

(3) Microstructure of this alloy under various deformation parameters were analyzed, and it shows that the γ' precipitates have an important effect on microstructure evolution. At γ' sub-solvus temperature, γ' precipitates promote dynamic recrystallization nucleation, and the recrystallized grains are tiny;

however, at γ' super-solvus temperature, dissolution of γ' phase is beneficial for the mobility of grain boundaries, completely dynamic recrystallization has occurred, and the uniform equiaxed recrystallized grains were obtained.

Accurate Modelling of Flow Stress of AISI1025 at Room Temperature and Its Application to Precision Forging Simulation

M. S. Joun, M. K. Razali, J. B. Byun, and K. H. Lee

Abstract This paper evaluates and criticizes the Swift model of expressing strain hardening behaviours of metals at room temperature using an experimental tensile test and its FE prediction. A concept of reference flow stress curve composed of two ranges of strain divided by the true strain at the necking point is proposed, which predicts tensile test exactly from the standpoint of engineering and is thus employed to evaluate the Swift model. It has been shown that it has a weak point in describing the flow stress of typical strain hardening material with emphasis on necking. An improved Swift model is applied to obtain accurate flow stress of a commercial steel AISI1025 and it is employed to simulate a sequence of cold forging processes by precision complete analysis for process and die optimal design in terms of die life, which should be conducted under an accurate analysis model.

Keywords Flow stress · Material model · Strain hardening · Accuracy in terms of tensile test · Finite element analysis

1 Introduction

Recently, the implementation of high-strength steels in the automotive industry has become prevailing and desirable owing to their structured integrity and long-lasting properties. However, formability of such materials is unfavourable and thus an appropriate flow stress model for precision engineering together with optimal die and

process design is required to amplify the effectiveness of productive effort and cost reduction [1].

Several phenomenological and metallurgical flow stress models for stainless steels and common carbon steels [2] have been widely used in metal forming simulation. The common feature for these types of model is that these models can be expressed as a function of state variables, including strain, strain rate, and temperature. They can be fitted to convenient mathematical functions using macroscopic mechanical tests. Although this is a long-known fact, taking a look at the literature of metal forming simulations reveals that it is often overlooked [3]. This negligence can be related to some difficulties, i.e., the maximum strain that can be achieved in the characterization tests is limited and usually lower than that being reached in the actual bulk-forming processes [1]. Extrapolation of the obtained flow stress curves up to higher strain is essential, which is regarded as a major error source. A model with optimally determined material constants is inevitable to overcome the problems in extrapolation [4].

Research works in modelling flow stress in terms of strain hardening which is dominant in the cold metal forming are represented by well-known models such as the Ludwik model [5], Hollomon model [6], Swift model [7], and Voce model [8]. Nonetheless, it is a matter of fact that strain hardening behaviours at room temperature are greatly influenced by the pre-works, i.e., manufacturing process and heat treatment; by all means, a simple well-known function is not suitable to express flow stress at larger strain for cold forming [9].

Difficulties in material characterization and somewhat complicated and time-consuming remedies may push researchers to choose an easier way to model material behaviours under some assumptions. Flow stress curve at lower strain, normally up to 0.5, can be obtained using tensile, compression, ball indentation, torsion, and notch tensile tests [10]. In bulk metal forming, flow stress prediction exceeding 1.0 is necessary. However, there are no conventional flow stress models with proper material constant determination schemes until Joun et al. [1, 11] presented the practical approach of predicting true stress–strain curves with high accuracy from tensile test data, i.e., engineering stress–strain curve of a simple cylindrical specimen.

In this paper, research on material characterization of a typical strain hardening steel is conducted together with its application to an automatic multi-stage cold forging process.

2 Criticism of the Swift Model

Figure 1 shows the experimental engineering stress–strain curve of commercial steel AISI1025 denoted by a solid line and its corresponding true stress–strain curve in the upper side, called AFDEX-M8. The latter was obtained using a special function of AFDEX [12], which is based on a half and perfect FE model with rigid-plastic finite element method. It was shown [11] that the flow stress curve is also compatible with the predictions of tensile test by elastoplastic finite element method.

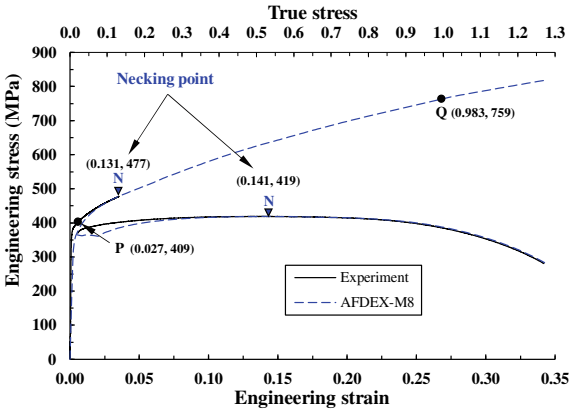

Fig. 1 Experimental and predicted engineering stress–strain curves and its associated true stress–strain curve denoted by AFDEX-M8. (Color figure online)

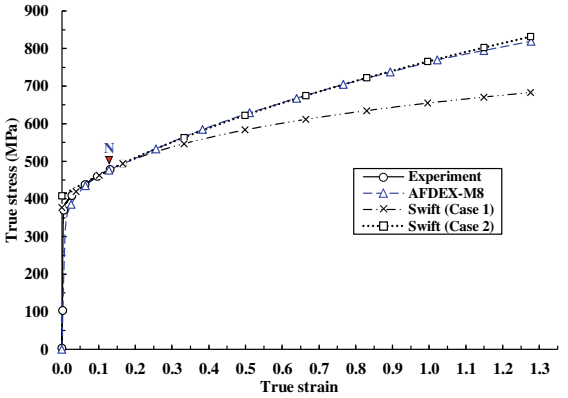
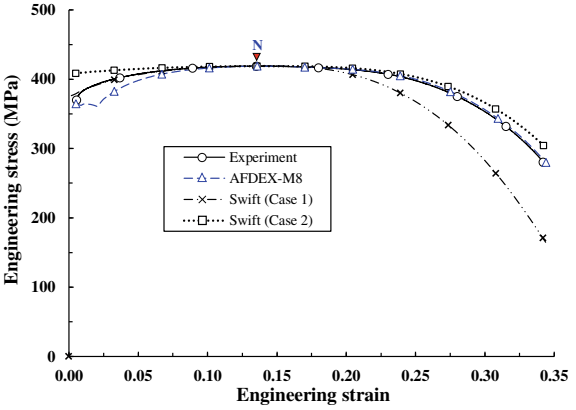
Figure 1 shows that the predicted tensile test, that is, engineering stress–strain curve is in good agreement with the experiments, especially at larger strain after the necking point, indicating that AFDEX-M8 can be used as a reference flow stress curve (denoted by RFS) after necking point. Note that the flow stress up to the necking point can be calculated from the simple arithmetic formula by relating true values to engineering values of stress and strain. The entire reference flow stress curve which will be used to evaluate the well-known Swift model can thus be defined by two curves, i.e., one for the left side of the necking point by a theoretical curve and the other for the rest by a numerically optimized curve.



Swift flow stress model [7] is a well-known flow stress model at room temperature, widely used in describing the flow stress curve with respect to strain. It is expressed by three parameters as follows:

$$\sigma = Y_o(1 + \alpha_1 \varepsilon)^{n_1} \tag{1}$$



where Y_o is the yield strength of material, and α_1 and n_1 are the first strain hardening constant and the first strain hardening exponent called in this paper, respectively. The necking point is very important when a material model is defined in terms of tensile test. To meet the necking point, two conditions [1] should be satisfied, that is, only one freedom is left to specify the Swift model.

To approximate the reference flow stress curve by the Swift model, two points were chosen, that is, P and Q representing the left and right sides of the necking point denoted by N in Fig. 1, respectively. Two different Swift flow stresses which pass P or Q are shown in Fig. 2a by Cases 1 and 2 for the points P and Q, respectively. Their corresponding material constants of the Swift model are summarized in Table 1.

Figure 2b compares the theoretical tensile tests predicted by three flow stresses, including Case 1, Case 2, and AFDEX-M8, and experimental tensile test. All predictions are in excellent agreement with the experiments around the necking point. It is shown that AFDEX-M8 meets quite well with experiments except at the lower strain.

(a) Flow stress

(b) Tensile test

Fig. 2 Comparison of experiments and predictions by AFDEX-M8, Case 1 and Case 2. (Color figure online)

Table 1 Two Swift models

Swift model	Y_o (MPa)	α_1	n_1
Case 1	376.7	21.50	0.179
Case 2	408.5	3.440	0.422

Of course, the reference flow stress curve can be used for predicting the tensile test almost exactly for the entire region of interested strain.

Cases 1 and 2, however, exhibit greater errors in the right and left sides, respectively, implying that the Swift model cannot satisfy the flow stress of the material before and after the necking point at the same time. Case 1 predicted an accurate engineering stress–strain curve up to the necking point but the curve bent quicker than the experiment because of the underestimated flow stress after the necking point, as can be seen in Fig. 2a. On the contrary, Case 2 showed a better prediction of the

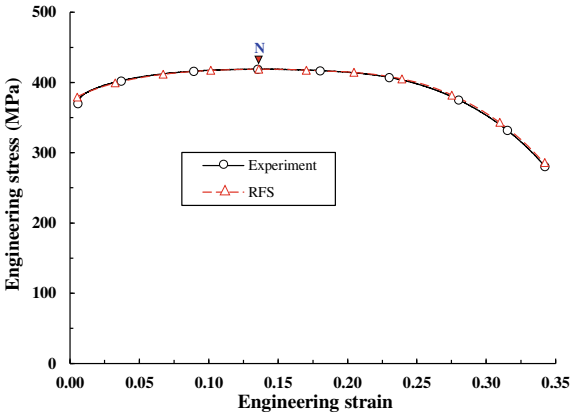


Fig. 3 Comparison of experimental and predicted engineering stress–strain curves by RFS. (Color figure online)

engineering stress–strain curve after the necking point but it overestimated the flow stress at lower strain before the necking point, resulting in non-negligible error.

Figure 3 compares the predicted tensile test obtained by the reference flow stress curve with the experimental tensile test, showing their exact agreement from the standpoint of engineering. It is noted that the reference flow stress was not formulated by a closed-form function and that it is not practical, especially either when it should be extrapolated for much larger strain or when a softening behaviour due to damage accumulation should be dealt with.

3 Introduction of Improved Swift Model

An improved Swift flow stress model developed in a previous study [13] is used, which is formulated as follows:

$$\sigma = Y_o\left(1 + \alpha_1\varepsilon + \alpha_2\varepsilon^{n_2}\right)^{n_1} \tag{2}$$

where α_2 and n_2 are called the second strain hardening constant and the second strain hardening exponent, respectively. Parameters Y_o and α_1 were determined in the same manner as with the Swift model (Case 1), then α_2 was calculated to meet the sampled point marked "Q" in Fig. 1 with n_2 fixed as 3.0. The calculated parameters were summarized in Table 2. Figure 4 shows the calculated flow stress based on the improved Swift model. It can be concluded that the improved Swift model can satisfy

Table 2 Parameters for the improved Swift model

Y_o (MPa)	α_1	α_2	n_1	n_2
376.7	21.50	30.69	0.179	3.0

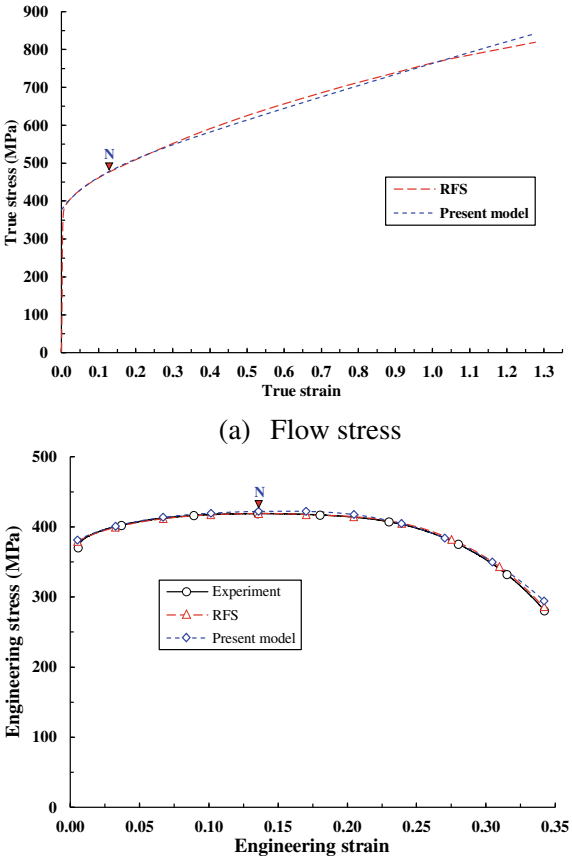

Fig. 4 Comparison of experiments and prediction by RFS and present model. (Color figure online)

both sides before and after the necking point with acceptable accuracy as well as the necking point accurately. Of course, RFS still has the highest accuracy, as can be seen in Fig. 3. On the contrary, the improved Swift model is formulated by a closed-form function with minimized material constants, which is practical and mathematically powerful for further study [14].

