a supersaturated state with a high number of solute atoms and vacancies is formed. Due to its high ductility, this heat treatment state allows cold forming. However, the blanks must be formed as soon as possible after quenching; otherwise, the material will age naturally. As a result, the strength of the material increases and thus its formability is reduced. Argandoña [12] investigated the formability of EN AW-7075 at room temperature in the ductile W condition. To set the final mechanical properties of the components, a subsequent heat treatment is necessary [13] which can be a combination of artificial ageing and the cathodic dip painting process, see Fig. 1. An extension of the process route is possible by controlled cooling of the blanks. Since copper-containing alloys of the 7000 series have a sensitivity to the quenching rate, it is possible to produce components with load-optimised tailored properties. For example, a spray field can be used to quench certain areas of the blank rapidly, while the remaining areas cool down slowly [14, 15]. Following artificial ageing, high strengths are achieved in the rapidly quenched areas. In the slowly cooled areas the strength is lower, but the ductility increases.

3 Experimental Setup

For the experimental investigations, the aluminium alloy EN AW-7075 in T6 state was examined. This alloy contains copper and is thus sensible for quench processes [13]. The mechanical properties are listed in Table 1.

Table 1 Investigated aluminium sheet metal material

	Sheet thickness (mm)	Ultimate tensile strength *UTS* (MPa)	Elongation at break *A* (%)	Copper content (wt.%)
EN AW-7075 T6	2.0	569	14.1	1.63

3.1 Formability in W-Temper State

A Nakajima test was carried out to investigate the formability of alloy EN AW-7075 in the W-temper state. This test was used to determine forming limit curves for various heat treatment conditions. Both the influence of the quenching rate and of the natural ageing time between solution heat treatment and the Nakajima test were investigated. For sample preparation, the Nakajima samples were, therefore, first solution heat-treated and then quenched. The solution annealing temperature (T_{SHT}) was 480 °C and was maintained for 10 min (t_{SHT}). For rapid quenching, the blanks were subsequently cooled in a pneumatically operated plate tool. This is shown in Fig. 2 on the left. To ensure uniform cooling of the blanks, the plates of the tool were water-cooled. In addition, and to simulate low cooling rates, the blanks were placed on spacers in the tool to prevent premature cooling. For this slow cooling of the samples, they were cooled down at air. The time–temperature curves for both quenching methods are shown in Fig. 2 on the right. In the pneumatic tool, a quenching rate of 250 K/s is reached in the temperature range of 400 °C–200 °C, at air of 1.11 K/s.

After quenching, the blanks were aged naturally for various times. The ageing duration was varied between 5 min and 30 days after quenching. However, the ageing period was not started until the temperature of the blanks dropped below 50 °C during quenching so that forming at room temperature could be ensured for the samples cooled at air. The different ageing durations were chosen according to the data of Ostermann et al., as shown in Fig. 3. This is based on the increasing hardness of the material with increasing natural ageing time.

The quenched samples were used subsequently to determine a forming limit curve for each quenching rate and ageing duration. A universal testing machine from the Erichsen company was used for this purpose, see Fig. 4 on the left. The tests were

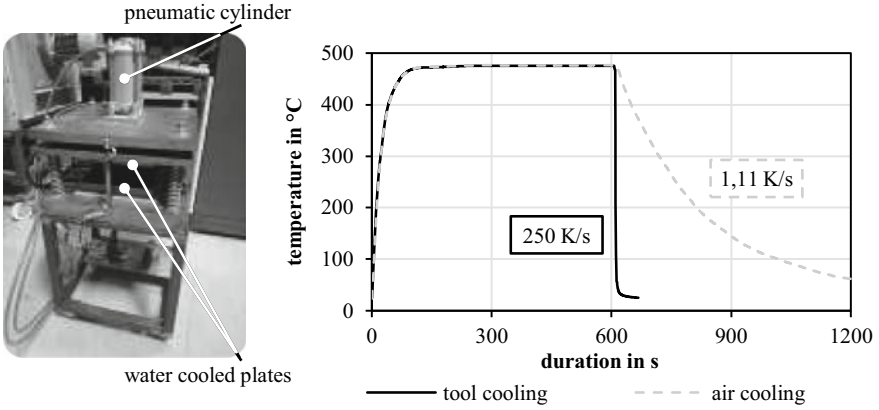

Fig. 2 Pneumatically operated tool (left) and time–temperature diagram of the quenching step for high and low cooling rates (right)

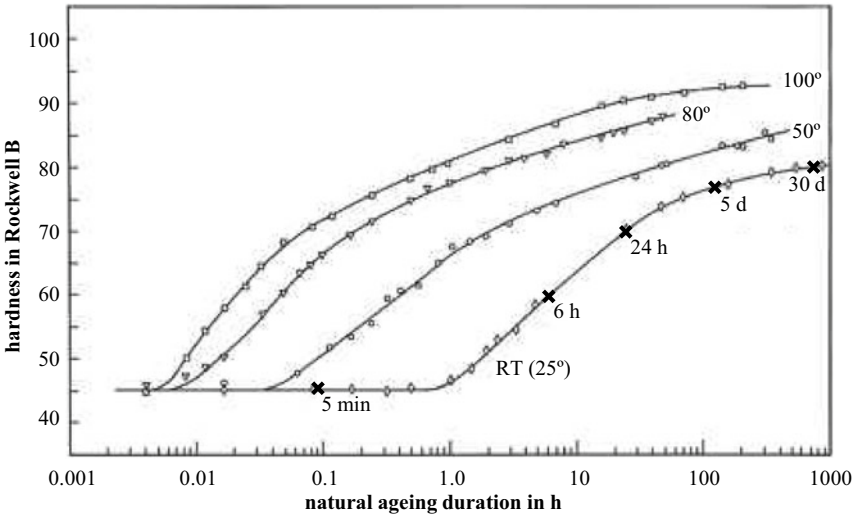

Fig. 3 Hardness development depending on the natural ageing time according to [13] and the selected ageing times according to the hardness evolution

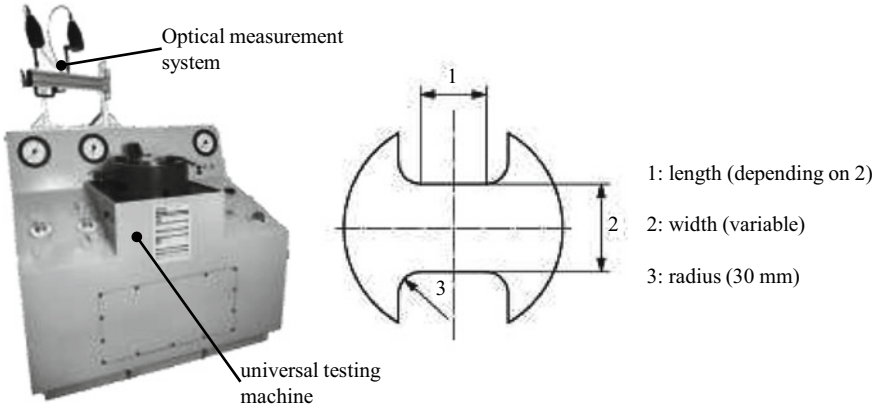

Fig. 4 Nakajima testing rig (left) and shape of the sheet metal samples (right)

carried out according to DIN EN ISO 12004-2. The hemispherical punch had a diameter of 100 mm. The clamping force to prevent the material from flowing was set to 300 kN and the punch speed during the test was 1.5 mm/s. The specimens were prepared according to DIN EN ISO 12004-2. The shape shown in Fig. 4 on the right was used. The rolling direction of the blanks was parallel to the orientation of the crossbar. The width of the crossbar was varied to set different stress states in the sample. A total of five crossbar widths were used, ranging from 30 to 160 mm.

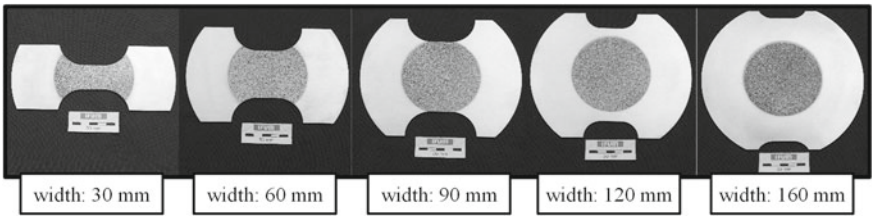

Fig. 5 Overview of the used test samples and the varied width of the crossbar

The optical measuring system Aramis from the company GOM mbH was used to evaluate the samples. For this purpose, a stochastic pattern was applied to the samples, which can be detected by the measuring system. The prepared samples with the varied crossbar widths are shown in Fig. 5. The evaluation of the samples was carried out according to the online method AM3 described in DIN EN ISO 12004-2. The maximum major and minor strain were determined immediately before the crack.

3.2 Tailored Tempering of EN AW-7075

In order to obtain areas with different mechanical properties in one part, the alloy EN AW-7075 was partially quenched after solution heat treatment. An adjustable compressed air-quenching facility as shown in Fig. 6 on the left was used for this purpose. By means of cooling nozzles, it is possible to cool down certain areas of the blank with different quenching rates. These areas achieve a higher strength after the heat treatment. To change the quenching rate, various parameters can be set. On the one hand, these are the number and arrangement of the cooling nozzles. It is either possible to use three nozzles arranged below the blank or a total of six nozzles.

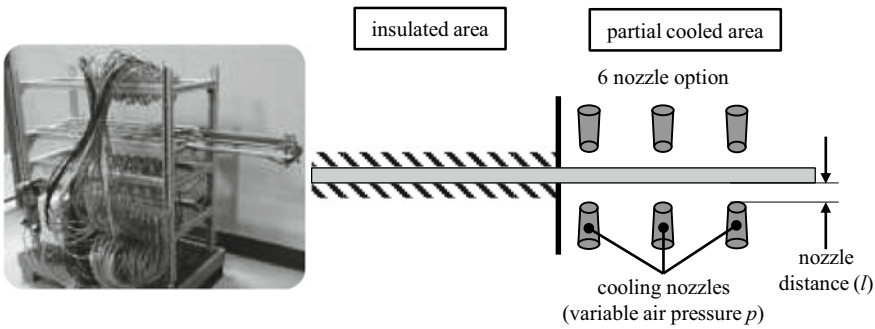

Fig. 6 Compressed air-quenching facility for partial quenching (left) and schematic overview of the adjustable compressed air-quenching facility parameters

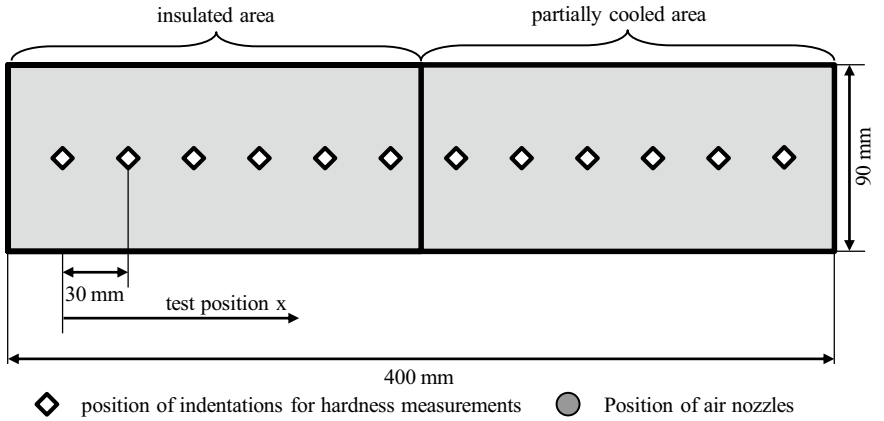

Fig. 7 Indentation positions for the hardness measurements of the partially quenched sheets

Furthermore, the distance (l) between the nozzles and the blank can be either 100 mm or 150 mm. In addition, the air pressure (p) can be adjusted between 1 and 6 bar. On the other hand, a low quenching rate is required for areas where low strength is to be achieved. This can be reached in the test setup used by insulation. A schematic layout of the compressed air-quenching facility is shown in Fig. 6 on the right. The solution heat treatment before quenching was performed at 480 °C for a duration of 10 min.

After solution heat treatment and partial quenching, the heat treatment was continued by artificial ageing of the sheet metal strips at 120 °C for 24 h. A Vickers hardness test was then carried out on the surface of the samples. A ZwickRoell ZHU250 hardness testing machine was used for this purpose. The test was equivalent to the HV10 hardness test. The positions of the hardness test are shown in Fig. 7. Five hardness indentations were made in each of the insulated and quenched areas. The tests were performed at a distance of 30 mm from each other.

The evaluation method shown in Fig. 8 was used to determine the hardness gradient and the transition zone length as a function of the quenching parameters. First of all, the mean value of the hardness of the first four hardness indentations and the last four hardness indentations was determined. These mean values are entered as lines 1 and 2 in the hardness profile. The distance between the intersection points of lines 1 and 2 with the hardness curve describes the transition zone. In addition, the difference between the two mean values along the transition zone is the hardness gradient. The hardness gradient and the transition zone are used as evaluation criteria.

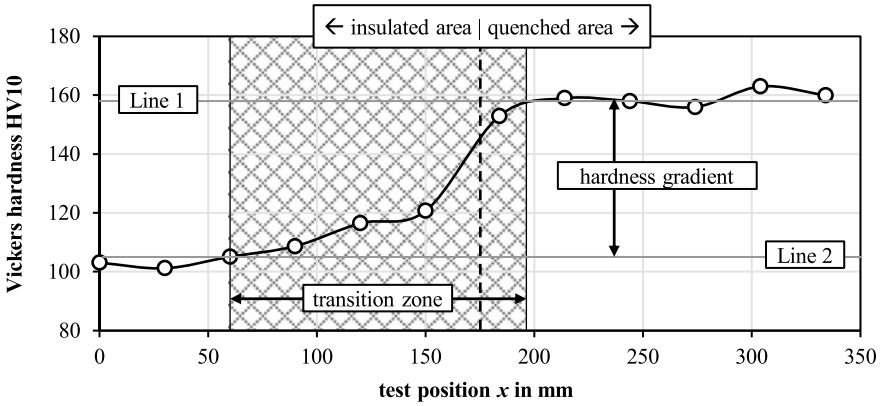

Fig. 8 Analysis method for the partially quenched sheets

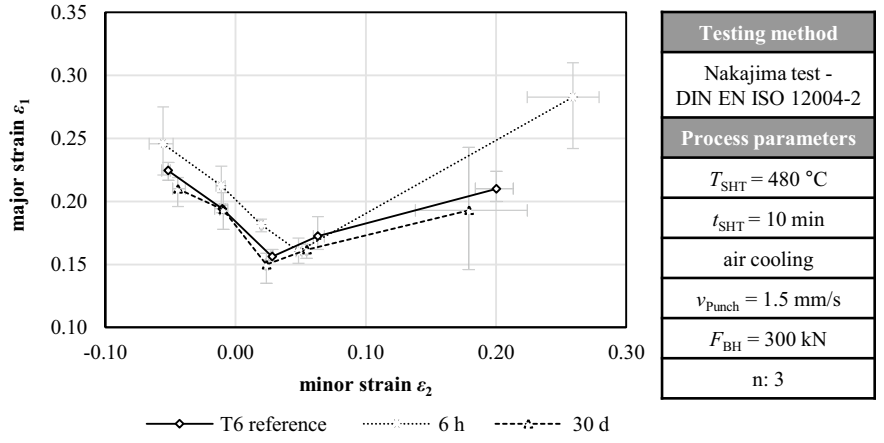
4 Results of the Experimental Investigations

4.1 Formability in W Temper State

First, the influence of the natural ageing time on the formability of the alloy EN AW-7075 after quenching was investigated. For this purpose, the Nakajima specimens were either quenched quickly in the pneumatic press or cooled slowly at air. As an example for natural ageing durations of 6 h and 30 days, the forming limit curves of the slowly cooled samples are shown in Fig. 9. As a reference, a forming limit curve for the investigated material in the T6 condition was also determined. The



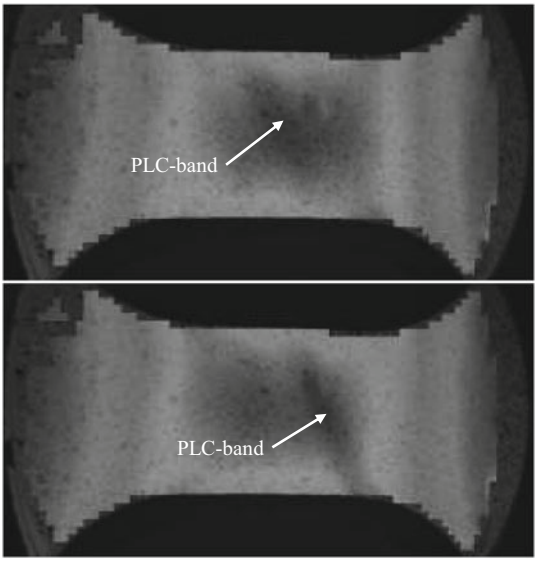


Fig. 9 Influence of the natural ageing time on the formability of EN AW-7075

lowest formability was found for all material states between a major strain degree of 0.14 and 0.16. The minor strain varies between 0.025 and 0.05. For strain states that remain within the range of uniaxial tension, the formability for the natural-aged samples are slightly higher than for the reference state. The highest formability is achieved with decreasing ageing time. The same behaviour can be observed for the biaxial stress state. Only the formability of the samples aged for 30 days is below the reference level. As before, the samples that have been aged naturally for the shortest time have the highest forming capacity. The same behaviour was determined for the rapidly quenched samples.

During the Nakajima experiments, a dynamic strain ageing was determined in the samples. This phenomenon is also known as Portevin–Le Chatelier effect. The plastic deformation occurs unevenly across the formed area. The effect is more pronounced in samples quenched quickly and exposed to a short natural ageing time. This can be explained by the higher amount of solute atoms immediately after quenching. The formation of PLC bands during the Nakajima experiments is shown in Fig. 10. In this figure, the major strain is represented on the sample surface. The dark bands indicate a localised plastic strain in the sample.

In addition to the influence of the natural ageing time, the influence of the quenching rate on the formability was investigated. The results for an ageing duration of six hours are shown in Fig. 11. The obtained results are representative of all ageing durations. The T6 condition of the material EN AW-7075 is shown as a reference. For the area of uniaxial tension up to the lowest major strain, the rapidly quenched samples have a higher forming capacity. This is slightly higher than the reference

condition. In the biaxial stress state, on the other hand, the formability of the slowly cooled specimens is higher than that of the rapidly quenched.

4.2 Tailored Tempering of EN AW-7075

To achieve partially different mechanical properties in sheet metal strips of the material EN AW-7075, these strips were quenched in a compressed air-quenching facility with varying parameters. In insulated areas with a low quenching rate, zones with reduced hardness should be tailored. In areas with a higher quenching rate, however, a higher hardness has to be obtained. In these areas, the sheet was quenched in the compressed air-quenching facility with varying air pressure, varying nozzle distance from the sheet, and either three or six nozzles. The influence of the number and arrangement of the nozzles is shown in Fig. 12. By quenching the sheet metal on both sides with six instead of three nozzles, the hardness level in the complete sheet metal increases. The quenching rate of the rapidly quenched zone is therefore so strong that the insulation is not fully suited to maintain the reduced hardness level in the insulated area. However, the hardness gradient and the width of the transition zone are only slightly affected by the number and arrangement of the nozzles.

The results of the determined hardness gradients and transition zones are shown in Fig. 13. The air pressure and the distance between the nozzles and the sheet metal were varied. The six nozzle configuration was used for all parameter variations. It was observed that with increasing air pressure the hardness gradient increases. With a nozzle distance of 100 mm the hardness gradient increases from 43 HV10 at 1 bar air pressure to 54 HV10 at 6 bar. For a nozzle distance of 150 mm the determined difference is more distinct. In this case, the hardness gradient increases from 28 HV10 to 53 HV10 when the air pressure increases. For both nozzle distances of 100 mm

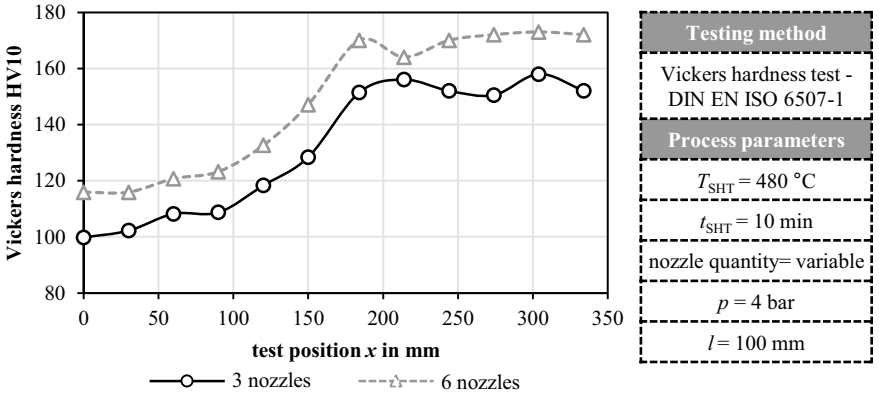

Fig. 12 Hardness profiles of partially quenched sheet metal strips by varied nozzle quantity

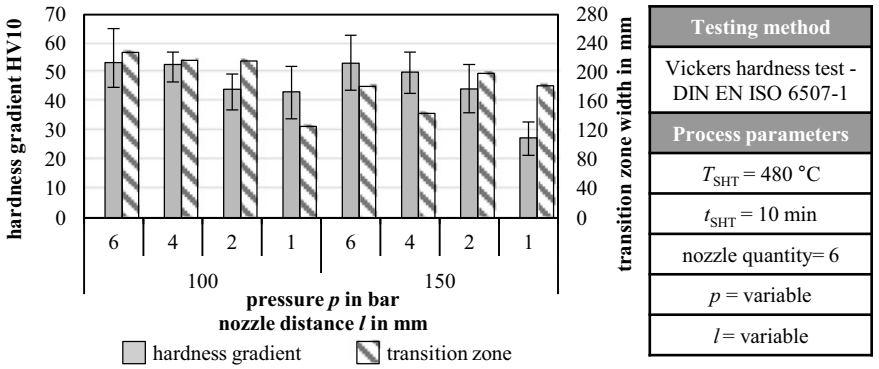

Fig. 13 Results for the hardness gradient and transition zone of partially quenched EN AW-7075

and 150 mm the influence of the air pressure on the transition area is rather small. At 100 mm a reduction of the transition area with decreasing air pressure has been determined. At a distance of 150 mm, on the other hand, no clear influence can be identified.

5 Conclusions and Outlook

The influence of the quenching rate and the natural ageing duration after quenching on the formability of the alloy EN AW-7075 in the W-temper state was investigated. Furthermore, it was determined how a partial quenching process can be carried out to produce components with locally adjusted tailored mechanical properties. It was shown that the W-temper state reaches an increased formability compared to

the T6 state. However, the formability decreases with increasing ageing time. For short ageing times after quenching, PLC bands are formed, which cause localisation of the strain and limit the formability. It has also been shown that in the stress state area of uniaxial tension, a rapid quenching rate after solution heat treatment is advantageous for formability. For the biaxial stress state, however, slow quenching rates are advantageous. In future experiments, the PLC effect will be investigated more closely by tensile tests. In addition, the process of solution heat treatment and quenching with subsequent forming will be transferred to a complex-forming geometry, and formability will be studied at the example of deep-drawing tests.

Additionally, the influence of the quenching conditions on the mechanical properties, particularly the hardness, was determined. By means of a compressed air-quenching facility setup, it was possible to produce sheet metal strips with locally adapted properties. A hardness gradient of up to 54 HV10 was obtained. For example, a transition zone of 144 mm at a hardness gradient of 50 HV10 was achieved. In future researches, the influence of alternative quenching media on others such as water–air mix shall be investigated. The aim will be to reduce the processing time while maintaining the hardness gradient and decreasing the width of the transition zone.

Acknowledgments The project "Tailored Tempering of 7xxx-Aluminum Alloys" Ref.-No. AiF 20190N was financed and supervised by the European Research Association for Sheet Metal Working (EFB). In the scope of the program to promote Industrial Collective Research, it was funded by the German Federation of Industrial Research Associations (AiF) by means of the Federal Ministry of Economic Affairs and Energy (BMWi) on the basis of a decision by the German Bundestag. Furthermore, the authors would like to thank the industrial partners in this research project.

Constitutive Model and Plate Forging Ability of 5052 Aluminum Alloy Under Different Temperatures

Yantao Li, Wenzheng Dong, Qiquan Lin, and Zhigang Wang

Abstract The hot tensile deformation behavior of 5052 aluminum alloy is investigated by uniaxial tensile tests with the temperature range of 523–723 K and strain rate range of 0.001–0.1 s^{-1}. The constitutive equation is established based on the Arrhenius-type equation and Zener–Hollomon parameters, which are applied to numerical simulation for solid boss forming by plate forging process. As a result, the flow stresses obtained from the constitutive equation are consistent with the experiments, and the proposed constitutive equation is succeeded to predict the deformation behavior in the plate forging process. The best forming temperature for boss solid forming is 673 K based on the boss forming ability analysis.

Keywords 5052 Aluminum alloy · Constitutive model · Plate forging · Numerical simulation

1 Introduction

In recent years, energy conservation and CO_2 emission have become a serious concern in the world. Under the pressure of energy savings and emission reduction, lightweight plays an important role in the field of automobiles. On the one hand, to reduce the weight of vehicles more lightweight materials such as aluminum alloy and magnesium alloy are used in car bodies [1]. On the other hand, various combined forming processes such as plate forging [2–4] have been proposed to manufacture

a function lightweight part. Up to now, a great deal of work has been done on the development of plate forging [5, 6].

As the material flow behavior of aluminum alloy during hot formation is complex, the process parameters of temperature, strain rate, and strain significantly influence its microstructure and properties. Many constitutive models such as Mirzadeh [7], Mirzaie et al. [8], Arrhenius-type with Zener–Hollomon parameters [9], Baktash and Mirzadeh [10] were proposed to predict the flow stress during hot formation. In the case of 5052 aluminum alloy, Lin et al. [11] studied the flow stress behavior by hot isothermal compression test. As among the plate forging process, the sheet deformation and the bulk deformation are mixed simultaneously, and more often the stretching or drawing is the main deformation mode. Thus, the hot tensile deformation behavior of 5052 aluminum alloy is investigated in the present work, and the plate forging ability for solid boss forming is also examined by numerical simulation and laboratory experiments.

2 Experimental Procedures

2.1 Uniaxial Tensile Testing

The commercial A5052-H24 with a thickness of 2 mm was prepared in the study. All tensile specimens were machined from the rolling direction as illustrated in Fig. 1, with a gage length of 30 mm. Isothermal uniaxial tension experiments under five deformation temperatures (523, 573, 623, 673, and 723 K) and three strain rates (10^{-3}, 10^{-2}, and 10^{-1} s^{-1}) were carried out on Instron 3369 universal testing machine. Load and displacement data were automatically collected.

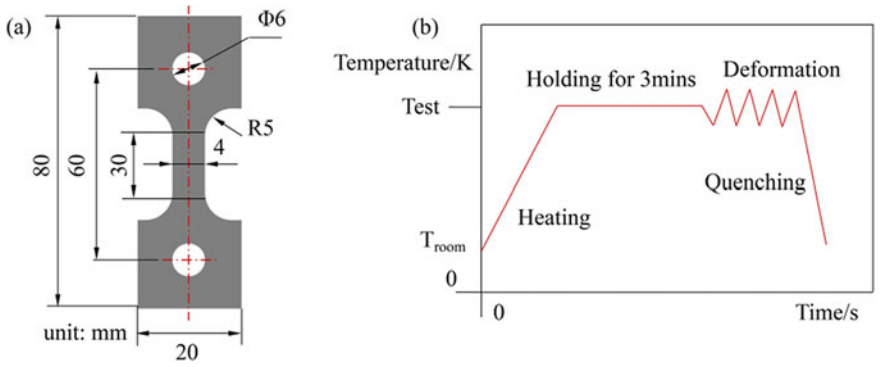

Fig. 1 **a** Size of tensile test specimen **b** Control conditions for hot tensile deformation. (Color figure online)

2.2 Experiment Setup for Solid Boss Forming by Plate Forging Process

Previously, a novel plate forging process named compression-drawing were proposed to form the solid boss on a plate product with a lower forming load [4]. Figure 2a shows the principle of the compression-drawing process. The drawing die moves upward with a velocity V and the blank is drawn when a constant punch load is applied to the bottom of the cup, and then a boss is extruded from the blank when the blank is compressed plastically. Compared with the traditional backward extrusion process, an extra counter-punch would be added to generate the backpressure in the opposite direction as well as bear the total processing load. The plate forging ability for solid boss forming is also examined by laboratory experiments on a hydraulic press, as shown in Fig. 2b. The process parameters used for the experiment are listed in Table 1.

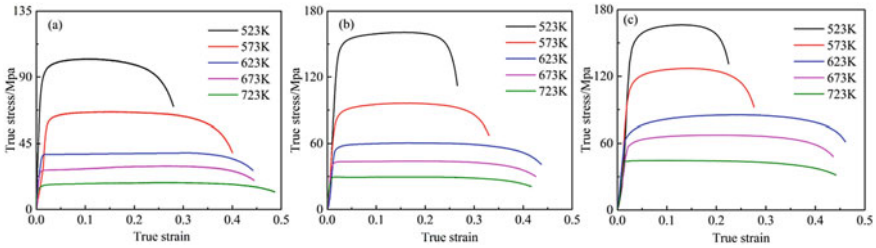

Fig. 3 True stress–strain curves at temperatures 523, 573, 623, 673, and 723 K under strain rate: **a** 0.001 s^{-1}, **b** 0.01 s^{-1}, and **c** 0.1 s^{-1}. (Color figure online)

3 Results and Discussion

3.1 True Stress–Strain Curve

The true stress–strain curves of 5052 aluminum alloy during uniaxial tension tests under different conditions are shown in Fig. 3. Obviously, the flow stress typically increases linearly, gradually reaches the peak at a particular strain, and then saturated approximately due to dynamic softening with dropping in the final stage. It can also be seen that the flow stress decreases with the temperature rising, increases with strain rate rising, which might be summarized as temperature negative and strain rate positive correlation in brief, respectively. Under the lowest strain rate of 0.001 s^{-1}, the total elongation is the highest with the lowest strength simultaneously, for there might be enough time and kinetics to complete dynamic recrystallization.

3.2 Constitutive Modeling

To examine the hot tensile deformation behaviors of 5052 aluminum alloy under different temperatures and strain rates, the Arrhenius-type constitutive equation and Zener–Hollomon parameter in an exponent-type equation were used [12].

$$\dot{\varepsilon} = Af(\sigma)\exp[-Q/(RT)] \tag{1}$$

where

$$f(\sigma) = \begin{cases} \sigma^{n_1}, & \alpha\sigma < 0.8 \\ \exp(\beta\sigma), & \alpha\sigma > 1.2 \\ \sinh(\alpha\sigma)^n, & \text{for all } \sigma \end{cases} \tag{2}$$

$$Z = \dot{\varepsilon}\exp[Q/(RT)] \tag{3}$$

Table 2 Values of material constants at a strain of 0.1

A_3/s^{-1}	α/Mpa^{-1}	n_2	$Q/(KJ \cdot mol^{-1})$
3.14×10^{14}	0.0211	5.055	162.72

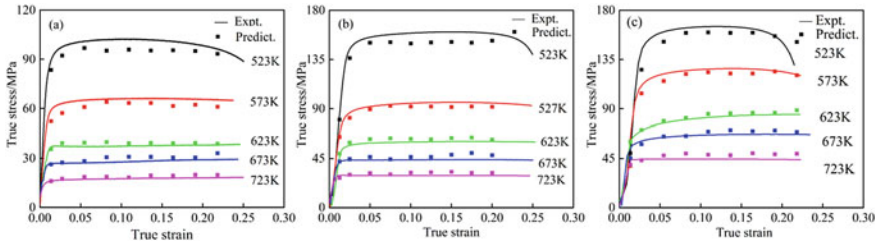

Fig. 4 Comparison of the Arrhenius model prediction with experimental true stress–strain under strain rate: **a** 0.001 s^{-1}, **b** 0.01 s^{-1}, and **c** 0.1 s^{-1}. (Color figure online)

Then, the relationship between strain rate and stress can be described as follows with different flow stress levels:

$$\dot{\varepsilon} = \begin{cases} A_1\sigma^{n_1}\exp\left(-\frac{Q}{RT}\right) & \text{for } \alpha\sigma < 0.8 \\ A_2\exp(\beta\sigma)\exp\left(-\frac{Q}{RT}\right) & \text{for } \alpha\sigma > 1.2 \\ A_3[\sinh(\alpha\sigma)]^{n_2}\exp\left(-\frac{Q}{RT}\right) & \text{for all } \sigma \end{cases} \tag{4}$$

where Q is the active energy for hot deformation, R is gas constant, T is temperature, A_1, A_2, A_3, α, β, n_1, n_2 are material temperature-dependent constants determined by experiment and among them $\alpha = \beta/n_1$.

Based on multivariate linear data analysis, the values of A_3, α, n_2, Q at a true strain of 0.1 are determined and listed in Table 2.

Figure 4 shows the true stress–strain responses of 5052 aluminum alloy with the Arrhenius model predicted curves. It is found that the predicted curves fit well with the experimental results. Moreover, in order to evaluate the deviation between prediction and experiment quantitatively, statistical analysis was conducted. The distribution of relative error, expressed as Eq. (5), is shown in Fig. 5.

$$error(\%) = \frac{\sigma_{\text{exp}} - \sigma_{\text{predict}}}{\sigma_{\text{exp}}} \times 100 \tag{5}$$

where σ_{exp} and σ_{predict} are the experimental and prediction flow stress. From Fig. 5, clearly, most of the absolute relative errors are fewer than 10%, demonstrating the Arrhenius model with excellent predictability. Meanwhile, it is worth noting the deviation is relatively large for a particular inspection point.

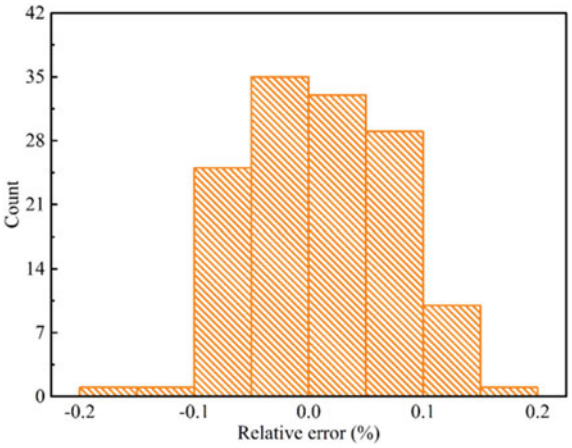

Fig.5 Statistical analysis of the relative error by the Arrhenius model. (Color figure online)

3.3 Application of Constitutive Model in Solid Boss Forming by Plate Forging

To validate the application of tensile model in solid boss forming by plate forging, the established constitutive model was introduced to DEFORM software to carry out the thermal-mechanical simulation. Figure 6 shows the FE model of solid boss forming by plate forging. The billet is defined as rigid plastic meshed by tetrahedral elements with local refinement, while the punch, die, counter-punch, and binder are defined as rigid. Numerical prediction of solid boss forming process during drawing is illustrated in Fig. 7. The bottom metal flows inward the solid boss cavity as well as flows outward the cylindrical wall. The solid boss height gradually increases to the maximum and then remains unchanged.