4 FE Analysis of an Automatic Multi-stage Cold Forging Process

For successful and competitive mass production of fasteners and auto-parts by an automatic multi-stage cold forging machine [15–18], die life is one of the hot issues to be managed scientifically, which needs high precision simulation of the process.

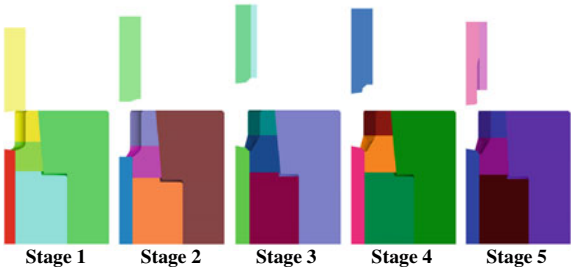

Fig. 5 Process design of the nut cold forging process. (Color figure online)

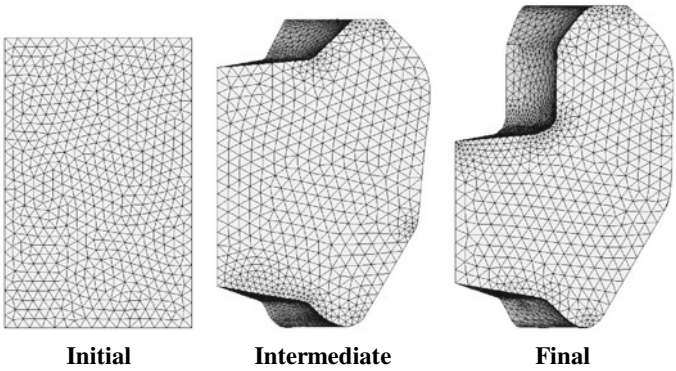

Fig. 6 Tetrahedral finite element mesh systems

A sequence of the typical nut forming process seen in Fig. 5 was simulated by an elastoplastic finite element method [19] with die elastic deformation considered, i.e., by completely coupled analysis. Die deformation due to shrink fit was also considered. The flow stress described in Fig. 4a was used for this purpose. Figure 6 shows typical tetrahedral finite element systems [20] during simulation. The frictional coefficient was assumed 0.05. The dependence of flow stress on the strain rate and temperature was neglected.

Figures 7, 8, and 9 show the predictions of change of metal flow lines, history of deformation with strain and die stresses, respectively. It should be emphasized again that the entire finite element simulation was conducted in a fully automatic way considering all factors affecting the material and die deformations.

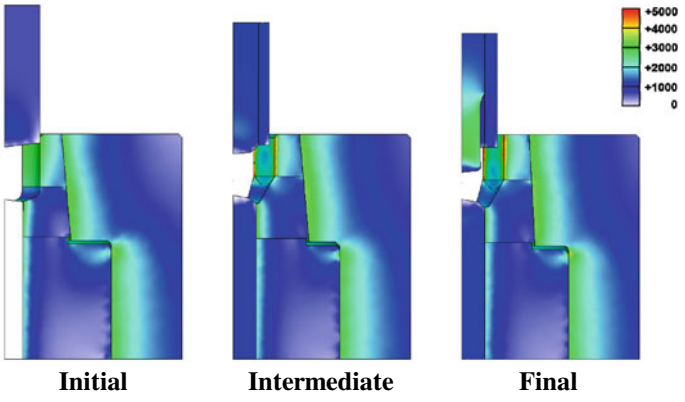

Fig. 9 Effective stresses of die parts. (Color figure online)

5 Concluding Remarks

The Swift model was evaluated and criticized to reveal its dominance and drawback using a tensile test curve of carbon steel. The main advantage of this model is the mathematical simplicity and accurate necking point prediction. On the other hand, the foremost shortage of this model lies in the fact that it cannot satisfy both flow stresses before and after the necking point at the same time in the case of the test example.

A reference flow stress was proposed to be used for material characterization at room temperature, which can describe flow stress at both sides of the necking point with higher accuracy. It was shown that the reference flow stress predicted almost the exact engineering stress–strain curve of the tensile test.

It was shown that the improved Swift model with a minimum number of material constants can depict the entire flow stress curve with high accuracy. It is noted that the improved Swift model is very useful because of its mathematical simplicity and extendability for reflecting the softening effect due to damage accumulation and extrapolating the flow stress at a much larger strain.

The improved Swift model was successfully applied to a precision simulation of an automatic multi-stage cold forging process of nut for the purpose of increase in die life, which needs accurate flow stress information.

Stress-Relaxation Age Forming of a Component with Complex and Large Curvatures: Simulation and Manufacturing

Qi Rong, Zhusheng Shi, Yong Li, and Jianguo Lin

Abstract Stress-relaxation age forming (SRAF) of a component (820 × 300 × 3 mm^3) with complex and large curvatures has been simulated and a corresponding SRAF test of an Al–Mg–Si alloy, AA6082-T6, has been carried out in this study. An FE model is established to simulate the stress-relaxation ageing (SRA) behaviour of AA6082-T6 during SRAF at various stress levels, ranging from elastic to plastic regions, and a unified constitutive model for SRA of the material has been implemented in the finite element (FE) software ABAQUS via the user-defined subroutine CREEP. An optimised tool surface was determined from the FE simulation through springback predication and compensation and was used for manufacturing test. A good agreement of the formed shape has been achieved between the FE simulation and the SRAF test, with a maximum shape error below 4 mm, satisfying the industrial requirement. The hardness results from the formed plate showed an insignificant change of strength during SRAF, and are in good agreement with the simulation. The effects of the initial plastic strain and creep strain generated during loading and stress-relaxation stages on the formed shape have also been analysed.

1 Introduction

Stress-relaxation age forming (SRAF), which is also called creep age forming (CAF), is a sheet metal forming technology combining material deformation and age hardening in one process, and has been widely employed in the production of extra-large panels in the aeronautics industry [1, 2]. For example, the SRAF method has been used for the production of upper wing skins of Airbus A380 superjumbo [3] and

Gulfstram G-IV Aircraft [2]. Because of the advantages of SRAF technology, it is beneficial to broaden its applications to other areas, such as the locomotive industry, where the panels normally have large size and complex shape. However, the current SRAF applications are for the panels with large size but relatively small curvatures and most experimental and modelling investigations so far are mainly focused on the SRA behaviours of the age-hardenable aluminium alloys in the elastic region. Very few studies have been done on SRAF of panels with large curvature, in which the material deformed in the plastic region. Yang [4] manufactured a singly curved stiffened panel with a curvature radius of 650 mm, which is the largest curvature of the SRAFed panel published so far. The unavoidable springback phenomenon occurring during SRAF varies with curvature and thickness of the plate as well as the SRAF process parameters, and to accurately predict it for the formed plate, the development and calibration of the material model for the SRA behaviour are very important. Recently, some modelling work has been carried out to predict the stress-relaxation/creep ageing behaviours in both elastic and plastic regions [5, 6], and both explicit and implicit algorithms have been used in previous studies on the FE simulations of the SRAF process of aluminium alloys [7–9]. However, no reports have been found on the FE simulations and SRAF tests of panels with large and complex curvatures.

Aluminium alloy AA6082 is one of the most used lightweight materials in the locomotive industry due to its good combination of strength and weldability [10, 11]. To broaden SRAF to the panels with large and complex curvatures in the locomotive industry, experimental investigation has been carried out on SRA behaviour of AA6082-T6 with initial loading in both the elastic and plastic regions [12]. The aim of the study is to use the FE simulation to guide the tool surface design for manufacturing a component with complex and large curvature. An FE model is built to simulate the SRA behaviour of AA6082-T6 during SRAF at various stress levels ranging from elastic to plastic regions. An explicit integration method has been used to solve a constitutive material model and implemented into ABAQUS for FE simulation of the SRAF process. The techniques and procedures for the implementation of the developed material model in ABAQUS are described in detail. The FE simulation has been carried out to determine the tool surface for SRAF of a panel with large and complex curvatures that was selected from an in-service high-speed train. The corresponding SRAF test has then been performed to validate the developed FE models in the prediction of springback behaviour during SRAF of the material. The hardness test of the specimens cut from the SRAFed plate has also been carried out to verify the post-form strength predicted by the FE model.

2 FE Simulation

2.1 Material Model

SRA behaviour in both the elastic and plastic regions of AA6082-T6 has been investigated at 160 °C up to 12 h in an earlier study [12], during which there is no significant change in the yield strength within the timeframe, which is important for the application of SRAF of peak-aged material. It was concluded that the enhanced stress relaxation with higher initial strains in the plastic region is mainly due to increased dislocation movement and decreased resistance of the material to stress relaxation deformation. Based on the analysis, the following set of constitutive equations has been developed [13] and employed in this study for the prediction of the stress-relaxation ageing behaviour of AA6082-T6 from elastic to plastic regions:

$$\dot{\sigma} = \mathrm{E}\dot{\varepsilon}_e = -\mathrm{E}\dot{\varepsilon}_c \tag{1}$$

$$\dot{\varepsilon}_c = A_1 \sinh\{B_1[(\sigma - \sigma_{th})(1-\overline{\rho})]\}\mathrm{sign}\{\sigma\} + k_4\dot{\sigma}_{\mathrm{dis}} \tag{2}$$

$$\sigma_{th} = C_{th}\overline{\lambda}^{-1} - C_1\overline{\rho}^{n_4} \tag{3}$$

$$\dot{\overline{\rho}} = A_3(1-\overline{\rho})|\dot{\varepsilon}_c|^{n_1} - C_p\overline{\rho}^{m_4} \tag{4}$$

$$\dot{\bar{l}} = C_L(Q-\bar{l})^{m_2}(1+\gamma_0\overline{\rho}^{m_3}) \tag{5}$$

$$\dot{\overline{\lambda}} = k_3\dot{\bar{l}} \tag{6}$$

$$\sigma_y = \sigma_{\mathrm{ss}} + \sqrt{{\sigma_A}^2 + {\sigma_{\mathrm{dis}}}^2} \tag{7}$$

$$\dot{\sigma}_{ss} = 0 \tag{8}$$

$$\dot{\sigma_A} = C_A(1-\bar{l})\dot{\bar{l}}^{m_1} \tag{9}$$

$$\dot{\sigma}_{\mathrm{dis}} = A_2 n_3 \overline{\rho}^{n_3-1}\dot{\overline{\rho}} \tag{10}$$

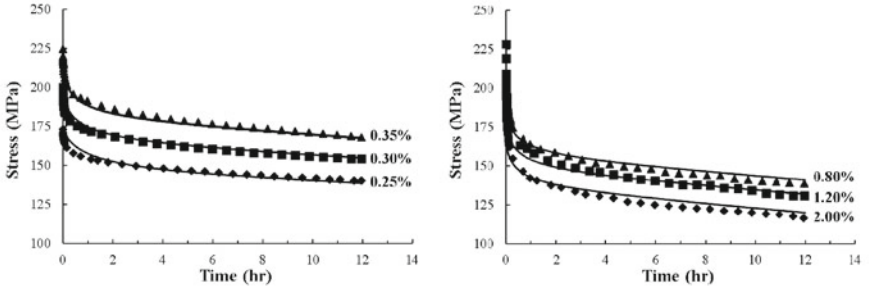
where A_1, A_3, B_1, C_p, C_A, C_L, C_{th}, k_3,k_4, m_1, m_2, m_3, m_4, n_1, n_4, Q, γ_0, C_1 are material constants to be determined from the experimental data.

Equation (1) is the relationship between the creep strain rate $\dot{\varepsilon}_c$ and stress-relaxation rate $\dot{\sigma}$, and E is the Young's modulus of the material. Equation (2) describes the evolution of creep strain rate $\dot{\varepsilon}_c$, which is a function of applied stress σ, threshold

stress σ_{th}, and normalised dislocation density $\overline{\rho}$; and the annealing effect on recovery has also been added since greater effect occurs due to the existence of non-shearable precipitates [14–16]. Equation (3) describes the evolution of threshold stress σ_{th}, which is a function of normalised inter-particle spacing $\overline{\lambda}$ and normalised dislocation density $\overline{\rho}$ [17, 18]. Equation (4) describes the evolution of normalised dislocation density $\overline{\rho}$, which is defined as $\overline{\rho} = (\rho - \rho_i)/\rho_s$, where ρ is the instantaneous dislocation density, ρ_i is the dislocation density in the as-received material before loading, and ρ_s is the saturated dislocation density during stress-relaxation ageing [19]. Equation (5) describes the evolution of precipitate size [8], where the normalised precipitate length $\overline{l}$ is used to represent, which is defined as $\overline{l} = l/l_p$, where l is the instantaneous precipitate length and l_p is the precipitate length at the peak-ageing condition, and thus $\overline{l}$ will evolve with an initial value of 1. The use of precipitate length is mainly due to the precipitation coarsening direction along its length direction during SRA of AA6082-T6 at 160 °C up to 12 h [12]. Equation (6) describes the evolution of the normalised inter-particle spacing, which is defined as $\overline{\lambda} = \lambda/\lambda_p$, where λ is the instantaneous inter-particle spacing and λ_p is the inter-particle spacing in the peak-ageing condition. $\overline{\lambda}$ will evolve with an initial value of 1 and follows a similar trend as $\overline{l}$. Equation (7) describes the evolution of yield strength σ_y, which is a function of solution hardening σ_{ss}, precipitation hardening σ_A, and dislocation hardening σ_{dis}. The evolution of these three strength components are described in Eqs. (8–10), respectively. The initial state of the studied material is at peak-aged condition, the solutes concentration and volume fraction of the precipitates will change little during further ageing, and thus the strength that comes from solute hardening is a constant, as shown in Eq. (8) [20, 21].

Since a large number of dislocations has been generated during loading to the plastic region, the initial value of the normalised dislocation density is no longer 0, and so are the initial dislocation hardening strength and threshold stress. The equations to model their initial value are summarised in Eqs. (11–13), respectively [22].

$$\overline{\rho}_0 = k_2 {\varepsilon_0}^{n_2} \mathrm{H}(\sigma_0 - \sigma_y) \tag{11}$$



$$\sigma_{dis0} = A_2 \cdot \bar{\rho}_0^{n_3} \tag{12}$$

$$\sigma_{th0} = B_2 - k_1 \cdot \sqrt{\overline{\rho}_0} \tag{13}$$

where k_2,n_2,A_2,n_3,B_2, and k_1 are material constants to be determined from the experimental data. $\mathrm{H}(\sigma_0 - \sigma_y)$ in Eq. (11) is the Heaviside step function; when $\sigma_0 \geq \sigma_y$, $\mathrm{H}(\sigma_0 - \sigma_y) = 1$, representing the dislocation densities generated by loading in the plastic region. Otherwise, $\mathrm{H}(\sigma_0 - \sigma_y) = 0$. Material constants in the equation were determined by fitting the simulated curves to the corresponding experimental results, and the determined material constants are listed in Table 1. Figure 1 compares the computed results with experiments for stress-relaxation behaviour of AA6082-T6 under different initial strain levels ranging from elastic (0.25%, 0.30%, and 0.35%)

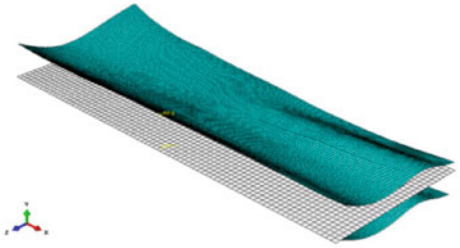
to plastic regions (0.80%, 1.20%, and 2.00%), and good agreement between them has been achieved. Additionally, 75–90% of the total stress relaxation has taken place in the first 5 h ageing process at all tested initial strain levels, and thus the ageing time of the SRAF test performed in this work is determined to be 5 h for better production efficiency.

2.2 Implementation of Material Model



The developed material model is implemented into the commercial FE solver ABAQUS via the user-defined subroutine CREEP for process simulation. Both explicit and implicit methods have been used in previous studies on the FE simulations of the SRAF process of aluminium alloys [7, 23], and the explicit method has been found to be more straightforward and convenient to use, with satisfying results. Therefore, the explicit integration algorithms are used in this work, and all the material constants and initial values are defined in the subroutine. The effectiveness of the developed FE model has been validated by stress-relaxation age forming (SRAF) of a singly curved plate, which deformed in the plastic region with a curvature radius of 700 mm.

The FE model created to simulate the SRAF process of an AA6082-T6 panel with large and complex curvatures is shown in Fig. 2, with the dimension of the objective shape and developed FE model for demonstration plate. The length and width of both upper and bottom tools in this model are, respectively, 800 and 280 mm. The blank is modelled with shell elements (S4R) in ABAQUS with a dimension of 800 × 300 × 3 mm. The penalty friction formulation is used, and the friction coefficient between the tool and the blank is defined as 0.1 [4]. In order to obtain satisfactory results in a more efficient way, the mesh convergence tests have been performed, and the results were obtained with different blank mesh sizes, i.e., 5, 10, 20, 25 mm. The maximum vertical deflections at $x = 0$ on the plate by using different mesh sizes are plotted in Fig. 3. From the point of view of efficiency and computational time, 10 mm was selected as the mesh size of the blank. The basic mesh properties of the model are summarised in Table 2.

For the easier implementation of the FE model, the whole SRAF process is regarded as an isothermal process and the heating and cooling processes are not taken into account since their durations are relatively short compared to the ageing process. Also, due to the slower creep deformation at a lower temperature, and a minor effect of different stress levels on the ageing behaviour of the material in this study, the thermal effects are ignored in the FE modelling. Therefore, the stress–strain

Table 2 Basic mesh properties of each part in FE model for the panel

Part name	Element type	Element number	Mesh size (mm)
Upper tool	Discrete rigid (R3D4)	9760	5
Bottom tool	Discrete rigid (R3D4)	9760	5
Blank	Shell (S4R)	2400	10

relationship of AA6082-T6 at the ageing temperature 160 °C is used to simulate the material properties evolution during loading in SRAF FE simulations in this study. A Young's modulus of 70 GPa and Poisson's ratio of 0.33 is defined for the elastic property of the material. The plastic part of the experimental stress–strain curve is inputted into the FE models to define the plastic properties of the material, and the inputted initial plastic strain ($\varepsilon_p = 0$) is defined at the point after which $\varepsilon \neq \sigma\ E$.

The numerical simulation of SRAF tests has been divided into five stages according to practical SRAF procedures, including:

1. Initial stage: Define the reference points of the upper and bottom forming tools. The bottom tool is fully constrained, and the upper tool can only move along its thickness direction. The blank is positioned close to the bottom tool at the initial stage.
2. Gravity stage: Position the tools and blank in the FE model automatically through a gravity stage simulation.
3. Loading stage: Apply a predetermined displacement along the thickness direction to fully load the upper tool onto the blank.
4. Stress-relaxation ageing stage: Hold all the parts for a controlled time, for example, 5 h in this study, during which the creep subroutine is activated, and the stress-relaxation ageing behaviour of the blank is simulated.
5. Unloading stage: The upper tool is set to lift to its original location, and the springback of the blank occurs.

The setting of boundary conditions is quite rigorous because of the large and complex deformations needed for the objective shape. The commonly accepted three-node boundary condition setting has been used, and the first node is selected as the first point on the blank contacted with the upper tool during loading, and the other two nodes are selected with the same x or y coordinates as the first node, respectively, in the y- and x-directions to control the translational and rotational movement of the blank.

Due to the difficulty in accurately predicting the springback of the panels after forming, especially for those with large and complex curvatures, springback compensation is an essential step in the tool shape determination process. Generally, springback is compensated by adding the dimensional difference between the objective shape and FE simulated shape of the formed blank to the tool shape used for the last simulation and generating a new tool shape to be used in the next simulation. An accelerated springback compensation method has been used in this study, and more details of the method can be found in an earlier study [24]. The optimised tool shape for producing the demonstration panel was obtained after three iterations of springback compensation that the maximum error between the formed shape by the optimised tool and the objective shape was controlled less than 2 mm.

2.3 Simulation Results

Figure 4 shows the effective stress distribution in the blank after each stage during SRAF by using the optimised tools. The maximum effective stress in the loaded blank was around 229 MPa, which already reaches the plastic region at 160 °C; the

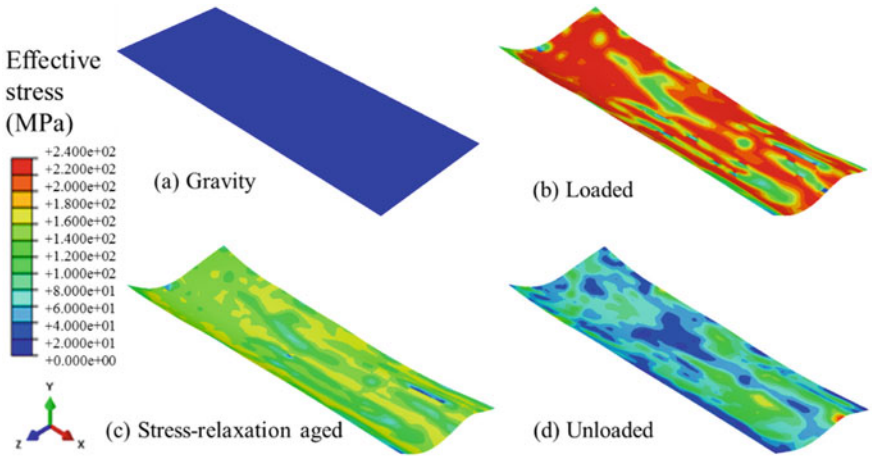

Fig. 4 Numerical results of the effective stress distribution in the blank after each stage during SRAF of the panel. (Color figure online)

minimum effective stress in the blank was around 32 MPa; and the effective stress in most of the loaded blank was in the range of 200–230 MPa. After 5 h of stress relaxation, the majority of the effective stresses decreased to around 160 MPa, with a maximum value of 175 MPa and a minimum value of 17 MPa. After full unloading, the residual stresses left in the blank were mainly in the range of 3–150 MPa, and higher residual stresses were observed at the locations with larger curvatures.

Figure 5 shows the simulated effective plastic strain generated after the loading stage of the SRAF process, and a maximum plastic strain of around 5.5% was achieved after loading.

Creep strain was generated during stress relaxation, and its evolution with ageing time is shown in Fig. 6, with a gradual increase in ageing time. The maximum creep strain generated during stress relaxation was less than 3% of the maximum plastic strain value during the loading stage, indicating the significant effect of the initial plastic strain on the final shape of the SRAFed workpiece.

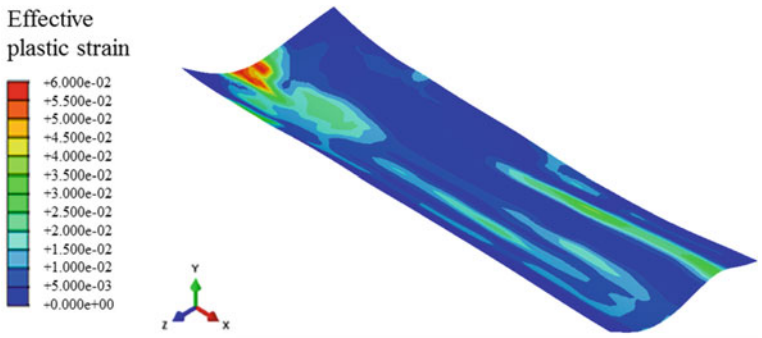

Fig. 5 FE simulated effective plastic strain of the panel after loading. (Color figure online)

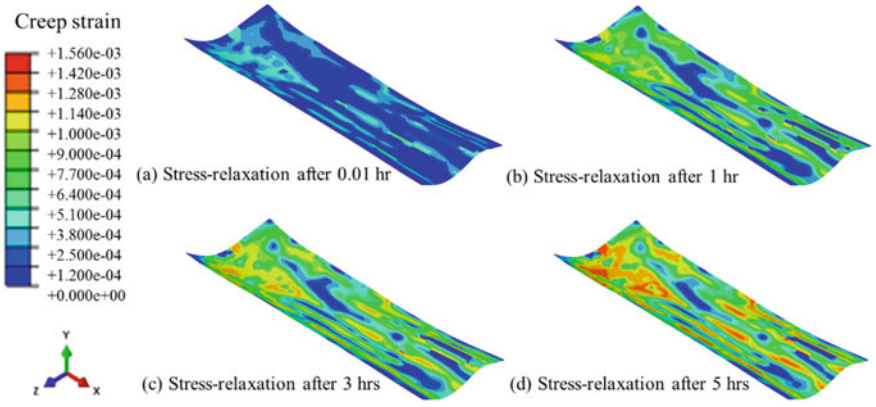

Fig. 6 Evolution of the FE simulated creep strain of the panel during stress-relaxation ageing. (Color figure online)