Figure 8 shows the comparisons of the boss height of the stamped parts obtained

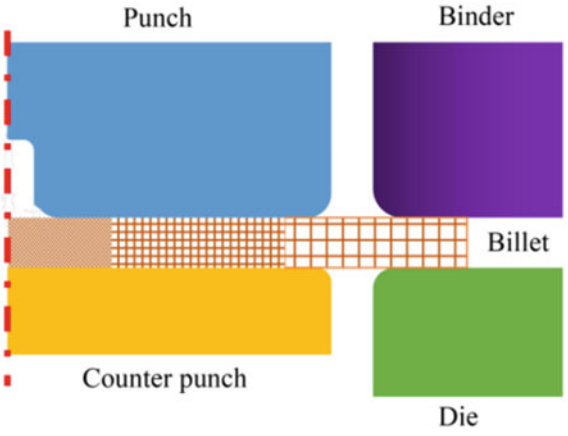

Fig. 6 FE model for solid boss forming by plate forging. (Color figure online)

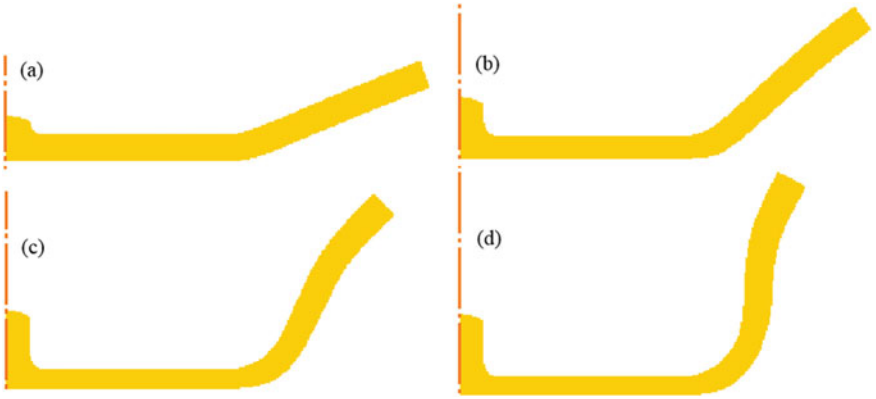

Fig. 7 Solid boss forming process during drawing. **a** Die stroke 5 mm, **b** Die stroke 10 mm, **c** Die stroke 15 mm, and **c** Die stroke 20 mm. (Color figure online)

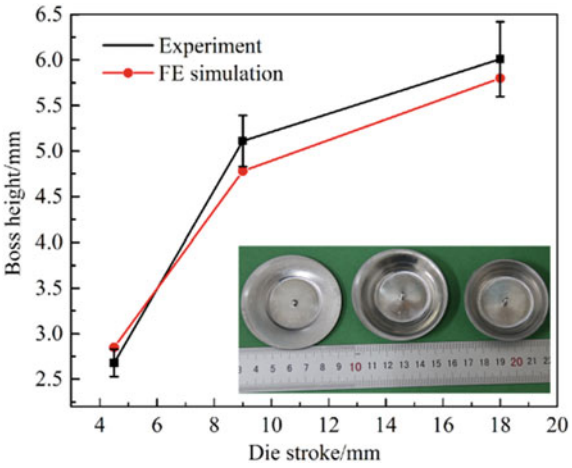

Fig. 8 Boss heights of formed parts obtained from simulation and experiment. (Color figure online)

from numerical simulation and experiment. Obviously, the boss height increases rapidly to the half of punch stroke and then gradually grows slowly. The figure shows that the prediction results based on the tensile model are in good accordance with experiments, with the difference of the boss height less than 15%, and the tensile model satisfies the accuracy demand of plate forging comprehensively. It could be indicated that the Arrhenius model is able to predict the trend of flow behavior and the tensile model is adequate to describe the flow behavior in solid boss forming by plate forging.

3.4 Boss Forming Ability Analysis

As in our previous studies, divided points are an important factor that affects the boss forming ability [4, 13]. To examine the boss forming ability, the decrease in volume of the bottom part and the boss volume are considered, and a dimensionless parameter ζ is defined as described in Eq. (6) to character the boss forming ability.

$$\zeta = \frac{\sigma_s}{p} \cdot \frac{V_b}{V_p} \tag{6}$$

where σ_s is the yield strength, P is the counter-punch pressure at the instant moment, V_b is the volume of the solid boss, and V_P is the volume of materials participating in extrusion deformation, illustrated in Fig. 9. In order to figure out the influence of process parameters on the boss ability analysis, different boss radii (d_b/2), which were found to play an important role in dimple defect, are chosen. The effect of boss radius and temperature on the boss ability is shown in Fig. 10. Obviously, it can be drawn that the boss ability increases with boss radius increasing. However, for the

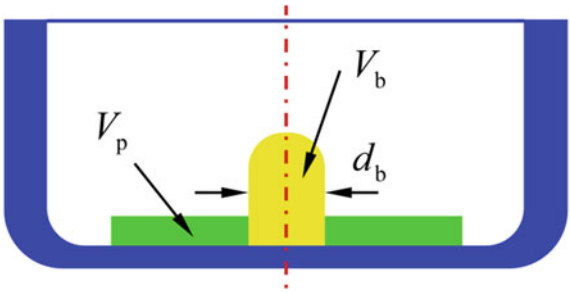

Fig. 9 Schematic drawing of the boss forming ability. (Color figure online)

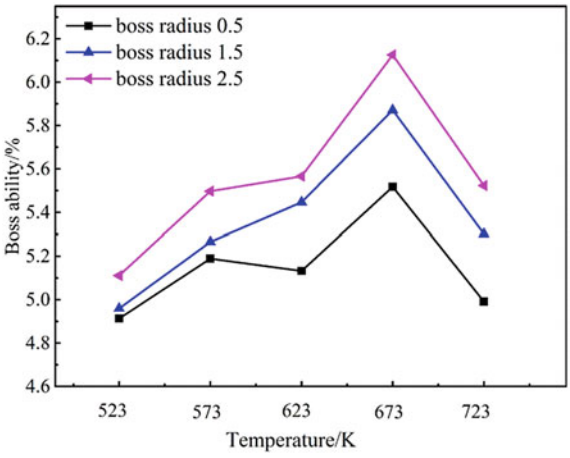

Fig. 10 Effect of boss radius and temperature on the boss forming ability. (Color figure online)

same boss radius, the boss forming ability increases with temperature increasing and reaches its maximum at 673 K.

4 Conclusions

(1) Flow behavior of 5052 aluminum alloy under hot conditions has been investigated by means of uniaxial tensile testing. The flow stress increases with the increasing of strain rate and decreasing of deformation temperature.
(2) The Arrhenius model is adequate to predict the material flow behavior with good accuracy. Tensile model is qualified to describe the flow characteristic in solid boss forming by plate forging.
(3) In the case of boss forming ability, the best forming temperature for solid boss forming is 673 K.

Research on Rolling Process and Superplasticity for 5A90 Al–Li Alloy

Li Xiaoxing, Chen Yangkai, Lang Lihui, and Xiao Rui

Abstract In order to study the tensile properties of Al–Li alloy 5A90 at high temperature, the Al–Li alloy sheet metal with a thickness of 1.6 mm was obtained by rolling the original plate with the original thickness of 7.3 mm. Universal tensile tests of the previously rolled sheet metals were carried out in the temperature range of 375–450 °C with a strain rate of 0.002 s^{-1}. The experimental results show that the elongation of the material reaches 600% at the temperature of 425 °C, the true strain reaches 2.0, and the peak stress at this temperature is 8.0 MPa.

Keywords Rolling · Superplasticity · 5A90 · Universal tensile

1 Introduction

To overcome the energy crisis, advanced manufacturing technology has been developed to achieve lightweight. The light alloy with low density and high strength is now widely used to replace traditional metal materials in the automotive industry and aerospace field. Al–Li alloy 5A90 has a lower density and higher strength than traditional aluminum alloys and it is an ideal material to replace conventional aluminum alloys. The quality of structural parts reduced by 10–15% and their rigidity increased by 15–20% with the application of 5A90. However, Al–Li alloys have poor plasticity, large springback, easy cracking, poor part accuracy, and surface quality during processing at room temperature. It is difficult to produce complex parts in traditional cold forming processes, which block the application of Al–Li 5A90 [1].

With the development and maturity of hot forming process, several materials, such as TA15, AA5083 aluminum alloy, show superplasticity at particular temperature and strain rate. It makes possible the plastic forming of sheet metal with large deformation and complex profile.

Pengchao et al. [2] investigated the thermal tensile and electro-plastic tensile properties of 5A90 Al–Li alloys. They pointed out that the plastic strain increased from about 0.3 to 0.55 with the rising tensile temperature from 110 to 290 °C. Ma et al. [3] researched the constitutive relationship in the temperature range from 200 to 450 and in strain rate range of 0.3×10^{-3} s^{-1} to 0.2×10^{-1} s^{-2}. The result shows that the max plastic strain is lower than 0.55. Zhang et al. [4] examined the superplastic deformation in hot forming for 5A90 Al–Li alloy with 655% elongation. Hongping et al. [5] put forward a rolling process and obtained 765% elongation. However, there are two major defects in the process plan. The serious cracking of the edge of sheet metal by cold rolling results in that only one of the three can be used. The other shortcoming is the serious pollution to the environment.

This paper studies the rolling process and superplastic properties of 5A90 aluminum–lithium alloy sheet metal. An optimal rolling process and relevant process parameters are proposed. This process causes less pollution to the environment. The results of the hot tensile experiment show the plastic strain up to 2.0. 5A90 Al–Li produced in this paper performs well in superplasticity and can satisfy the industrial application.

2 Rolling Process

Raw sheet metal of 5A90 Al–Li alloy is of 7.3 mm thickness. The chemical composition of this sheet metal is shown in Table 1.

Rolling process greatly affects the degree of fine crystallization of sheet metal. Thus there is a great influence of elongation of 5A90 under a high-temperature situation. The effect of reduction on properties of 5A90 has been investigated for each pass at high temperatures. The complete process plan is as follows.

Step 1. Soaking 2 h at 475 °C and then cooling in water.

Step 2. Sheet metal is soaked for 48 h at 300 °C and 4 h at 400 °C.

Step 3. The sheet metal is rolled in five steps at high temperature with a rolling speed of 0.427 m/s, and baked again 20 min after each pass. The thinning of each pass is 15% of the thickness of the previous pass, respectively. After these passes, the thickness of the sheet metal is 45% of the previous thickness.

Step 4. Preheating at 360 °C, then rolling in the transverse direction of the rolling direction in Step 3, the reduction is the same with Step 3; the thickness of sheet metal is 1.5 mm at the end of this step.

Table 1 The chemical composition of 5A90 Al–Li alloy (wt.%)

Si	Fe	Cu	Mg	Na	Li	Ti	Zr	Others	Al
0.15	0.2	0.05	5.4	0.0015	2.1	0.1	0.12	0.05	Margin

Step 5. Soaking 1 h at 500 °C in an air furnace and then water quenched.

The hot mill is shown in Fig. 1. The diameter of the work roll is 350 mm which has the capacity to roll a sheet up to 400 mm in width. Roll speed is in the range of 0–30 r/min. The maximum roll force is 1500 kN. The rolled plate is edge crack free and its surface quality is good. The plate after pickling is shown in Fig. 2.

Fig. 2 The plate after pickling. (Color figure online)

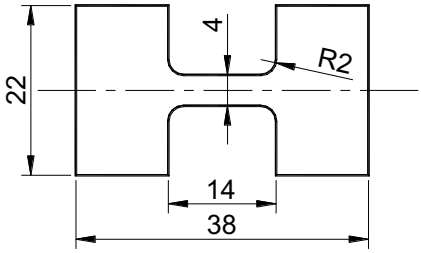

Fig. 3 The geometry of the dog-bone specimen

3 Tensile Experiment and Results

The UTM5504X electronic universal testing machine of Suns with a stroke of 150 mm is used to test the tensile behavior of 5A90 at high temperatures. An approximately constant stretch rate is ensured by controlling the stretch speed step-by-step by MaterialTest4.0 software. The testing machine is equipped with a PID automatic temperature controller for temperature control. The temperature control accuracy of the heating device is in the range of ±3 °C. The maximum experimental temperature of the single pull device is 500 °C. The force–displacement sensor in the range of 0–1000 N is used in these tests. The dimensions of the high-temperature dog-bone specimen are shown in Fig. 3. After processing by wire electric discharge machine, the sides of the specimen were polished with 600# sandpaper.

Xinming et al. [6] pointed out that the conditions for reaching superplasticity are in the strain rate range of 0.0005–0.001 s^{-1} and in the temperature range of 450–500 °C for 5A90 Al–Li alloy sheet metals by multi-pass rolling method. The elongation of 5A90 Al–Li alloy under the temperature of 450 °C and the strain rate of 0.001 s^{-1} is maximum. Ying [7] raised the elongation is considerable under the temperature of 400 °C and three strain rates (0.01 s^{-1}, 0.0025 s^{-1}, and 0.00025 s^{-1}). So, the universal tensile test is performed in the temperature range of 375 to 450 and at the strain rate of 0.002 s^{-1}.

The stress–strain curve of this material is shown in Figs. 4, 5, and 6. As the experimental temperature increases, the maximum true strain increases first and then decreases. The maximum strain reaches its maximum value 2.2 at 425 °C. The relationship between peak stress and temperature is shown in Fig. 7. From the influence of temperature on the elongation of this sheet metal, as shown in Fig. 8, the max elongation is 300% at 425 °C.

4 Conclusion

In this paper, the Al–Li alloy sheet metal of thickness 1.6 mm was obtained by rolling the original plate with the original thickness of 7.3 mm. To obtain the tensile properties of the previous rolled sheet metal, the universal tensile tests were carried

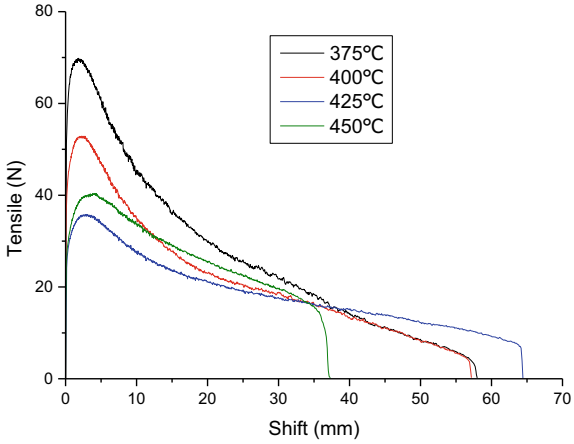

Fig. 4 Tensile–shift curves of 5A90. (Color figure online)

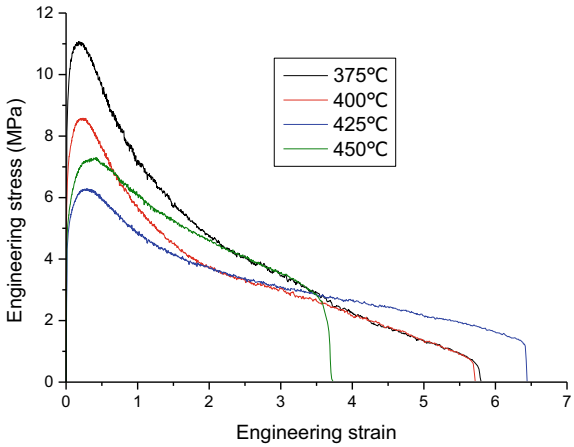

Fig. 5 Engineering stress–strain curves of 5A90. (Color figure online)

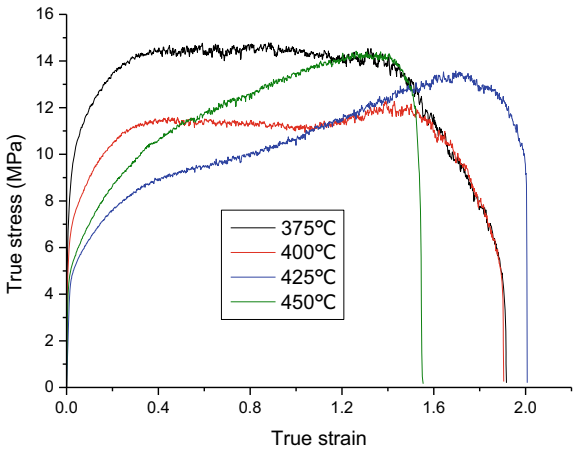

Fig. 6 True stress–strain responses of 5A90. (Color figure online)

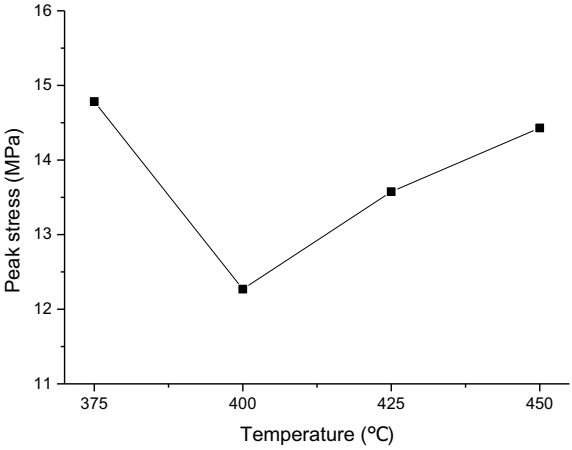

Fig. 7 Peak stress of 5A90

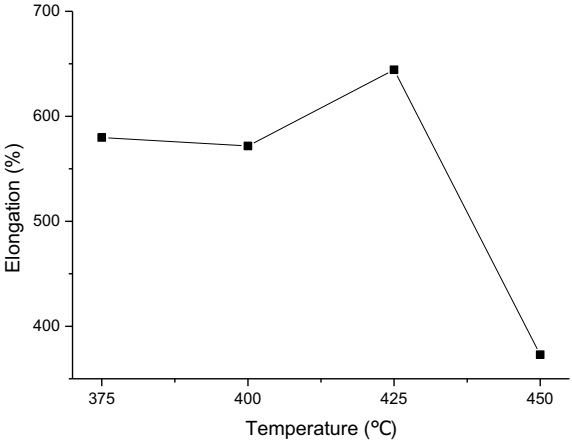

Fig. 8 Elongation of 5A90

out in the temperature range of 375–450 °C with a strain rate of 0.002 s^{-1}. From the above investigation, we can come to the following conclusions.

The 5A90 sheet metal rolled with the parameters of this paper is edge crack free and its surface quality is good.

The experimental results show that the elongation of the material reaches 600% at the temperature of 425 °C, the true strain reaches 2.0, and the peak stress at this temperature is 8.0 MPa. That is to say, the best forming temperature is 425 °C. And the rolled sheet metal shows good superplasticity.

Extrusion and Drawing

Co-Extrusion of Compound-Cast AA7075/6060 Bilayer Billets at Various Temperatures

Hui Chen, Danai Giannopoulou, Thomas Greß, Tim Mittler, Jonas Isakovic, Wolfram Volk, and Noomane Ben Khalifa

Abstract A combination of dissimilar AA7075/6060 aluminum alloys benefits the advantages of high strength and good corrosion resistance in one hybrid component. Static compound casting using appropriate casting conditions can achieve intermetallic bonding at the interface of the core AA7075 and sleeve AA6060. The inhomogeneous bonding due to non-uniform thermal conditions during static compound casting can be eliminated by the following co-extrusion procedure. Direct hot extrusion of compound-cast AA7075/6060 bilayer billets at a temperature of 420, 450, and 480 °C is conducted to analyze the influence of extrusion temperature on the interfacial bonding. The evolution of the interfacial bonding properties at different extrusion temperatures of as-cast billets is depicted by light optical metallography and mechanical push-out test.

Keywords Compound casting · Co-extrusion · Bond strength

1 Introduction

The requirement of energy efficiency and emission regulations increased the pressure on automotive OEMs to improve the CO_2 levels, fuel efficiency, and exhaust gas emissions. Lightweight innovation is the countermeasure thus far. A potential strategy in manufacturing lightweight components without scarifying the performance of the components is to use functionally graded composite materials. The components

produced by multi-materials with different characteristics provide beneficial advantages such as high strength to weight ratio, high corrosion resistance, and thermal conductivity.

Different approaches have been developed and used to produce composite profiles and semi-finished products by extrusion, which can avoid the disadvantages such as the heat-affected zone, porosity, or grain growth in the conventional fusion joining method [1]. With the aim to increase strength, stiffness, functionality, or the adjustment of certain electrical properties, processes such as co-extrusion, composite extrusion with particle-reinforced extrusion billets, or composite extrusion with the continuous embedding of continuous composite elements have been successfully implemented [2].

Co-extrusion of bimetal billets is the state-of-the-art in manufacturing straight, bar-type, semi-finished products that exhibit an optimal combination of desired properties. Several investigations were focused on predicting the material flow of bimetallic composite [3, 4], which indicates the flow stress ratio, the die angle, and die friction as the key factors [5]. Another important factor in co-extrusion of bimetals is the integrity of the bond between the materials [6]. Most of the materials used in the current bimetal rod extrusion are not bonded before the extrusion process. The extrusion billets are pre-processed by milling, surface cleaning, and brushing, which is time- and energy-consuming [7]. In the work of [8], the aluminum/titanium compound extrusion billets are prepared with a titanium-core integrally molded in the aluminum billet. An intermetallic layer between the joint partners before extrusion was obtained. Comparing with extrusion of composite billet by insertion of the Ti6Al4V core into an AlSi1MgMn billet, the bonding strength of using molded billet is much higher. The billet with inserted core into aluminum sleeve presents an oxide layer that hinders the formation of bonding during plastic deformation [9]. The adhesive and/or cohesive bond between the bimetals interface can be only achieved through plastic deformation under favorable process conditions, e.g., temperature, hydrostatic pressure, etc. [10].

The static compound casting of Al/Al bimetal can fabricate billets with initial intermetallic bonding prior to extrusion. The formation of bonding in an equal material system attributes to the remelting, recrystallization, and diffusion of the partner materials [11]. The metallurgical bonding between AA7075 and AA6060 can be achieved under favorable process conditions using the dendrite coherence point (DCP) as a critical value [12].

In the present work, the influence of the extrusion temperature on interfacial bonding between AA7075/AA6060 compounds is investigated. The AA7075/AA6060 compound billet is fabricated by static compound casting. The interfacial bonding of the compound extrudate after hot extrusion at different temperatures is characterized by metallography and mechanical test.

2 Materials

A rotational geometry was chosen as an analyzing example. As-cast billets are produced by static compound casting methods according to [12]. The core material is a commercial AA7075 aluminum alloy with chemical compositions of 90.5Al–1.63Cu–0.18Si–0.27Fe–2.20 Mg–5.48Zn–0.19Cr in wt.%. The sleeve material is an AA6060 aluminum alloy with chemical compositions of 98.8Al–0.02Cu–0.50Si–0.17Fe–0.48 Mg–0.01Zn–0.02Cr in wt.%. The steel die made of hot-working steel 1.2343 was designed and produced for the static compound casting. Therefore, the steel die can be heated by heating cartridges. The first substrate casting step was to pour the 720 °C ± 10 °C core AA7075 melt into the die mold cavity, while graphite insert was used to mold the sleeve geometry till the solidification of the core. After the core AA7075 solidified and cooled down to 400 °C, the graphite insert was pulled out and the AA6060 melt with a temperature of 750 °C ± 10 °C was poured into the cavity between the core and the die mold. The temperature profiles of the substrate, the sleeve, and the die were recorded by thermal couples. The core AA7075 has a diameter of 35 mm and the sleeve AA6060 has a diameter of 65 mm. Several cast billets were produced under this casting condition. A reference as-cast billet was used for light optical metallography (LOM), SEM/EDS analysis, and mechanical characterization (push-out test and micro-hardness test) of the interfacial bonding. An additional three as-cast billets were used for further hot extrusion experiments.

3 Experimental Conditions

The direct hot extrusion experiments used a flat-face die with a diameter of 28 mm. The container of the hot extrusion setup has a diameter of 50 mm. The as-cast billets were machined to a round bar with a diameter of 49 mm and length of 170 mm from the casting gate (Fig. 1a). The core AA7075 aluminum alloy has a solidus temperature of 476 °C; therefore, the maximum hot extrusion temperature was chosen to be 480 °C. The three hot extrusion experiments were carried out under 480, 450, and 420 °C. The as-cast billets were heated to the target temperatures and homogenized for three hours, respectively. The extrusion container and flat-face die were also heated up to the corresponding forming temperature via heat cartridges. The billets were inserted into the container while the side of the casting gate faced the extrusion die.

After hot extrusion, the cross-sectional samples with a thickness of 2 mm were extracted from three positions of the extrudate by diamond saw cutting. The cross-sectional samples were designated as E1, E2, and E3, which were corresponding to the positions of the cross-sectional samples extracted from the referential as-cast billet (Fig. 1b). The cross-sectional samples extracted by electrical discharge machining from the referential as-cast billet at positions of 50, 90, and 130 mm away to the casting gate were designated as C1, C2, and C3. The cross-sectional samples

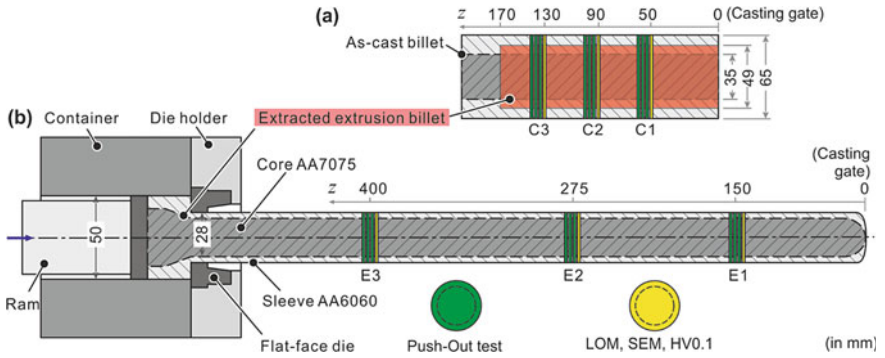

Fig. 1 **a** Dimension of the as-cast billet and extraction of specimens for further work; **b** Hot extrusion setup and the location of cross-sectional specimens for interface characterization. (Color figure online)

were prepared for metallography analysis according to [13]. The Vickers' microhardness of the near interface region was determined with an EMCO test machine using an indentation load of 0.1 kg on those polished cross-sectional specimens. An additional three specimens at the corresponding three positions were extracted for the push-out test to analyze the axial shear bonding strength between the core and the sleeve materials.

The setup and configuration of the push-out test on the as-cast samples were described in [13], which guided a similar configuration in designing the push-out test setup for an extrudate specimen (Fig. 2). The edge of the punch r_p and die r_i was 0.1 mm. The clearance between push-out punch and die $(d_d - d_p)/2$ was 0.5 mm. The core diameter d_i was not constant throughout the whole extrudate since the uniform distribution of the core and sleeve materials can be obtained only in the middle of the extruded profile [6]. Therefore, several pairs of punch and die with different diameters were produced to ensure the distribution of the bonding interface in between the die and the punch. The push-out test setup was installed on a universal test machine Zwick/Roell Z250. The push-out test speed was 1 mm/min. The maximum shear force F_{max} was recorded to calculate the axial shear bonding strength between the core AA7075 and the sleeve AA6060 according to Eq. (1)

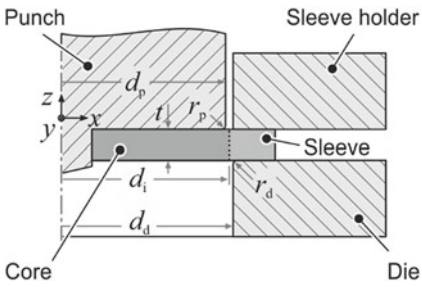

Fig. 2 Configuration of the push-out test

$$\tau_{axial} = \frac{F_{max}}{\pi d_i t} \tag{1}$$

where d_i is the diameter of the interface and t is the thickness of the disc-like sample.

4 Evaluation of the Interface Bonding

4.1 Metallography

A comparison of the bonding interface between the core AA7075 and the sleeve AA6060 in as-cast state and extruded states under different temperatures was presented in Fig. 3. The observation samples were as-cast sample C1 and extrudate sample E1 that were at positions close to the casting gate. The partial cohesive bonding is presented in the as-cast state (Fig. 3a). Many gaps existed at the interface of the core AA7075 and the sleeve AA6060. There were also macroscopic voids

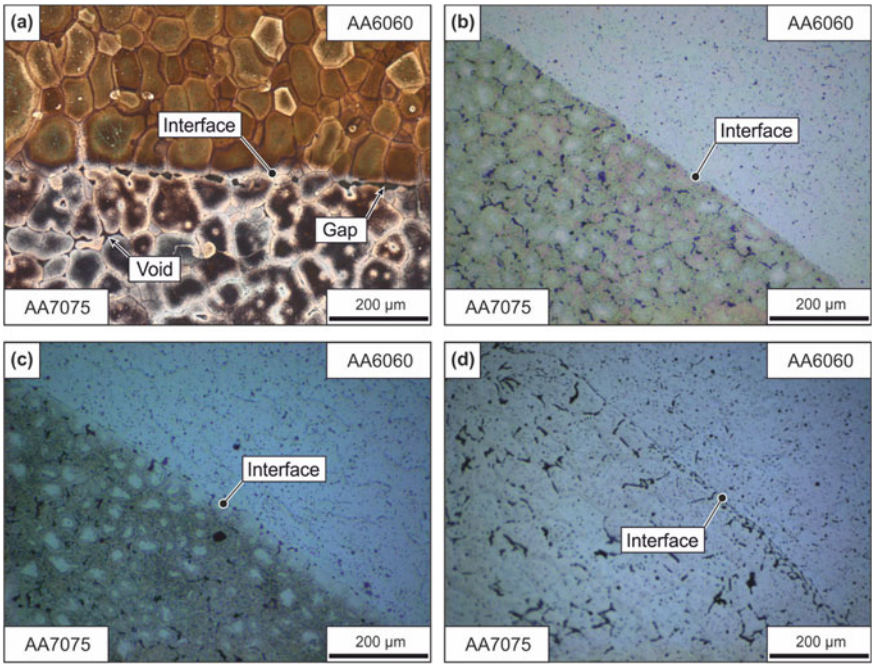

Fig. 3 Microstructure of the near interface region in the cross-section samples at 50 mm to the casting gate: **a** as-cast sample C1; **b** extrudate sample E1 by extrudate temperature of 480 °C; **c** extrudate sample E1 by extrudate temperature of 450 °C; **d** extrudate sample E1 by extrudate temperature of 420 °C. (Color figure online)

inside the core AA7075 due to the thermal stress during the second phase (compound) casting step in fabricating the billets.

After hot extrusion, the serve plastic deformation at high temperatures and high pressure reduced the gaps between the core and the sleeve materials. At a high extrusion temperature of 480 °C, a sufficient cohesive bonding between the core AA7075 and the sleeve AA6060 can be achieved (Fig. 3b). No gaps or macroscopic void at the interface can be observed in a light optical micrograph. The voids inside the core were also eliminated. There were still a few voids at the interface when an extrusion temperature is 450 °C (Fig. 3c). The diffusion zone between the core and the sleeve materials at this extrusion temperature was relatively wider than the other two experimental temperatures. When the extrusion temperature was even lower (420 °C), the clear interface between the core AA7075 and the sleeve AA6060 is presented in the optical metallography (Fig. 3d).

4.2 SEM Analysis

Figure 4 shows SEM images at the near interface region of the extrudate sample E2, i.e., the middle position of the extrudate. The SEM images presented no micro-voids inside the core AA7075 at extrusion temperatures of 480 °C and 450 °C. Few micro-voids still existed after the hot extrusion at 420 °C. Particles existed on the grain boundaries in both core AA7075 and sleeve AA6060. According to the SEM/EDS analysis, those coarse particles in sleeve AA6060 should be α-AlFeSi phase [14]. The α-AlFeSi phase was stable, which was difficult to dissolve into Al matrix and presented after hot extrusion at different temperatures. There were coarse particles and needle-like particles in core AA7075. Under higher extrusion temperature, the coarse particles broke into needle-like particles, which dissolved into Al matrix and then precipitated during extrusion [15]. Higher extrusion temperature enhanced the solubility of the alloying elements [16]. Therefore, few particles were precipitated after hot extrusion [17]. Figure 4 shows that few particles existed in the

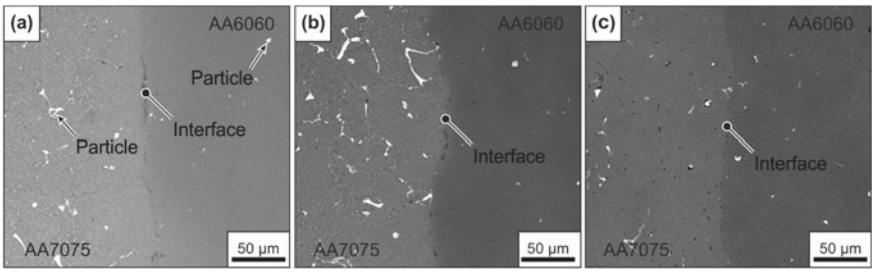

Fig. 4 SEM micrographs of the interface between core AA7075 and sleeve AA6060 after extrusion temperature of **a** 480 °C, **b** 450 °C, and **c** 420 °C

core AA7075 after hot extrusion at high temperature, which means that extrusion at higher temperature reduces the number of particles in the core AA7075 material.

4.3 Mechanical Characterization

A significant improvement of the interfacial bonding strength was achieved for extruded billet by hot extrusion process compared with the initial static compound-casted billets (Fig. 5). The shear strength values of extruded billets by the push-out test showed much higher results at the corresponding positions after hot extrusion compared with the as-cast billet. The initial as-cast billet had the highest bonding strength in the middle (C2, z-position of 90 mm), while a relatively lower interfacial bonding strength is presented at the position close to the casting gate (C1, z-position of 50 mm). The bonding strength of the as-cast billets strongly depended on the z-positon. This was due to the metallurgical interaction and dissolution of the microstructure of AA7075 between the joining partners during the compound casting.

After hot extrusion, the highest bonding strength is still present at the middle of the extrudate. Nevertheless, the bonding strength values along the extrudate were more homogeneous. Higher bonding strength can be expected at the position close to the casting gate. The extrusion temperature played a positive role in enhancing the bonding strength between the core AA7075 and the sleeve AA6060. The axial shear bonding strengths along the whole extrudate increased with the increasing extrusion temperature.