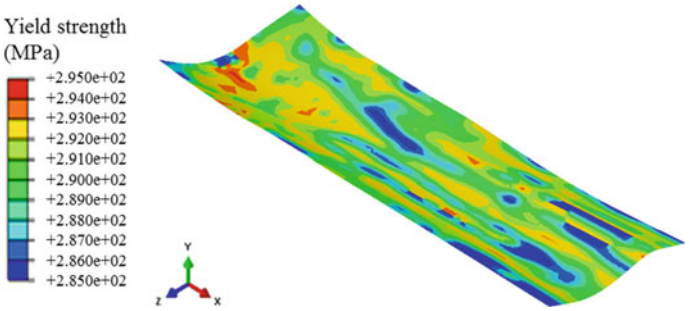

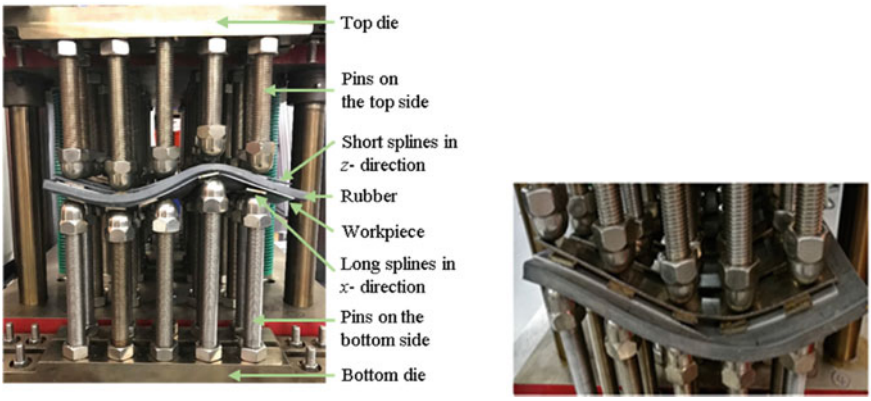

Fig. 7 FE simulated yield strength of the panel after unloading. (Color figure online)

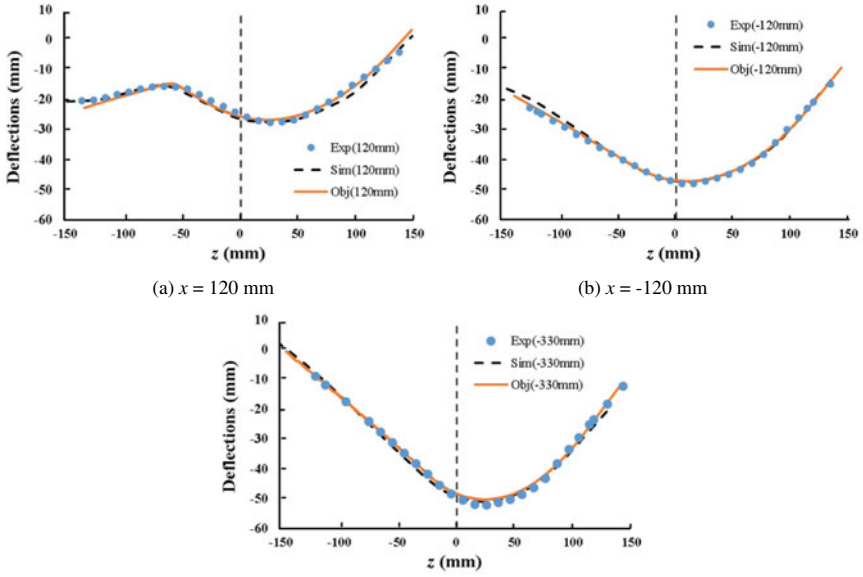
The resultant yield strength of the SRAFed panel at room temperature was predicted to be in the range of 285.5–295 MPa as shown in Fig. 7, with an insignificant variation of yield strength of the SRAFed material compared to its initial state which was set as 290 MPa based on the material model.

3 SRAF Test Verification

SRAF tests were performed using a flexible forming tool with multi-forming pins, as detailed in an earlier study [25]. Figure 8 shows the toolset for SRAF test. The height of each forming pin was determined according to the optimised tool shape, and the blank was prepared with a dimension of $820 \times 300 \times 3$ mm^3. The blank was first loaded to have full contact with the top and bottom pins of the forming tool so



(a) View from x+ direction (b) View from x- direction

Fig. 8 Views of tool setup for SRAF test. **a** View from the $x+$ direction. **b** View from the $x-$ direction. (Color figure online)

that it be deformed to the predetermined shape of the tool surface. The tools were tightened and the whole toolset was moved into a pre-heated furnace. The 5 h SRA was started once the blank reached 160 °C. After the 5 h SRA process, the toolset was moved out of the furnace and unloaded. A 3D coordinate measurement machine CMM LKG90C was employed to measure the deflections of the SRAFed blank.

Figure 9 shows the measured deflections of SRAFed panel (symbols) at selected locations and the results obtained from the FE model (dashed lines) and the objective shape (solid lines). As can be seen, a very good agreement has been achieved among these three sets of data. The maximum deviation among them is within 4 mm, which is less than 5% of the total deflection of the panel and fulfils the general dimensional accuracy requirement for panel assembling in the industry. These deviations may come from the limitations of the lab-scale flexible tool currently used such that the flexible pins are not close enough to generate exactly some specific, large curvature. Such deviations can be further decreased by using the tool with more forming pins or even using solid tools.

The strength of the SRAFed material was evaluated by the hardness test, using Zwick hardness tester with 30 N load (HV3). Six samples were cut from the as-received plate and the SRAFed plate, respectively, five tests for each sample, and the hardness results are shown in Fig. 10, including their variations. It was found that the

(a) x = 120 mm

(b) x = -120 mm

(c) x = -330 mm

Fig. 9 Comparison of the formed shape along the z-direction by using the optimised tool from experiments (symbols) and FE simulation results (dashed lines) with the objective shape (solid lines) of the demonstration panel at cross-sections with the indicated x position. **a** $x = 120$ mm. **b** $x = -120$ mm. **c** $x = -330$ mm. (Color figure online)

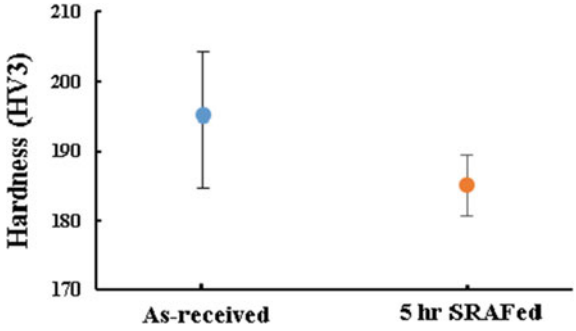


Fig. 10 Hardness results of the as-received and the SRAFed plates. (Color figure online)

average hardness decreased from 195.2 ± 9 HV3 to 185.2 ± 5 HV3 after 5 h SRA at 160 °C. The results correspond well with the simulated results that the SRA process contributes insignificant effect to the strength evolution of AA6082-T6 during SRAF. The current study also shows that sufficient strength has been maintained after SRAF and is adequate for industrial application.

4 Conclusions

Finite element simulation has been carried out on stress-relaxation age forming of AA6082-T6 for a component (820 × 300 × 3 mm^3) with complex and large curvatures. The evolutions of the stress and strain distributions and mechanical property of the blank during SRAF have been predicted by FE simulations. An optimised tool surface was obtained through springback compensation and was used to carry out the corresponding SRAF of an AA6082-T6 panel for verification. It was found that the maximum creep strain generated during stress relaxation was less than 3% of the maximum value of the plastic strain during the loading stage, showing the very significant effect of the initial plastic strain on the final shape for components with large curvature. It was also observed that less springback occurred at the locations with larger curvatures. The successful manufacture of the industrial panel with a maximum shape error of 4 mm and the correct prediction of a minor change in the strength/hardness of the SRAFed plate compared to the as-received plate have proven the feasibility and the accuracy of the developed modelling and springback compensation techniques. It also shows the importance of FE simulation to guide the tool surface design. The work in this study provides a series of numerical and manufacturing tools for the SRAF process of AA6082-T6, which can be applied to other heat-treatable aluminium alloys and guide further industrial manufacturing of panels with complex and large curvatures through SRAF technology.

Acknowledgments Much appreciated is the strong support received from CRRC Qingdao Sifang Co., Ltd. The research was performed at the CRRC Sifang-Imperial Centre for Rail Transportation Manufacturing Technologies at Imperial College London.

Toward an Efficient Industrial Implementation of W-temper Forming for 7xxx Series Al Alloys

Ricardo Trân, Lukas Kertsch, Sebastian Marx, Shreyas Hebbar, Verena Psyk, and Alexander Butz

Abstract Manufacturing technologies for parts made from ultra-high-strength 7xxx series aluminum sheet material have been the focus of research in recent years. A promising approach is W-temper forming, where sheet material is cold formed after heat treatment. Conventional heat treatment routes are very time-consuming and inefficient. In this study, a new more efficient and industry-orientated transfer tool concept has been developed. Heating and cooling of the sheets take place in separate contact tempering stages, which allow superior heating and cooling rates in comparison to conventional methods. To analyze the influences of temperature rates and deformation on microstructure and mechanical behavior, thermo-mechanical experiments in a Gleeble simulator were carried out. The results prove the great potential of the transfer tool concept with inline heat treatment for series production. The process-dependent mechanical properties determine a suitable process window for the industrial application of the W-temper forming of the analyzed alloys.

1 Introduction

Legal requirements to reduce CO_2 emissions and the resulting demands for lower fuel consumption are prompting the automotive industry to push ahead with lightweight construction strategies, such as material sciences, construction design, and systems engineering, to reduce vehicle weight [1, 2]. Owing to its low density of 2710 kg/m^3, aluminum has great potential for lightweight construction and is therefore already

being used to replace conventional steel materials to significantly reduce vehicle weight [3, 4].

Currently, precipitation-hardenable alloys of the 7xxx series are increasingly used in the automotive industry, especially EN AW-7020 and EN AW-7075. Different production routes have already been researched in the field of processing semi-finished sheet metal products. However, a breakthrough across industries has been slowed down so far due to the complex tool and system requirements. Especially the use of high-strength aluminum profiles and tubes for the production of complex-shaped components with cross-sections ranging from single-chamber profiles with constant wall thicknesses to multi-chamber profiles with different wall thicknesses and with various flanges is currently a challenge in terms of forming technology due to the limited formability of these semi-finished products.

Temperature-supported processes can be used to significantly increase the forming capacity of high strength, precipitation-hardenable 7xxx series aluminum alloys [5, 6]. In particular, the processes of forming in solution-annealed, quenched and naturally aged state, the so-called W-temper forming [7–10], as well as forming under quenching conditions, the so-called Hot Form Quenching (HFQ®) [11, 12] are subjects of current research and scientific discussion (see Fig. 1) [13]. Both process variations are based on heat treatment in order to distribute the precipitated alloying elements, which are responsible for the high strength, homogeneously in the microstructure by solution annealing and thus to improve the forming behavior. The challenge with Hot Form Quenching® or hot stamping is that the forming process is carried out with a component heated to approximately 500 °C, which requires expensive cooled and temperature-wear resistant tools, heat-resistant lubricants, and extraction equipment [14]. In the case of W-temper forming, which is the focus of this study, the semi-finished product is quenched after heating up to solution annealing temperature. This significantly increases the forming capacity for a short amount of time, which leads to very high possible degrees of deformation in the subsequent cold forming process [9, 13]. At the same time, the advantages of a typical cold forming process, such as the wide range of applicable lubricants and the simpler

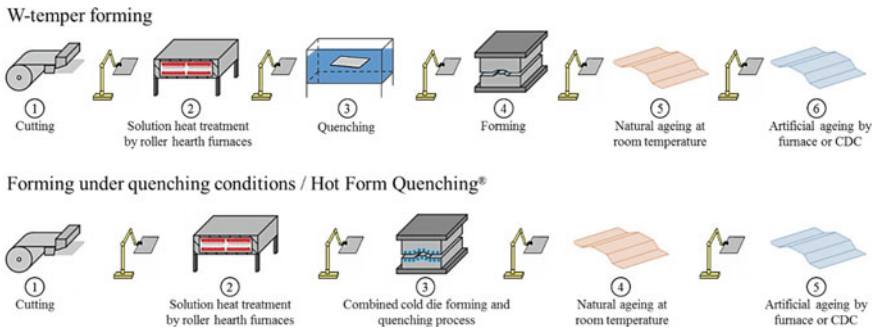

Fig. 1 Process routes for W-temper forming and forming under quenching conditions, the so-called Hot Form Quenching®, according to Ref. [3]. (Color figure online)

tool design, can be used. After forming, the components are cured either over time (natural aging) or in a temperature-supported process (artificial aging). During this process, fine particles are precipitated in the material structure, which has a significant strength-increasing effect [15].