The micro-hardness in the near interface region of the cross-sectional specimens was summarized in Fig. 6. The tests were conducted perpendicular to the AA7075/6060 interface that was indicated as positon of $x = 0$ mm. The micro-hardness at the core material presented a much higher hardness value under higher

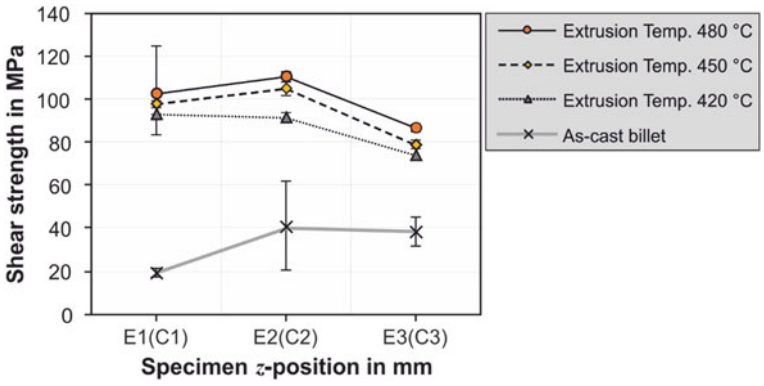

Fig. 5 Shear strength of the interfacial bonding by using push-out test. (Color figure online)

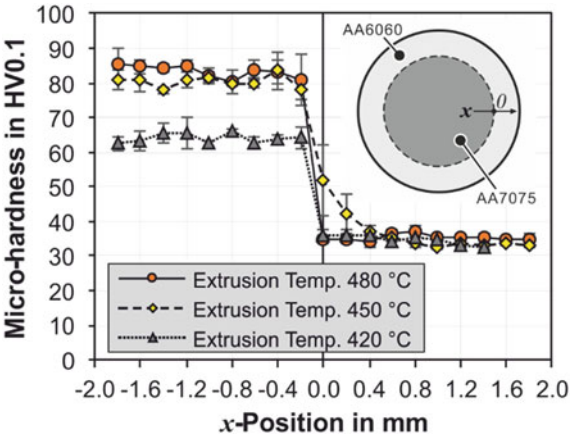

Fig. 6 Micro-hardness in the near interface region of the cross-sectional specimens. (Color figure online)

extrusion temperature, which suggested that the higher temperature improved the mechanical properties of the core material. The hardness of the sleeve showed similar values no matter which extrusion temperatures were used.

The width of the diffusion zones between the core AA7075 and the sleeve AA6060 was 200 μm under extrusion temperatures of 480 and 420 °C. A larger transition area between core and sleeve materials was presented when extrusion temperature was 450 °C, which had been proven by the light optical metallography results, as shown in Fig. 3c.

5 Summary

Co-extrusion of AA7075/AA6060 bimetal billets at different temperatures was conducted in this work. The rotational composite billets were fabricated by static compound casting. Homogeneous interface bonding can be hardly achieved by compound casting. Due to the different thermal expansion ratios of the bimetal, the thermal stress induced voids inside the core AA7075 and gaps at the interface during the solidification and cooling in compound casting. These defects can be improved by hot extrusion. The shear bonding strength between AA7075 and AA6060 increased from 19 to 102 MPa by hot extrusion at 480 °C. Homogenization of the interfacial bonding along the extrudate was another benefit of the consequent hot extrusion process after compound casting. Higher extrusion temperature not only increased the interfacial bonding strength but also improved the mechanical properties of the core AA7075 material, while the void inside the core AA7075 can be eliminated at an extrusion temperature of above 450 °C.

Reducing Aluminum Extrusion Transverse Weld Process Scrap

Gregory J. Oberhausen, Anselm A. A. Christopher, and Daniel R. Cooper

Abstract Nearly 20% of the aluminum produced globally is extruded. Up to one-quarter of this aluminum is scrapped in the form of extrusion butts and segments of extruded profiles that contain weak solid-state "transverse" welds that are created between consecutively extruded billets in direct extrusion. In this article, extrusion of differently colored clay billets is used to conduct a parametric study on the effect of extrusion ratio, die angle, friction coefficient, profile shape, and dummy block profile on the transverse weld length. Shorter transverse weld lengths require smaller lengths of the extruded profile to be extracted and scrapped. The results show that the transverse weld length can be reduced by decreasing the extrusion ratio, die angle, or friction coefficient. The profile shape also has a strong influence; the transverse weld length was found to scale with the cross-sectional perimeter to area ratio of the extruded profile. Additionally, it is shown that the dummy block profile (a previously unexplored design variable) can be modified to decrease the weld length. A concave dummy block was designed using an estimated velocity field for axisymmetric extrusion of solid rods, decreasing the weld length by 44%. The industry implications of this work and the need for further research are discussed.

1 Introduction

Aluminum is one of the five materials (steel, cement, paper, plastic, and aluminum) whose production is responsible for over half of all annual greenhouse gas emissions released by industry globally [1]. The energy efficiency of the primary aluminum production process is reaching the thermodynamic limit [2]; therefore, significant emission reductions must be delivered through electricity grid decarbonization and/or material efficiency [3]. Global material flow analyses (MFAs) of the aluminum sector reveal significant ostensible opportunities to increase material efficiency by reducing

manufacturing scrap generation. Cullen and Allwood [3] found that 40% of all liquid aluminum is scrapped before reaching a final product, and those billets destined for extrusion account for 20% of all semi-finished aluminum. In their mass balanced MFA, Cullen and Allwood calculated that 25% of the extrusion billet is scrapped during the metal forming process. Elsewhere, the European Aluminum Association (EAA) surveyed 69 extruders (894 kt of product; 32% of European production) and found that between 22 and 24% of the extrusion billet volume is scrapped during the metal forming process [4, 5].

There are many sources of scrap in the aluminum extrusion process. Sheppard [6], in his seminal textbook on aluminum extrusion, identifies many of these sources as insignificant because each accounts for less than 2% of the total initial billet volume. These insignificant scrap sources include the material deformed by the grippers during the stretching process as well as material remaining in the die after a tool changeover. Sheppard identifies the two most significant sources of scrap: removal of the billet butt and the transverse weld. The approximate locations of the billet butt and the transverse weld within the extrusion process are shown in Fig. 1.

The billet butt is scrapped because it contains a concentration of impurities which would reduce the aesthetic, mechanical, and electrical properties of the final profile if it were to be extruded through the die [7]. To prevent this effect, it is a standard industry practice to not press the whole length of the billet through the die; thus, allowing the billet butt to be sheared off between strokes of the main hydraulic ram [6]. The source of the impurities in the billet butt is the billet skin, which contains oxides and solid-phase inclusions, such as spinels ($MgAl_2O_4$), carbides, nitrides, and intermetallics, developed during billet casting [7]. The billet skin impurities concentrate in the billet butt during the extrusion process due to the material flow inside the billet. While the center of the billet flows through the die, the billet skin has a tendency to stick to the container walls due to friction [6, 8], forming a conglomeration of billet skin in the last 5–20% of the initial billet length [6]. To the authors' knowledge, the shearing of billet butts is common place in the industry [9]. An alternative to butt shearing is "Dick's extrusion method" [6] which utilizes a dummy block with a diameter smaller than that of the container walls. After the initial stroke of the press, the billet skin is left intact on the container walls and a second press-stroke is then used to remove the skin in the form of a "skull". Dick's method is less prevalent in current industry practice [9], which is probably because of the extra time that results from the second press-stroke for each billet.

Transverse weld scrap is the segment of the extruded profile that contains the interface between two consecutively extruded billets. This interface forms a solid-state weld that elongates over a significant length of the extruded material and is typically removed from the extruded profile due to concerns of it having lower strength than surrounding material [6]. Reviewing the literature, however, the authors have found only one recorded instance of the transverse weld strength being experimentally tested. Den Bakker et al. [10] test the transverse weld tensile strength of a series of dog-bone samples extracted from a hollow AA6082 extrusion. They find that the weld strength varies by position with respect to length along the weld; dropping to around 75% of the strength of the parent metal. Sheppard [6] does not quantify the contribution of transverse weld removal to total extrusion scrap rates; however, Mahmoodkhani et al. [11] and Hatzenbichler and Buchmayr [12] found that the transverse weld length (TWL) accounted for 20 and 15% of the initial billet volume in profiles for which the billet butt accounted for 12 and 10% of the initial billet volume, respectively. The rest of this article will focus on existing and novel methods of reducing the TWL, as this is the largest source of scrap identified in the extrusion process.

1.1 Previous Work on Reducing the Length of the Transverse Weld Scrap

Parametric studies often use finite element models (FEMs) to investigate methods of reducing the billet butt volume and TWL [8, 11–15]. Extensive experiments are probably avoided due to their high cost and the significant time expended in processing and measuring the TWL. However, it is common for a single extrusion to be performed on the simplest set of parameters, from which the extrusion pressure and experimentally measured billet butt or TWL are used to validate the FEM [8, 11, 12, 14, 15]. The parameters that have been studied by previous researchers include die angle, extrusion ratio, ram velocity, ram-billet friction coefficient, billet length, temperature, and bearing length for solid profiles, in addition to port bridge diameter, welding chamber radius, and baffle plate height of the specialty porthole die used in hollow extrusions [8, 11–15]. The finite element software packages used in these studies are DEFORM™ [8, 11, 12, 14] and HyperXtrude™ [13, 15]. The alloys studied are AA3003 [11], AA6005 [13], AA6063 [8, 14], AA6082 [12], and AA7N01 [15].

The parametric studies found in the literature were performed by making slight alterations to validated finite element simulations such that the effect of individual parameter changes on the TWL could be isolated and measured. Studies on solid, axisymmetric profiles have looked at the effects of die angle, extrusion ratio, ram velocity, ram-billet friction coefficient, bearing length, and billet length on the TWL [11, 12]. Decreasing the extrusion ratio was found to have the largest effect of reducing the TWL [12]. The use of a smaller die angle [11], increasing billet length, or increasing temperature [12] was also found to have a significant effect in reducing

the TWL. Bearing length, ram velocity, and ram-billet friction coefficient were found to have an insignificant effect on the TWL [12]. No studies on non-axisymmetric solid profiles have been found in the literature. The hollow profile studies [13, 15] examined non-axisymmetric profiles (no studies on hollow axisymmetric profiles were found) and also looked at extrusion ratio, temperature, and ram speed, as well as porthole die dimensions, including the port bridge diameter, welding chamber radius, and baffle plate height. It was again found that decreasing the extrusion ratio has a significant impact in reducing the TWL [15]. Increasing the port bridge diameter, welding chamber radius, and baffle plate height were all found to have a significant effect in decreasing the TWL as well [15]. On the contrary to solid profiles, however, it was found that an increase in the ram speed could actually decrease the TWL [13, 15], and that the temperature no longer had a significant impact [15]. Although Zhang et al. [15] suggest that the ram speed would affect the material flow velocity through the die and therefore affect the transverse weld formation, neither they nor Chen et al. [13] offered an explanation for the varying impacts they observed between the solid and hollow profiles.

Previous research on reducing the TWL has examined neither the effect of the profile shape nor the effect of the dummy block profile geometry. In addition, previous work has been focused primarily on FEM studies. This work will examine the effect of common and novel extrusion design variables on the TWL using a multi-colored clay extrusion technique before discussing the significance of the results and the implications for the industry.

2 Methodology

2.1 Equipment

The experiments in this study were conducted on a hydraulic press extrusion setup developed for this research, shown in Fig. 2. The press container is made of aluminum, 127 mm long, with an internal diameter of Ø25.4 mm. The interchangeable dummy block is made of steel and was turned on a lathe to produce a sliding fit with the container. Several sets of dies were also produced for use with this press (Fig. 3). Die sets were machined and polished from a Ø42 mm aluminum rod. The first set is designed for axisymmetric solid rod extrusions of varying diameters corresponding to extrusion ratios of 4, 6.67, 10, and 25. The next set was produced for rectangular profiles of the same extrusion ratios. The third and final set of dies are more complex geometries, one cross and one with dual circles, both with an extrusion ratio of 4. Each die in these three sets has one side with a flat face (a die angle of 90°) and one side with a tapered 45° die angle.

2.2 Billet Material

The billets used in the experiments were made from plasticine clay, which is a low-cost material that can be used to adequately model hot-metal deformation [16]. In addition, the use of differently colored plasticine for consecutive billets enables the

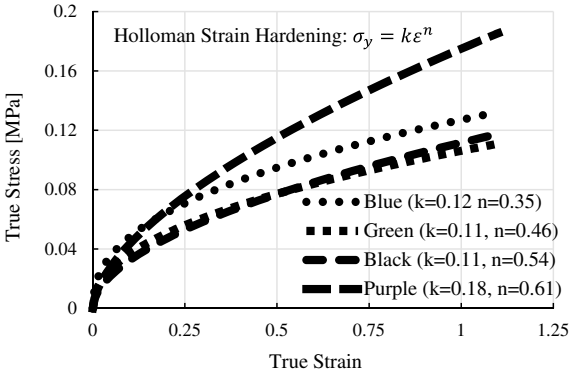

Fig. 4 Flow curves of four different colors of plasticine

transverse weld in an extruded profile to be easily located using a scalpel to section the profiles, as opposed to the lengthy and expensive sectioning, polishing, and etching process that is required for aluminum extrusions.

2.2.1 Billet Flow Curve

The elastoplastic properties of plasticine are dependent on its color [16], which is an indicative of the additives present in the clay. The two colors of plasticine used in this work must have similar mechanical behavior to maintain a consistent material flow through the die, as would be the case in real industrial extrusion of aluminum billets. The flow curve of differently colored plasticine was determined using a uniaxial compression test [16], and fitted to a power-law Hollomon strain hardening model [17], as shown in Fig. 4. Based on these results, the green and black were chosen for the experiments. In each extrusion trial, the green billet was extruded first, followed by the black billet.

2.2.2 Billet-Tool Friction Condition

Plasticine extrusions were conducted using different lubricants to examine the effect of friction on the TWL. Friction ring compression tests were conducted in order to determine the Coulomb friction coefficient (μ) under different lubrication conditions [17, 18].

During a friction test, a ring of plasticine (initially of height $h_0 = 25.4$ mm, inner radius $r_0 = 12.7$ mm, and thickness $t_0 = 9.5$ mm) was covered in lubricant and axially compressed between two platens, reducing the height (h). The test was intermittently paused in order to measure the inner radius (r) of the ring at the mid-plane at different levels of compression. The changing inner radius is indicative of the friction conditions; e.g., if there were zero friction the radius would increase, whereas with sticking friction it would decrease [17, 18]. Green plasticine and aluminum

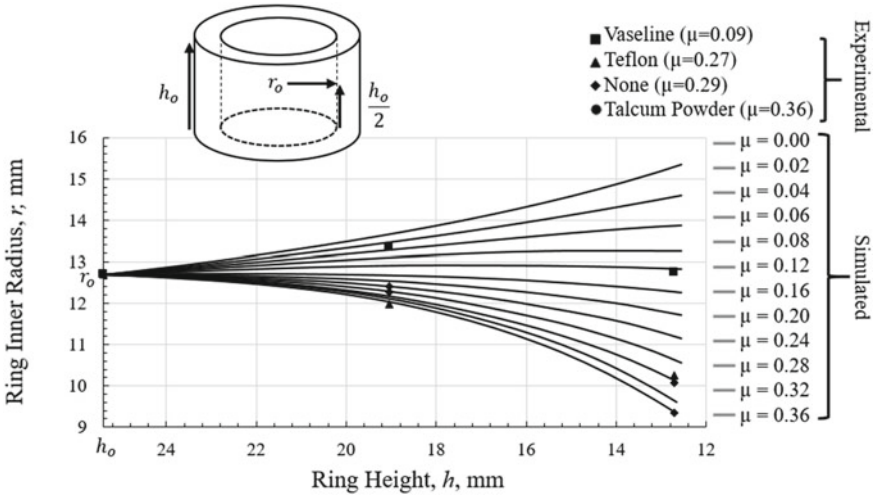

Fig. 5 Friction ring compression test results: experimental data points for different lubricants, and simulated curves for different modeled friction levels

platens of the same surface finish as the extrusion container were used in the friction tests. Additional trials tested the effect of using Vaseline®, Teflon® spray, and talcum powder as lubricants, as well as the use of no lubricants at all. An Abaqus FEM was produced to simulate the change of the inner radius during compression for different contact friction conditions. These FEM results were compared to the experimental results (see Fig. 5) in order to estimate the friction coefficient (μ) associated with each of the different lubricants. The axisymmetric, quarter-sized Abaqus model was meshed using 1,000 linear CAX4 elements with reduced integration and enhanced hourglass control. The validity of the model was confirmed by comparing the simulated and actual compression loads and ensuring that the energy dissipated due to contact stabilization was less than 1% of the internal energy of the model. The interfaces between the billet and the bottom and top plates were modeled using penalty tangential behavior at a range of friction coefficients from 0 to 0.36.

2.3 Dummy Block Geometry

The majority of the experiments conducted in this work used a conventional flat-faced dummy block; however, an attempt was also made to adjust the TWL by changing the geometry of the dummy block face in order to alter the material flow through the die. The material at the center of the billet-on-billet interface travels through the die quicker than the material at the interface periphery, which causes the elongation of the "bullet-shaped" weld. It was hypothesized that the TWL could be reduced by changing to an initially concave billet-on-billet interface geometry (see Fig. 6a). A

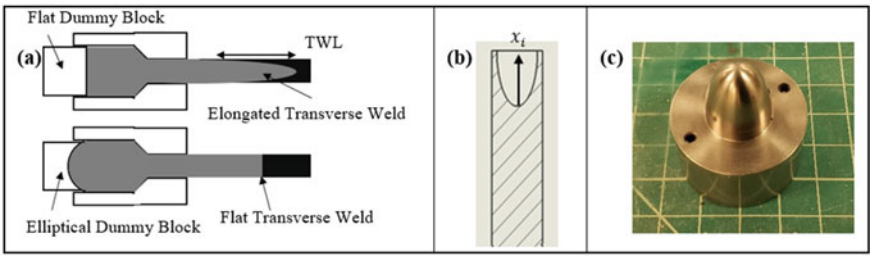

Fig. 6 **a** Transverse weld geometry formed in conventional extrusion (top) and profiled dummy block and billet extrusion (bottom). **b** Section view of elliptical concave ram used in profiled dummy block and billet experiments. **c** The convex forming element used as part of the profiled billet mold. (Color figure online)

trial dummy block and billet geometry were designed using analytical velocity field analysis, as described below.

For axisymmetric profiles, the flow of metal through the die can be estimated using a velocity field first proposed by Avitzur [19], where velocity discontinuities appear as spherical "caps" at the die entry and exit, see Fig. 7. To understand the difference in material flow between the center and outside of the billet, consider two particles (A and O, Fig. 7) both situated at the end of a billet (on the interface with a previously extruded billet) but at different radial positions. A is located near the edge of the billet (next to the container wall) and O is located on the billet center axis. During the extrusion process, both particles enter the velocity field with speed v_i (the ram speed). O then passes through the spherical-cap velocity discontinuity before A. Both particles exit the die at speed v_o, where v_o is equal to the product of v_i and the extrusion ratio (R_i^2/R_o^2). The TWL can be estimated as the difference in the axial positions of A and O once they emerge from the die (A'' and O'').

The velocity field is broken into three regions. The first region, I, contains material traveling at the same speed as the ram, v_i. This region ends at the first spherical-cap velocity discontinuity, along which points A' and O are found. The field line at this

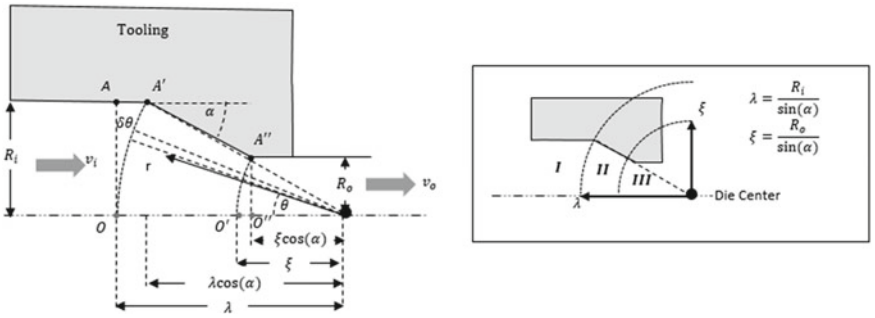

Fig. 7 Estimated velocity field for solid axisymmetric extrusion. Velocity discontinuities are seen as circular arcs on this 2D image

first spherical-cap velocity discontinuity indicates the start of region II, with material traveling at increasing speed in the direction of the die center, labeled on Fig. 7. Region II ends at the second spherical-cap velocity discontinuity, with a smaller radius (on which lie points A'' and O'). The material then enters region III in which all materials (irrespective of their radial positions) travel in the extrusion direction at speed v_o. Point A'' is located at the end of the conical die taper, marking the exit of particle A from the forming region. Point O'' is found within region III, traveling at the velocity of the exiting profile, v_o.

The time taken by particle A to travel through region I, from point A to A', is shown in Eq. 1.

$$t_{AA'} = \frac{\lambda(1 - \cos\alpha)}{v_i} \tag{1}$$

On entry to region II, material flows toward the die center at $v_i\cos\theta$, ensuring that the normal component of velocity is continuous on the velocity discontinuity surface; however, the parallel component of the velocity is discontinuous in this kinematically admissible velocity field [17]. Next, to find the changing velocity in region II, consider a small area of material traced out by $\delta\ \theta$ at a distance r from the die center (Fig. 7). The area of this strip is $2\pi r^2 sin\theta\delta\theta$. Volume conservation, therefore, dictates that the velocity toward the die center at any point along the length, r, from the entrance to the exit of region II is given by Eq. 2.

$$v(r, \theta) = \frac{v_i\lambda^2\cos\theta}{r^2} \tag{2}$$

It follows that the the time taken by particle A to travel through region II, from A' to A'', is given by Eq. 3.

$$\begin{aligned} dt = \frac{dr}{v(r,\ \alpha)} \rightarrow t_{A'A''} &= \int_{\xi}^{\lambda} \frac{r^2 dr}{v_i\lambda^2\cos\alpha} \rightarrow t_{A'A''} \\ &= \frac{1}{3v_i\cos\alpha}\left(\frac{\lambda^3 - \xi^3}{\lambda^2}\right) \quad for\ \theta = \alpha \end{aligned} \tag{3}$$

Similarly, the time taken by particle O to travel through region II, from O to O', is given by Eq. 4.

$$t_{OO'} = \frac{1}{3v_i}\left(\frac{\lambda^3 - \xi^3}{\lambda^2}\right) \tag{4}$$

Lastly, the time taken by particle O to travel through region III, from O' to O'', is given by Eq. 5.

$$t_{O'O''} = \frac{\xi(1 - \cos\alpha)}{v_o} \tag{5}$$

The difference in the time taken for particles A and O to travel from initial to final positions (A'' and O'') can then be used to solve for the total extra distance traveled by particle O into the profile, the TWL, shown in Eq. 6.

$$Transverse\ weld\ length\ (TWL) = v_0 \times (t_{AA'} + t_{A'A''} - t_{oo'} - t_{o'o''}) \quad (6)$$

The difference in distance particles A and O travel into the profile can be reduced by using a billet with a leading concave and trailing convex face, extruded with a concave dummy block. This offsets the initial axial position of A and O; particle O being shifted further back a distance, x_i, toward the ram in region I (Fig. 6b). The offset distance (x_i), which according to the stylized velocity field model above, will result in the axial alignment of A'' and O'' (TWL = 0), as given in Eq. 7.

$$\begin{aligned} x_i &= v_i \times (t_{AA'} + t_{A'A''} - t_{oo'} - t_{o'o''}) \\ &= \frac{Transverse\ weld\ length\ (flat\ billet\ scenario:\ eqn6)}{Extrusion\ ratio} \end{aligned} \quad (7)$$

Using the above analysis, a concave dummy block geometry was designed for axisymmetric extrusion of a solid rod with a die angle of $\alpha = 45°$ (see Fig. 6b). A mold with a convex forming element of identical geometry, shown in Fig. 6c, was machined and used in conjunction with the concave ram to make billets with a concave recess at one end and a convex protrusion at the other end. These profiled billets were then loaded into the extrusion press with the convex end of the billet nested into the concave ram. Multiple billets were then consecutively extruded and the TWLs measured.

Table 1 The values of the parameters studied in each of the sets of experiments

Trials	Extrusion Ratio	Die angle	Friction Coefficient	Profile Shape	Dummy Block & Billet Geometry
Set 1	4, 6.67, 10, 25	Tapered (45°), Flat (90°)	Unlubricated ($\mu = 0.29$), Vaseline ($\mu = 0.09$)	Axisymmetric, rectangular	Conventional (flat)
Set 2	4	Tapered (45°)	Unlubricated	Axisymmetric, rectangular, cross, dual-circle	Conventional (flat)
Set 3	4	Tapered (45°)	Unlubricated	Axisymmetric	Conventional (flat), Profiled (concave)

2.4 Experiments

A parametric study was performed on the TWL as a factor of the extrusion ratio, die angle, friction coefficient, profile shape, and dummy block profile. Table 1 summarizes the 35 different experiments conducted. Each experiment was performed three times in order to increase the reliability of the results. The resulting TWLs were measured using high-resolution photography input into IC Measure computer software [20]. The length of the weld was measured from the tip to the point at which the cross-sectional area of the old billet was just 5% of the total cross-sectional area of the profile. This criterion of 5% area is used in industry as a standard point at which the effect that the transverse weld has on lowering profile strength is deemed to be no longer significant [11]. For the axisymmetric profiles, longitudinal scalpel cuts along the length of the extruded profile revealed the complete weld geometry. For non-axisymmetric shapes, however, a salami-slicing approach was used to determine the weld geometry (see Fig. 8).

3 Results

The TWLs measured in this study ranged from 55 to 570 mm, increasing by a factor of 10 from a Vaseline® lubricated tapered axisymmetric die with an extrusion ratio of 4, to an unlubricated, flat rectangular die with an extrusion ratio of 25. The effects of the extrusion ratio, die angle, and friction coefficient on the TWL are shown in Fig. 9. The effect of the profile shape on the TWL is presented in Figs. 10 and 11.

The effect of the extrusion ratio was studied on both lubricated and non-lubricated, axisymmetric, tapered, and flat die faces. The results from the axisymmetric experiments in Fig. 9 show that as the extrusion ratio increases, the weld length increases significantly. The TWL from using unlubricated, flat dies increased by 500% from 73 mm at an extrusion ratio of 4 to 430 mm at an extrusion ratio of 25.

The results in Fig. 9 also show that the use of the tapered die reduced the TWL in nearly all scenarios. Similarly, the TWL decreased in nearly all the trials where Vaseline® was used to lower the friction coefficient. The influence of lubrication on the TWL was greatest in the case of the tapered dies at higher extrusion ratios. For example, the Vaseline® decreased the TWL associated with the tapered die by an insignificant amount at an extrusion ratio of 4, increasing to a 30% reduction at an extrusion ratio of 25. In contrast, the percent reduction in the TWL caused by using

Fig. 8 Incremental cross-sectional "salami-slicing" cuts of the cross profile. (Color figure online)

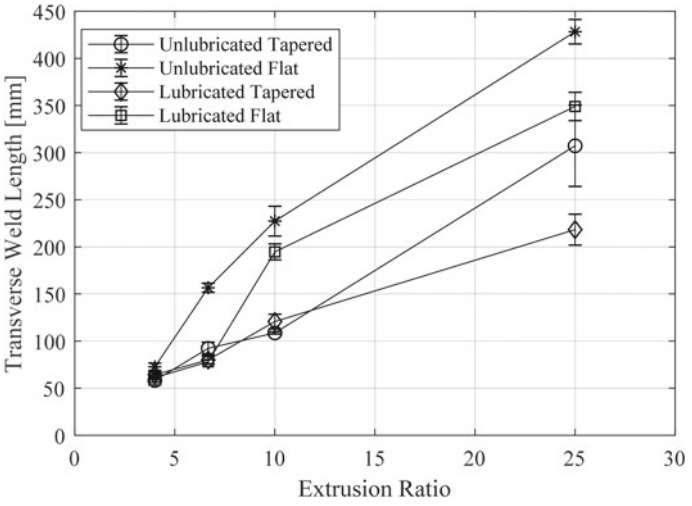

Fig. 9 Transverse weld lengths in axisymmetric solid profiles at varying extrusion ratios, die angles, and friction coefficients

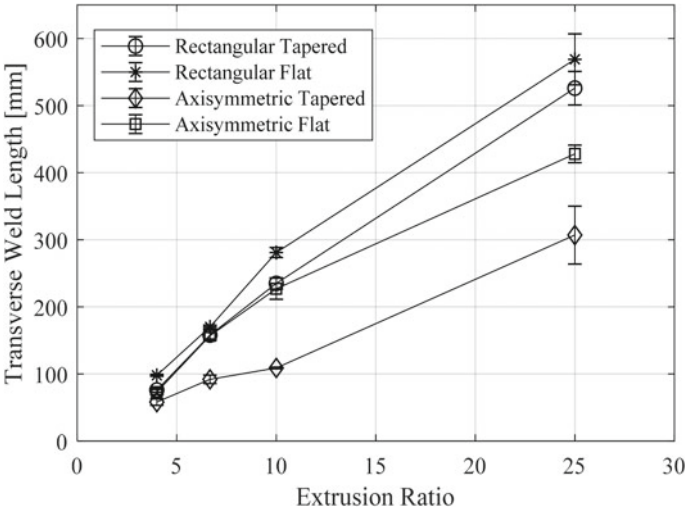

Fig. 10 Transverse weld lengths in axisymmetric and rectangular solid profiles at varying extrusion ratios and die angles (unlubricated friction conditions)

lubrication was relatively constant across different extrusion ratios in the case of the flat dies.

The results in Fig. 10 show that extruding the rectangular profiles produced longer TWLs than extruding the corresponding axisymmetric profiles at the same extrusion ratio. The amount the TWL increased varied by scenario, from 8% in the case of flat

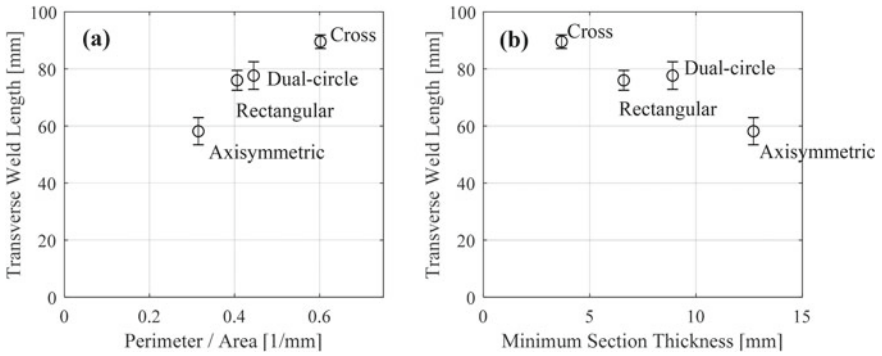

Fig. 11 Transverse weld lengths against **a** the ratio of profile cross-sectional perimeter to area and **b** the profile minimum section thickness. All profiles represent an extrusion ratio of 4

dies at an extrusion ratio of 6.67, to a 110% increase in the case of tapered dies at an extrusion ratio of 10. The second set of profile shape trials included two, more complex profiles both at an extrusion ratio of 4; one cross-shaped, one dual-circle, as shown in Fig. 3. Figure 11 shows the measured TWLs for the various extruded profile shapes when plotted against (a) the ratio of profile perimeter to area and (b) the minimum section thickness of each profile. These plots show that, for the shapes chosen in this research, the TWL increases as the ratio of the perimeter to area increases.

Figure 12 shows that the concave-profiled dummy block and profiled billets produced a TWL of 31 mm, which represents a 44% reduction in weld length from the 55 mm weld that was produced using a flat dummy block and conventional billet geometry. The resulting weld profile is shown to have changed drastically, inverting at the tip.

4 Discussion

In this section, we discuss the physical reasons behind the experimental trends and the implications for reducing process scrap in the industry.

4.1 Extrusion Ratio

The extrusion ratio is a term that equals the cross-sectional area of the press container divided by the cross-sectional area of the extruded profile. A smaller extrusion ratio reduces the TWL by reducing the relative velocity difference between the material flowing at the interior and exterior of the profile (Fig. 7). An extruder has limited flexibility to change the profile geometry requested by a customer; therefore, the extruder can only reduce the extrusion ratio by using a press with a smaller container diameter. Reduced container and therefore billet diameters would, however, reduce plant throughput without a concurrent increase in billet length in order to maintain overall billet volume. A smaller extrusion ratio also reduces the ram force required to push material through the die; however, longer billets would increase the ram force through higher billet-container frictional forces. Chien et al. [21] recently showed that for AA6063 extrusions at 454 °C, decreasing the billet diameter from 254 to 203 mm and simultaneously increasing the length of the billet to maintain a constant volume of aluminum resulted in a 1.9% decrease in extrusion load. This would allow for the length of the billet to be increased even further before the maximum load rating of the press is reached. Chien et al. show that a marginal increase in throughput could be achieved while also decreasing the extrusion ratio, and from this research, it can be reasoned that the transverse weld scrap amount would also be decreased.

4.2 Die Angle and Friction

In the industry and in the literature, it is often assumed that a flat die forms a dead metal zone (DMZ) with a DMZ angle (equivalent in function to the die angle) of close to 45°. The DMZ is a volume of stationary material at the face of the die over which the billet material shears, allowing it to flow through the die. If it were the case that a flat die forms a 45° DMZ angle, then we would expect that the TWL results from using the flat and 45° unlubricated tapered dies might be similar. However, our results show that using a tapered die significantly reduces the TWL, particularly at higher extrusion ratios. Sectioning partially extruded billets from this work (Fig. 13) revealed that the DMZ angle formed on an unlubricated, flat die of extrusion ratio 4 was close to 45° (Fig. 13a) but that this DMZ angle greatly increased at higher extrusion ratios (Fig. 13b) becoming much closer to a truly square/flat material flow. Elsewhere, Sluzalec [22] found that the relationship between the DMZ angle and

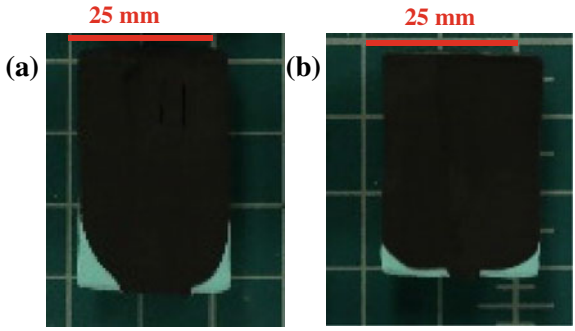

Fig. 13 Longitudinal cross-sectional cut after partial extrusion of the second billet to show DMZ of **a** extrusion ratio = 4, and **b** extrusion ratio = 25. DMZ is in green. Aspect ratio of billets (diameter:initial length) = 1. (Color figure online)

extrusion ratio changes based on the aspect ratio of the billet used (billet length to diameter). He found that for an aspect ratio of 1 (the ratio used in this research), the DMZ angle increases with the extrusion ratio. However, as the aspect ratio is increased through an increase in billet length, the DMZ was found to decrease as the extrusion ratio increases.