During the solution heat treatment, all soluble precipitate phases dissolve and their constituent elements distribute within the aluminum matrix. In order to provide the potential for the formation of hardening precipitates, the cooling has to be performed at a critical rate or faster to avoid detrimental quench-induced precipitation [16, 17]. From the supersaturated solid solution, the most important precipitation sequence in 7xxx series aluminum alloys involves Mg and Zn-rich phases [18]. Already at room temperature, Guinier–Preston (GP) zones, i.e., Al, Zn, and Mg-rich clusters can form. During typical artificial aging treatments the metastable phase η' with the approximate chemical composition $MgZn_2$ forms. These precipitates are most efficient for hardening. During over-aging or at elevated temperatures, the stable phase η ($MgZn_2$) can form. This is not desirable because these precipitates are less effective for hardening. Further stable phases may precipitate, too, but they are of minor relevance under realistic process conditions [18]. Furthermore, various intermetallic phases are typically present [19]. Although they may have negative effects on the mechanical properties, they usually already form during solidification and cannot be dissolved below the solidus temperature.

Currently, chamber or roller hearth furnaces are commonly used to heat the semi-finished products to approximately 500 °C. These heating concepts work according to the thermal radiation and convection principle and, therefore, transfer the heat to the workpiece very slowly [20]. In addition to the large space requirements of such plants, the heating process is also disadvantageous from an economic point of view. With contact heating, for example, heating times can be reduced by up to 90% compared to conventional furnace heating. However, despite the obvious economic potential, contact heating is currently not used on the W-temper route.

2 Objective

Within this study, the development and construction of a unit for contact heating and contact cooling of sheet metal blanks made of precipitation-hardenable aluminum alloys is presented (see Fig. 2).

Heating and quenching routes are to be identified, which are suitable for setting material states for improved cold forming processes. It is essential that high-strength states comparable to the initial state are achieved even after subsequent aging treatment. The industrial transferability of W-temper forming is to be demonstrated in a meaningful demonstrator scale. To this end, the Fraunhofer Institute for Mechanics of Materials IWM identifies relevant process windows for practical application in extensive material investigations. Based on the temperatures, heating and cooling rates, and holding times that have to be achieved, a tool concept for W-temper forming is

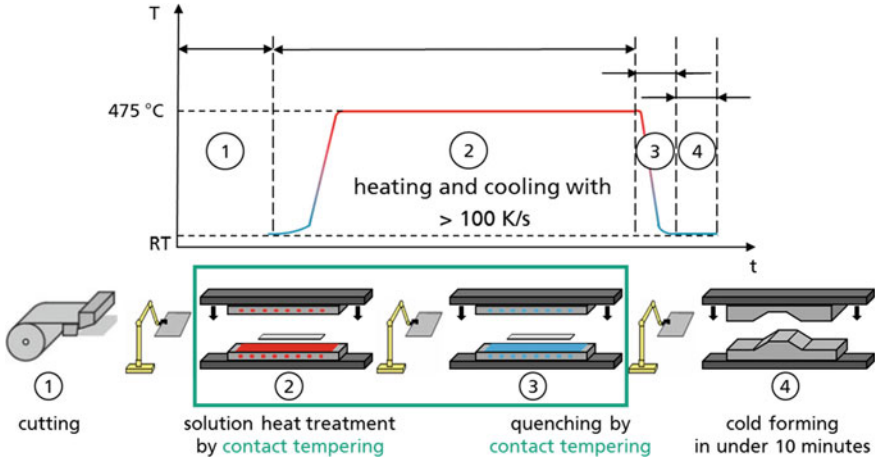

Fig. 2 Process sequence for the processing of heat treatable aluminum alloys by contact tempering. (Color figure online)

developed and tested at the Fraunhofer Institute for Machine Tools and Forming Technology IWU. The results of this study show which heat treatment routes can be used to improve the microstructural properties of the alloys EN AW-7020 and EN AW-7075 for subsequent cold forming by means of contact tempering and demonstrate the potential of contact tempering for industrial applications.

3 Material Characterization and Process Parameter Identification

To define feasible process windows for the W-temper forming of the two Mg-Zn aluminum alloys, sheets of 2.0 mm thickness in a T6 temper state were tested. The alloy EN AW-7020 is practically copper-free, whereas the alloy EN AW-7075 contains a significant amount of Cu and also a higher content of Zn and Mg. The chemical compositions are given in Table 1.

For both alloys, differential scanning calorimetry (DSC) measurements were done using a Netzsch Pegasus 404 °C at various heating and cooling rates. The DSC signals are shown in Fig. 3. In the displayed diagrams, endothermic reactions like the dissolution of a precipitate phase cause upward peaks, whereas exothermic reactions

Table 1 Chemical composition of the analyzed alloys in mass percent

Alloy	Al	Zn	Mg	Cu	Fe	Si	Mn	Cr	Zr	Ti
EN AW-7020	Bal.	4.92	1.27	0.06	0.13	0.05	0.15	0.10	0.09	0.02
EN AW-7075	Bal.	7.26	2.92	1.72	0.11	0.08	0.03	0.19	0.04	0.04

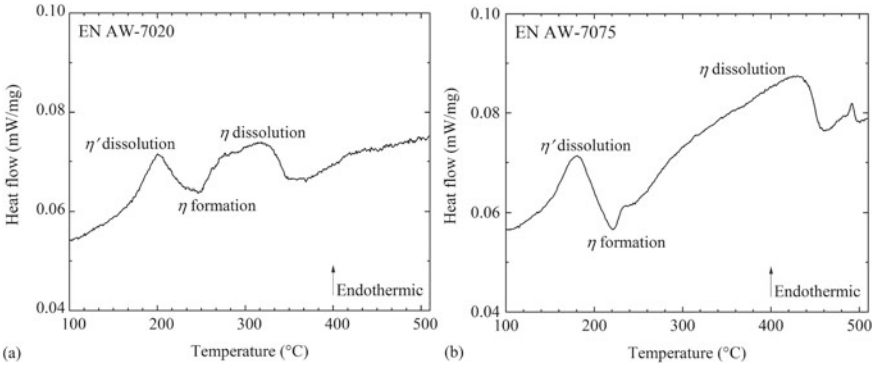

Fig. 3 DSC signals of the alloys **a** EN AW-7020. **b** EN AW-7075 during heating at the rate of 5 K/min

like the formation of a new phase cause downward peaks. By this, the temperature ranges within which precipitate phases are stable as well as suitable heat treatment temperatures can be identified. It has to be taken into account that the reaction temperatures during heating may be slightly overestimated. From the DSC curves, 480 °C was identified as a suitable solution heat treatment temperature for both alloys. Besides, two candidate retrogression temperatures were identified for the alloy EN AW-7020. Already at the relatively low temperature of 225 °C, it can be assumed that all hardening η' precipitates are dissolved, but with the risk of forming undesired equilibrium precipitates, mainly η, during the retrogression heat treatment. At a higher temperature of 360 °C, all Mg–Zn precipitates including η should be dissolved. For the alloy EN AW-7075, too, the lower temperature of 225 °C is a candidate retrogression temperature for the same reason. However, since the dissolution of equilibrium precipitate phases is only completed above 450 °C in this alloy, there is no direct counterpart for the higher retrogression temperature as found for the alloy EN AW-7020. Therefore, several elevated retrogression temperatures for EN AW-7020 between 300 °C and 400 °C were chosen.

To simulate the inline W-temper process, the heat treatments and the subsequent characterization by tensile tests were carried out in the thermo-mechanical simulator Gleeble 3150 using standard tensile test specimens. This makes it possible to heat, quench, and deform without unnecessary interruption due to changing the testing device. In the Gleeble, the specimens are heated by resistance heating. The temperature is controlled with a thermocouple in the specimen center while the jaws are water-cooled resulting in an inhomogeneous temperature along with the specimen. Consequently, only the center region of the specimens, which actually undergoes the simulated process, is further considered. A heating rate of 20 K/s was selected for all heat treatments. Quenching after the heat treatment was done with compressed air. The critical quenching rate to suppress precipitation during cooling is 3 K/s in the temperature range between approximately 320 °C and 180 °C for the alloy EN

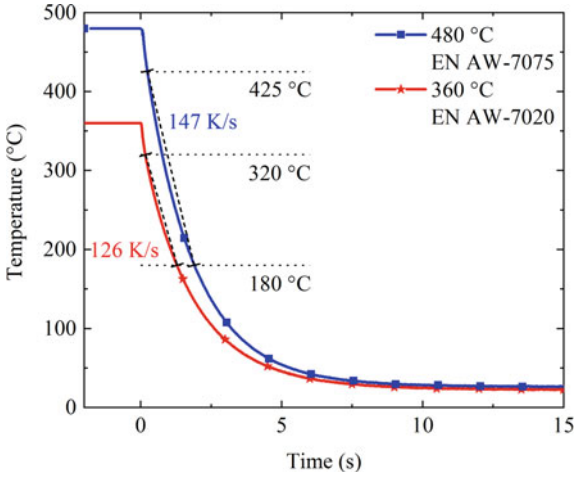

Fig. 4 Temperature over time during air quenching from different temperatures in the Gleeble 3150 and average cooling rates achieved in the critical temperature ranges for the alloys EN AW-7020 and EN AW-7075. (Color figure online)

AW-7020 [17] and 100 K/s between 425 °C and 180 °C for the alloy EN AW-7075 [16].

These critical temperature ranges reported in the literature are consistent with the temperature ranges where the stable precipitates were present in the DSC experiments: The upper limits coincide with the temperatures at the maxima of the respective η dissolution peaks of both alloys taking into account that they are shifted to slightly lower values due to the fast cooling. Below 180 °C, however, the formation of η' is more likely. Figure 4 shows the temperature over time during air quenching in the Gleeble leading to an average cooling rate of 147 K/s between 425 °C and 180 °C as well as 126 K/s between 320 °C and 180 °C. This is faster than the critical rates reported in the literature and should therefore be sufficient to avoid quench-induced precipitation. Various holding times at the solution heat treatment temperature of 480 °C followed by air quenching were tested for the alloy EN AW-7020. The hardness decreased from 121 HV in the as-received state to 56 HV after only 5 s and further to 50 HV after 30 s while it did not significantly change at longer holding times. Therefore, a holding time of 30 s was chosen for all further heat treatments. The suitability of the various selected heat treatment temperatures was evaluated based on the hardness and ductility after quenching as well as on the gain in hardness during the subsequent artificial aging in a furnace at 120 °C. The stress–strain curves of the tensile tests are shown in Fig. 5. For the alloy EN AW-7020, the yield stress could be reduced from 319 MPa in the as-received state to the value of 76 MPa after both solution heat treatment at 480 °C and retrogression heat treatment at 360 °C. The maximum elongation increased significantly and also the strain hardening increased. However, the strain at fracture and ultimate tensile strength could not be quantified after the heat treatments, because the specimens broke outside the gauge length due to the inhomogeneous temperature distribution in the Gleeble heat treatments. For the alloy EN AW-7075, the yield stress dropped from 530 to 160 MPa after the solution heat treatment at 480 °C. Further tests on the alloy EN AW-7075 after solution heat

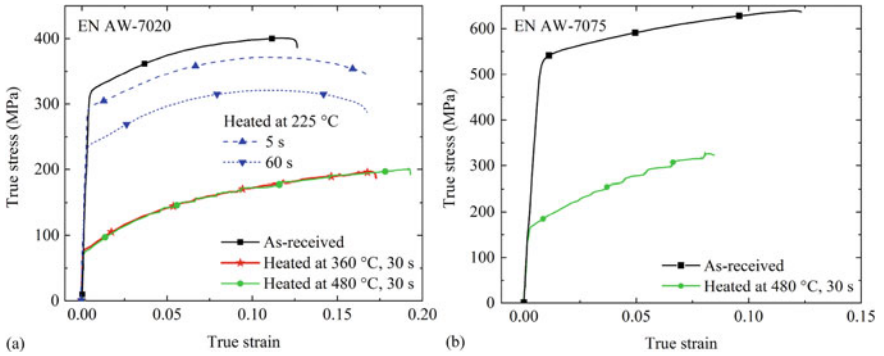

Fig. 5 True stress–strain diagrams of (**a**) EN AW-7020 (as-received, solution heat treated at 480 °C, and retrogression heat treated at 225 °C and 360 °C). **b** EN AW-7075 (as-received and solution heat treated at 480 °C), strain rate is 0.1 s^{-1}. Note that all specimens heat treated at 360 °C and 480 °C broke outside the gauge length. (Color figure online)

treatment in a furnace as well as published experiments [21] suggest that the elongation at fracture is 18–20% for both alloys. The heat treatment at 225 °C, even with longer holding times, results in poor ductility as shown for the alloy EN AW-7020. Therefore this temperature is not further considered. With increasing softening after the heat treatment, the specimens exhibit an increasingly serrated flow behavior due to the Portevin–Le Châtelier (PLC) effect, which might affect the surface quality of formed parts.

Figure 6 shows the hardness evolution during artificial aging. For both alloys, the hardness of the as-received T6 temper could be restored after solution heat treatment and subsequent aging. Besides, a retrogression heat treatment at 360 °C and re-aging led to a very similar behavior for the alloy EN AW-7020 such that this is an interesting

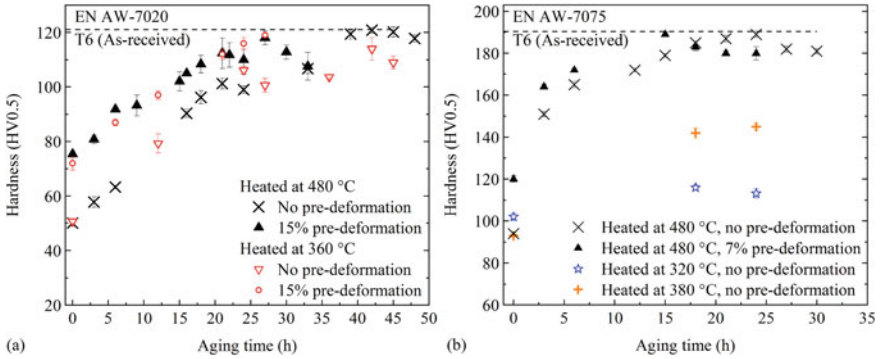

Fig. 6 Hardness evolution during artificial aging at 120 °C in the alloys **a** EN AW-7020 (as-received, solution heat treated at 480 °C, and retrogression heat treated at 360 °C**). b** EN AW-7075 (as-received, solution heat treated at 480 °C, and retrogression heat treated at 320 °C and 380 °C) without and with pre-deformation. (Color figure online)

alternative to the solution heat treatment at a higher temperature. For the alloy EN AW-7075, the solution heat treatment at 480 °C is the only feasible option because the retrogression heat treatments at all investigated temperatures resulted in poor re-aging performance. In addition, the effect of a tensile deformation subsequent to quenching and before aging was studied. As can be seen in Fig. 6, in all considered cases similar peak hardness values as without pre-deformation were achieved. The time to peak hardness, however, was significantly reduced due to the pre-deformation and the rate of hardness loss in the over-aging regime was increased.

Overall, the results can be summarized as follows: For both tested materials, a solution heat treatment at 480 °C followed by quenching at a rate of 147 K/s between 425 °C and 180 °C is suitable to significantly reduce the yield stress and increase the ductility as well as to restore the as-received T6 hardness by artificial aging. For the alloy EN AW-7020, a retrogression heat treatment at 360 °C followed by quenching at a rate of 126 K/s between 320 °C and 180 °C and re-aging leads to very similar results and is, therefore, an interesting alternative. However, for the alloy EN AW-7075 the retrogression heat treatments at all investigated temperatures result in poor material properties and are therefore not suitable for practical applications. A plastic deformation between quenching and aging reduces the time to peak hardness.

4 Tool Design and Experimental Setup

Based on the identified requirements regarding heat treatment temperatures and the required quenching rates, a transfer tool was developed in which sheet metal blanks can first be heated to the target temperature by contact tempering and then be quenched in a second contact tempering tool to set the W-temper state. In the third stage, the heat-treated sheets are then to be cold formed. An electrical heating concept with a total output of 2400 W was used to temper the heating stage. In the heating stage, surface pressures of up to 4.5 MPa can be set for a blank size of 300 × 300 mm. This surface pressure is necessary to ensure sufficient heat transfer. Significantly higher surface pressures could result in the sheet being deformed already during heating. In the quenching tool, the surface pressure is set via the closing force of the press. Investigations by Merklein et al. [14] showed that significantly higher cooling rates can be achieved by increasing the surface pressure during cooling. Saturation of the maximum achievable heat transfer coefficient was achieved at a surface pressure of approx. 30 MPa. Taking into account the sample size used, a press closing force of 2700 kN was set accordingly in the cooling stage. To ensure the highest possible cooling rates, the cooling plates are continuously water-cooled to approximately 20 °C.

Plates with a wall thickness of 2.0 mm are used. In order to determine the heating and cooling rates, a sheet metal plate was fitted with five thermocouples on the front and back. These are each installed in a groove and in different sheet areas. They are located both directly above and between the heating elements and both at the edge and in the center of the sheet (see Fig. 7).

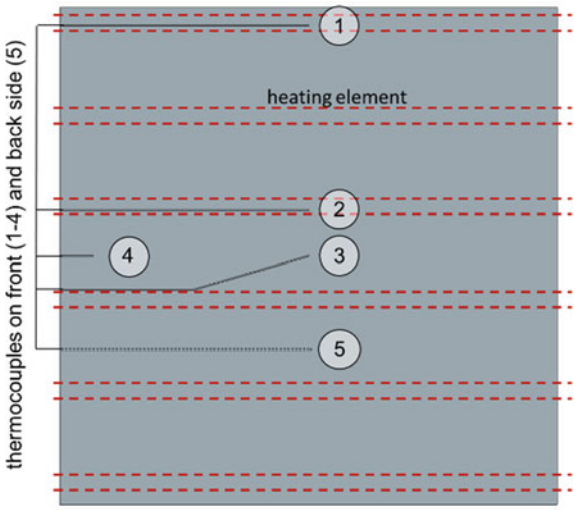

Fig. 7 Arrangement of the thermocouples (type K) in the testing sheet. The position of the heating elements is marked with red dotted lines. (Color figure online)

5 Results of Technological Tests

In order to validate the developed contact heating tool for an industrial application, heating and cooling tests were carried out with the previously prepared test plate (see Fig. 7). First of all, it was investigated how much faster the heating is compared to furnace heating and further whether the critical cooling rates for setting the W-temper state can be achieved by contact cooling. For this purpose, the heating tool was first heated up to 360 °C. A higher tool temperature would result in faster heating of the sheet metal samples due to the higher temperature difference. Figure 8 shows the heating curve of the sheet metal in the tool. The curve represents the averaged

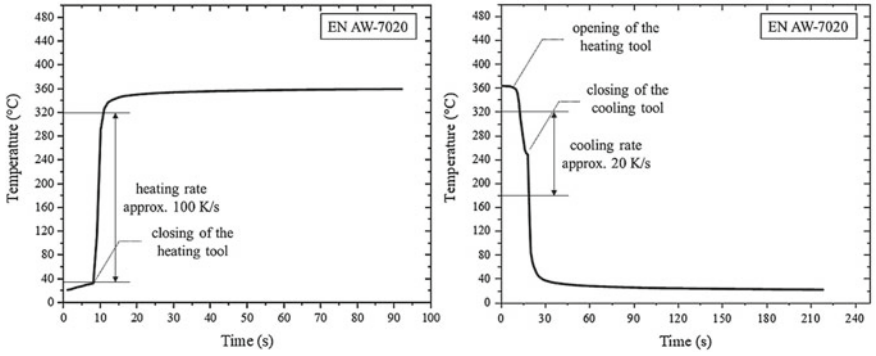

Fig. 8 Temperature profile for heating (left) and cooling (right) of the sheets (EN AW-7020) by contact tempering. Heating tool with a temperature of 360 °C and cooling tool with a temperature of about 20 °C

course of the five recorded thermocouple curves. The deviation of the measured temperatures was in the range of 5 K, which proves the homogeneous temperature distribution within the sheet. Despite the different thermocouple positions, no significant temperature differences were found in the sheet metal, which proves the homogeneous heating of the specimen. From room temperature to 320 °C a heating rate of approx. 100 K/s is achieved. In order to exclude an influence of the heating rate on the material condition, the heating rates determined in the experiment are to be transferred in further Gleeble experiments. To reach 360 °C, considerably more time is required. If the holding time had no influence on the set material condition, the tool could be tempered higher in order to shorten the heating time even further. However, the higher the tool temperature is above the target temperature, the hotter the sheets become, which could be relevant if critical holding times have to be observed. Reference [15] shows that for EN AW-7020, a holding time of only 1 min is sufficient to achieve significantly improved forming properties after subsequent cooling. Increasing the holding time does not improve the material properties. Similar investigations were carried out in Ref. [22] for the alloy EN AW-7075. In this case, too, the holding time could be reduced to 1 min without risking a deterioration of the material properties after cooling and subsequent aging treatment. The results presented in this study confirm these impressions and show that even a holding time of only 30 s is sufficient to both reduce the yield stress and to achieve sufficient strength after artificial aging.

Both in the preliminary investigations and the literature, it became clear that above all the critical cooling rates must be achieved. To determine the actual cooling rates, the heated sheet metal was transferred from the heating stage to the cooling stage. As Fig. 8 shows, significant cooling was already determined by placing the sheet in the lower part of the tool. After closing the tool and applying the closing force of 2700 kN, which equals a surface pressure of 30 MPa, the sheets cooled down rapidly to room temperature. In the test with the contact cooling tool, an average cooling rate of approx. 22 K/s in the temperature range between 320 °C and 180 °C was achieved if an initial temperature of about 360 °C was set. This means that the cooling is much faster than the critical cooling rate of 3 K/s for EN AW-7020 defined in Ref. [17]. The results have shown that by means of contact heating and cooling, the samples can not only be quickly heated to the target temperature of 360 °C but also quickly cooled back to room temperature. Based on the results of the previous Gleeble trials, this allows the inline heat treatment of EN AW-7020 to be carried out exceedingly efficiently on an industrial scale.

In the second series of tests (see Fig. 9), the heating tool was heated up to 480 °C. From the moment the sheet was inserted into the contact heating tool up to 420 °C an average heating rate of approximately 100 K/s was achieved (see Fig. 9). As in the heating tests to 360 °C, the heating time to the target temperature of 480 °C could be significantly reduced by a higher mold temperature. After heating, the sample was transferred to the cooling tool. The sheet metal was already cooled down to about 430 °C by the transfer and placement in the tool (see Fig. 9). The cooling rate is significantly increased by closing the tool. In the critical temperature range from 420 °C to 180 °C, an average cooling rate of approx. 145 K/s is achieved. Thus, the

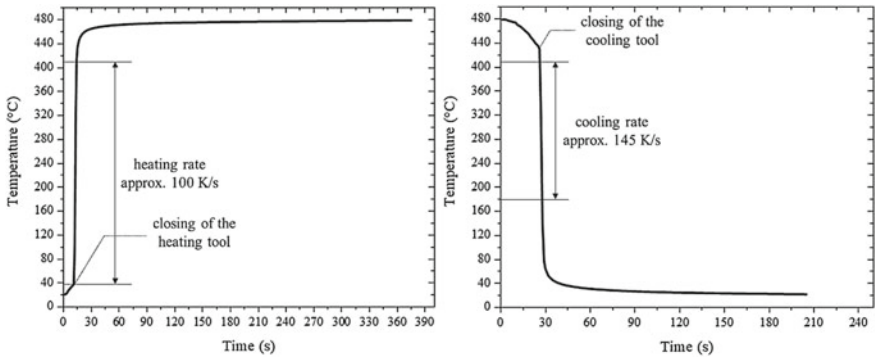

Fig. 9 Temperature profile for heating (left) and cooling (right) of the sheets by contact tempering. Heating tool with a temperature of 480 °C, and cooling tool with a temperature of about 20 °C

cooling rate in the critical temperature range is significantly higher than described in Ref. [15]. Also with reference to the Gleeble tests carried out, it should be possible to set an optimum W-temper condition for a subsequent cold forming process.

As already mentioned, higher tool temperatures and thus higher temperature differences between tool and sheet could significantly increase the heating rates. Lower holding times mean that the heating-up times and thus the cycle times in industrial applications for contact heating can be significantly reduced once again, which increases the efficiency of the entire process chain of W-temper forming by the use of contact tempering. Exemplary heating tests of the same samples as used for the contact tempering trials in a chamber furnace heated to the target temperature have shown that the heating process takes about eight times longer (see Fig. 10).