When using flat dies, the effect that reducing the friction has on the TWL is relatively constant across the extrusion ratios, whereas the effect that reducing the friction has on the TWL when using tapered dies appears to grow with the extrusion ratio (Fig. 9). One explanation for this observation is that the DMZ angle formed behind the flat die increases as friction is lowered, as observed by Sluzalec [22] for billet aspect ratios of 1. An increasing DMZ angle would act to increase the TWL (analogous to increasing the die angle) and therefore counteracts some of the positive effects of decreasing the TWL through reduced friction. To isolate the effect of friction on TWL (independent of DMZ/die angle), it is therefore recommended to observe the changes in TWL on the tapered dies. This research suggests that adding a lubricant to lower the friction coefficient can significantly reduce TWLs at higher extrusion ratios. However, many extruders are reluctant to use lubricant between the billet and container wall for fear that this could cause surface defects on the extruded profile, including blistering [6].

4.3 Profile Shape

The effect of the profile shape on the TWL has not been previously studied. Figure 11 suggests (for a given cross-sectional area) the TWL scales with the perimeter of the extruded profile cross-section. This may be because a larger perimeter suggests a thinner average section thickness and, locally, this manifests itself as a more extreme material flow; equivalent to a local increase in the extrusion ratio. For example, in the extrusion of the cross profile the old (green) billet can be seen further along the profile in the thin extremities of the cross rather than in the thicker central portion (see

Fig. 8). A larger perimeter also causes greater frictional forces, which, as discussed elsewhere, will lead to a higher TWL.

An extruder may have limited opportunities to influence the shape of the extruded profile requested by a customer. However, designers should be fully aware of the material efficiency and environmental implications of their component designs. There is probably some scope for improved profile shapes that reduce the TWL, which can be found through greater awareness of the process scrap ramifications.

4.4 Dummy Block Profile

This article has presented a simple case study that highlights the potential of using profiled dummy blocks and billets to control material flow through the die and to subsequently reduce the TWL. The TWL decreased by 44% in the case study (Fig. 12). The reason the TWL did not decrease to zero because the velocity field that is used to design the profiled block and billets is an idealization of extrusion and drawing flow through conical dies, neglecting, for example, the effect of friction along the container walls.

Further studies must address the technical feasibility of the profiled dummy block concept across a wider variety of profile shapes as well as the use of real aluminum material rather than a clay proxy. The benefits from reduced scrap generation will have to be reconciled against barriers to industry take-up that may include the costs of the new dummy blocks and new casting molds or forming apparatus that are needed to make the profiled billets.

5 Conclusions and Future Work

The removal of transverse welds between consecutively extruded billets is a key material inefficiency in the aluminum extrusion industry. This study has shown the potential to reduce the TWL through reduced extrusion ratios, die angles, friction coefficients, and profile perimeter to area ratios. Additionally, it has been demonstrated that adjustments to the dummy block profile (a previously unexplored design variable) might be an option to further decrease the weld length. Future work will include defining a process window for the profiled dummy block concept considering more realistic extrusion profiles (e.g., hollow non-axisymmetric shapes) and exploring the potential to reduce the TWL while constraining dummy block stresses to the elastic region and minimizing the costs of any new profile-specific dummy blocks and casting molds or forming apparatus.

Introduction of a New Method for Continuous Aluminum Hot Extrusion

Johannes Gebhard, Patrick Kotzyba, Oliver Hering, and A. Erman Tekkaya

Abstract The new extrusion process combines the conventional methods of direct and indirect aluminum hot extrusion by an innovative container and die setup with a moving or stationary valve. The process enables the continuous extrusion of aluminum profiles without any interruptions. With both variants, moving or stationary valves, the usual dead cycle times can be used for a continuous extrusion process. Furthermore, due to the continuous material flow, a stationary profile exit temperature can be achieved, which leads to constant material properties. As of now, a continuous extrusion press for aluminum is not available. The new process concept is analyzed on the basis of scaled experimental models using the model material plasticine and numerical simulations. The similarity of the model material was validated by aluminum extrusion experiments. Various model material colors were investigated, and the resulting material flow and process forces of the new process were analyzed.

Keywords Hot extrusion · Physical process modeling · Extrusion press

1 Introduction

Hot aluminum extrusion is a common process for producing long semi-finished profiles from cylindrical billets. Particularly for the processing of aluminum alloys, direct and indirect extrusion are of economic importance. Due to increasing product requirements, process control plays an increasingly important role. One of the most important factors in this context is the achievement of a constant profile exit temperature since this has a decisive influence on the mechanical properties of the profiles. The most important process parameters are the billet temperature and ram speed, which influence the temperature in the forming zone and thus the product properties [1]. In order to achieve a temporally constant temperature profile, and consequently stationary forming, the billet can be used with an axial temperature gradient, adjusted

to the extrusion speed. Alternatively, the system is locally heated or cooled. In various studies, both the lateral grading of billet temperature [2] and the adjustment of the ram speed [3] were investigated. The process could be controlled in a way that a constant profile exit temperature is reached during the forming of a billet for a certain time window, however, the outlet temperature cannot be kept completely constant. In addition, both the heat generated by forming and the heat dissipation are influenced by the extrusion speed [4]. Associated with the process-related waiting times when loading the billets, there is a transient temperature profile in the forming zone.

The microstructure has a direct influence on the mechanical properties and could be analyzed and characterized by EBSD measurements [5]. Especially when using high-strength AA7xxx alloys, the profile exit temperature must be kept in an operating window, in order to achieve good mechanical product properties [6]. One method to avoid process errors caused by excessive temperatures is active die cooling near the guide surfaces [7]. As a result, productivity can be increased significantly but still, no constant outlet temperature is achieved.

In addition to a constant profile outlet temperature, a continuous process sequence is desirable, especially with regard to the development of new extrusion technologies. From conventional hot extrusion, numerous non-conventional processes have been developed, such as composite extrusion with continuous [8] and discontinuous reinforcement elements [9] and co-extrusion of aluminum and magnesium [10]. Process extensions include curved profile extruding [11] and extrusion with variable wall thicknesses without [12] and with a mandrel [13]. However, the basic procedure is unchanged and consists essentially of the steps billet feeding, billet loading, upsetting, pressing, and removal of the discard. In particular, for the mentioned non-conventional processes, the dead-cycle-time between two billets is of great disadvantage, since the profile exit is interrupted and it leads to a drop of temperature and therefore to unsteady conditions. This can cause quality loss or reduced efficiency. But even for conventional profile extrusion, the resulting dead-cycle-time during block change limits the efficiency and cost-effectiveness of the extrusion process. Hot extrusion is strictly not a continuous or stationary process, but a quasi-stationary process. The development of an uninterrupted, continuous extrusion process offers the potential for a significant increase in economic efficiency as well as an expansion of existing process limits, in particular for non-conventional hot extrusion processes.

Plasticine is a well-known material for visualizing the flow behavior [14] and the process forces [15] of metallic materials. The composition of the material influences the plastic properties. Wanheim [16] investigated both yield stress and hardening behavior with different fractions of wax, hardener, and kaolin. Since it can be colored differently, it is suitable for the visualizing of the material flow [17]. Schöpfer and Zulauf [18] adjusted strain hardening and strain rate-dependent flow properties of Beck's plasticine by adding oil. The similarity can be achieved for flow behavior, friction, and forming heat, with some limitations also for heat transfer [19]. Dicks [20] has shown that the material flow of plasticine and aluminum is similar in hot extrusion.

With increasing computing power and advanced finite element simulation software, numerical methods for process design and analysis are mainly used. The FEM

is a flexible method for describing the complex thermal and mechanical processes involved in extrusion molding [21]. For continuous extrusion, the two methods of direct and indirect extrusion are combined by a moving valve. For a successful numerical simulation, the resulting different boundary conditions must be linked together. This concerns the material flow in the extrusion die, valve, hollow ram, or second container. Usually, only stationary material is considered for aluminum extrusion with an Eulerian approach of discretization. Due to the movement of the valve and the hollow ram, the flow volume changes in the presented continuous extrusion during a cycle. Therefore, the extrusion cycle needs to be split and investigated stepwise. Because no continuous extrusion press exists, the numerical approach cannot be validated experimentally. Therefore, in particular, physical process modeling, while maintaining similarity, can serve to validate the numerical investigation.

2 Continuous Extrusion

In the following, a new method for continuous extrusion is presented in which billets and profiles are comparable to conventional extrusion. The method distinguishes itself from the existing conform process [22] by significantly higher extrusion ratios and higher flexibility. The process considered here, and from now on referred to as continuous extrusion, is a combination of direct and indirect extrusion and allows the production of endless profiles, with the steady material flow in the extrusion die. The process was developed and patented in cooperation between the IUL and the SMS group GmbH [23]. The main components of the press are shown schematically in Fig. 1. Between two containers, a valve is arranged, which allows the material to flow only in the extrusion direction. During extrusion, the press is operated by two main hydraulic cylinders, the first cylinder is used for direct extrusion and the second cylinder for indirect extrusion. Accordingly, the ram for indirect extrusion is designed hollow. The die is positioned in the extrusion direction behind the hollow ram according to Fig. 1.

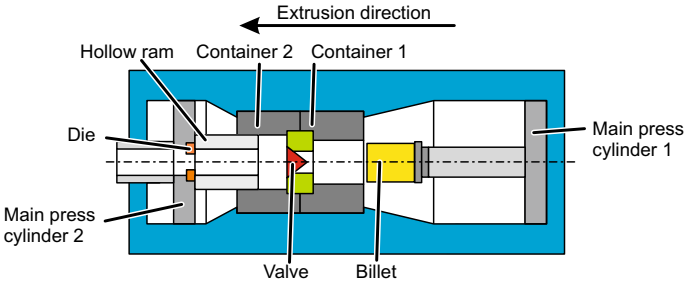

Fig. 1 Schematic of the main components of the continuous extrusion press. (Color figure online)

The process sequence can be subdivided into the two phases of direct and indirect extrusion, with both phases merging smoothly. Before the direct extrusion phase begins, the billet is supplied laterally and inserted into container 1. Then the ram is moved in the extrusion direction. Due to the material flow, the valve is opened and the material flows into container 2 and exits at the die (Fig. 2a). In order to allow indirect extrusion by moving the hollow ram, a part of the material must remain in container 2. For this purpose, the hollow ram is moved in the extrusion direction and the volume of container 2 is increased (Fig. 2b).

For indirect extrusion, the hollow ram is moved against the extrusion direction. The valve is closed by the resulting material flow against the extrusion direction. At the same time, the material from container 2 is pressed through the hollow ram and the extrusion die (Fig. 3a). Since the two containers are spatially separated by the valve, the next billet can be loaded into recipient 1, while indirect extrusion is maintained (Fig. 3b).

As soon as the material from container 2 is extruded and the hollow ram is in its final position, the initial state (Fig. 2a) is reached and the cycle can be repeated. Depending on the volumes of the two containers, the ram velocities can be selected or regulated so that the profile exit velocity remains constant during the whole cycle.

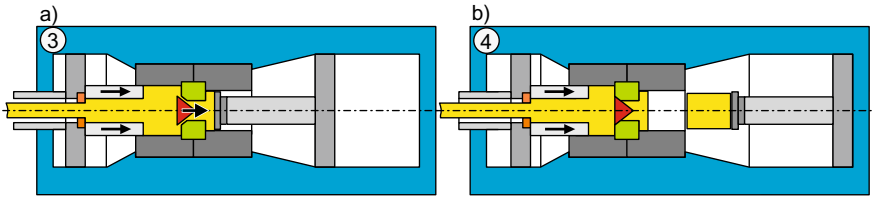

Fig. 3 Schematic sequence of the indirect phase of continuous extrusion (steps 3 and 4). (Color figure online)

3 Similarity of Plasticine and Aluminum

To investigate the continuous extrusion process, physical process modeling and FEM were used. While the commercially available software HyperXtrude can be used to simulate aluminum hot extrusion, the model material must first be characterized to establish the similarity to aluminum. Afterward, physical experiments are conducted on a scaled model of the continuous extrusion press using the characterized material. The used model material is plasticine which was provided by Becks Plastilin. The material behavior was investigated by upsetting tests and a direct comparison for direct aluminum hot extrusion. Figure 4 shows the setup of the compression test and the flow curves for the strain rates $\dot{\varphi} = 0.0067\ s^{-1},\ 0.1\ s^{-1},\ 0.22\ s^{-1}$. The specimens have a diameter of $d = 32$ mm and a height of $h = 50$ mm and are compressed into a cylindrical shape. The specimens were lubricated with talcum powder, compressed, and evaluated until the point of barreling.

The flow curves show a significant dependency of strain rate; also the plasticine shows nearly no strain-dependent hardening. This behavior is comparable to aluminum in hot conditions. Therefore, it is assumed that the chosen plasticine can be used to model the behavior of aluminum for the process of extrusion. Since it was not possible to reach strain rates that are comparable to aluminum extrusion, a comparative experimental setup was chosen to validate the similarity of plasticine.

To directly compare a scaled model with plasticine to the real-sized process of aluminum extrusion, an existing porthole die was scaled by the factor of $d_{\mathrm{I}}/d_{\mathrm{II}} = 3.088$ where d_{I} represents the dimension of the full-size aluminum extrusion die and d_{II} represents the dimensions of the model. The scale factor was also applied to the diameters of the containers to compare the process forces.

The aluminum extrusion experiments were conducted on a 10 MN direct extrusion press with the aluminum alloy AA6060. Billets, die, and container were heated to 450 °C and the profiles were extruded with a ram velocity of 1 mm/s. The setup and die geometry are shown in Fig. 5a. A similar setup was conducted with plasticine and a scale factor of 3.088. All parameters—die dimensions, container diameter, billet

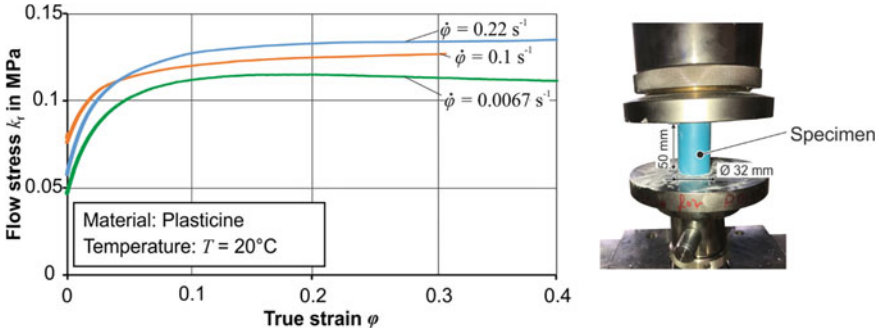

Fig. 4 Flow curves for the used plasticine. (Color figure online)

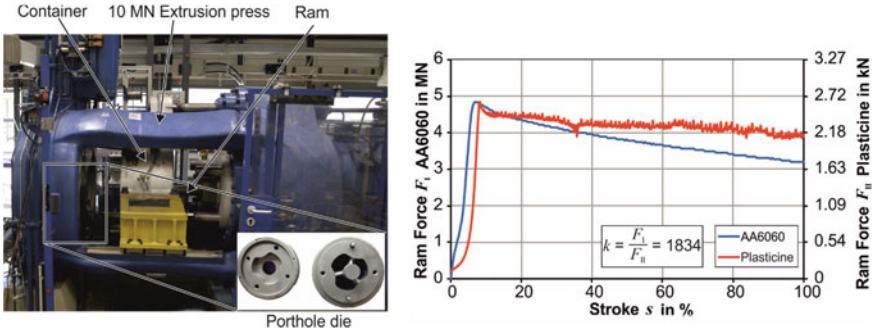

Fig. 5 **a** Experimental setup of extrusion experiments and **b** comparison of ram forces with respect to scale. (Color figure online)

length, and extrusion speed—were scaled accordingly. To compare the ram forces, the force–stroke curve of the model experiments was scaled dependent on flow stress and dimensions. The ratio of the ram forces can be determined by

$$k = \frac{F_{\mathrm{I}}}{F_{\mathrm{II}}} = \frac{d_{\mathrm{I}}^2 \cdot \sigma_{\mathrm{f,I}}}{d_{\mathrm{II}}^2 \cdot \sigma_{\mathrm{f,II}}} = 1834$$

Figure 5b shows the ram forces for aluminum extrusion and the scaled force of plasticine.

With the calculated scaling factor k, the ram forces of the plasticine model and the aluminum extrusion experiment nearly match for the maximum ram force. With advancing ram stroke, the friction in the model experiment between ram and container increases, and therefore, the process force deviates from the real-sized extrusion experiment. This can be explained by uneven sealing since no expanding dummy block was used in the model. Therefore, the validation of the model is done by comparing the maximum extrusion force. For the used plasticine, the model matches the behavior of aluminum AA6060.

4 Analysis of Continuous Extrusion

The introduced process of continuous hot extrusion consists of the direct pressing phase and the indirect pressing phase (Figs. 2 and 3). During the direct phase, the material is pushed through the first container, the valve, the second container, the hollow ram, and finally, the extrusion die. The process was simulated in HyperXtrude with an Eulerian approach. The complete cycle is separated into direct and indirect extrusions. Figure 6 shows the flow volume and contour plot of the continuous extrusion process. The material, AA6060, is modeled with a sine hyperbolic material law based on Zener-Holomon, e.g., Seller-Tergart. For the direct phase of the extrusion

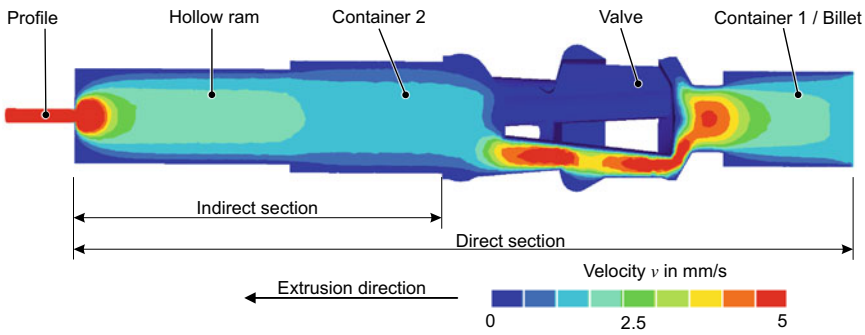

Fig. 6 Flow volume of the continuous extrusion process. (Color figure online)

cycle, the whole flow volume is considered (compare Fig. 6). It is assumed that the valve stops the material flow in the reverse extrusion direction. To compute the indirect pressing phase, only the flow volume of the hollow ram and container 2 are taken into account. The element edge length in the generated mesh in the direct and indirect part is 6 mm. The speed of hollow and direct ram is 1.47 mm/s in order to match the scale of the model experiments. The initial billet temperature and the temperature of the press were set to 450 °C.

The velocity distribution in Fig. 6 shows two major forming zones, the first one is at the valve and the other forming zone is in the hollow ram. The ram force during the direct phase is, therefore, considerably increased. With a diameter of 100 mm for container 1 and the inside of the hollow ram, a profile diameter of 14.7 mm ($R = 64$), the maximum ram force of direct extrusion is $F_{\mathrm{sim,I,direct}} = 6.3$ MN and for the indirect phase $F_{\mathrm{sim,I,indirect}} = 2.6$ MN. The indirect phase is comparable to a conventional extrusion process, where a similar process force would be reached.

The numerical investigations show process forces and material flow but cannot predict the functionality of the moving valve since only stationary forming is considered. Therefore, a model of the continuous extrusion press was constructed with polymer standard parts and additive polymer manufacturing (FDM). The press was scaled to a container diameter of $d_{0,\mathrm{II}} = 34$ mm and installed to a ZWICK universal testing machine with a maximum force of 250 kN. The setup is shown in Fig. 7.

To continuously extrude, two independently moving rams are necessary. Since this is not possible in the testing machine, the continuous cycle is again separated into two steps, the direct and the indirect phase. The direct extrusion phase is achieved by blocking the relative displacement between hollow ram and container 2 with stands and applying load on the ram (Fig. 7). By removing the stands and applying load on container 1, the indirect phase of the continuous extrusion cycle is performed where the hollow ram is pushed into container 2. During both phases, profile extrusion is achieved. To fill container 2, the stands are put between container 2 and the backup plate of the testing machine such that the hollow ram and die are in distance to the backup plate. When a billet is loaded into container 1 and pressed, container 2 is filled with plasticine until the die reaches the backup plate of the machine. When the

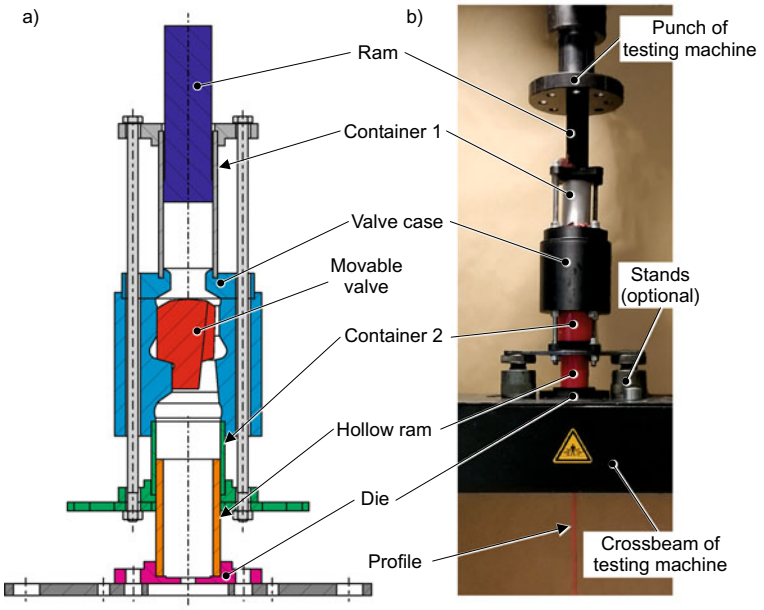

Fig. 7 **a** Model of the continuous extrusion press and **b** setup in the universal testing machine. (Color figure online)

ram is moving further, the material is pushed through the die and the direct extrusion phase continues. With this sequence, the whole cycle of continuous extrusion, except the simulation movement of ram and hollow ram can be investigated.

Figure 8a shows the ram forces of the direct extrusion phase and the indirect phase. Since the material has to flow through the valve, container 2, and hollow ram, the process force is significantly higher than for conventional direct extrusion. The force for the indirect phase is approximately 40% of the ram force during the direct phase. As mentioned earlier, the force of the indirect phase is comparable to conventional

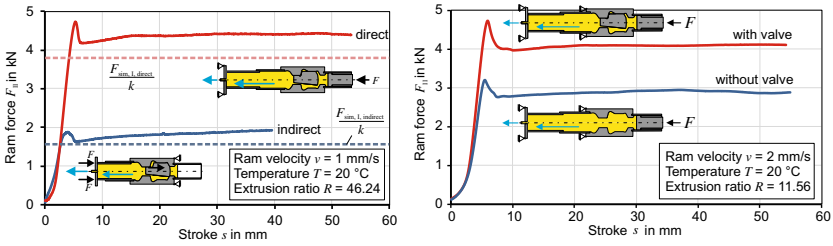

Fig. 8 Process force **a** with movable valve and **b** without valve for the direct and indirect phase of the process. (Color figure online)

aluminum extrusion. This leads to the conclusion that the valve consumes a lot of energy and needs to be examined further.

During the experiments, the material flow was as desired and the valve prevented material flow from container 2 to container 1. However, it was also observed that the valve did not move during the experiments. The position of the valve was measured tactile between the phases from the side of container 1, showing that it is not necessary to spatially separate container 1 and container 2 to enable continuous extrusion. When comparing the forces of the plasticine model and the numerical simulations with aluminum on the real-sized press, the same scaling method can be used as mentioned earlier. The forces ($F_{\mathrm{II,direct}}$ and $F_{\mathrm{II,indirect}}$) can be scaled with the factor $k = 1664$ and compared with the numerical simulations. The numerical forces are approximately 13% lower than the forces obtained with the plasticine model.

Figure 8 b shows the ram force–stroke curve for the direct extrusion step with and without the movable valve for another extrusion ratio and ram velocity. The force can be reduced to approximately 27%. Even without the movable valve, an extrudate is produced in the following indirect phase and just a minor amount of material is flowing from container 2 into container 1. This leads to the conclusion that the chamber between containers 1 and 2 can be designed suitably for the material flow to reduce the force of the direct phase and simultaneously preventing the reflux in the indirect phase.

In addition to the ram forces, the material flow in the continuous extrusion process was examined. To visualize the material flow, differently colored billets, in this case blue and yellow, were pressed in sequence. After pressing the third billet, the process was stopped and the remaining material was removed carefully from the press. Figure 9 shows the removed material and a plot of the material flow in the longitudinal cross-section.

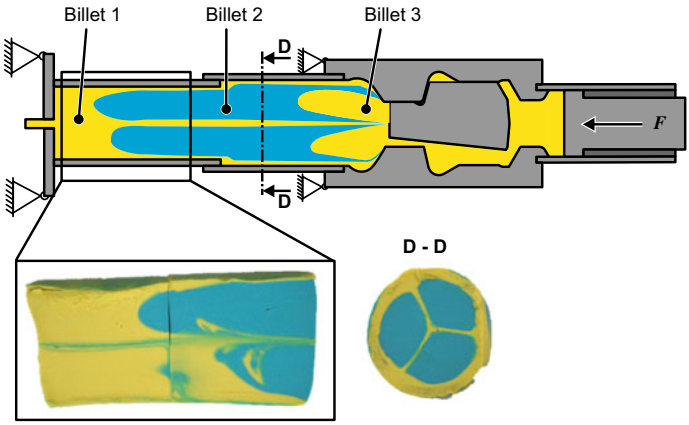

Fig. 9 Material flow visualized with differently colored plasticine during the direct phase of the extrusion cycle. (Color figure online)

The movable valve acts comparable to a porthole die with three bridges, and three longitudinal weld seams can be observed. The depicted flow pattern also applies to the profile. In this case, a symmetrical round profile of 5 mm diameter was produced. The longitudinal and lateral cross-section shown in Fig. 9 is also valid for the final extrudate.

5 Conclusion and Outlook

The process of continuous hot extrusion can be performed with a stationary valve that is adapted to the material flow. The advantages are reduction of the flow volume and no moving parts in the valve. While the reduced flow volume allows a smaller press size and easier cleaning or change of alloys, the usage of stationary parts increases the durability and risk for failures; for example, due to jamming or clamping of the moving valve. To prove the concept of a stationary valve, the model was modified according to Fig. 10.

With the given diameters for die exit and stationary die, direct extrusion and indirect extrusion could be realized. After the indirect phase of extrusion, just a small amount of plasticine has flown back, against the extrusion direction (Fig. 10). Nearly all of the contents in container 2 were extruded to a profile. This leads to the conclusion that the chosen parameters represent the process limit for the indirect phase of the press. When the diameter of the stationary valve is enlarged, more material flows back to container 1.

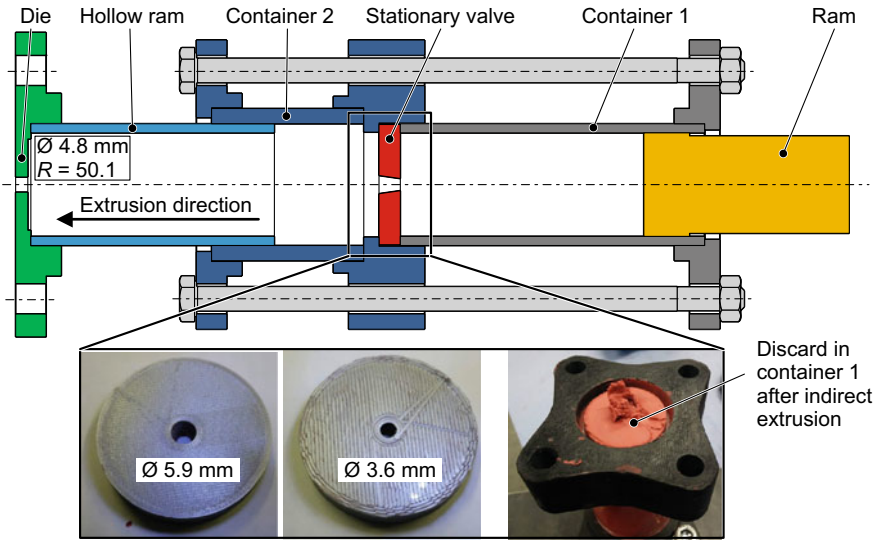

Fig. 10 Schematic of the continuous extrusion press with stationary valve, and result obtained with plasticine. (Color figure online)

With the process of continuous extrusion, constant profile extrusion can be realized. The concept of the process was investigated numerically and, by using the method of similitude, with a scaled model of the press. The model material was compared with aluminum AA6060. It was shown that the chosen material is suitable to represent the material flow of aluminum under the condition of hot extrusion. Since the model was used on an existing universal testing machine with only one moving axis, the continuous pressing cycle was reproduced by moving ram and hollow ram sequentially. By using differently colored plasticine, the material flow was analyzed. In addition, it was shown that the two containers of the press do not necessarily need to be spatially separated by a moving valve. An inter-chamber adapted to the material flow can be utilized to prevent material flowing in the opposite extrusion direction from container 2 to container 1. In summary, the following key points can be concluded:

- The continuous extrusion process can be modeled with Eulerian FEM approaches
- The process forces are more than twice as big during the direct phase compared to conventional extrusion
- The movable valve leads to additional longitudinal weld seams
- Due to the movable valve, the transverse weld will experience higher strain, leading to better welding
- Material flow against the main extrusion direction can be prevented by a moving or stationary valve
- A stationary valve needs to match the used extrusion die to enable continuous extrusion
- The process window for the stationary valve needs to be investigated in more detail.

Study on Complex Extrusion of Multi Billets: Evaluation of Mechanical Properties of Butt-Joined Products and Analysis of Joining State

Michihiko Hoshino and Izuru Otake

Abstract In recent years, an aluminum double-skin panel, which has a complicated and wide cross-sectional shape, is manufactured by extrusion and used for railway vehicles. It is difficult to manufacture a double-skin panel exceeding 600 mm width in the current forward extrusion process. However, from the viewpoint of weight saving, there is a demand to make a double-skin panel with larger widths. So we propose to manufacture double-skin panel with complex extrusion of multi-billets. Complex extrusion of multi-billets is suitable for producing complicated and wide extruded shapes. We focused that the joint part of the double-skin panel is joined in a plate shape. In this study, industrial pure aluminum A1050 and representative extruded alloy A6063 were extruded into a plate shape, and the joining state was evaluated by tensile test, micro Vickers hardness test, microscopic observation, and numerical analysis.

Keywords Complex extrusion · Double-skin panel · Joining stress

1 Introduction

At present, some railway vehicles have a double-skin structure using a complex and wide cross-sectional shape manufactured by extrusion. Railway cars of this structure are made by welding a number of double-skin panels formed long by direct extrusion. There is a demand to increase the width of the structural panel from the viewpoint of reducing the welding length and reducing the weight. However, by the current extrusion, the width of the structural panel is limited to about 600 [mm]. Because in case of that the diameter of billet is over 600 [mm] and the width of double-skin structure is more than 600 [mm], extrusion ratio is about 50 and extrusion force is more than 100 [MN].

In this study, it is proposed to produce wide double-skin panel using complex extrusion of multi-billets. The complex extrusion of multi-billets is a processing

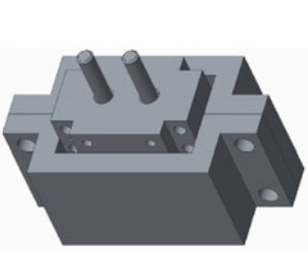
method in which multiple billets are extruded with a single die and formed into a single product [1, 2]. In this extrusion method, it is possible to extrude the same or different material types of workpieces and to join these workpieces during extrusion [3, 4]. It is important to control the flow of the workpieces by the die with suitable shape in order to manufacture the wide double-skin panel with good joining [5].

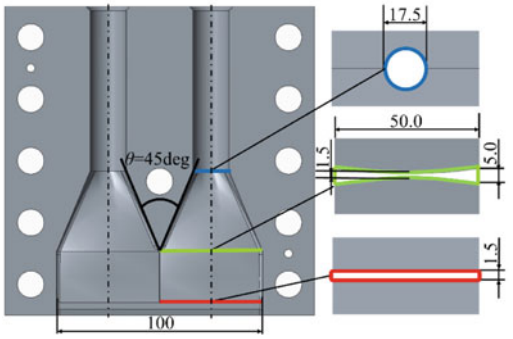
In the previous research, a model experiment using oil clay and the numerical simulation for a butt-joining, which is the basic pattern of the joining of the double-skin panel, have been achieved. It is clear that the effects of the ironing shape of the die approach part and the joining angle when the workpieces run across are important to the strength of joining the workpieces [6, 7]. And the extrusion force of complex extrusion of multi billets is letter than one of conventional extrusion.

In this study, complex extrusions of multi-billets of A1050, which is a pure aluminum for industrial use, and A6063, which is a typically extruded alloy, are achieved, and it is possible to manufacture good extruded products. It is understood that these joining strength is satisfactory from the results of tensile test. Furthermore, the joining condition of the workpieces is evaluated by the micro Vickers hardness test of the products and microstructure observation of the joint parts with an optical microscope. The results of the experiments are in good agreements with the estimation of the stress generated in the width direction of the joints of the workpiece by numerical analysis.



2 Experimental Method

2.1 Aluminum Alloy Extrusion Experiment



The experimental equipment (dies and two punches without bolts and nuts) used in this experiment and the inner dimensions of the die are shown in Fig. 1, and θ in the figure is defined as the merging angle. In the section from blue line to green line in Fig. 1, ironing in the thickness direction is applied to the center of each axis, and the workpiece flows not only in the extrusion direction but also in the width direction.

The geometry of die is designed in such a way that ironing in the thickness direction is applied at the end of each die approach part in order to achieve good joining between the workpieces.

In this experiment, first, billets of A1050 and A6063 were inserted into the container shown in Fig. 1, and the whole container with billets was heated to 600 °C in an electric furnace. Next, two punches were set in each hollow container and workpieces were extruded with an Amsler compression tester 3MN until just before the workpiece was joined. After the first extrusion process, workpieces were added to the container, and they were reheated to 600 °C in an electric furnace and then pressed. Thereafter, this procedure was repeated four times for every 60 mm of the ram stroke. Table 1 shows the experimental conditions and Table 2 shows the chemical composition of the test materials.

2.2 Tensile Test of Extruded Products

In this test, a tensile test specimen in the width direction was manufactured from the center part, which includes the joint surface, and the base metal part of the extruded plate-shaped product. A uniaxial tensile test result was evaluated by efficiency strength R_{str} which is obtained by dividing the tensile strength of the joint $\sigma_{B,join}$ in the test results by the tensile strength $\sigma_{B,base}$ of the base metal, and efficiency elongation r_e which is obtained by the uniform elongation of the joint e_{join}

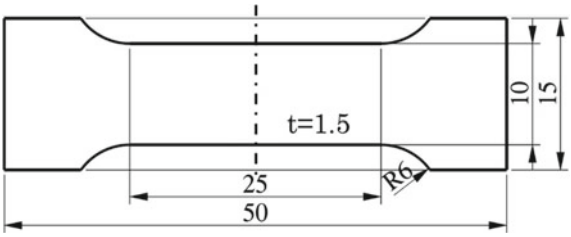

Fig. 2 Dimension of tensile test piece

divided by the uniform elongation of the base metal e_{base}. The bonding condition was evaluated by comparing the ratio R_{str}, r_e, and the proof stress $\sigma_{0.2}$.