6 Summary and Conclusions

Within the study, the immense potential of contact tempering was demonstrated and an approach for industrial application was presented. Contact heating and contact cooling could adjust the W-temper state necessary for cold forming of the aluminum alloys EN AW-7020 and EN AW-7075. Gleeble tests have shown that for both EN AW-7020 and EN AW-7075, a solution heat treatment at 480 °C and subsequent quenching is appropriate to obtain sufficient formability and to arrive at similar hardness after aging as in the as-received T6 temper. In addition, for EN AW-7020, heating to 360 °C and subsequent cooling is sufficient to achieve significantly improved forming properties without deteriorating material properties after aging. Further investigations to reduce the holding times are planned. It is also necessary to find out whether the heat treatment parameters determined for the material in the T6 temper and the tool technology developed are also suitable for the use of semi-finished products in the T4 condition. As a next step, a forming tool will be

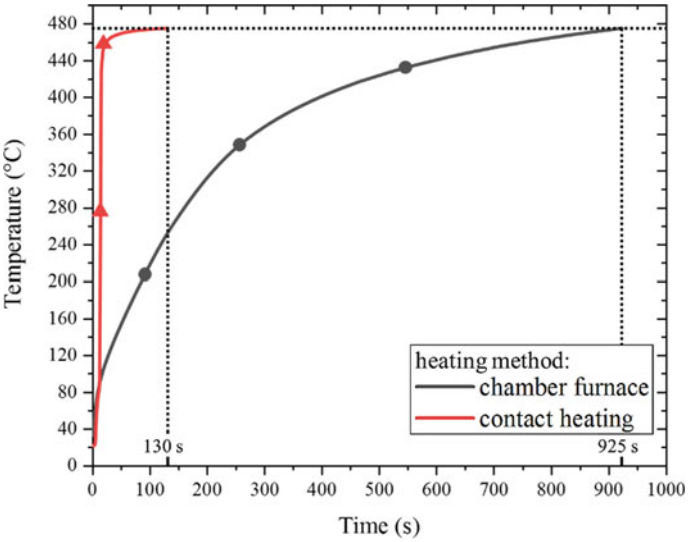

Fig. 10 Comparison between temperature profiles of 2.0 mm sheet material heated by chamber furnace and contact heating. (Color figure online)

developed to produce a demonstrator component after the cooling stage. Furthermore, the tempering concept will be adapted to the use of tubes and hollow profiles.

Calibration and Validation of Stress–Strain Curve in High-Strain Region of Mild Steel Sheet

Hideo Tsutamori, Takeshi Nishiwaki, and Hiroaki Onishi

Abstract Stress–strain curve in the high-strain region is one of the most important models that must be taken into consideration for high-precision sheet metal forming simulation. In this study, using mild steel sheets, tensile tests were conducted with a necked shape specimen at the center in order to generate non-uniform elongation. Using image analysis, strain–load relationships were obtained using multiple gauge lengths, and stress–strain relationships were obtained by inverse analysis using FE simulation. With a sufficiently small gauge length it is possible to get stress–strain curve in the high-strain region. The advantage of this method is that the experiments can be implemented only with a uniaxial tensile test. For validation, the original hole expansion test model that is not affected by friction is proposed. The thickness strain distribution along the hole with large plastic strain is compared with the experimental and numerical results to indicate the validity of this method.

Keywords Stress–strain curve · Inverse analysis · Uniaxial tensile test · Mild steel sheet

1 Introduction

The stress–strain curve is one of the most essential and fundamental properties for numerical simulation of sheet metal forming. The curve is usually obtained by a uniaxial tensile test. It is well known that a stress–strain curve is correct within the uniform elongation. However, in the non-uniform elongation region of the uniaxial tensile test, stress–strain relationship can be obtained but is not correct. Since the cross-sectional area is not constant, the stress after elongation becomes non-uniform, which means the average value within the gauge length. On the other hand, large plastic strain regions are often seen in the formed sheet panels of mechanical or automotive parts, for example, the edge of holes or bending and unbending regions.

That effective plastic strain is larger than the ultimate uniform elongation of stress–strain curve. The stress–strain curve in the high-strain region is an important material model for numerical simulation. So far, there are various studies to obtain the stress–strain relationship in the high-strain region. A method of observing the necking during the test using CCD camera has been proposed [1–3], and there is a study of using optimization software to obtain the stress–strain curve in the tensile test of the bar specimens [4]. A plane share test [5] or bending test [6] may be used to obtain the stress–strain curve in the high-strain region. In this paper, we propose a method for obtaining stress–strain curve in the high-strain region of mild steel sheet by inverse analysis using digital image correlation (DIC) system and FE analysis. Furthermore, an evaluation of the curve in the high-strain region was conducted by hole expansion test using the uniaxial tensile test. Since this hole expansion test does not include friction or bending, it was possible to validate the stress–strain curve in the high-strain region by comparison between the experimental and numerical analysis.

2 Model of Stress–Strain Curve in the High-Strain Region

Before extending a stress–strain curve in the high-strain region, it is necessary to obtain an s–s curve in the uniform elongation range. This is the base s–s curve up to the true strain ε_{ext} at the extension point. In this study, mild steel sheets were used, and ε_{ext} was set to 0.2. Next, upper and lower limit curves are prepared expediently. The upper limit curve uses the Swift hardening model [7] of Eq. (1). The lower limit curve employs the Voce hardening model [8] of Eq. (2). In these equations, σ is a true stress, ε_p is an effective plastic strain, ε_0 is constant, and F, n, σ_0, σ_∞, and D are positive constants.

$$\sigma_{sw} = F\left(\varepsilon_0 + \varepsilon_p\right)^n \tag{1}$$

$$\sigma_{vo} = \sigma_\infty + (\sigma_0 - \sigma_\infty)e^{-D\varepsilon_p} \tag{2}$$

The plastic strain ε_{cnc} ($<\varepsilon_{\text{ext}}$) which is a connection point on the base s–s curve is determined. The base curve, the upper limit curve, and the lower limit curve are smoothly connected at the connection point. In this study, it was set to 0.05. The true stress at the connection point is defined as σ_{cnc}, and the following equations are obtained from the connection conditions at the point (ε_{cnc}, σ_{cnc}) on the base s–s curve.

$$\sigma_{\text{cnc}} = F(\varepsilon_0 + \varepsilon_{\text{cnc}})^n \tag{3}$$

$$\sigma_{\text{cnc}} = \sigma_\infty + (\sigma_0 - \sigma_\infty)e^{-D\varepsilon_{\text{cnc}}} \tag{4}$$

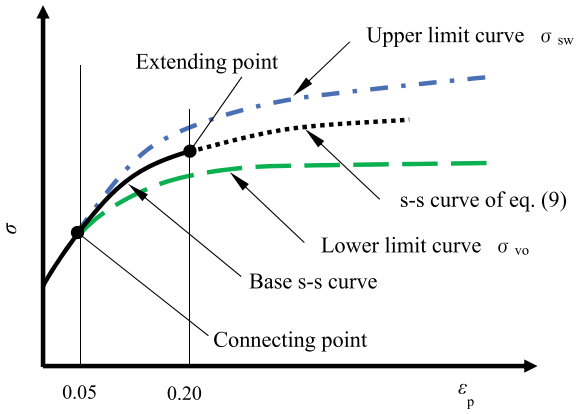

Fig. 1 Model of s–s curve in the high-strain region. (Color figure online)

The following equations are also obtained from the tangent continuous condition:

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\varepsilon_p} = nF(\varepsilon_0 + \varepsilon_{\mathrm{cnc}})^{n-1} \tag{5}$$

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\varepsilon_p} = -D(\sigma_0 - \sigma_\infty)\mathrm{e}^{-D\varepsilon_{\mathrm{cnc}}} \tag{6}$$

The value of $\mathrm{d}\sigma/\mathrm{d}\varepsilon_p$ is given by the base s–s curve. Equation (7) is obtained by the second derivative continuous condition between Eqs. (1) and (2) at the connection point. Equation (8) is obtained by the assumption that the stress value is the average between the upper and the lower limit curves at the extending point. The constants ε_0, F, n, σ_0, σ_∞, and D are obtained by solving the six equations from (3) to (8). Figure 1 shows the above-described curves and the connection and the extending points.

$$\frac{\mathrm{d}^2\sigma}{\mathrm{d}{\varepsilon_p}^2} = n(n-1)(\varepsilon_0 + \varepsilon_{\mathrm{cnc}})^{n-2} = D^2(\sigma_0 - \sigma_\infty)\mathrm{e}^{-D\varepsilon_{\mathrm{cnc}}} \tag{7}$$

$$\sigma_{\mathrm{ext}} = \frac{F(\varepsilon_0 + \varepsilon_{\mathrm{ext}})^n + \left\{\sigma_\infty + (\sigma_0 - \sigma_\infty)e^{-D\varepsilon_{\mathrm{ext}}}\right\}}{2} \tag{8}$$

Further, in Eq. (9), the extension curve is defined by linear interpolation of the upper limit curve σ_{sw} of Eq. (1) and the lower limit curve σ_{vo} of Eq. (2).

$$\sigma = \left(1 - t\left(\varepsilon_p\right)\right)\sigma_{vo} + t\left(\varepsilon_p\right)\sigma_{sw} \tag{9}$$

$t\left(\varepsilon_p\right)$ in Eq. (9) is a function of the effective plastic strain and represented by Eq. (10).

$$t\left(\varepsilon_p\right) = 0.5 + a\left(\varepsilon_p - \varepsilon_{\mathrm{ext}}\right) + b\left\{e^{-c\left(\varepsilon_p - \varepsilon_{\mathrm{ext}}\right)} - 1\right\} \tag{10}$$

Here, $0 \leqq t(\varepsilon_p) \leqq 1$; a, b, and c, are constants. $t(\varepsilon_p)$ is assumed as a linear combination of constant 0.5, a term proportional to the effective plastic strain and a term that decreases exponentially with respect to the effective plastic strain. How to get the value of variables a, b, and c is shown in Sect. 6.

3 Uniaxial Tensile Test

The uniaxial tensile tests were conducted using two geometrical types of specimen. Figure 2 shows the geometries of the specimen. Type A is a specimen that meets the Japanese uniaxial tensile test standard with 25×60 mm straight width and length. This was used for the purpose of measuring the base s–s curve within uniform elongation and identifying anisotropic parameters. Tensile tests were carried out in three directions with respect to the rolling direction, and the repetition number was three for each direction. These mechanical properties are shown in Table 1.

On the other hand, the type B specimen has an arc shape on both sides. This is deformed non-uniformly from the beginning of the tensile test. These are used to

calibrate the s–s curve in the high strain region in Sect. 6. The displacements were measured by image analysis, in which the gauge lengths were 2 mm and 5 mm from the center, and the load force was measured by the load cell.

4 Bulge Test

In the high-strain region, even in the uniaxial tensile test, the stress state becomes biaxial stress, and it is important to measure the biaxial stress and employ an appropriate anisotropic yield function. In this study, a hydraulic bulge test was conducted. Table 2 shows the normalized values of the equi-biaxial stress at which the plastic work is equal to the work of 20% plastic strain in the uniaxial tensile test in the rolling direction, and the plastic strain increment ratio at that time.

5 Identification of Yield Function Parameters

In this study, YLD2000-2D [9] was used for the yield function because it can consider equi-biaxial stress state. To calculate the anisotropic parameters, we used flow stresses and r values of the uniaxial tensile tests of 0°, 45°, and 90° in the tensile directions, and the results of the bulge test. The anisotropic parameters α1–α8 were solved by numerical calculation with order m of yield function set to 6. Table 3 shows the results of anisotropic parameters of YLD2000-2D.

6 Calibration of Stress–Strain Curve in the High-Strain Region

Optimization software LS-OPT was used to obtain the s–s curve in the high-strain region. The variables are a, b, and c in Eq. (9). The evaluation functions are the relationship between nominal stress and nominal strain in tensile tests with type

Table 4 Optimization results of variables by LS-OPT

a	*b*	*c*
0.036	−0.378	1.258

B specimen using multiple gauge lengths. The variables are calculated so that the differences between the experiments and the numerical simulation results become minimum by the mean square error method. Table 4 shows the result of variables. Figure 3 shows tensile test using type B specimen. Figure 4 shows the comparison of relationship results between nominal stress and nominal strain with 5 mm of gauge length. For the arc specimens, the nominal stress means the load force divided by the initial section area of the center and nominal strain means the displacement divided

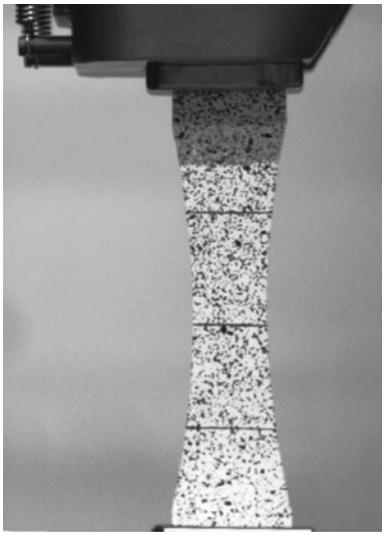

Fig. 3 Experimental photo of type B specimen

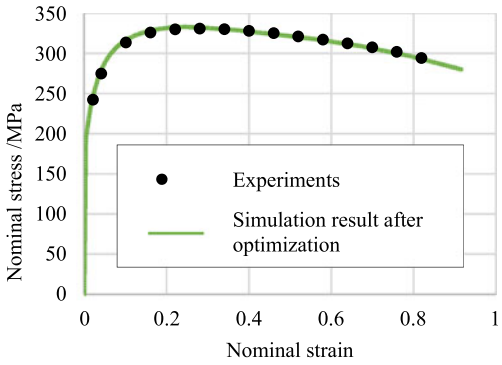

Fig. 4 Comparison result of gauge length 5 mm. (Color figure online)

by the initial length in this study. Dot points are experimental results and solid curve is simulation result after optimization. Figure 5 also shows the same comparison with 2 mm of gauge length. In general, good agreement was obtained although there was some dissociation at a nominal strain of more than 0.6 with a gauge length of 2 mm. Figure 6 shows the s–s curve (true stress-effective plastic strain curve) including the high-strain region by the proposed method.

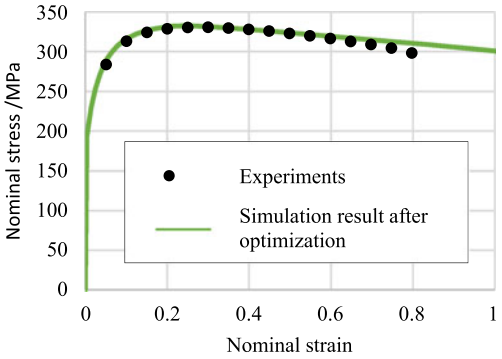

Fig. 5 Comparison result of gauge length 2 mm. (Color figure online)

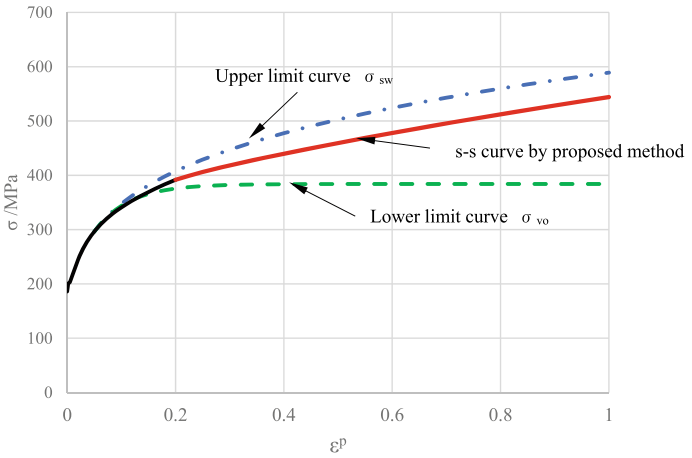

Fig. 6 Stress–strain curve obtained by the proposed method. (Color figure online)

7 Validation of s–s Curve in the High-Strain Region Obtained by the Proposed Method

In order to evaluate the validity of the obtained stress–strain relationship in the high-strain region, a hole expansion test was conducted and the thickness strain distribution along the hole edge was compared. The hole expansion test is often used [10–13] to evaluate the prediction accuracy of the anisotropic yield function. However, it is difficult to separate influences of friction modeling and the Bauschinger effect from the evaluation, since it includes a contact with the dies and bending deformation. Therefore, the original hole expansion test was conducted with a uniaxial tensile tester using a specimen with a notch and a hole in the center as shown in Fig. 7. Accurate evaluation is possible because the proposed method does not need to consider a friction model or bending model. The strain distribution around the hole was measured by the DIC method, and the thickness strain was calculated assuming constant volume during plastic deformation. Figure 8 shows the thickness distribution at 1 mm from the hole edge before the test when the hole diameter is 7.00 mm. The upper and lower limit curves are also shown due to comparison. The proposed method and the experimental results showed good agreement, and the maximum value of the effective plastic strain was 0.29 in this condition. Figure 9 shows a comparison of the thickness distribution when the hole diameter is 7.31 mm. Similarly, the experimental results agreed well with the proposed method. The maximum

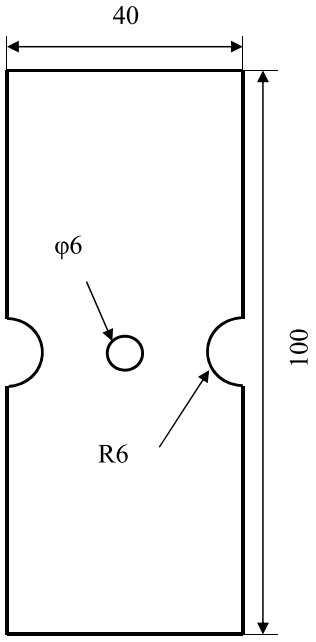

Fig. 7 Geometry of a uniaxial hole deformation test

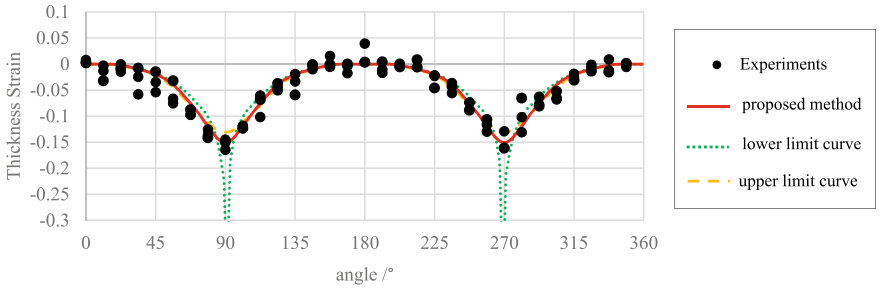

Fig. 8 Comparison of thickness distribution when hole diameter is 7.00 mm. (Color figure online)

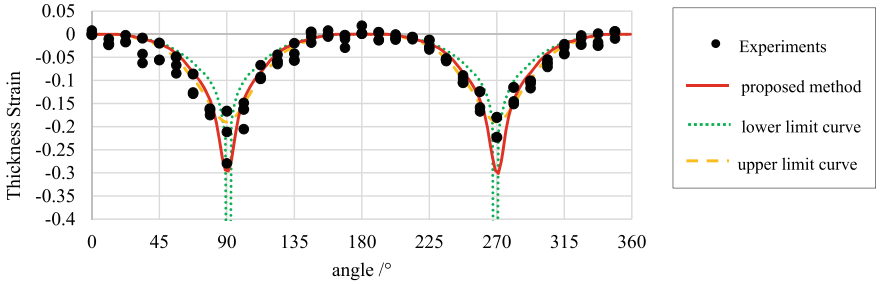

Fig. 9 Comparison of thickness distribution when hole diameter is 7.31 mm. (Color figure online)

value of the effective plastic strain was 0.51. These results revealed the validity of the proposed extending method of the s–s curve.

8 Concluding Remarks

An accurate s–s curve in the high-strain region is one of the important issues for improving the prediction of the sheet metal forming simulation. In this study, we proposed a method to obtain s–s curve in the high-strain region using the uniaxial tensile tester, DIC, and FE simulation. The key messages of this work are summarized as follows:

1. The upper and lower limit curves were defined using the base s–s curve up to uniform elongation, and a s–s curve model in the high-strain region with three variables was proposed.
2. Using the optimization software LS-OPT, three variables were specified, and a s–s curve in the high-strain region was obtained.
3. The hole expansion test which does not include bending or contact with the die was proposed.

4. The validity of the proposed extending method of s–s curve by uniaxial hole expansion test was confirmed.

Influence of the Quenching Rate and Natural Ageing Duration on the Formability and Mechanical Properties of EN AW-7075

B.-A. Behrens, S. Hübner, H. Vogt, O. Golovko, S. Behrens, and F. Nürnberger

Abstract Due to the low density and high tensile strength, the aluminium alloy EN AW-7075 offers a high lightweight potential for structural components. In recent years, 7xxx-aluminium alloys have been the subject of numerous investigations in the field of warm and hot forming and suitable heat treatments to fully use their potential for applications in automotive bodies. Alternatively, forming blanks of these alloys at room temperature in the W-temper state is favourable since conventional tools can be used. However, this condition is unstable. As the ageing duration after quenching increases, the formability decreases due to natural ageing. Hence, the objective of this investigation was to determine the formability of EN AW-7075 as a function of the ageing time. Furthermore, since the quenching rate after solution heat treatment influences the resulting mechanical properties, an adapted process route to manufacture components with tailored properties was explored. For this purpose, samples were partially quenched after solution heat treatment and then artificially aged. To determine the influence of the quenching rate, hardness tests were carried out.

Keywords 7xxx-aluminium alloys · Cold forming · Formability · Tailored tempering

1 Introduction

Nowadays, the most common lightweight material in the automobile industry is aluminium. In car bodies mainly the alloy series 5000 and 6000 are used for structural or shell parts, respectively. However, the highest strength aluminium alloys belong to the 7000 series. These materials have the same specific strength as hot-stamped

steels and an additional feature of increased elongation at break [1]. In particular, the substitution of hot-stamped steel components by components made of 7000 series aluminium alloys can lead to a significant reduction in body weight. However, these alloys have so far been rarely used in car body construction. The reason for this is the low formability of the materials at room temperature in the highest strength state. Therefore, various approaches are currently being investigated to improve the formability of the alloys.

One approach is the warm forming of the high strength material after quenching and artificial ageing (in T6 condition according to EN 515). The improved formability of this process is based on the dissolution of η' precipitations and dynamic recovery effects at elevated temperatures [2]. Sotirov et al. [1] and Behrens et al. [3] have determined the increased formability for this process route for the alloy EN AW-7075. The influence of the heat treatment condition of the initial material on the formability has also been examined by Kumar et al. [4]. Noder et al. have investigated a process variant for non-isothermal forming [5]. They and Behrens et al. [6] have determined an over-ageing of the aluminium alloys. This is caused by the additional heat treatment for warm forming.

Another approach is the hot forming process route. Therefore, the aluminium blanks are heated to temperatures above the recrystallisation temperature. The sheet material is subsequently transferred into a water-cooled press tool and simultaneously formed and quenched [7]. Argandoña et al. [8] have used this process route to form defect-free B-pillars. However, due to the solution heat treatment process, the formed components have no usable mechanical properties. Therefore, an artificial ageing step must be carried out afterwards. The increase in strength is based on the forming of finely dispersed metastable precipitations [7]. The precipitation sequence determined by Degischer [9] and Löffler [10] describes partially coherent η' precipitations as the main hardening phase for 7000 series aluminium alloys. For the alloy EN AW-7075, Behrens et al. [11] have additionally investigated the influence of the quenching rate on the mechanical properties, which should be chosen according to the copper content of the alloy.

However, warm and hot forming solutions require additional process steps and a complex tooling system in comparison to cold forming processes. Alternatively, the forming of such blanks at room temperature in the W-temper state is favourable since conventional tools can be used. Therefore, in this paper, a cold forming process route is investigated.

2 Cold Forming Process Route

The high strength of the 7000 series aluminium alloys results in a limited formability in T6 condition at room temperature. Therefore, different approaches like the W-temper process are examined to increase the formability. This process is named after the W-temper heat treatment state. This condition is achieved after solution heat treatment and quenching of the material. The alloying elements remain dissolved and

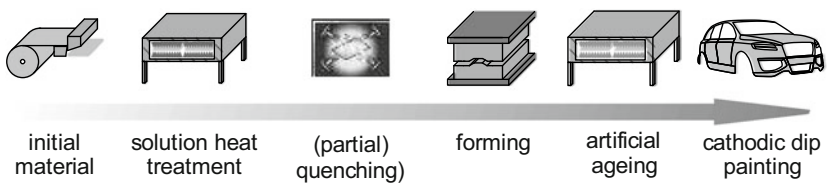

Fig. 1 Cold forming and heat treatment process route for the 7000 series aluminium alloy