The tensile test speed is 0.375 mm/min. The geometries of this specimen shown in Fig. 2 is special in order to match small extruded products.

2.3 Micro Vickers Hardness Test

In this test, a test piece was manufactured by cutting and polishing the workpiece immediately after joining to the plane of symmetry in the thickness direction, and a micro Vickers hardness test was performed at 11 measurement positions in the width direction shown in Fig. 3. The test load was 300 gram-force for A1050, 500 gram-force for A6063, and the load holding time was 15 s. The joint condition was evaluated by comparing the hardness distribution at the joint with one at the other part.

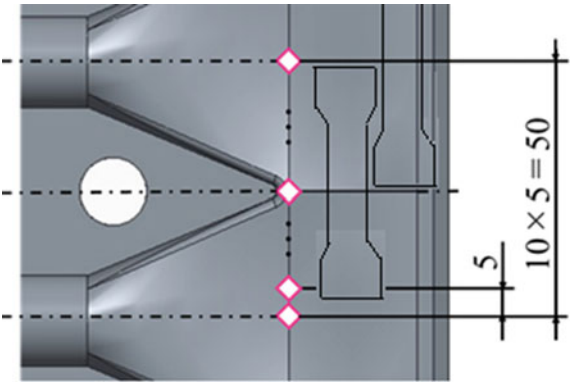

Fig. 3 Measurement position of Vickers hardness test. (Color figure online)

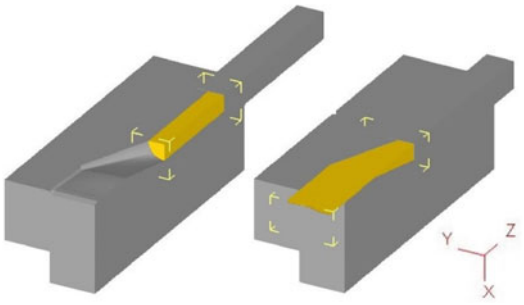

2.4 Microscopic Observation of the Joint

In this observation, the specimen after the micro Vickers hardness test was further polished, then etched with 50 °C NaOH 1.0 mass% aqueous solution for 20 s. The specimen was observed using an optical microscope. From the observation results, the bonding state of the workpiece was evaluated based on the presence or absence of the bonding interface, inclusion of impurities, and roughening of grain surfaces.

2.5 Numerical Analysis

In the numerical analysis, the joining stress (hereinafter referred to as σ_{join}) generated in the width direction of the joint of the workpiece is estimated using DEFORM-3D V11.0 released by Scientific Forming Technologies Corporation, and the bonding state was evaluated based on whether or not the joining stress σ_{join} exceeded the deformation resistance σ_y of the work material.

Figure 4 shows the analysis model of the numerical analysis, Fig. 5 shows the measurement points of the joining stress σ_{join}, and Table 3 shows the analysis conditions. The stress generated in the direction of the arrow in Fig. 5 is defined as the joining stress σ_{join}. For the convenience of the material data, the analysis was performed assuming that the workpiece was A1050 and A6061, and the extrusion temperature was 450 °C. The reason is using A6061 instead of A6063 is that material database of A6061 has higher range of temperature than one of A6063 in DEFORM-3D V11.0.

3 Results and Discussion

3.1 Tensile Test of Extruded Products

The nominal stress–nominal strain diagram of A1050 measured in this test is shown in Fig. 6, and the maximum load point of each specimen is shown by the broken line. From Fig. 6, it was found that the proof stress $\sigma_{0.2}$ of A1050 was almost the same between the base metal and the joint, and the joining efficiency R_{str} determined from the tensile strength was 90.9%.

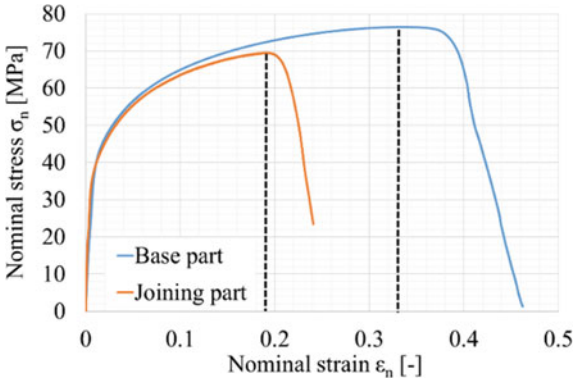

Fig. 6 Stress–strain curve of tensile test (A1050). (Color figure online)

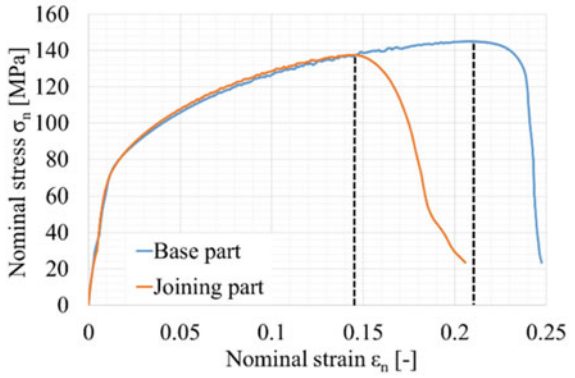

Fig. 7 Stress–strain curve of tensile test (A6063). (Color figure online)

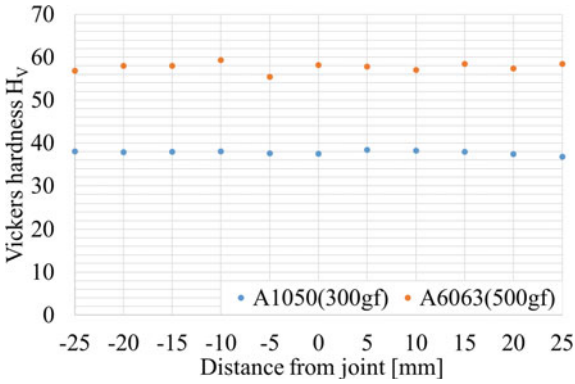
However, the elongation ratio r_e obtained from uniform elongation was as small as 55.9%. The nominal stress–nominal strain diagram of A6063 measured in this test is shown in Fig. 7, and the maximum load point of each specimen is shown by the broken line.

From Fig. 7, it was found that in A6063, the proof stress $\sigma_{0.2}$ showed almost the same value in the base material and the joint, and the joining efficiency R_{str} determined from the tensile strength was 94.8%. However, the elongation ratio r_e obtained from uniform elongation was as small as 74.9%. In addition, it is possible to be confirmed that the serrations seen in the Al–Mg alloy have occurred after yielding.

3.2 Micro Vickers Hardness Test

Figure 8 shows the results of the micro Vickers hardness test for A1050 and A6063 measured in this test. No significant difference in Vickers hardness was found



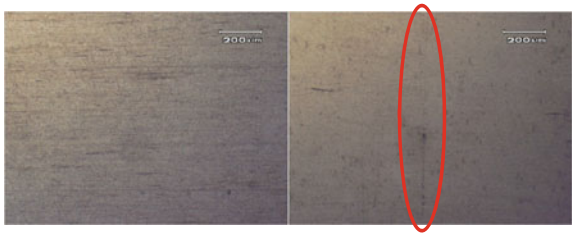


Fig. 8 Hardness distribution of the extruded product in the width direction. (Color figure online)

(a) A1050 (b) A6063

Fig. 9 Enlarged view of a joint interface of extruded product. (Color figure online)

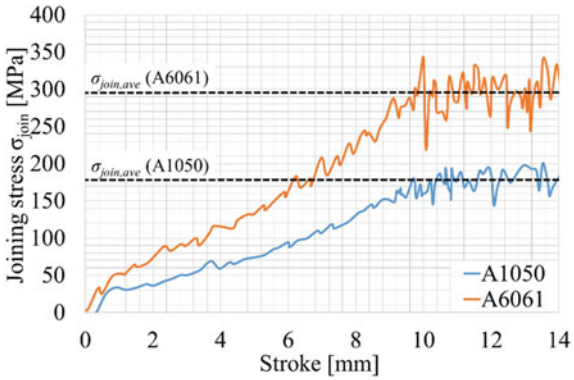
between the workpiece joint and the other parts. Therefore, it was found that there was no difference in strength between the joint and the base material.

3.3 Microscopic Observation of the Joint

Figure 9 shows a photograph of the joint observed with an optical microscope. From Fig. 9, the joint interface cannot be confirmed in A1050, but can be confirmed in the long circle of A6063. This difference is because A6063 has more second phase than A1050, and an additional element exists at the grain boundary of α phase (pure aluminum grain). In both A1050 and A6063, defects such as inclusion of impurities could not be confirmed.

3.4 Numerical Analysis

Figure 10 shows the joining stress–stroke diagram of A1050 and A6061. The broken line shows the average value of the joining stress after a stroke of 10 mm where the joining stress σ_{join} is constantly generated. The stroke was offset to the position



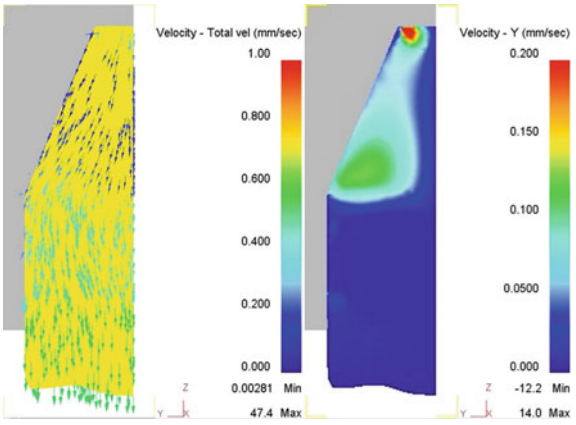


Fig. 10 Joining stress–stroke curve of complex extrusion of multi-billets. (Color figure online)

where the joining stress σ_{join} started to rise. From Fig. 10, the average of the joining stress σ_{join} was 177.7 MPa for A1050 and 296.0 MPa for A6061. This value reaches 9.5 times the deformation resistance of A1050 $\sigma_y = 18.6$ MPa which is calculated at forming temperature from material database of DEFORM-3D V11.0 and 13.0 times the deformation resistance of calculated A6061 $\sigma_y = 22.8$ MPa from the same database at the measurement point of joining stress, and the workpieces have sufficiently yielded. Therefore, it is clear that good joining has been achieved.

Figure 11 shows the velocity vector and the Y-direction velocity distribution of the workpiece in the steady-state of extrusion. Since there was no significant difference between A1050 and A6061 in both the velocity vector and the Y-direction velocity distribution, only the case of A1050 is described. From Fig. 11(a), before the start of joining of the workpiece, the workpiece flows in the Y-direction due to the ironing in the thickness direction at the center of the extrusion axis. In addition, since the flow in the width direction of the workpiece is not completely uniform in the die bearing

(a) Velocity vector (b) Y-direction velocity

Fig. 11 Velocity distribution in the approach part and bearing part of die. (Color figure online)

part, there is room for improvement in the design of the die approach part. From Fig. 11(b), it can be seen that the workpiece in the Y-direction immediately before the start of welding of the workpiece flows in the Y-direction at a speed of about 0.1 mm/s, more than twice the speed after the start of welding. This confirms that the shape of the die approach contributes to the joining of the workpiece.

4 Conclusion

1. From the results of the tensile test, it was found that the proof stress $\sigma_{0.2}$ of the base metal and one of the joint part was almost the same, and the joining efficiency R_{str} was 90.9% for A1050 and 94.8% for A6063.
2. From the results of the micro Vickers hardness test and the microstructure observation with an optical microscope, it is clear that the bonding in multi-billet extrusion with ironing was good.
3. From the numerical analysis, it was found that the joining stress σ_{join} generated in the width direction of the workpiece reached 9.5 times the deformation resistance σ_y of A1050 and 13.0 times the deformation resistance σ_y of A6063.

From the above results, it is possible to produce a wide plate of A1050 and A6063 by using complex extrusion of multi-billets.

Effect of Expansion Ratio on Formability in Tube Drawing with Diameter Expansion

H. Kawaguchi, T. Kuboki, I. Akasaka, Y. Terashita, M. Akiyama, and S. Kajikawa

Abstract Conventional tube drawing methods have the disadvantage that thickness reduction in one pass is small. This paper proposed a tube drawing method for overcoming this disadvantage, and the method expands the diameter at the same time of drawing. At first, the tube is flared by pushing the plug into the tube end. After that, the plug is drawn by chucking the flared end, and the entire tube is expanded. Tensile circumferential and axial stress reduces the tube thickness effectively during the plug drawing. In this study, the effect of expansion ratio on formability, such as thickness reduction and dimensional accuracy, was investigated by experiments and finite element analyses (FEA) for verifying the effectiveness of the proposed method. As a result, the thickness reduction increased with an increase in the expansion ratio, and the maximum thickness reduction ratio was 0.3 when an aluminum alloy of AA1070 was used. Furthermore, the deformation mechanism was considered by FEA.

1 Introduction

Metal circular tube materials are widely used in industrial machines and automobile parts. It is mainly manufactured by drawing with diameter constriction. At present, there are many studies about drawing with diameter constriction [1, 2]. However, there is a limit of the thickness reduction in one pass in conventional drawing with diameter shrink. Therefore, drawing multiple times is required when manufacturing a thin-walled tube.

Tube drawing with diameter expansion has been proposed as a method to improve the drawing limit [3, 4]. The proposed method is composed of two processes: flaring and drawing, as shown in Fig. 1. At first, form the gripping part in the flaring process (Fig. 1a). After that, grasp the gripping part and draw the plug through the tube into the drawing process (Fig. 1b).

In this method, it is possible to realize efficient thickness reduction compared to the conventional tube drawing with diameter shrink. As shown in Fig. 2, circumferential stress is compressive in the case of the conventional method, while circumferential stress is tensile in the proposed method. Therefore, the proposed method is effective for reducing the thickness, because radial deviatoric stress is large compared to the conventional method. In this study, the thickness reduction obtained by the tube expansion drawing process is investigated and the dimensional accuracy of the molded product is evaluated. The tube expansion drawing was performed, and the thickness reduction and processing accuracy of the molded product were evaluated by measuring the dimensions of the molded product.

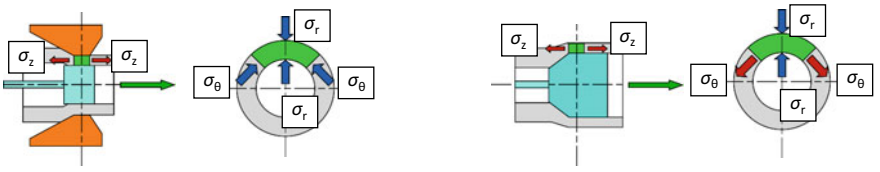

Fig. 2 Deviatoric stress of plug drawing and expansion drawing. **a** Drawing with diameter shrink, **b** Drawing with diameter expansion. (Color figure online)

2 Experimental and Analysis

2.1 Experimental Method and Condition

First, the flaring experiment was performed, and a plug is inserted into the tube as shown in Fig. 3. After that, the drawing experiment was performed. Figures 4 and 5 show a schematic diagram and a photograph of the drawing experiment.

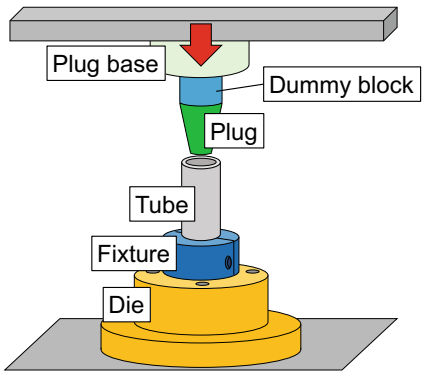

Fig. 3 Expansion pushing machine. (Color figure online)

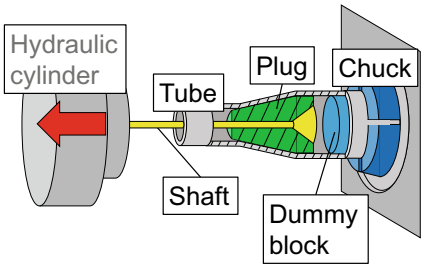

Fig. 4 Drawing machine. (Color figure online)

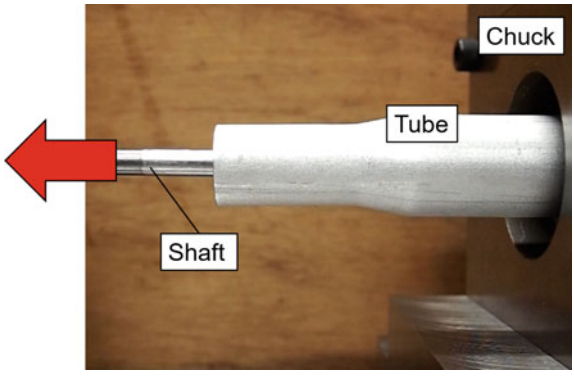

Fig. 5 Photograph of drawing machine. (Color figure online)

Table 1 Tube material conditions

Material	AA1070, STKM13C
Initial thickness t_0/mm	2
Outer diameter d_0/mm	30
Length L_0/mm	200

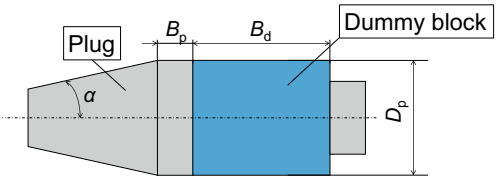

Fig. 6 Geometrical parameters of plug with dummy block. (Color figure online)

Table 2 Plug conditions

Half angle α/°	12
Bearing length B_p/mm	15
Dummy block length B_d/mm	43
Plug diameter D_p/mm (Expansion ratio E)	28, 30, 32, 34, 36 (0.077, 0.15, 0.23, 0.31, 0.38)

Table 1 shows the material conditions. Two types of materials, which are aluminum alloy 1070 and steel of STKM13C (Japan Industrial Standard, JIS G 3445), were used. The deviation between the central axis of the outer and inner diameter of the tube, which indicates the value of eccentricity, is 0.049 mm for AA1070 and 0.028 mm for STKM13C, respectively. Figure 6 shows a schematic diagram of the plug used in the experiment, and Table 2 shows the plug conditions. A dummy block, which becomes a core of the chucked part in the drawing process, was incorporated in the plug. This dummy block prevents the crush of the tube by chucking. The expansion ratio of the tube was varied by changing the plug diameter. From this experiment, the effect of the expansion ratio on the thickness reduction and dimensional accuracy was investigated.

2.2 Analysis Method and Condition

Finite element method (FEM) analysis was performed using the model shown in Fig. 7 in order to consider the experimental results. Table 3 shows the properties of the materials in Swift's law. Swift's law is shown in the following equation.

$$\sigma = F(\varepsilon + \varepsilon_0)^n$$

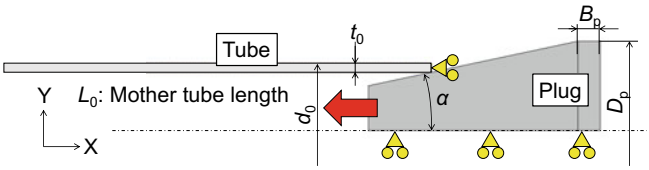

Fig. 7 FEM analysis model. (Color figure online)

Table 3 Mechanical properties in Swift's law

Material	A1100	STKM13C
Strength coefficient F /MPa	121	725
Hardening exponent n	0.048	0.023
Offset of strain ε_0	0.0013	0.0032

The analysis conditions are the same as that of the experiment and are shown in Tables 1 and 2. Furthermore, the friction coefficient was 0.3 [4], and the number of elements was 300 in the axial direction and 13 in the radial direction. The finite element method code "ELFEN", which was developed by Rockfield Software Limited in the UK, was used for numerical analysis. The static implicit method was used for the numerical calculation. The model is two-dimensional with axisymmetry, and the von Mises yield criterion was adopted. The element type was four-node rectangular.

2.3 *Measuring Method*

Figure 8 shows a schematic diagram of the molded product. The thickness and inner diameter of the molded tube were measured. Thickness was measured at 10 mm intervals in the axial direction and measured at 45 intervals in the circumferential direction at each axial position by using an acoustic wavemeter. After measuring the thickness, the tube was cut at 30 mm intervals using a band saw, and the inner

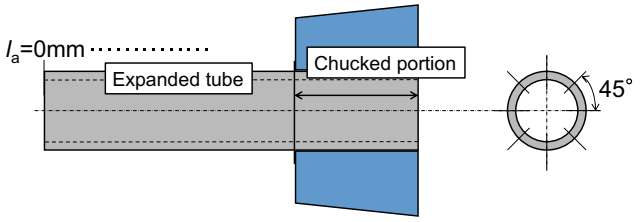

Fig. 8 Measuring method of the expanded tube. (Color figure online)

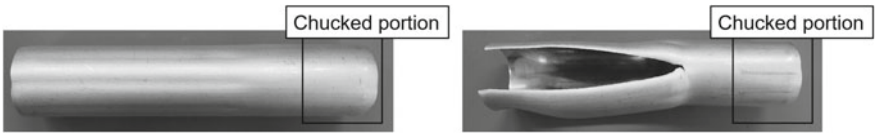
diameter of each tube piece was measured at 90° intervals in the circumferential direction by using a caliper.



3 Results and Discussion

3.1 Evaluation of Thickness Reduction

Figure 9 shows examples of success and failure, and Table 4 shows the molding results under each condition. When the plug diameter $D_p = 36$ mm for AA1070 and $D_p = 34$ mm for STKM13C, cracks occurred as shown in Fig. 9b. The maximum diameter without cracks is defined as the limit diameter D_{max}.

Figure 10 shows the relationship between distance l_a from the tube end and thickness reduction ratio γ. In both materials, the thickness reduction ratio γ increased as the expansion ratio E increased, and the experiment and analysis matched qualitatively. Under all conditions, the thickness reduction ratio γ was constant in the middle part of the tube, but the thickness reduction ratio γ was low near the tube end compared to the middle part. It is because the axial tensile stress was small near the tube end. Compared to that at the middle part, the thickness reduction ratio γ was also low in the part near the chucked part in the experiment, because the plug applied axial compressive stress to the chucked tube end during the flaring process in the first step. In FEM, thickness reduction did not decrease at the fixed end because only the drawing process was analyzed.

Figure 11 shows the effect of expansion ratio E on the thickness reduction ratio γ, which was averaged in the stable thickness range except for each tube end. In Fig. 11, the experimental and analysis results were compared. In both materials,

(a) Success (b) Failure

Fig. 9 Photograph of the formed product. **a** Success, **b** Failure

Table 4 Molding results

Plug diameter D_p/mm (Expansion ratio E)	28 (0.077)	30 (0.15)	32 (0.23)	34 (0.31)	36 (0.38)
AA1070	○	○	○	○	×
STKM13C	○	○	○	×	

○:Success × :Failure

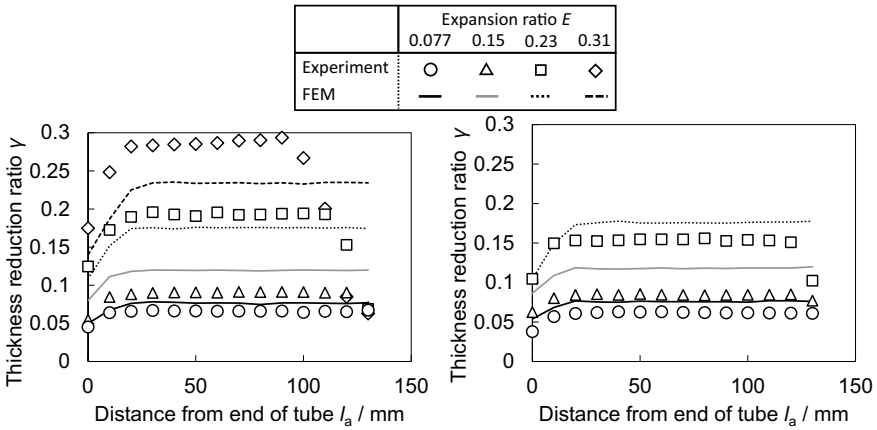


Fig. 10 Relationship between distance from the end of tube l_a and thickness reduction ratio γ. **a** AA1070, **b** STKM13C

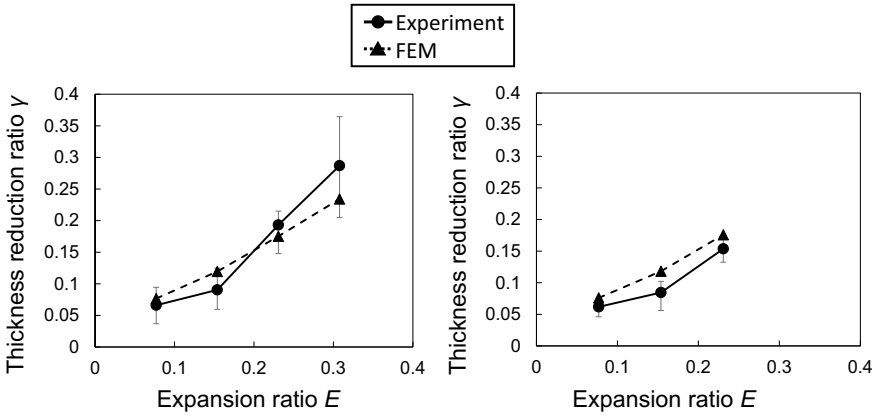

Fig. 11 Effect of expansion ratio E on thickness reduction ratio γ. **a** AA1070, **b** STKM13C

there was no significant difference between the results of the experiment and the analysis. In Fig. 11a of AA1070, when the expansion ratio E was 0.31, thickness reduction ratio γ was approximately 0.3. This value exceeded the thickness reduction ratio γ of 0.2 in the conventional tube drawing [5]. However, this condition had a larger error bar than the other conditions. Figure 12 shows a photograph of the tube draw under the condition of $E = 0.31$. The wall thickness was locally reduced and became unstable in the circumferential direction. This effect increased the error bar in the large expansion ratio.

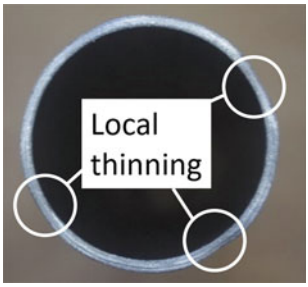

Fig. 12 Molded products locally thinned in the circumferential direction (AA1070, $E = 0.31$). (Color figure online)

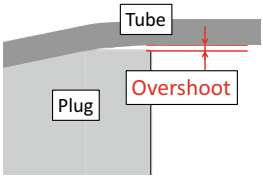

Fig. 13 Overview of overshoot. (Color figure online)

3.2 Evaluation of Tube Inner Diameter

Figure 13 shows "overshoot" in the expansion drawing. There was a gap between the plug diameter D_p and the tube inner diameter d_i after expansion drawing. Overshoot g_o was defined in the following equation.

$$g_o = (d_i - D_p)/2$$

Overshoot g_o should be small for improving the dimensional accuracy of the inner diameter. Figure 14 shows the relationship between distance from the end of the tube l_a and overshoot g_o in the experiment and analysis. The overshoot g_o was low at the tube end, and then increases as the distance from the end of tube l_a increases regardless of the material kind. The overshoot became stable when l_a is larger than 30 mm. The overshoot g_o was the largest when the expansion ratio E was the smallest at 0.077, and the overshoot g_o decreases as expansion ratio E increases.

The average value of the overshoot g_o was calculated for 30 mm $< l_a <$ 90 mm in Fig. 14, and the effect of expansion ratio E on overshoot g_o was summarized in Fig. 15. As a result, it was found that the overshoot g_o of AA1070 was larger than that of STKM13C. It is because the bending radius was larger at the plug corner during the drawing in the case of AA1070, in which the work hardening exponent was large compared to that of STKM13C as shown in Table 3.

The reason why the overshoot g_o becomes large when the expansion ratio E is small is analyzed. Figure 16 shows the axial stress distribution at the expanded straight part. As shown in the part [A] in Fig. 16a, axial tensile stress is applied to the inside of the tube, and compressive stress is applied to the outside of the tube. When the expansion ratio E was small, the tensile stress inside the tube expands to

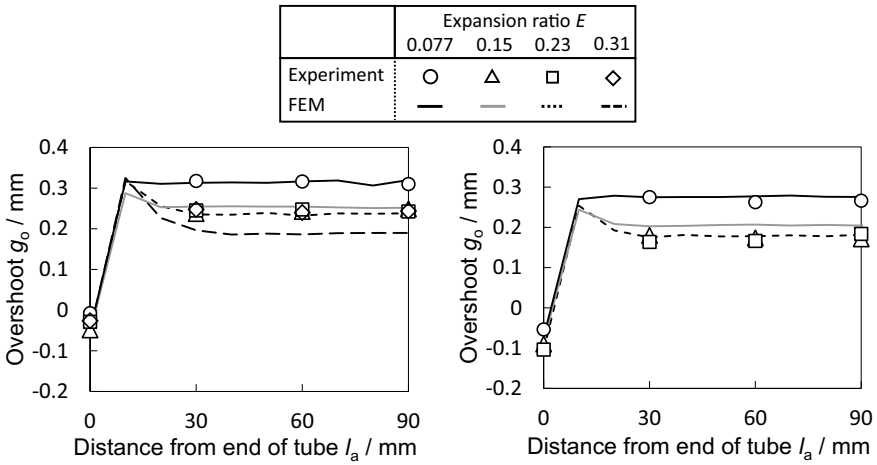

Fig. 14 Relationship between distance from the end of tube l_a and overshoot g_o. **a** AA1070, **b** STKM13C

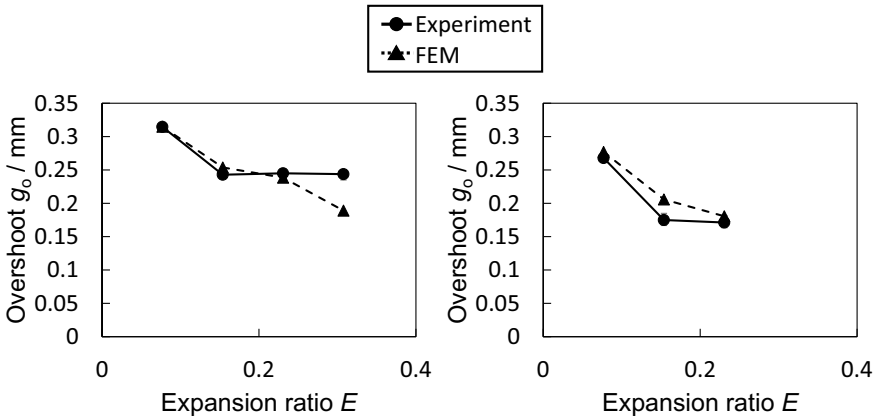

Fig. 15 Effect of expansion ratio E on overshoot g_o. **a** AA1070, **b** STKM13C

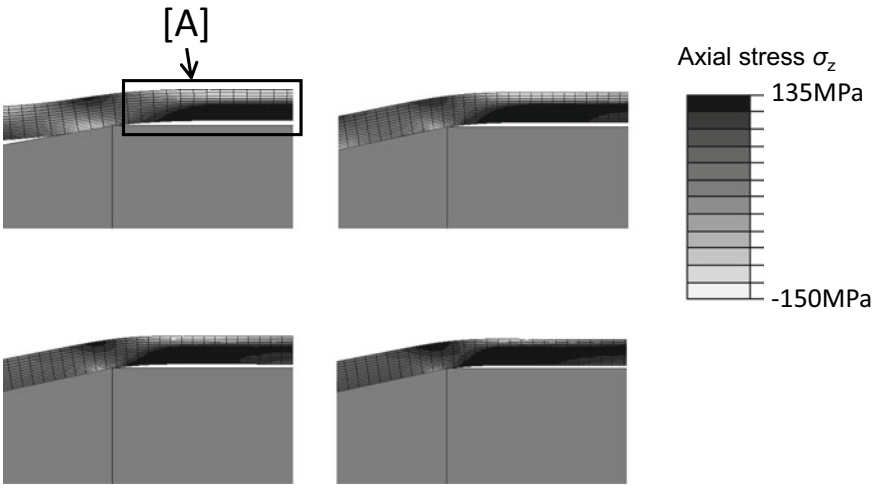
the outside with the increase in the expansion ratio E as shown in Fig. 16b, c and d. Furthermore, Fig. 17 shows the relationship between the axial load F_z applied to the fixed tube end and the expansion ratio E during the drawing. As the expansion ratio E increased, the axial load F_z also increased. These results indicated that the large expansion reduces the overshoot g_o by stretching the tube strongly in the axial direction.



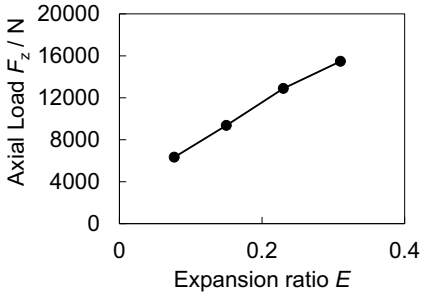


Fig. 16 Axial stress distribution at the expanded straight part (AA1070). **a** $E = 0.077$, **b** $E = 0.15$, **c** $E = 0.23$, **d** $E = 0.31$

4 Conclusions

In this study, the thickness reduction and dimensional accuracy were evaluated by experiments and finite element analysis for the realization of the tube expansion drawing. The results can be summarized as follows:

- The effect of the expansion ratio E on the thickness reduction ratio γ was investigated. The thickness reduction ratio γ also increased as the expansion ratio E increased.
- When the expansion ratio E was 0.31, the thickness reduction ratio γ was about 0.3, whose value exceeded the thickness reduction ratio γ in the conventional drawing method. However, local thinning was observed, and the wall thickness became unstable in the circumferential direction.
- The overshoot g_o was generally larger for AA1070 than for STKM13C.

- The overshoot g_o is the largest when the expansion ratio E is the smallest at 0.077, and the overshoot g_o decreases as expansion ratio E increases. It is considered that when the expansion ratio E is large, the axial load increases and the overshoot is suppressed.

Investigation of Forward–Backward–Radial Extrusion Process of Aluminum Alloy Wheel Hub

Qiang Wang, Mu Meng, Xubin Li, and Zhimin Zhang

Abstract As a kind of extrusion process, the forward–backward–radial extrusion (FBRE) process can be used to produce complex-shaped parts with hoop protrusions or flanges. The control of metal flow is the key to affect forming, strain distribution, and forming load during the FBRE process. On the basis of summarizing the research of the FBRE process, this paper presents the numerical and experimental results of aluminum alloy hub production using this method. Material flow behavior and strain distribution within the final product were investigated by finite element methods. The parameters such as billet size, die corner radius, and friction conditions are optimized and determined to control the material flow in different sections. While the uniformity of extrusion deformation is greatly improved, the extrusion forming load is reduced, and the aluminum alloy hub was manufactured by the FBRE process. The comparison between the theoretical and the experimental results shows good agreement.

Keywords Forward–backward–radial extrusion · Aluminum alloy · Metal flow · Equivalent strain

1 Introduction

Nowadays, the extrusion process has been widely used in the manufacturing industries due to minimum material waste, high dimensional accuracy, and better mechanical properties of products [1, 2]. The basic or primary operations of extrusion are forward extrusion, backward extrusion, and radial extrusion according to direct relationships between the material flow and the punch movement [3]. There are combined simultaneous processes in which a billet is extruded simultaneously in the forward, backward, and/or radial directions relative to the punch movement. These combined extrusion processes offer the potentiality of producing a variety of relatively complex-shaped engineering components. Furthermore, combinations of

extrusion processes can also facilitate eliminating the need for multistep forming and reducing the production cost.

Many researchers have been interested in the study on combined extrusion. Kuzman et al. investigated the influences of tool geometry, friction, and lubrication, as well as workpiece properties, on balanced material flow in a combined backward–forward rod extrusion process [4]. Lee et al. proposed a new forward–backward combined extrusion process of a piston pin for an automobile part which can secure simultaneous filling for elimination of the flow defect [5]. In a study by Ho-Joon Choi et al., the effect of die geometrical parameters and friction factor on the punch load, volume ratio of the flange to can, and workpiece height are analyzed and summarized quantitatively during radial–backward extrusion [6]. Farhoumand and Ebrahimi investigated the effect of geometrical parameters such as die corner radius and gap height, as well as process conditions such as friction, on material flow, forming load, and strain heterogeneity in the FBRE process [7, 8].

In the present study, the forward–backward–radial extrusion (FBRE) process will be used to produce an aluminum alloy hub. Material flow behavior and strain distribution within the final product were investigated by finite element methods. The parameters such as billet size, die corner radius, and friction conditions were optimized to control the material flow in different regions. Finally, forming experiments were conducted and the microstructure and mechanical properties of the extruded hub were investigated, which aims at verifying the validity of the proposed method.

2 FBRE Process of Wheel Hub

Figure 1 shows the three-dimensional model of the hub. The hub is a typical cylindrical part with a flange, circular bosses and ribs on the flange, and side ribs on the cylinder wall. The geometrical shapes are complicated and the deformation is large. The upper and lower cylinders and the flange with bosses and ribs could not accomplish in a single pass by conventional hot forging. Considering the above-mentioned reasons, the FBRE process was adopted for the aluminum alloy hub.

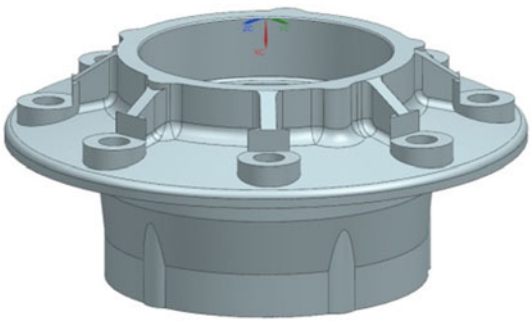

Fig. 1 Three-dimensional model of the wheel hub. (Color figure online)

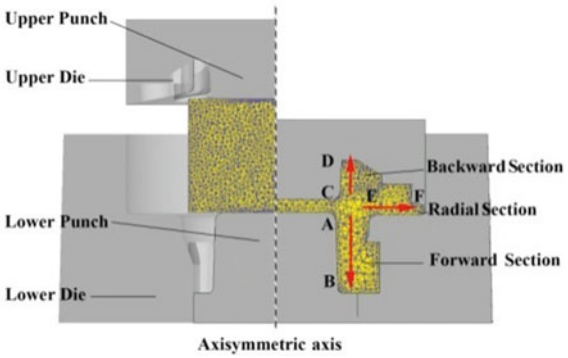

Fig. 2 Schematic diagram of the wheel hub FBRE process. (Color figure online)

Forward–backward–radial extrusion is a forging process in which material flows into the die cavity in the backward, forward, and radial directions by means of punch axial movement. During FBRE process of the aluminum alloy hub, the upper punch and upper die move downward, while the lower punch and lower die are stationary, which causes radial flow into a die cavity, forward and backward flow between the punch and the die—by means of which a flange and can are formed, and backward flow into upper a die cavity—forming circular bosses and ribs on the flange. Different from the common FBRE process, die cavity forming flange is the gap height that changes with the movement position of the upper die. Figure 2 shows the initial (left side) and final (right side) positions of the upper punch and upper die in the process, while the arrows show the direction of material flow in different directions, respectively.

As known, it is possible to restrict the metal flow into the flange and/or can by die geometrical parameters such as die corner radius and gap height, as well as process conditions such as friction. For the FBRE of wheel hub, the parameters of billet size and die corner radius are mainly studied and determined. The parameters are also schematically illustrated in Fig. 2.

3 FE and Experimental Procedure

3.1 Simulation

The commercial finite element software DEFORM 3D-6.1 was used to analyze the FBRE forming process. The employed material in this study was the 7A04 aluminum alloy (Al-6.15wt%Zn-2.63wt%Mg-1.6 wt%Cu). The stress–strain relation of this material, determined from the compression test, was input into the FE software [9]. The material model was defined as elastic–plastic. All die parts were considered as rigid bodies. A tetrahedral element type was used and the mesh sensitivity test was executed. The suitable mesh number was reported to be 100,000. The simulation

type was the Lagrangian incremental. The global re-meshing was chosen and the type of interference depth selected was relative and its value was selected to be 0.7. The conjugate-gradient was chosen as the solver of the simulation. The shear friction model was used to describe the friction behavior between the billet and the tools.

Since the geometrical parameters and friction conditions influence the metal flow into the flange and/or can, different billet size, die corner radius, and friction coefficients are selected in the simulation. The friction coefficient (μ) was 0.08, 0.12, 0.25, 0.3, and 0.4, respectively. The die corner fillets were 5, 10, 15, and 20 mm, respectively. The three different cylindrical billets with the height-to-diameter ratios of 0.38, 0.66, and 1.07 were selected.

3.2 Experimental Procedure

Cylindrical billets with 200 mm diameter, 132 mm length, and height-to-diameter ratio 0.66 were sawed from extruded 7A04 alloy bar. The die corner fillet in the experimental setup was 10 mm. The contact surfaces between the billet and the tools were forehand lubricated with oil-based graphite. The deformation billets were heated to 470 °C, whereas the temperature error was controlled within a divergence of $\pm$ 5 °C. The forming mold was pre-heated to a matching temperature with the billet. The FBRE process was performed in a 12.5MN capacity hydraulic oil press machine with a ram speed of 5 mm/s. The products processed were solution treated at 470 °C for 2 h and then subsequently aged at 125 °C in an air furnace.

Microstructure and mechanical properties specimens were cut from the can and flange and machined into tensile specimens of 5 mm gauge diameter and 25 mm gauge length. Tensile testing was carried out on an Instron-100kN material test machine at a speed of 1 mm/min. Microstructure examination was performed with an optical microscope (OM). The grain size was determined using a linear intercept method from a large number of non-overlapping measurements.

4 Results and Discussion

4.1 Equivalent Strain Analysis

The effect of billet size, die corner radius, and friction coefficient on the effective plastic strain of the FBRE wheel hub was analyzed by finite element methods. In the forward section (from point A to point B), backward section (from point C to point D), and radial section (from point E to point F), one path was considered on their thickness center lines, respectively. Different paths in cross-section of the FBRE sample were defined and mapped in the deformed mesh, as shown in Fig. 2. The effective strain value of 10 points was selected to be used in the forward section,

and the distance of each two points application was 8.5 mm, which is 5 points and 8.5 mm in the backward section and 10 points and 7.0 mm in the radial section.

The equivalent plastic strain for various frictional conditions has been depicted in Fig. 3. The equivalent strain in each region has the same change trend under different friction. In the forward and backward sections, the equivalent strain decreases along extrusion direction as a whole, and reaches the minimum at the end position. But in the radial section, the equivalent strain increases along the extrusion direction. When the friction coefficient is 0.4, the equivalent strain is the smallest in three regions. As the friction coefficient increases from 0.08 to 0.3, the equivalent strain of the same point increases in the forward section, decreases in the backward section, and basically does not change in the radial section.

The effect of various die corner radius on the equivalent strain in forward, backward, and radial sections of the FBRE sample is depicted in Fig. 4. Similarly, the equivalent strain is the maximum in the vicinity of point A which rapidly declines toward point B, point C maximum to point D minimum, and point E minimum to point F maximum. This is due to intense deformation at the corner of the punch which causes localized larger strain. When the die corner radius is 10 mm, the equivalent strain is smaller than that of other die corner radius in three regions. These show a shift in material flow preferences when the die corner radius is 10 mm.

The quantitative values of the effective strain of the FBRE sample for various billet sizes are compared, as shown in Fig. 5. As can be seen from the figure, the

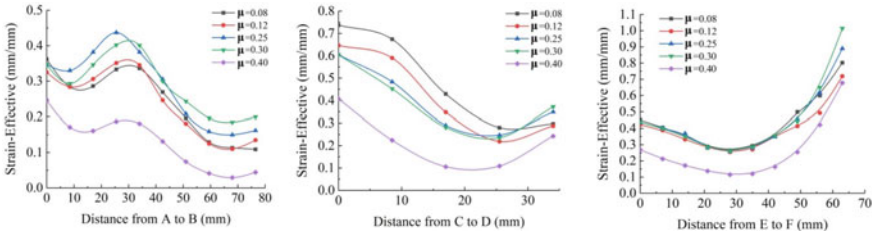

Fig. 3 Effect of friction on the equivalent plastic strain in different sections of an FBRE processed hub (h/d = 0.66, R = 10 mm). (Color figure online)

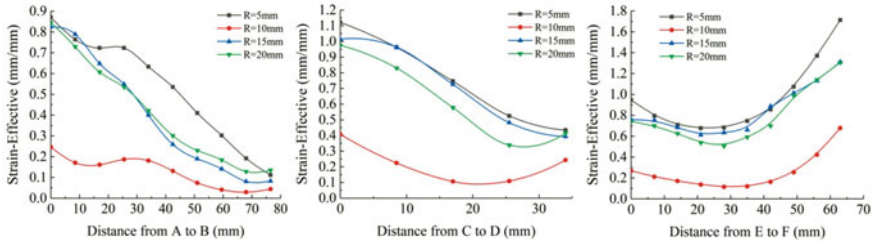

Fig. 4 Effect of die corner radius on the equivalent plastic strain in different sections of an FBRE processed hub (h/d = 0.66,μ = 0.4). (Color figure online)

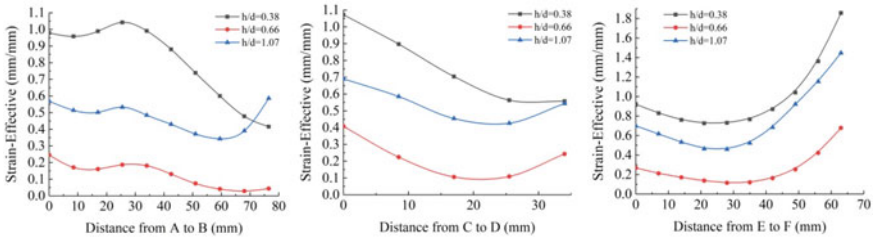

Fig. 5 Effect of billet size on the equivalent strain in different sections of an FBRE processed hub(R = 10 mm, μ = 0.4). (Color figure online)

equivalent strain in the height-to-diameter ratio of 0.38 is larger than those of other billets in three regions. The relatively small equivalent strain is obtained when the height-to-diameter ratio is 0.66, which shows that the material tends to progress more into the forward, backward, and radial sections simultaneously due to an easier flow when the billet diameter is close to the cylinder diameter. Besides, increasing the height-to-diameter ratio to 1.07 enlarges the equivalent strain due to the large upsetting deformation in the early stage.

4.2 Microstructure and Mechanical Properties

The 7A04 alloy wheel hubs were extruded successfully in one step without cracks or discontinuities according to the present technique. Both the extrusion part and finished product are shown in Fig. 6. The FBRE process of aluminum alloy hub can reduce forming operation and production cost compared with conventional hot forging.

The mechanical properties remarkably improved for the 7A04 alloy hub. The UTS and the TYS were over 560 MPa and 480 MPa, respectively, the elongation was above 8% in both can and flange areas. The difference of the UTS and the TYS between the can and the flange was less than 5%. It is noted that the mechanical property anisotropy was obviously reduced due to the relatively uniform deformation. Figure 7

Fig. 6 The wheel hubs by FBRE process. **a** Extrusion part, **b** finished product. (Color figure online)

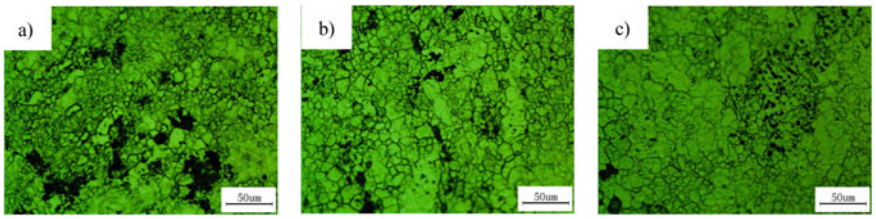

Fig. 7 Microstructure of 7A04 alloy part extruded in. **a** Upper can, **b** lower can, **c** flange areas. (Color figure online)

shows the microstructure of the analyzed areas of the 7A04 alloy hub in the T6 condition. It is obvious that the extrusion specimens have recrystallized and the grains refine greatly. Microscope observation showed that small recrystallized dynamically grains of mean size is about 8 ~ 10 μm, which is connected with localization of strains large values in these areas. At the same time, a large amount of fine and uniformly distributed second-phase particles can be observed in both can and flange areas. A more detailed microstructure and mechanical properties would be necessary to better understand the difference in effective strain amount obtained for the can and flange sections.

5 Conclusions

The forward–backward–radial extrusion process of aluminum alloy hub was analyzed in this paper. The effect of geometrical parameters such as billet size and die corner radius, as well as process conditions such as friction, on material flow and equivalent strain was investigated. It is found that the friction has a different effect on the equivalent strain in the forward, backward, and radial sections of the FBRE sample. When the height-to-diameter ratio of the billet is 0.66 and the die corner radius is 10 mm, the material tends to progress more into the forward, backward, and radial sections simultaneously due to an easier flow. The simulation results were verified experimentally and the 7A04 alloy wheel hubs were manufactured successfully in one step by the FBRE process.

Forging

Galling-Free Micro-Forging of Titanium Wire with High Reduction in Thickness by β-SiC Dies

Tatsuhiko Aizawa, Koh-Ichi Ito, and Tatsuya Fukuda

Abstract SiC-coated SiC die and punch were used for forging titanium wire to have a triangular cross-section higher than 30% reduction in wire diameter. Computer numerical control (CNC) stamper was utilized to describe the elasto-plastic behavior of titanium wire in dry forging. Precise analyses on the contact interface between SiC coating punch and titanium work were made to investigate the mass transfer of metallic titanium as well as titanium oxide debris particles onto SiC coating surface. On the basis of these experimental results, how to design the die materials for dry metal forming of titanium was reconsidered for biomedical applications of wrought titanium.

Keywords Galling-free forging · Titanium · SiC-coated dies

1 Introduction

Most light metals and alloys are easy to make adhesion onto the die surfaces without the use of protective coatings during metal forming [1]. Diamond-like carbon (DLC) coating was effective to be free from adhesion of aluminum and aluminum alloys even in mechanical milling and cutting [2]. In particular, nano-laminated DLC coating was useful to sustain low friction and wear in ironing, forging, and stamping [3–5]. Ceramic dies were also useful to dry metal forming [6]; e.g., aluminum alloy and cold-rolled steel sheets were successfully deep-drawn by using the dry SiC or ZrO_2-sintered dies. Among those light metal work materials, pure titanium and titanium

alloys are difficult or nearly impossible to be free from galling in metal forming. Under the upsetting of titanium wire, the SKD11 die surface was covered by the titanium films transferred from work material [7]; TiO_2 debris particles splashed around the dies from the oxidized surface of wire in each upsetting process. No improvement was reported in dry deep-drawing of titanium sheet by using any sintered dies of SiC, Si_3N_4, Al_2O_3, and ZrO_2 [6]. In particular, failure in dry deep-drawing by SiC die requires reconsideration on the material compatibility between SiC die and titanium in metal forming [8]. This difficulty is also identified as one of the greatest issues to hinder the near-net shaping of titanium and titanium alloys to biomedical parts and tools [9].

The authors proposed to employ the thick and dense SiC coating as a die material for dry upsetting and forging of pure titanium wires in cold [10–14]. Since SiC-sintered substrates have a porosity of 1.0–0.5% as well as glassy grain-boundary layers, they suffer from the adhesion and mass transfer of titanium. This galling of titanium to sintered SiC die resulted in a severe reduction of deep-drawability in practice [6]. SiC coating by chemical vapor deposition (CVD) is fully dense without any secondary phases. Hence, this SiC coating is a suitable die material to reconsider the material compatibility between its crystalline structure with covalent bonding and the titanium works. After upsetting and forging experiments in the previous studies, no transfer of titanium was detected on the contact interface of SiC coating punch and die. Adhesion of titanium oxide debris particles took place on the punch surface outside of the initial contact zone between SiC punch and titanium work.

In the present study, this SiC-coated SiC die and punch are used for micro-forging of titanium wire to have a triangular cross-section. This forging with a higher reduction of wire diameter than 30% becomes suitable to investigate the possibility of titanium transfer onto the punch and die surfaces and to describe the adhesion behavior of oxide debris particles. Computer numerical control (CNC) stamper is utilized to describe the elasto-plastic behavior of titanium wire in dry forging with up to 35% reduction in diameter. Precise analyses on the contact interface between SiC coating and titanium work are performed to investigate the mass transfer of metallic titanium as well as the titanium oxide debris particles onto SiC coating surface. On the basis of these experimental results, how to design the die materials for dry metal forming of transition metals including titanium is reconsidered for biomedical applications of wrought titanium.

2 Experimental Procedure

A dense, thick SiC layer with a thickness of 3 mm was formed onto the sintered SiC substrate by the thermal CVD process. X-ray diffraction (XRD), laser microscopy, and three-dimensional profilometer were utilized to characterize the deposited SiC coating. CNC stamper was used to make micro-forging of pure titanium wire with the diameter of 0.98 mm by using this SiC-coated SiC die and punch. Scanning electron

microscopy (SEM)–electron dispersive X-ray spectroscopy (EDX) was also utilized to describe the adhesion process on the SiC coating punch.

SiC-coated SiC die. A sintered SiC block with an average porosity of 0.5% was prepared as a substrate for thermal CVD to synthesize and deposit the polycrystalline SiC coating. As depicted in Fig. 1, this coating has a single phase of β-SiC and has 3C–SiC crystallographic structure. The average grain size is 10 μm. Different from other SiC-coatings by CVD and physical vapor deposition (PVD), there are no amorphous phases in this β-SiC coating.

As reported in [15], the thickness of amorphous SiC coating is at most 7 μm by CVD or PVD. In addition, these amorphous coatings have less strength and toughness than needed in cold stamping and forging.

Figure 2a depicts a SiC-coated SiC substrate with a coating thickness of 3 mm. This substrate is directly used as a punch. The femtosecond laser machining system

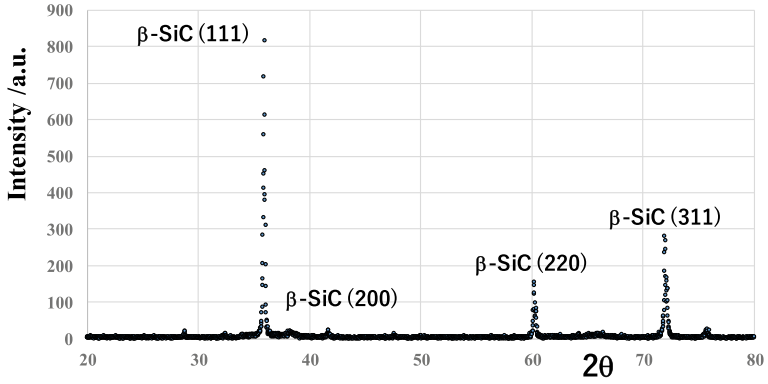

Fig. 1 XRD diagram of CVD-coated SiC thick film onto the sintered SiC substrate. (Color figure online)

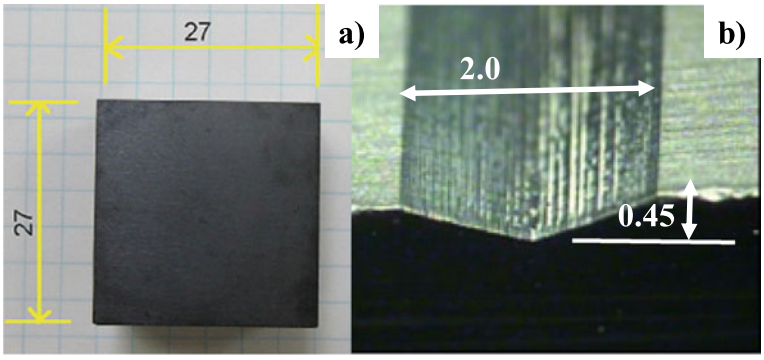

Fig. 2 SiC-coated SiC punch and die. **a** Punch with a flat surface, and **b** die with a triangular groove to fix the titanium wire. (Color figure online)

was utilized to cut a triangular groove into the SiC-coated SiC die as shown in Fig. 2b. The groove depth is 0.45 mm; its width is 2.0 mm. Owing to this thick SiC coating, the titanium wire with a diameter of 0.98 mm is forged into this groove with direct contact to SiC coating to shape the cylindrical wire to the triangular one with a higher than 30% reduction in diameter.

Cassette dies. These SiC punch and core die were fixed into the upper and lower cassette dies, respectively, as shown in Fig. 3. In particular, the cubic SiC punch was locked in the upper die to make micro-forging experiments.

Forging process by CNC stamper. Figure 4 depicts the CNC stamping system for this micro-forging experiment. In this CNC stamper, four loading axes were independently controlled to move upward and downward with less allowable eccentric loading. The maximum load was 50 kN; the loading sequence was controlled by the history of stroke. The sum of powers by four motors as well as the stroke was monitored during stamping.

In the following experiments, the punch was controlled to move down from the height of 80 mm down to 42 mm by 10 mm/s for 3.8 s in the first term. In the second term, the stroke speed was reduced to 0.02 mm/s to precisely decrease the height of 42 to 41.7 mm for 15 s. SiC punch was expected to be in contact with the work during this term, and the work was loaded to the specified height (δ_L) for each reduction; e.g., $\delta_L = 41.5$ mm for 10% reduction, 41.4 mm for 20%, and so forth. In the third term, the stroke was kept constant by δ_L for 0.5 s before the increase of stroke by 10 mm/s.

Observation and measurement. SEM–EDX was utilized to make microstructure and element mapping analyses on the contact surface of SiC-coated SiC punch with the deformed titanium wire.

Titanium wire work. A pure titanium wire of industrial-grade I with a diameter of 0.98 mm and length of 20 mm was employed as a work material in the micro-forging process. Its chemical compositions were listed as follows: hydrogen content was 0.0012 mass%, oxygen 0.097 mass%, nitrogen 0.007 mass%, iron 0.042 mass%, and carbon 0.007 mass%, respectively, for titanium in balance.

Fig. 4 CNC stamping system for upsetting experiments. (Color figure online)

3 Experimental Results

CNC stamping system is employed to make micro-forging experiments with the use of the SiC-coated SiC punch and die. The relationship between the applied power and stroke is in situ measured to describe the elasto-plastic behavior in forging.

Micro-forging behavior. A cylindrical wire with a diameter of 0.98 mm is forged by lowering the SiC-coated SiC punch with the increasing reduction (r) of wire diameter and shaped into triangular wires. Figure 5 depicts the variation of cross-sections in the forged titanium wire at r = 10, 20, and 35%, respectively. When r = 10%, the top of the wire begins to be flattened by compression in forging. When r increases to 20%, this flattening advances to broaden the contact surface area to the SiC-coating punch. The bottom of the wire partially fills the cavity of the triangular groove in the die. Up to r = 35%, the flattening width at the top of the wire becomes broader than 1 mm. The filling depth of titanium into the triangular groove reaches 0.3 mm. The present forging behavior of titanium wire is governed by the flattening process on contact with the punch surface as well as the filling process into the triangular groove in the die.

Figure 6 depicts the applied power to stroke relationship in forging. The punch commences to be in contact with a titanium wire; the power or the load begins to increase at point A. The wire is compressed in the longitudinal direction up to point B after observation on the forged wire cross-sections. The flattening process of wire advances from point B and the contact area to SiC coating punch broadens monotonously with increasing stroke. At point C, the filling process into a groove

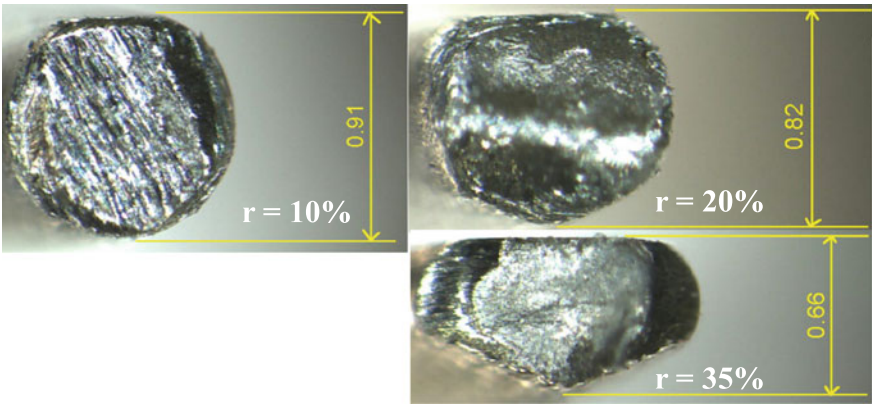

Fig. 5 Forging behavior of a cylindrical wire with the diameter 0.98 mm to shape into triangular wires with the increasing reduction of diameter. (Color figure online)

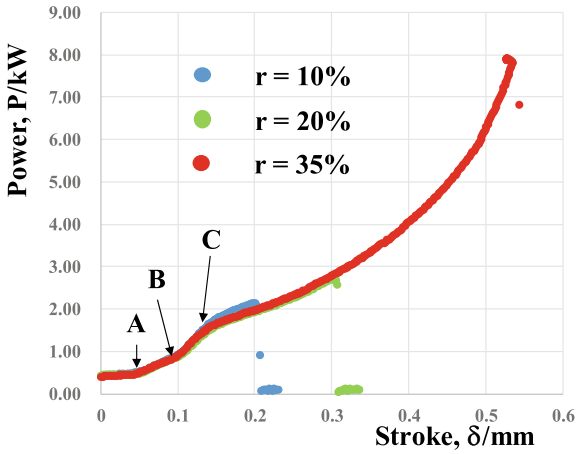

Fig. 6 Power to stroke relationship in forging of titanium wire with the increasing reduction of diameter. (Color figure online)

in die starts. After this point, the work hardening of wires takes place together with flattening along with the SiC coating punch and filling into a groove in die.

SEM analysis on SiC-coated SiC punch. SEM analysis was made on the SiC coating punch surface after cold, dry forging of titanium wire by r = 35%. As shown in Fig. 7a, a contact trace to titanium work is seen on the SiC coating. As closely observed by SEM in Fig. 7b, this trace consists of two layers. Two B-regions neighboring to C-region are colored in white with a difference to the original SiC coating in the A-region, while the C-region is colored in gray with dotted black spots. This trance width, including the C-region and its upper and lower B-regions, just corresponds to the contact interface width around 1.2 mm between the wire and the SiC coating punch at r = 35%. This reveals that the C-region with a width of 0.2 mm is an initial contact surface at r < 10% and that both B-regions are extended

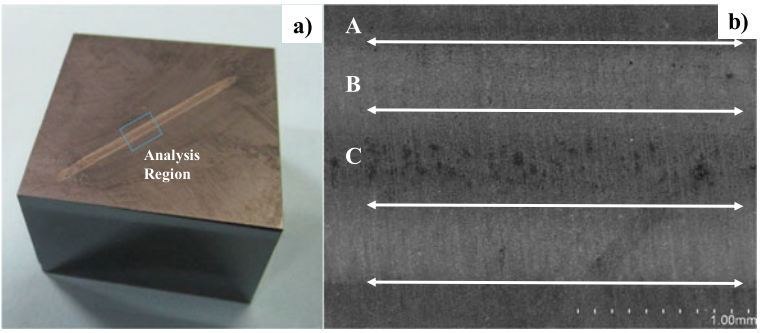

Fig. 7 Observation on the SiC coating punch surface after cold forging in dry at r = 35%. **a** Surface condition of SiC coating punch and **b** SEM analysis on the contact zone and its vicinity. (Color figure online)

contact interfaces by flattening of wire along the punch surface at r > 10%. That is, C-region is an initial contact interface of wire to SiC coating under high compressive stress, and two B-regions are formed by extension of contact area in flattening of wire along with the SiC coating punch.

SEM–EDX analyses on SiC-coated SiC punch. The SEM image and EDX element mapping on the C-region are shown in Fig. 8. The black dots in this C-region, denoted by "a," are isolated carbon from SiC coating. The white layers, denoted by "b," are titanium oxides. No mass transfer of titanium only in metallic is detected in this EDX analysis. This reveals that carbon is isolated from β-SiC crystals under high compressive pressure in initial contact of titanium wire to SiC punch but that

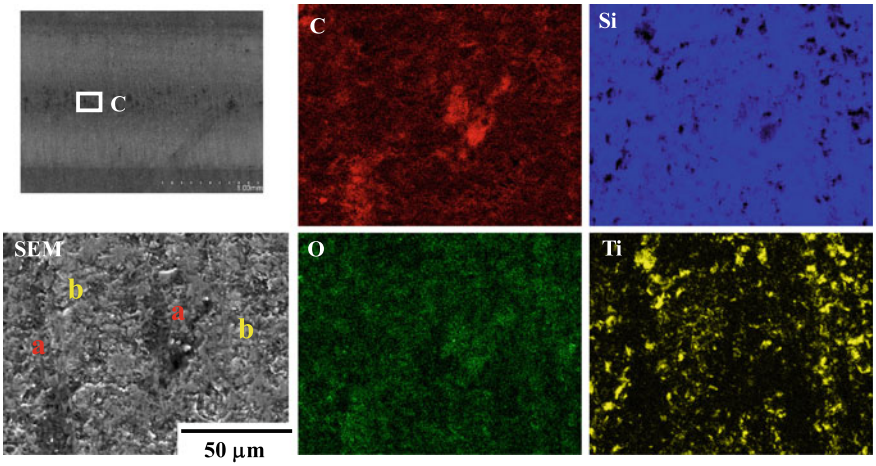

Fig. 8 SEM analysis and EDX element mapping on the C-region in the trace on the SiC coating. Titanium and oxygen mappings are coincident with each other. (Color figure online)

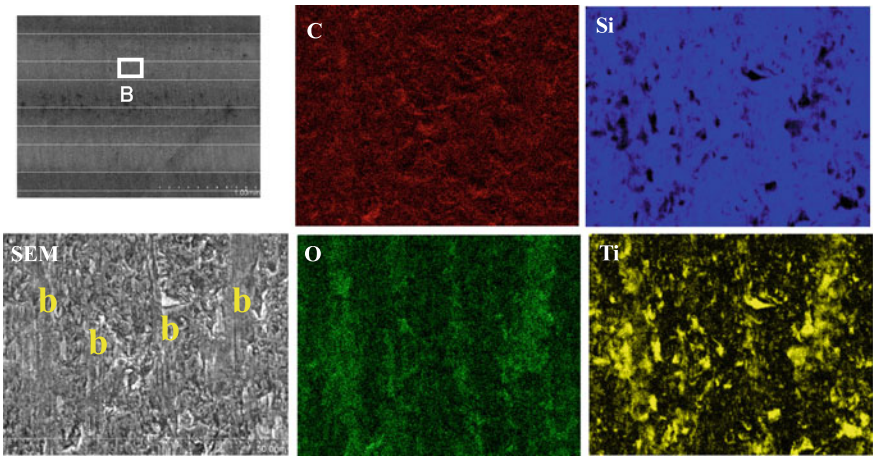

Fig. 9 SEM analysis and EDX element mapping on the B-region in the trace on the SiC coating. Titanium and oxygen mappings are just coincident with each other in a similar manner to Fig. 8. No carbon segregation is seen in the carbon mapping. (Color figure online)

titanium oxide debris particles from the wire deposit onto the SiC coating surface and form the titanium oxide layers in the lateral direction by flattening process.

Figure 9 depicts the SEM image and element mapping on the B-regions, neighboring to the C-region. Since carbon distributes uniformly in these B-regions without segregation, carbon does not isolate from SiC crystalline structure. Titanium and oxygen mappings are coincident with each other; titanium oxide debris particles also deposit on these regions in a similar manner in the C-region. These deposited titanium oxide debris form layers in the lateral directions. This implies that titanium debris deposits form a thin film on the SiC coating and this film grows with flattening of wire on the SiC punch surface. There are no deposits of debris particles outside of these B-regions.

This SEM–EDX analysis proves that metallic titanium does not transfer onto SiC coating punch even at its initial contact interface to titanium wire and that titanium oxide debris particles do not splash over the punch surface but deposit on the punch surface and form the thin layers radially from the initial contact zone together with the flattening process of wire on the punch surface.

4 Discussion

Galling or work material transfer to die surfaces is induced mechanically and chemically in metal forming. The former mechano-chemical galling is often observed in hot stamping and forging. The steel sheets adhere to the tool steel die when the temperature on the interface goes beyond the flash temperature [3]. The oxide glasses are

deformed by mold stamping just above the glass-transition temperature and cemented onto the DLC-coated mold-stamping dies [16]. The latter chemical galling possibly occurs even in cold stamping and forging. Upsetting and deep-drawing of titanium sheets experienced severe galling in practice [6, 7]. As discussed in [11–14], this chemical galling comes from the material compatibility between titanium and die surface material. Pure titanium versus the tool steel die or the sintered SiC die with glassy zones are typical pairs with attractive compatibility to enhance the chemical galling process.

Material compatibility in solid-state contact is often discussed by the classical theory on this compatibility [8, 17]. After this HSAB (hard and soft acid and base) principle, a pair of materials in contact is identified as acid–base pair. In the present case, titanium ions are classified into the hard acid group while the Si-oriented ion is grouped into the hard base one. Then, hard acid and base pair are easy to react on the contact interface. The present experiment proves that no direct transfer of metallic titanium takes place even under the high compressive stress state enough to trigger the isolation of carbon from SiC crystals. The classical treatise is never true to describe the present galling-free material compatibility in solid-state contact condition. New theoretical understanding with the use of computational chemistry [18] is necessary to describe the solid-state interaction between SiC coating and transient metals in metal forming.

After precise EDX analysis on the element mapping, carbon isolates and agglomerates as a black dot on the SiC coating surface only at the initial contact interface of SiC punch to wire. Since titanium is never detected on these high carbon content zones in Fig. 7, this carbon isolation has nothing to do with the attraction of carbon by the direct reaction between carbon and titanium [19]. When SiC single crystal is held at the elevated temperature over 1500 K, carbon is left by isolation of Si on the SiC surface and grows as a graphene layer [20]. In the present situation, the flash temperature on the contact interface between titanium wire and SiC coating is much lower than the critical temperature to ignite Si-isolation from SiC crystals. In the phase diagram for Si–C binary system [21], β-SiC crystalline structure is stable in the higher carbon content regions than 50% from RT and atmospheric pressure up to 2400 K and 50 GPa, respectively. Assuming that titanium wire is elasto-plastically contact on the SiC coating with the area of 100 μm $\times$ 20 μm at the load of 10 kN around the C-region in Fig. 6, the applied pressure on the contact surface reaches 5 GPa. Hence, the Si–C phase diagram teaches that unstable isolation of carbon from β-SiC phase could be never feasible at this low-pressure range and low flash temperature. To be noticed, the carbon supersaturation into SiC 3C-structure drives fast rate growth of β-SiC crystalline layer in CVD coating [22]. Under the high compressive stress state, the carbon could isolate from this supersaturated state in β-SiC 3C-structure and agglomerate at the highly pressurized contact interface. In the present experiment, the carbon agglomerates align in dots on the initial contact zone as shown in Fig. 8. Since this dot size is nearly equivalent to the β-SiC grain size, the isolated carbon atoms from the carbon supersaturated β-SiC crystals form this carbon agglomerate in each β-SiC grain. This predicts that this formation of dotted carbon agglomerates has a superficial grain size effect of β-SiC grains.

5 Summary

Dense, thick, β-SiC coating with cubic structure and covalent bonding has the potential to work as a galling-free die for dry forging of transient metals, including the pure titanium as well as the titanium alloys. The pure titanium circular wire is forged into a triangular bar without metallic titanium transfer onto SiC coating punch and die. Titanium oxide debris particles deposit onto the SiC punch surface and form thin adhesive layers onto SiC punch surface in the lateral direction. This adhesive trace is too thin to hinder the successive forging in mass production. Those debris particles never splash around the atmosphere in forging.

The supersaturated carbon isolates from β-SiC crystals at high contact pressure and agglomerates as a dot on the contact interface. This distribution of free carbon agglomerates has grain size dependence of β-SiC coating. What triggers this isolation of carbon from β-SiC crystallographic structure must be studied by the tribo-testing and metal forming simulations in experiments and by the first principle calculation in the theoretical treatise. These free-carbon agglomerates have no reaction with titanium during forging. This agglomerate is expected to be working as a tribo-film to reduce the friction on the contact interface in the practical application of SiC coating as a die in metal forming.

Acknowledgments The authors would like to express their gratitude to Mr. S. Kurozumi (Nano-Coat Film, LLC.) and Mr. T. Yoshino (Komatsu-Seiki Kosakusho, Co., Ltd.) for their help in the experiment.

Deformation Mechanism of the Tooth Material Filling for Precision Forging of Spur Gears

Wei Feng, Zengjie Feng, Mengjuan Zhou, Ling Mao, and Xiangyang Jia

Abstract Spur gears are an important transmission part used widely in many industries. Precision forging of spur gears has a lot of advantages compared with the conventional mechanical cutting method. However, it is very difficult to fill the corner well and the forging load is also very large, especially in the final forming stage during the precision forging of spur gears. So, a three-dimensional (3D) finite element (FE) model for precision forging of spur gears was built by DEFORM-3D software. The stress and strain states in different forming stages and positions of billet have been studied. Also, the Lode parameter μ_σ was calculated, and the metal flow line method was used to reveal the deformation mechanism of the tooth material. Results show that the Lode parameter of the tooth shape is negative at the beginning of the tooth filling and is positive at the final stage of the tooth filling. Also, the stress state changes from two-directional compressive stress and one-directional tensile stress to three-directional compressive stress.

Keywords Spur gears · Precision forging · Deformation mechanism · Lode parameter

1 Introduction

It is well known that precision forging gears have advantages of high efficiency, low cost, as well as increased surface quality, compared with the conventional mechanical cutting methods [1, 2]. However, the corner filling is difficult and the forging load

is very large, especially in the final forming stage during precision forging of spur gears, which reduces the product quality and shortens the mold life [3].

To solve these problems, many types of research were done, most of which focused on die designs, billet shapes, deformation conditions, etc. An idea of movable cavity die design was proposed by Tuncer and Dean, in which the better friction condition can improve forming quality and reduce forming load [4]. A two-step forging technology was developed by Jung to produce well-shaped helical gears with lower forging load [5]. Zuo performed relief-cavity designs in different sizes and studied the effects of different designs on corner filling, billet stress, die stress, forming load, and material utilization to determine the optimal design [6]. Jin investigated the effects of forging parameters on uniformity in deformation and microstructure of AZ31Bstraightspur gear, concluding that decreasing deformation temperature or increasing strain rate is positive to get fine-grained microstructure but negative to the uniformity in both deformation and microstructure [7]. Sadeghi found that the billet/die interface friction can influence forging pressure through changing metal flow during gear forging [8].

Although the quality of gears produced by precision forging is influenced by various factors besides designs of die and billet, the fundamental solution to spur gears forging problems is to change metal deformation mode, referring to the metal-plastic forming principle.

The Lode parameter μ_σ can reflect the influence of the middle principal stress on the material yielding and failure criterion [9]. So it is used to indicate the directionality of the stress state and the type of the strain state and is also used to study the effect on the localization of plastic flow in a micromechanical model by many scholars [11].

It is well known that the flow line can make mechanical anisotropic properties present in the metal. The better mechanical properties can be obtained along the longitudinal direction and the lower along the transverse direction. Many scholars researched the metal flow law and optimized the forming process by the metal flow line method to control and improve the mechanical properties of the forged product [12].

Forging of spur gears is a complicated metal-plastic forming process. Especially, the corner filling is very different and the forging load is very large. Therefore, it is necessary to explore the metal deformation mechanism in precision forging process of spur gears. In this work, a three-dimensional finite element model for precision forging of spur gears was built, the stress and strain states in different forming stages and positions of corners have been studied, and the material flow law was obtained by metal flow line method. Besides, the Lode parameter μ_σ was calculated to reveal the mechanism of the material deformation by simulating the process.

2 Establishment of 3D FE Model

To analyze the metal deformation mechanism in precision forging process of spur gears, a 3D FE model of a spur gear was established to simulate the precision forging process using the finite software DEFORM-3D, based on the rigid visco-plastic theory with conjugate gradient method and direct iteration, as shown in Fig. 1.

For the spur gear studied in this work, its specifications of a number of teeth, normal module, pressure angle, and teeth width are 18, 2 mm, 20°, and 20 mm, respectively. Also, it is a pitch diameter of 36 mm and a root diameter of 31 mm. The billet is a cylinder with a diameter approximately equal to the root diameter of the spur gear. The height of the billet is defined according to the law of volume constancy of the material in metal plastic deformation. The designed size of the billet is $\varphi 31\ mm \times 26\ mm$ and the material is 20CrMnTiH, a kind of low-carbon gear steel used widely in China. The billet is defined as a plastic body and all the dies are regarded as rigid ones in FE modeling. The flow stress curve introduced in the material library is obtained through the hot compression test of this material [13]. The die material is AISI-H13. In order to save the simulation time, a quarter of the model is built. The element number of the billet is 50000 after using the meshing window. The constant shear friction factor between the dies and the billet is 0.25. Environment temperature is 20°C and the forming temperature of the billet is 850 °C. The punch speed is 10 mm/s.

3 Results and Discussion

3.1 Decision of Different Forming Stages

Figure 2 gives the variation curves of forming load with stroke of punch. As shown in Fig. 2, the forming load increases gradually with the increasing stroke in the early forming stages and increases quickly in the final forming stage. To study the law of material flowing and deformation mechanism, the whole forging process of spur gears is divided into four stages according to the variation trend of forming load and teeth shape filling condition, as shown in Fig. 2. Points 1, 2, 3, and 4 in Fig. 2 correspond to different filling moments. Point 1 indicates that the deformation degree is 35%, the billet filled the cavity, and the maximum diameter of the billet is equal to the base circle diameter at the moment. Point 2 indicates that the deformation degree is 75%, the billet continued to fill the cavity, and the maximum diameter of the billet is equal to the pitch circle diameter at the moment. Point 3 indicates that the deformation degree is 80%, the billet is almost full of the teeth cavity except for the corner, and the maximum diameter of the billet is equal to the addendum circle diameter at the moment. Point 4 indicates that the deformation degree is 100%, the billet filled the corner, and the forging load reached the maximum at the moment.

The teeth shapes of the billet under different deformation degrees are shown in Fig. 3. It can be seen from Figs. 2 and 3 that the forging force increased gradually at the stage I, II and III. When the billet begins to contact the root of the tooth die, the forming load increases sharply at the final forming stage IV because of the free area reducing and metal flow resistance increasing, in which the tooth filling is very hard and the forming load rises rapidly. Therefore, it is vital to study the deformation mechanism to reveal the cause of corner filling and large forming load during spur gears precision forging.

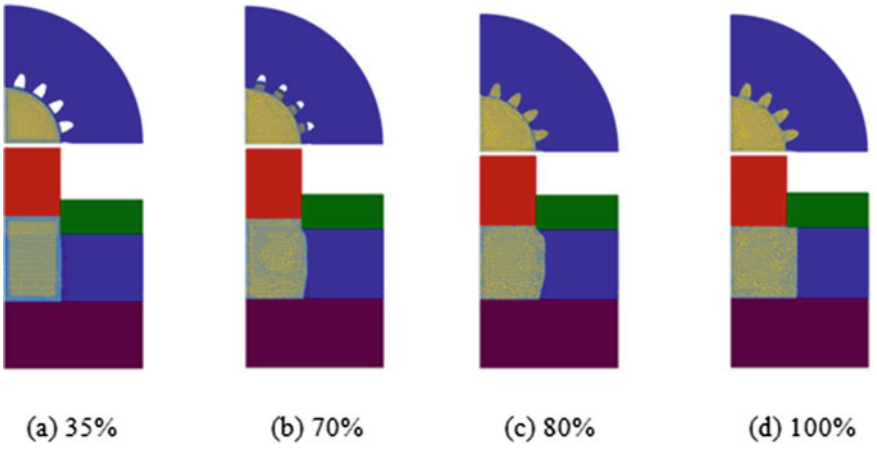

Fig. 3 The teeth shape of the billet under different deformation degrees. (Color figure online)

3.2 Deformation Zones in Different Forming Stages

Based on the forming force and metal flow principle, the spur gears precision forging process can be approximated as two basic deformation modes, namely cylinder upsetting deformation and extrusion deformation.

To illustrate the forming progress in detail, the billet is divided into three deformation zones according to different deformation characteristics and force conditions. All the zones of different forming stages are shown in Fig. 4.

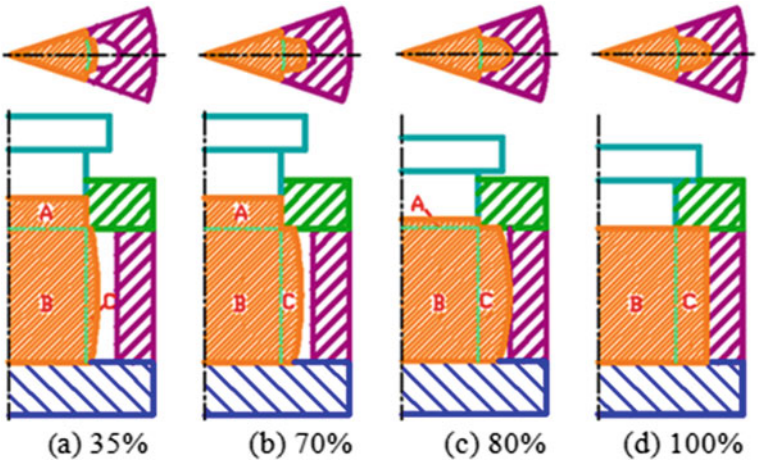

Fig. 4 Deformation zones of different forming stages. (Color figure online)

For zone A, at the forming stages I, II, and III, the plastic deformation of the metal does not occur and only moves down rigidly under the pressing of the punch. And part of metal in zone A flows into zone B and participates in deformation. For zone B, the material is compressed by the material in zone A and filled into the cavity. Metal in zone C is subjected to extrusion deformation and metal filled the tooth cavity due to the radial pushing from the material in zone B and circumferential compression from the teeth cavity. For zone C, the deformation is uneven in the axial direction because of friction from die parts. Deformation in zone C is more complicated compared to the other zones.

3.3 Deformation Characteristics Under Different Forming Stages

To decide the deformation type in spur gears precision forging, a flownet method was used to study the deformation characteristics of each zone in different forming stages. The flownet method is a kind of post-processing method of the DEFORM-3D software, in which the user can be allowed to place some form (2D or 3D) of a grid onto the object and let the simulation track the deformation of the grid throughout the deformation. This is an excellent way in which to visualize any potential irregularities in the grain structure or to view potential surface defects.

Figure 5 shows the deformation characteristics of grids under different forming stages during precision forging spur gears. It can be shown in Fig. 5 that the shape of grids in zone A has not deformed because of the constraint of the sleeve. For zone B, grids are compressed axially and elongated radially with the deformation degree increasing. The distribution of radial elongation is uneven at the forming stages III and IV, which is larger in the middle and smaller at both ends, as shown in Fig. 5 c and d. However, the axial compression is more and more severe with the increasing deformation degree. In addition, the vertical lines of coordinate grids bend into the teeth cavity, respectively. For grids in zone C, the axial compression and radial elongation increased gradually with the increasing deformation degree.

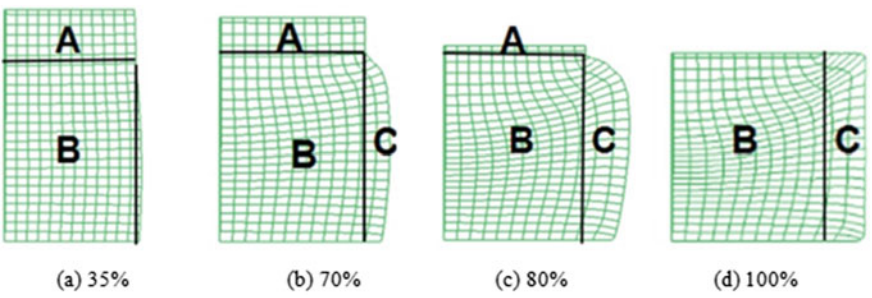

Fig. 5 Deformation characteristics of grids under different forming stages. (Color figure online)

Also, the horizontal lines of coordinate grids continue bending to the top and bottom sides of the billet, and the vertical lines bend to the addendum. Besides, the grid deformation of zone C is more severe than that of zone B.

3.4 The Stress State of Different Forming Stages

In order to research the deformation mechanism in detail, the tooth portion is divided into five regions ①, ②, ③, ④, and ⑤, as shown in Fig. 6. Regions ①, ②, ③, ④, and ⑤ represented zones closing to groove, root, the upper, the middle, and the lower end of the tooth, respectively.

Based on the three-dimensional finite element for precision forging of spur gear, the point tracking method was used to extract stress states and strain states in each forming stage. Table 1 shows the stress state of five regions under different forming stages. From Table 1, it can be found that: (1) The stress state in the groove of a tooth is always three-directional compressive stress under different forming stages; (2) The stress state of the upper and the lower zone of the tooth shape converts from two-directional compressive stress and one-directional tensile stress in forming stages I and II to three-directional compressive stress in forming stages III and IV; (3) The root and the middle of the tooth shape change from two-directional compressive stress and one-directional tensile stress state in forming stage I to three-directional compressive stress state in forming stages II, III, and IV.

Table 1 Stress states of five regions in each stage

Regions	I	II	III	IV
①	0	0	0	0
②	1	0	0	0
③	1	1	0	0
④	1	0	0	0
⑤	1	1	0	0
inline media object				

3.5 The Strain State of Different Forming Stages

In precision forging of spur gear, the metal flow is not only affected by stress state but also the strain state. Generally speaking, the stress state at an arbitrary point of a material can be described using three principal stresses or the three stress invariants [10]. The Lode parameter μ_σ, which varies from -1 to 1, not only can be used to represent the stress state but also to decide qualitatively the type of the strain state for engineering problem [10, 13]. The Lode parameter μ_σ is defined as follows:

$$\mu_\sigma = \frac{2\sigma_2 - \sigma_1 - \sigma_3}{\sigma_1 - \sigma_3} \tag{1}$$

where σ_1, σ_2, and σ_3 are the largest principal stress, the middle principal stress, and the third stress, respectively.

When $\mu_\sigma < 0$ the deformation type is the tensile strain, when $\mu_\sigma > 0$ the deformation type is compression strain, and when $\mu_\sigma = 0$ the deformation type is the plane strain. Therefore, the Lode parameter μ_σ was calculated to reveal the strain type of billet at different stages. All the principal stress information of the selected regions can be obtained according to tracking points, and then the Lode parameter μ_σ can be calculated according to Eq. (1). Table 2 shows the Lode parameter μ_σ calculated under different regions and forming stages according to Table 1.

It can be found that from Table 2: (1) For region ①, ②, $\mu_\sigma < 0$ in the whole forming process, the deformation type is the elongation deformation. (2) For region ③, ⑤, μ_σ

Table 2 Lode parameter μ_σ of five regions in each stage

Regions	I	II	III	IV
①	−0.51	−0.39	−0.63	−0.55
②	−0.22	−0.53	−0.59	−0.46
③	−0.48	−0.46	−0.24	0.21
④	−0.53	0.10	0.26	0.21
⑤	−0.47	−0.46	−0.25	0.23

< 0 in stages I, II, and III, the deformation type is the elongation deformation; $\mu_\sigma > 0$ in stage IV, the deformation type is compression deformation. (3) For region ④ $\mu_\sigma < 0$ in stage I, the deformation type is the elongation deformation; $\mu_\sigma > 0$ in stages II, III, and IV, the deformation type is the compression deformation.

4 Conclusions

A 3D FE model for precision forging of spur gears was established to reveal the mechanism of the material flow. And the stress state, strain states, and the Lode parameter μ_σ in different forming stages and positions of the billet have been studied.

Conclusions can be drawn that the forming load increases quickly in the final forming stage. The Lode parameter μ_σ of the tooth portion is negative at the beginning, meaning tensile deformation, and μ_σ is all positive at the final forming stage, meaning compression deformation. Meanwhile, the stress state of the upper and the lower of the tooth portion changes from two-directional compressive stress and one-directional tensile stress in forming stages I and II to three-directional compressive stress in forming stages III and IV, while the middle of the tooth shape is always three-directional compressive stress state except for the forming stage I.

Compression of Printed CFRT Composite: Shaping Parameters and Material Health

Eric Becker, Victor Haguenauer, Ludovic Freund, Damien Félix, and Régis Bigot

Abstract EPITHER is an innovative way of shaping composite materials that seek to combine the strength of continuous fibre reinforced thermoplastic (CFRT) composite materials with the high production rates existing in the forging industry. The use of composites in the manufacture of structural parts must make it possible to lighten the driving parts of vehicles and to give part of the solution to the reduction of CO_2 emissions. Good material health is crucial for the production of structural parts, and some of the parameters associated with it are a direct consequence of the shaping conditions and have an influence on the strength of the final product. With a view to controlling and optimizing the shaping parameters, this study begins by defining the relevant material characteristics to be measured in order to judge the quality of the latter, then studying the links between the process and the finished product.

1 Introduction

Actually, automobile, aeronautics, and aerospace industries are the main sectors for the application of composite material and the percentage of composite present inside vehicles is increasing year after year. These materials present interesting characteristics, in particular a very attractive weight/mechanical characteristics ratio. This attractive ratio gives a real interest to integrate composite into vehicles, and it could lead to a reduction of weight and thus CO_2 emissions of made vehicles. Currently, few composite manufacturing processes allow the production of thick composite structure, especially if the matrix of the composite is thermoplastic. The shaping process described in this article is patented by the SETFORGE companies, the Arts et Metiers Institute of Technology and the Institut de Soudure. This process makes it possible to realize oriented-carbon fibre (CF)/thermoplastic composite parts from raw material usually in the form of commingling yarn in order to produce structural and thick parts.

To develop this process, it is important to study the influence of the shaping conditions on the quality of the composite product. In this study, the choice was made to study the material health of composite products with the aim of qualifying them. Numerous studies have looked at the influence of various parameters on the mechanical characteristics of the composite. In particular, concerning the influence of the fibre content [1–3] tends to increase the values of Young's modulus as well as the limit at break of the composite. Tekinalp et al. [3] compared the results of mechanical tests carried out on printed composite test pieces obtained by compression. Thus the tested pieces have different fibre content levels and also a substantial or low presence of porosity. Ashir et al. [4] studied the influence of porosities on the resistance of composite material plates. Increasing fibre content leads to an overall increase in the mechanical characteristics of composite products. Increasing the porosity ratio has the opposite effect [3, 4]. The observed trends are consistent with those described by homogenization methods: "rules of mixture" [5–7]. The main objective of this study is to determine the impact of the shaping conditions on the material health of made samples. Here the tested parameter is the compression ratio and itd influence on porosity ratio and fibre content is presented.

2 Method

2.1 Process Description

The described process can be decomposed into two main steps:

- Printing of the preform, additive manufacturing makes possible the realization of preforms with a mastery of fibres orientation and easy handling.

Table 1 Material datasheet CF/PA12 9 T LABS (Source 9 T LABS)

Composition		
Carbon fibre:	STS40F13(24 k)	Toho Tenax
Matrix system	PA12	ESMChemie
Fibre volume content	50%	
Density of composite	1.405 g/cm^3	

- Shaping step gives the part its final shape with good tolerances and tends to decrease void content.

2.1.1 Drop-Off and Pre-Consolidation of the Raw Material

The device used to manufacture the preforms is a CarbonKit 9 T LABS associated with an Ultimaker2 3D printer. The combination of these two systems allows depositing pre-consolidated composite yarn. This composite yarn is composed of a mixture of long and oriented (planar orientation) carbon fibre associated with a PA12 thermoplastic. Table 1 shows the characteristics associated with the material supplied by 9 T LABS. The used system does not mix the fibre and the matrix during the printing process, while most composite printers do. This difference is related to the format of the material used which is in the form of co-blended yarn. Eichenhofer et al. [8, 9] present a head allowing the printing of several multi-threaded threads, CF/thermoplastic, and allowing the manufacture of robotic continuous mesh. Wang et al. [10] present a review of 3D printing techniques for composite materials.

The composite preforms produced for this study are produced by printing 70 layers of theoretical height 0.27 mm thick for a final thickness of 18.9 mm. The printing temperature is set at 200 °C and the feed rate is 4 mm/s.

2.1.2 Forging Step

The shaping step consists of:

- Placement of the preform (Fig. 2a) in the steel tools.
- Heats tools and preform in a convection oven up to a temperature of 250 °C until the temperature in the composite, controlled by a thermocouple, reaches the set.
- Compression of the part along the stacking axis of the layers with an Instron traction/compression machine until a given height. The compression speed is set to 10 mm/min and the compression force is measured during the process. The part is kept under pressure while cooling.
- Demoulding and deburring of the part.

In this study, five parts with different compression ratios were made. Figure 2a presents a composite preform obtained by 3D printing. This preform is rigid and can be easily handled. Figure 2b shows a part obtained after compression, and the final

Fig. 1 CarbonKit 9 T Labs FC composite long fibre printing system implanted on Ultimaker 3D printer (Source 9 T LABS). (Color figure online)

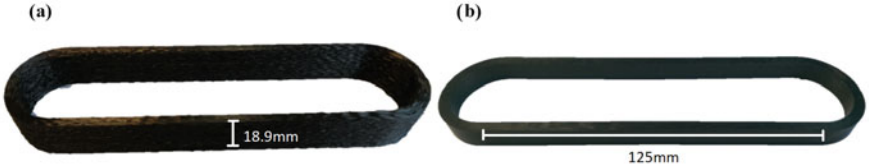

Fig. 2 **a** Printed preform, **b** Forged part. (Color figure online)

height is a function of the displacement command. The objective of this stage is to consolidate the part and suppress as much as possible the porosities present in the preforms.

2.2 Sampling and Analysis

2.2.1 Parts Characteristics

Dimension measurements are made on preforms and finished parts. The purpose is to obtain the shaping ratio τ_c from the height of the preform h_i (18.9 mm) and the final height of the part h_f:

$$\tau_c = 1 - \frac{h_f}{h_i} \tag{1}$$

The composite preforms are also weighted before the forging step in order to obtain the mass of material integrated into the tool m_i. After forging and deburring the finished parts are also weighed so as to obtain m_f, the final mass of the sample. Equation (2) makes it possible to obtain the loss of material τ_l (percentage of material lost during deburring step).

$$\tau_l = 1 - \frac{m_f}{m_i} \tag{2}$$

2.2.2 Micro and Macrographic Analysis

Test parts produced in the frame of this study are then sectioned and polished in order to produce micrographs. The sections produced correspond to the straight part of the forged part. The microscopies are carried out with a KEYENCE VHX-7000 optical microscope. This microscope makes it possible to realize image assemblies automatically. Thus it is possible to observe the entire section of a part with sufficient resolution to observe each of the fibres individually. Figure 3 shows images taken from sample C-PA 42 (described in Table 2).

According to the method presented by Ledru and et al. [11], fibres, matrix, and void content are determined by image analysis of the micrographs. This method is realized in two main stages: (i) binarization and (ii) thresholding of the image in order to separate the fibres from the rest of the image to obtain the volume ratio of fibre or to separate the porosities from the rest in order to get the porosity ratio. To facilitate the separation of porosity, a reduction of image resolution is necessary. Once the images have been processed, software is used to measure the surface of fibres or porosities.

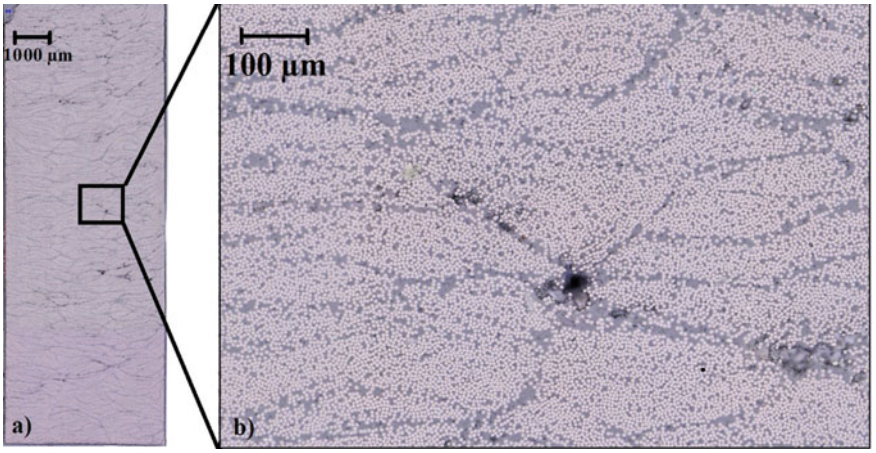

Fig. 3 **a** Image of a complete section of the sample C-PA 42, **b** Zoomed view, fibre appears in white, matrix in light grey, and porosity in grey/black. (Color figure online)

Table 2 Result of the shaping of the five samples

Sample	Ratio of compression [%]	Mass of preform m_i [g]	Mass of final part m_f [g]	Preform height h_i [mm]	Height after compression h_f [mm]	Mass of burr [g]	Loss of material τ_1 [%w]	Max pressure [Bar]
C-PA 0	0	22.87	22.87	19.075	19.075	0	0	0.0

3 Results and Discussion

3.1 Process Analysis

The five parts were compressed at different shaping ratio, thus the pieces have a height h_j different from each other. It is possible to define the theoretical shaping ratio T for these samples. It corresponds to the shaping ratio which makes it possible to fill functional gaps and to remove porosities present initially in the composite preforms integrated into the tool without causing the material to leak out of the tool.

If this shaping ratio is applied, the resulting part should have a very low porosity ratio as well as a non-existent loss of material. The expression of the shaping ratio is given in Eq. (3).

$$T[\%] = 1 - \frac{m_p}{\rho_c \cdot h_i \cdot S} \tag{3}$$

ρ_c is defined in Table 1 and corresponds to the density of the composite for fibre content of 50%v. m_p is the mass of the preform, h_i is the initial height of the preform. S corresponds to the surface of the bottom of the tool, and the value of this parameter was obtained from the measurements made on the tool. Equation (3) is applied for the five preforms. The values of T obtained are in the range from 41.91% to 42.95% for an average of 42.37%. The values of T change little from one preform to another due to the regularity of deposit by the fused filament fabrication (FFF) system.

As described above, the shaping step consists of compressing a preform of known mass and dimensions with rigid tools. Considering a composite preform inside the mould, his volume is containing: (i) a volume of composite, (ii) a volume of air present in the porosities of the preform, as well as (iii) a volume of air between the preform and the walls of the tool (functional gaps).

Considering the following hypothesis true, the evacuation of the material out of the tool only occurs after the complete filling of the tool. A shaping ratio higher than the value of T relating to a preform can result in a part without porosity but with an evacuation of the excess material. The excess material is then deburred which leads to a loss of material that should be minimized. Conversely, a value of shaping ratio lower than T leads to a part with dimensions that do not correspond to those imposed by the tool and/or containing porosities. Table 2 shows the data from shaping obtained for the five samples. The imposed shaping ratios are between 0% (printed preform C-PA 0) and 54.5%. The applied pressure ranged from 0 to 205 bars.

Figure 4 shows the pressure applied during shaping and the loss of material as a function of the compression ratio. The average value of the theoretical compression ratio T of 42.3% is represented by the vertical line.

Phase A described in Fig. 4 corresponds to samples whose shaping ratios were lower than T. The samples present in this field have low shaping pressures as well as a low loss of material. However, the sample C-PA 31 does not have a non-loss of material, and this testifies to the fact that a quantity of material flows outside the tool. Phase B in Fig. 4 corresponds to the area where the applied shaping ratio is higher than T. The material losses observed are substantial (up to 15.9%w), and the same applies to the pressures applied (13–205 bars).

The sample C-PA 42 was shaped with a ratio of shaping close to T. This sample has a loss of material of 1.22% and undergoes a pressure of 13 bars. It might be possible that this sample has a low porosity ratio.

The micrographs used for image processing also testify to the consequences of the displacement of matter. Figure 5 shows the surface condition of the external face of samples C-PA 0, 31, and 42. The observations of these images confirm the previous conclusions:

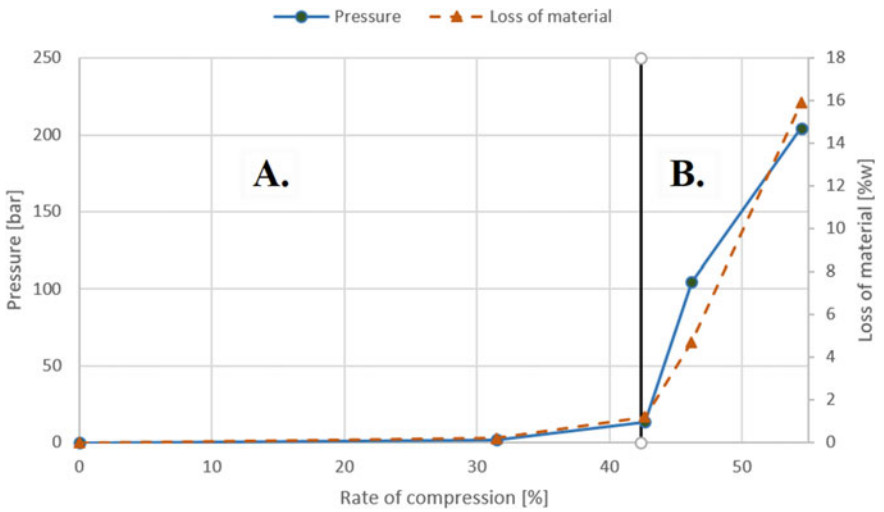

Fig. 4 Pressure and loss of material function of compression ratio. (Color figure online)

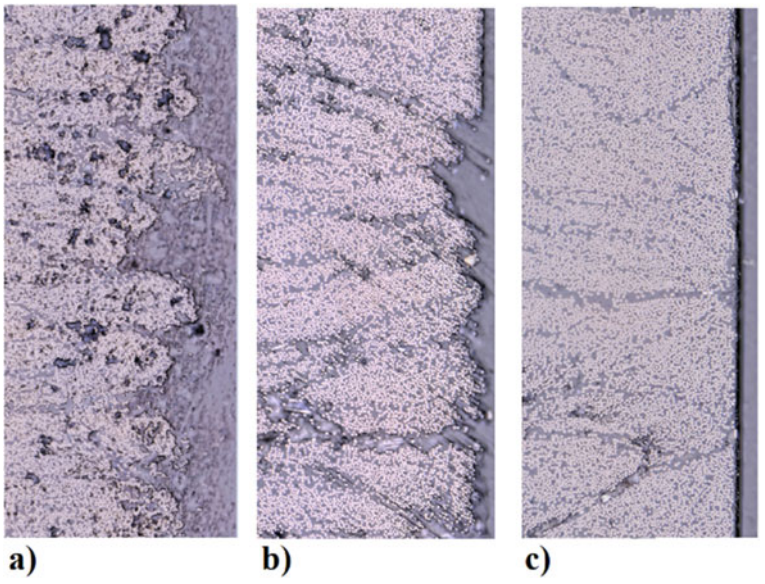

Fig. 5 External surface of samples C-PA 0 (**a**), C-PA 31 (**b**), and C-PA 42 (**c**). (Color figure online)

- The samples C-PA 0 and 31 show a surface condition that is not planar with the ratio of shaping applied did not make it possible to fill the functional clearances.
- The samples C-PA 46 and 52 have a planar surface state which testifies to the filling of the functional clearances.

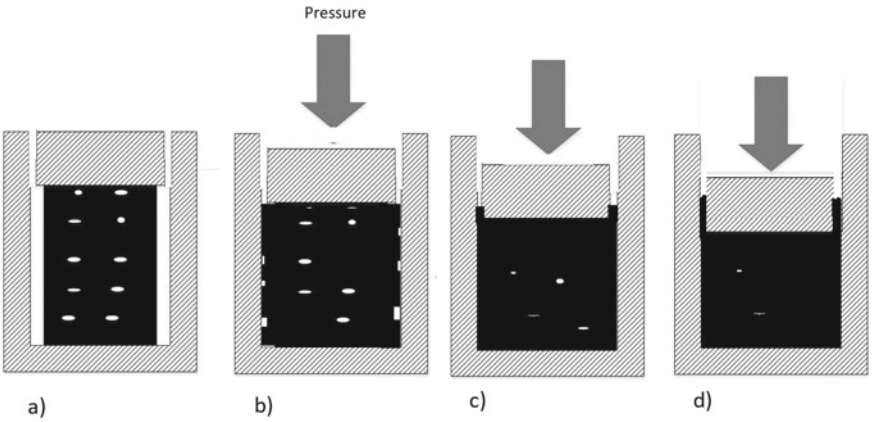

Fig. 6 **a** Initial condition (C-PA 0), **b** Start of compression (C-PA 31), **c** Low porosity and small loss of material (C-PA 42), and **d** Low porosity and high loss of material (C-PA 54)

To resume previous results and observations, during the shaping process the material moves and generates several phenomena: (i) the material flows so as to fill the functional gaps which allow the placement of the printed preforms in the mould. (ii) The material then tends to fill the voids presents in the preform and to evacuate some air. (iii) Once the volume of the tool is mostly filled with material, and if the displacement and the force are sufficient, the material flows outside the tool by the functional gaps of the latter and make a flash. Figure 6 shows the state of the samples at the end of compression. For (b), in view of the results in Table 2 the two phenomena (i) and (ii) occur. For (c) and (d), the functional clearances are filled, so phenomena (ii) and (iii) occur simultaneously.

3.2 Influence of Compression Ratio on Matter Health

This section presents the results of the image processing and their analysis. Table 3 presents values of the fibre volume fraction, the porosity ratio, and the fibre ratio.

Table 3 Fibre, matrix, and porosity volume fraction for each sample

Sample	Ratio of compression [%]	Fibre volume fraction [%v]	Porosity volume fraction [%v]	Fibre ratio [%]
C-PA 0	0 (Printed preform)	42.60	19.42	52.86
C-PA 31	31.5	44.16	12.68	50.56
C-PA 42	42.7	51.39	0.89	51.84
C-PA 46	46.2	51.70	0.68	51.32
C-PA 54	54.5	51.86	0.23	51.98

The results of the fibre ratio for the five samples are in the range from 50 to 53%, and these values are close to the value of 50% given by the supplier (Table 1). This low variability testifies to the fact that from one sample to another the composition of the composite material does not change or little despite an evacuation of material that could have been substantial. Material evacuation, therefore, has no influence on the fibre content of the composite in this tool configuration, and for this type of material, it is possible that different shaping conditions could lead to an increase in the fibre content. Mayer [12] presented results for the use of the same process with a PPS/carbon fibre composite and observed a flash mainly composed of a matrix which could thus lead to an increase in the fibre content in the parts concerned.

Sample C-PA 0 corresponding to a preform at the print outlet has a porosity ratio of 19.42%. This value is quite similar to the results of Tekinalp et al. [3], who also studied the composite parts (oriented short fibres) obtained by the FFF process. The parts presented have a similar appearance to the preforms produced with the 9 T LABS system, and the porosity ratio is estimated between 16 and 27%. In order to check the quality of the image processing results, a transition from the volume percentages to mass percentages is realized. From these values and the densities of the components, the mass of the samples is calculated. Thus the masses of the samples calculated have deviations of the order of 5% with the measured values, which testifies to the good quality of the results of the image processing.

Overall, increasing the shaping ratio tends to decrease the porosity ratio of the forged samples. However, samples C-PA 46 and 54 show a consequent loss of material for a slight reduction in the porosity ratio compared to sample C-PA 42. For a decrease from 0.89 to 0.23% of porosity, the loss of material increase from 1.22 to 15.9%. Given the various parameters studied, the C-PA 42 sample presents the optimal characteristics for this tool configuration. This conclusion is consistent with the conclusions of paragraph 3.1, where the application of a shaping ratio equal to or close to T leads to optimal results.

4 Conclusions and Perspectives

This article presents an innovative shaping process for composite materials. This process makes it possible to (i) produce thick structural parts, (ii) great control of the orientation of the fibres, as well as (iii) good material health of the parts produced within a particular porosity ratio of less than 1%. The objective of this study is to study the influence of the shaping conditions and parameters on the quality of the resulting composite products. If necessary, the variant parameter is the shaping ratio, and the parameters studied are the volume ratio of the fibre as well as the porosity ratio. A theoretical value of the shaping ratio was presented and compared with the experimental case. The results of this study led to the following conclusions:

1. In this tool configuration, the application of high pressure (100–200 bar) leads to a consequent material spin and reduces the porosity ratio up to 0.23%.

2. The results of the image processing, particularly the values of the fibre/matrix ratio compared to the volume of material of the samples allow us to conclude that the spin had no influence on the fibre/matrix ratio of the composite.
3. The C-PA 42 sample has the most interesting characteristics: a porosity ratio of less than 1% for a mass loss of 1.22%. Thus, even in this tool and shaping configuration, it is possible by applying the theoretical compression ratio during shaping, to obtain composite products with interesting material health.

Influences of Key Forging Parameters on Cold Orbital Forging of Thin Parts with High Circular Ribs

Wuhao Zhuang, Xinghui Han, Lin Hua, and Wei Feng

Abstract In this paper, a cold orbital forging process is proposed to manufacture thin parts with high circular ribs. First, a FE model was established for the numerical process analysis. Then a verification experiment was performed to verify the validity of the FE model developed above. By using the FE simulation method, the influences of several forging parameters on the cold orbital forging of thin parts with high circular ribs were investigated. The results show that effective strain can be obviously improved by increasing feed velocity of cavity die, but has less change with different friction factors. Synchronism of metal flowing between the inner rib and the outer rib can be improved by decreasing feed velocity of cavity die and friction factor. Moreover, the circumferential metal flowing degree can be slightly reduced by increasing feed velocity of cavity die and friction factor.

Keywords Cold orbital forging · Thin part with high circular ribs · Metal flowing analysis

1 Introduction

Thin part with high circular ribs (Fig. 1) is quite difficult to be fabricated by the conventional forging process. This is because the die cavities of circular ribs are narrow and deep, and metal flowing inside these die cavities is quite difficult. On the other hand, the forging load is huge to forge the thin baseplate by using the conventional forging process. In order to improve the metal flow capacity and reduce forging load, the cold orbital forging process is a good alternative. By now, the forming mechanism of cold orbital forging process has been revealed [1–4]. Cold

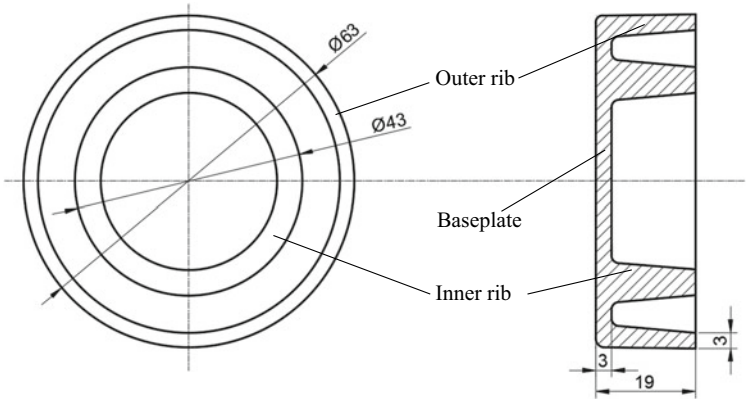

Fig. 1 Drawing of thin parts with high circular ribs

orbital forging processes of cylindrical parts [5], flanged parts [6, 7], deep groove parts [8], and gear parts [9–11] have been developed. However, no research has been reported about cold orbital forging of thin parts with high circular ribs. In this paper, a FE model of the cold orbital forging of thin parts with high circular ribs was established, and the validity of this FE model was verified by experiments. By using this FE model, the influences of several cold orbital forging parameters on effective strain distribution, height difference between the inner rib and outer rib, and circumferential metal flowing degree were revealed comprehensively.

2 Establishment and Verification of FE Model

In order to investigate the influences of key forging parameters on cold orbital forging of thin parts with high circular ribs, a rigid plastic FE model is developed, as shown in Fig. 2. This FE model consists of three parts: orbital die, cavity die, and billet. The orbital die is a tilted cone die, and performs rotational motion during cold orbital forging at the rotational speed of 8π rad/s. The cavity die performs feed motion during cold orbital forging, and the feed velocity of cavity die $v = 4$ mm/s. To simulate the plastic deformation of cold orbital forging, the billet should be set as rigid plastic type, and meshed by using tetrahedral mesh. The total mesh count is set as 100,000. The material of the billet is AISI-1006 steel and the strain–stress curves of this steel are shown in Fig. 3. The lubricating conditions between billet and dies are defined by using shear friction, and friction factor $m = 0.12$.

To verify the validity of FE model developed above, a cold orbital forging experiment of thin parts with high circular ribs was executed under the same forging parameters and a MoS_2 grease was used as a lubricant between the billet and dies. The cold orbital forging parts are shown in Fig. 4. As can be seen from Fig. 4, the

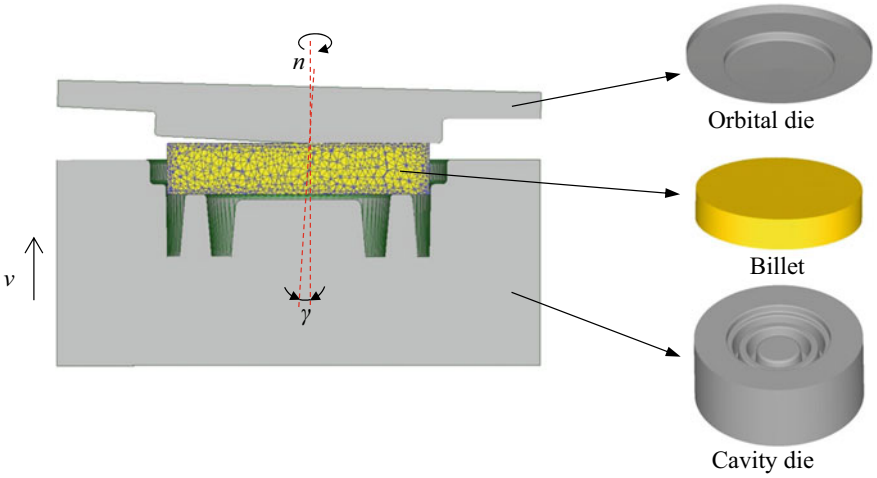

Fig. 2 FE model of cold orbital forging of thin parts with high circular ribs. (Color figure online)

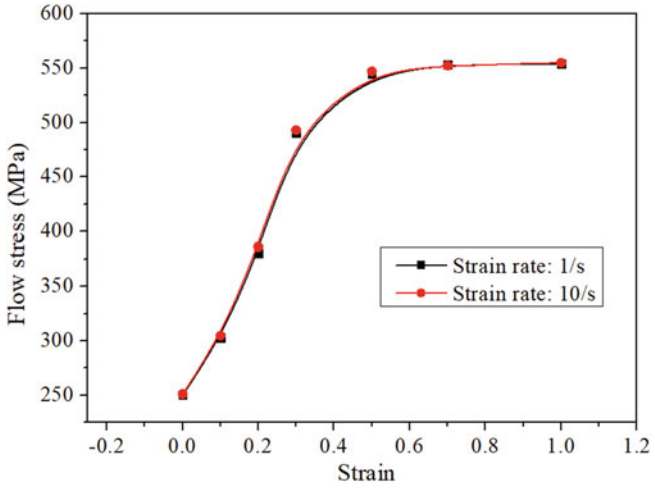

Fig. 3 Strain–stress curves of AISI-1006 steel. (Color figure online)

simulation forged part is quite similar to the experimental forged parts, which can effectively validate the validity of the FE model developed above.

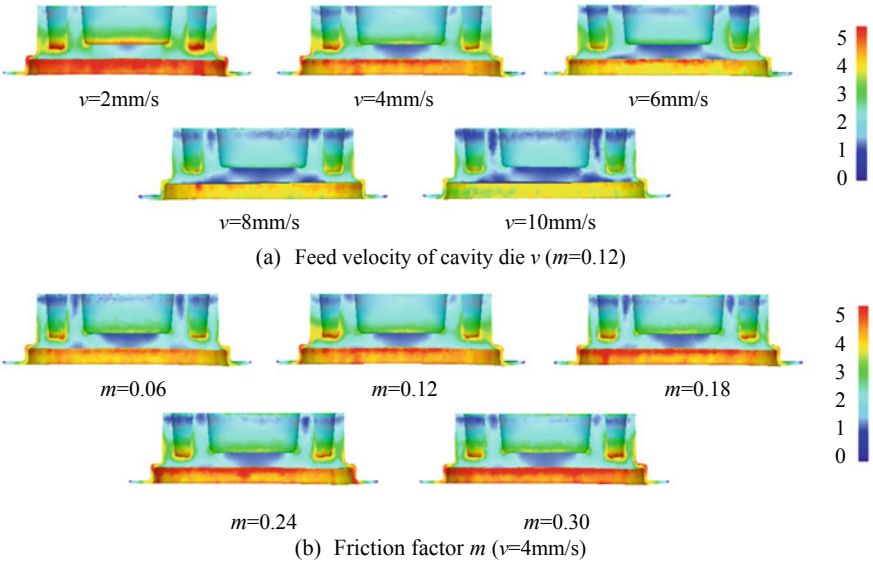
(a) Simulation part (b) Experimental part

Fig. 4 Cold orbital forging dies of thin parts with high circular ribs. (Color figure online)

3 Influences of Key Parameters on Cold Orbital Forging of Thin Parts with High Circular Ribs

3.1 Effective Strain Distribution

Figure 5 shows the evolution of effective strain distribution with different key forging parameters. It can be seen from Fig. 5a that the effective strain of the whole part significantly decreases with increasing feed velocity of cavity die v. The reason is that larger v means less number of revolution circles of orbital die, so the repeated rolling deformation of the billet can be reduced, and the intensity of plastic deformation can be decreased. In Fig. 5b, the distribution of effective strain is weakly affected by



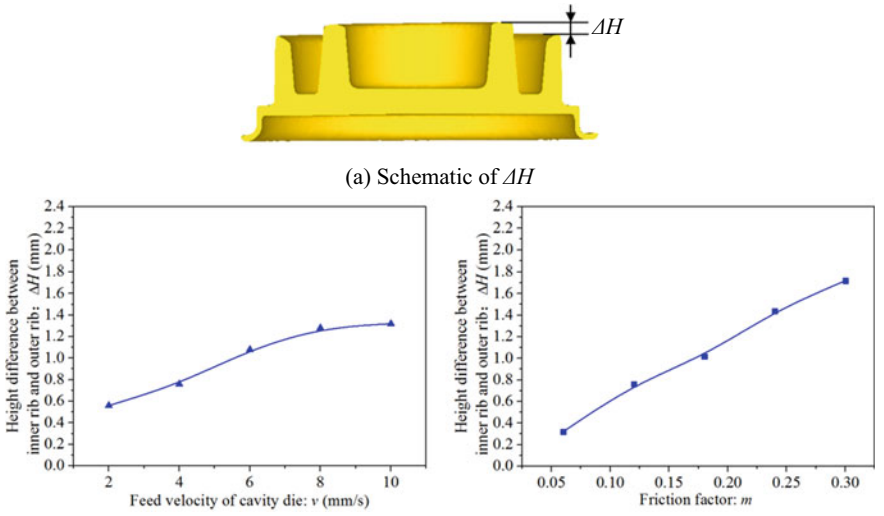


Fig. 5 Effective strain distribution under different forging parameters. (Color figure online)

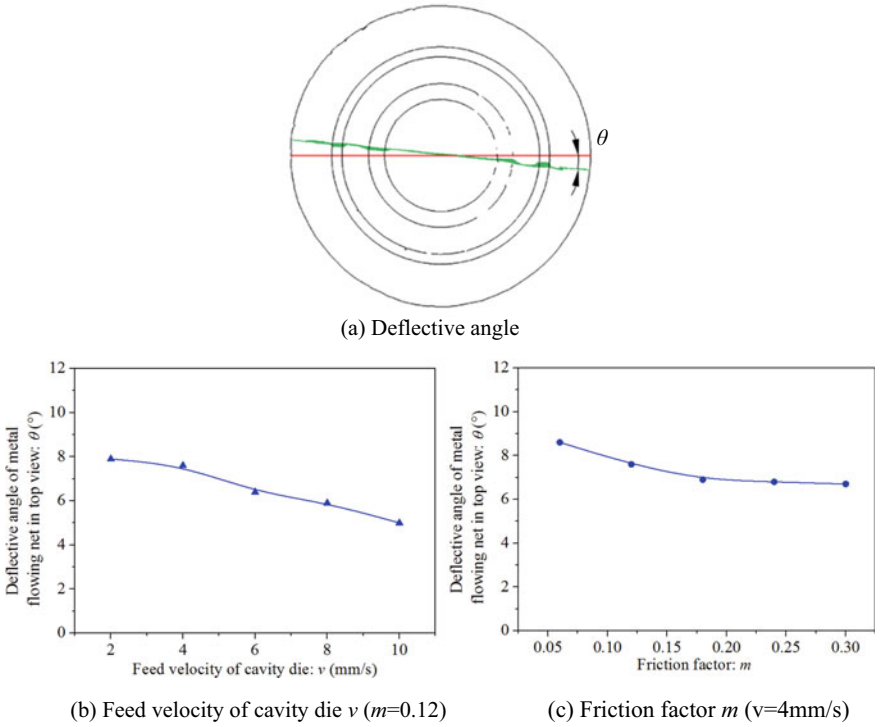
friction factor *m*. This is because larger *m* only increases the friction resistance on the surface of the billet, but has a little effect inside the billet.

3.2 Height Difference Between Inner Rib and Outer Rib

In cold orbital forging of thin parts with high circular ribs, the metal flowing process of the inner rib and the outer rib is non-synchronous. This non-synchronous metal flowing would cause unbalanced force between the inner rib and the outer rib, which would lead to a high crack risk of cavity die. In this paper, the maximum height difference between the inner rib and the outer rib ΔH is designated to appraise the non-synchronism of metal flowing between the inner rib and the outer rib (Fig. 6a), and the effects of key cold orbital forging parameters on ΔH are revealed in Fig. 6. It can be seen from Fig. 6b, with increasing feed velocity of cavity die v, ΔH gradually increases. This is because that the larger the v is, the less time it takes to execute radial metal flowing so that the outer rid cannot be fully formed owing to less metal flowing in the radial direction. With increasing friction factor m, the metal flow resistance in the radial direction increases, and less metal can flow into the die cavity of the outer rib so that the height of the outer rib is smaller than that of the inner rib and ΔH markedly increases, as shown in Fig. 6c.

(a) Schematic of ΔH



(b) Feed velocity of cavity die v (m=0.12)

(c) Friction factor m (v=4mm/s)

Fig. 6 Height difference between the inner rib and the outer rib under different forging parameters. (Color figure online)

3.3 Circumferential Metal Flowing Degree

In cold orbital forging of thin parts with high circular ribs, the orbital die repeatedly rolls on the surface of the billet, which leads to obviously circumferential metal flowing. In order to intuitively reflect the circumferential metal flowing degree in this cold orbital forging process, a deflective angle θ is defined, as shown in Fig. 7a. In Fig. 7a, the red line is a labeled line on billet before cold orbital forging, and the green line is the final position of the labeled line after cold orbital forging. Figure 7b and c shows the influences of key parameters on deflection angle θ. As observed from Fig. 7b, θ slightly drops with increasing v. This is because that larger v leads to less rolling times of orbital die on the surface of the billet so that less metal is driven in the circumferential direction. In Fig. 7c, θ slightly reduces with increasing m, which is due to larger frictional resistance.

(a) Deflective angle

(b) Feed velocity of cavity die v (m=0.12)

(c) Friction factor m (v=4mm/s)

Fig. 7 Influences of key parameters on circumferential metal flowing degree. (Color figure online)

4 Conclusions

(1) Effective strain can be obviously improved by increasing feed velocity of cavity die, but the fiction factor has a trivial effect on effective strain distribution.
(2) Synchronism of metal flowing between the inner rib and the outer rib can be improved by faster feed velocity of cavity die and smaller friction factor.
(3) Circumferential metal flowing degree can be slightly reduced by larger feed velocity of cavity die and friction factor.

FE-Based Investigation on the Influence of Inhomogeneously Heated Billets on Subsequent Forging Processes

Arne Jagodzinski, Hendrik Gerland, Mareile Kriwall, Jan Langner, Malte Stonis, and Bernd-Arno Behrens

Abstract Multi-stage forging process chains are often used for the efficient production of complex geometries. Typically, these consist of homogeneous heating, one or more preform stages, and the final forging step. By inhomogeneously heated billets, the process chains can be simplified or shortened. This shall be achieved by setting various temperature fields within a billet, resulting in different yield stresses. These can influence the material flow, leading to easier production of complex parts. In this study, the influence of inhomogeneously heated billets on the forming process is investigated by means of FEA. For this purpose, two process chains including inhomogeneous heating and three homogeneously heated reference process chains are developed and compared. Each process chain is optimized until form filling and no defects occur. Target figures for the assessment are necessary forming force, the amount of material necessary to achieve form filling and die abrasion wear. For process chains with inhomogeneously heated billets, the results showed a small time window of about 5 s for a successful forming in terms of form filling. Forming forces and die abrasion wear increase for inhomogeneously heated billets due to higher initial flow stresses. However, the flash ratio decreases when billets are heated inhomogeneously. Depending on their size, inhomogeneously heated billets show up to 11.8% less flash than homogeneously heated billets. This shows a potential for the use of inhomogeneous heating to make forging processes more efficient. Subsequently, experimental tests will be carried out to verify the results of the simulations.

1 Introduction

In forging technology, the use of materials and energy, especially for heating the billets, is accountable for a large amount of the manufacturing costs [1]. For this reason, it is very important for the forging industry to use manufacturing processes that are as material- and energy-efficient as possible in order to increase their competitiveness and make a contribution to conserving resources. One way of reducing energy consumption and the associated costs is to increase the efficiency of billet heating. Lowering the forming temperature also has a major impact on the manufacturing costs of forgings. By reducing the temperature from 1,200 to 1,080 °C, manufacturing costs can be reduced by approximately 12% [2].

The research project "Use of different flow stresses for forming inhomogeneously heated billets" investigates the influences of inhomogeneous billet heating on subsequent steps of a forging process chain. The aim is to adjust the flow stresses of the billet by means of different temperatures that are set in the billet by inductive heating and thus influence the forming behavior. This enables a more efficient design of production processes with regard to the material and energy input.

The goal of the present study is to investigate an inhomogeneous billet heating with regard to its influence on the necessary flash ratio to achieve form filling as well as on the die abrasion wear and the forming force of subsequent forging process steps. The investigation is carried out purely simulation-based, using a sample part with a geometry based on a common rail geometry. The sample part has two areas in which, due to secondary shape elements, large deformations take place and a lot of material is required to achieve form filling as well as two areas with a low mass.

Furthermore, by replacing a complicated preforming step, such as cross-wedge or forge rolling, with a simple preforming process, such as upsetting or flattening, it has to be examined whether the use of inhomogeneous heating can contribute to a simplification of the manufacturing process. The necessary mass predistribution shall be achieved during the simple preforming by the different flow stresses arising in the differently heated areas.

To achieve this goal, several forging process chains must be designed first. In addition to a realistic reference process chain, a process chain with a simple flattening step as a preform operation and a process chain without a preform operation are created. These process chains are additionally divided into a version with homogeneous heating and one with inhomogeneous heating. This results in a total of five process chains for each billet. Each of the five process chains is further subdivided into two different part sizes so that the scaling effects can be considered later in the investigation. All process chains to be created are optimized with regard to their billet size until a defect-free and form-filling process is achieved, while the flash ratio is decreased to a minimum. Afterward, a parameter study will be conducted to compare the designed process chains and thereby identify the effects of the inhomogeneous heating using the design of experiments (DoE) method. The results of the parameter study will also be used to identify a suitable parameter field for subsequent experimental trials.

2 State-of-the-Art

In forging processes, the combination of induction heating and flash reduced forging can lead to a significant decrease in energy consumption. Behrens et al. investigated the influence of induction heating on the energy consumption of a multi-directional forging process. They designed a flash reduced forging process for a two-cylinder crankshaft including inductive heating and reheating of the part. In the first investigation, they were able to reduce the energy necessary for the heating of the part from 4.85 kWh/part to 4.74 kWh/part, including the reheating [3]. By further optimizing the process, they were able to achieve a further reduction in energy consumption. It was possible to reduce the total energy consumption to 3.27 kWh/part, which corresponds to a reduction of 24% [4]. Both heating and reheating were performed homogeneously for these studies.

Recent research has looked at different approaches and processes for partial heating of billets and their subsequent forming. In the Transregio 30 (TRR 30)—"Process-integrated production of functionally graded structures on the basis of thermo-mechanically coupled phenomena"—different temperatures in a forging billet were considered. In subproject A1, Matzenmiller investigated the possibility of hot/cold forming of a shaft end after partial heating [5]. In subproject B2 of TRR30, Mahnken investigated the thermomechanical die loading during hot/cold forming with partial heating [6].

Özmen, Okman, and Tekkaya investigated the influence of partial heating on the forming of steel, titanium, and aluminum billets in different experiments. For this purpose, they heated the raw parts laterally by means of gas or induction heating and laser irradiation and then carried out a compression process [7, 8]. Merrygold considered hot/cold forming by layering and upsetting solid and hollow cylindrical billets at different temperatures [9].

All the above-mentioned investigations dealt with partial heating, whereas in the research project described in this paper inhomogeneous heating and its influence on the forging process are considered. While partial heating often only heats a certain area of the billet—in industrial practice, for example, it is usual to heat only the head side of a billet to form simple shapes such as screw heads or valves—inhomogeneous heating heats the entire billet (see Fig. 3). For this purpose, the billet is divided into several zones and these are heated to different degrees. The inhomogeneous temperatures lead to different flow stresses and thus to a change in the forming behavior in the temperature zones.

An inhomogeneous billet heating was performed by Kruse et al. [10]. They heated the steel component of a serially arranged friction-welded tailored forming part made of steel and aluminum in an inductor. Due to the heat conduction in the part, this led to an inhomogeneous temperature profile after heating. After the heating, the billet was cross-wedge rolled. For the experiments described in this paper, a monomaterial part was used which is completely heated in an inductor. The inhomogeneous temperature profile was not set by heat conduction but by the coil geometry.

3 Investigations and Results

3.1 Process Design

In this paper, the analysis of the influence of inhomogeneously heated billets on subsequent forging processes is presented. For this study, five different process chains had to be designed using FE simulations. Each of these process chains is divided into a large and a small version, depending on the size of the final geometry. In this chapter, the process chains and the simulation model used are described.

The starting point for the design of all process chains was a sample part that is approximated to the shape of a common rail. As mentioned above, the process chains are each divided into a large and a small version, depending on the size of the final geometry. This is due to the possibility of scaling effects in the later parameter study. The geometry of the final part is shown in Fig. 1. While the lengths (l_f) and diameters (d_f) change for the two different sizes, the ratio of the two remains the same. For both sizes the ratio is $l_f/d_f = 8.35$. The main objective of the process design is to identify suitable billet sizes for all process chains as well as suitable temperature profiles for the inhomogeneously heated process chains, which are required to achieve form filling depending on the different heating and preform operations.

The five process chains developed are divided into two process chains with inhomogeneous billet heating and three reference process chains which contain homogeneous billet heating. Two of the homogeneously heated reference process chains have a forging sequence identical to the two inhomogeneously heated process chains. The third homogeneously heated process chain, hereinafter referred to as the "reference process chain", consists of a preform forging step in a partially closed die, followed by a final forging step in an open die. This process chain serves as a benchmark for the performance of the inhomogeneous heating to a conventional stage sequence for the production of the sample part. The influences of inhomogeneous heating are

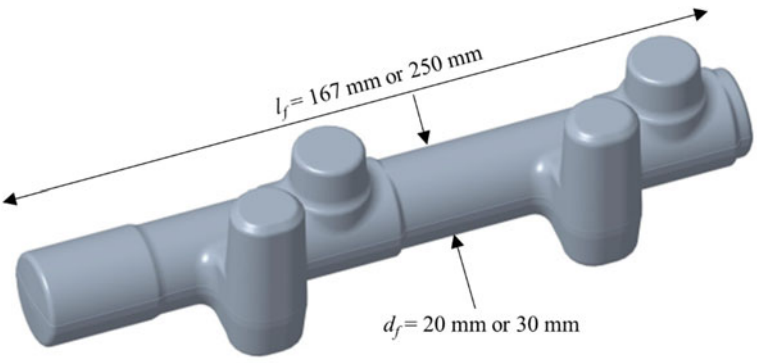

Fig. 1 Geometry of the sample part in two dimensions. (Color figure online)

evaluated in the remaining four process chains. Since two of these process chains only differ concerning the way of heating (homogeneous and inhomogeneous), they are hereinafter referred to as "Process chain I A / B" and "Process chain II A / B". Process chain I consists of a homogeneous (A) or inhomogeneous (B) billet heating, followed by a flattening which serves as a simple preforming operation and the final forging step in an open die. Due to the inhomogeneous temperature profile and the resulting inhomogeneous flow stress distribution in process chain I B, the flattening should lead to a predistribution of mass by forming the hot areas of the component more strongly than the warm areas. Process chain II also starts with a homogeneous (A) or inhomogeneous (B) billet heating. It does not, however, have a preforming step, but only a final forging step after the heating. An overview of the five considered process chains is shown in Fig. 2. In order to be able to evaluate scaling effects in the later course of the investigations, a large and a small version are created for each process chain, which differ in the size of the final geometry (see Fig. 1).

Table 1 Regression coefficients of Hensel–Spittel equation for 42CrMo4

A	m_1	m_2	m_3	m_4
Solidity	Dependence of temperature	Dependence of strain hardening	Dependence of equivalent strain rate	Dependence of equivalent strain
1,872.0667 N/mm^2	−0.00289	−0.1123	0.14368	−0.04879

The setup of the FE simulations is identical for the design of all process chains as well as for the parameter study (see Sect. 3.2). The simulations were performed via the FEA-software FORGE NxT 2.1 using the press kinematic of a hydraulic press and non-deformable dies. The material used for the billets is 42CrMo4 (1.7225). Its material description and therefore its flow curves are based on the flow curve equation by Hensel and Spittel. This equation describes a materials' forming behavior as a function of the temperature T, the effective strain ε, the strain rate $\dot{\varepsilon}$, as well as the coefficients A and $m_{1\text{-}9}$ [11]. However, FORGE NxT 2.1 uses a shortened version of the equation only using the coefficients m_1 to m_4 (see Eq. (1)). The necessary regression coefficients are stored within the material database of the program and are shown in Table 1.

$$\sigma_f = A \bullet e^{m_1 T} \bullet \varepsilon^{m_2} \bullet e^{\frac{m_4}{\varepsilon}} \bullet \dot{\varepsilon}^{m_3} \tag{1}$$

The following parameters were used in the FE simulations of the process design (see Table 2).

The temperatures set for the inhomogeneously heated billets were 1,250 °C for the hot parts and 900 °C for the warm parts of the billet. The inhomogeneous heating was achieved in the simulations by assigning the so-called temperature boxes to the desired temperature ranges. This feature of FORGE NxT 2.1 allows assigning certain temperatures to individual nodes of the FE mesh. However, this results in very discrete transitions between the different temperature ranges. These are defined as ideal inhomogeneous heating but can hardly be achieved in a real process due to compensation processes. Therefore, a short waiting time of 5 s was implemented before the start of the first forging step. Figure 3 shows an inhomogeneously heated part before and after an initial waiting time of 5 s.

It was possible to achieve form filling and defect-free forging processes for all investigated process chains. In Fig. 4 the workpieces of all process chains are shown directly before final forging.

Table 2 Simulation input parameters for the process design

Die temperature T_{die}	Ambient temperature T_a	Billet Material	Forming Speed v	Friction coefficient μ	Friction factor m	Mesh size for big billet size/small billet size
250 °C	50 °C	1.7225	100 mm/s	0.15	0.3	1.5 mm/1 mm

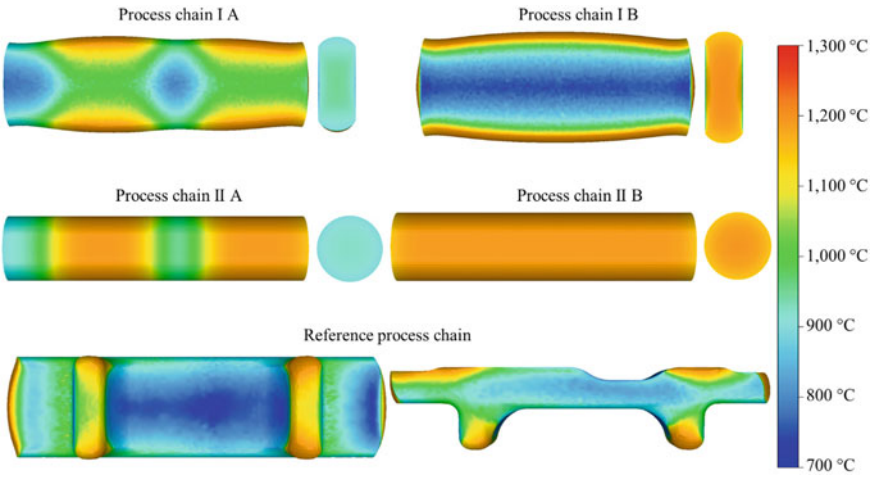

Fig. 4 Workpieces of all process chains before final forging. (Color figure online)

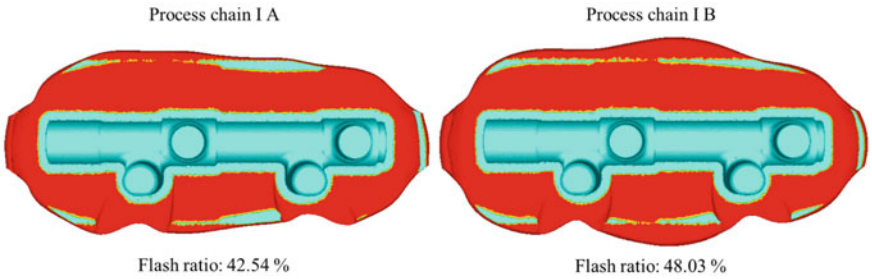

Fig. 5 Contact analysis of final forgings of process chain I. (Color figure online)

Figure 5 shows the contact analysis of the final forgings of process chain I A and process chain I B. It is clearly visible that the flash ratio of process chain I B is higher than the flash ratio of process chain I A.

3.2 Parameter Study

This chapter presents the parameter study that was carried out to determine the influences of the inhomogeneous billet heating on the subsequent steps of the designed forging process chains. The study was designed according to the DoE method as a full factorial two-stage experimental design using the software Minitab 17. With the exception of the forming speed, the simulation input parameters correspond to those of the process chain design (see Table 2). The forming speed was varied as well as

Table 3 Input parameters for the parameter study

Forming speed v	Initial waiting time t_i	Final geometry size d_f, l_f
100–300 mm/s	5–20 s	$d_f = 20$–30 mm, $l_f = 167$–250 mm

the initial waiting time and the final geometry size. The study's input parameters and their levels are shown in Table 3. This results in a total of 40 simulations.

For the evaluation of the parameter study, the comparison of versions A and B of the different process chains is of particular importance. As these process chains differ only in the type of heating selected, they have the greatest significance with regard to the influences of inhomogeneous heating. The comparison of the process chains I and II with each other serves to estimate whether a simple preforming process, such as flattening, is effective for reducing material consumption. The comparison of the two process chains I and II with the reference process chain serves to examine the efficiency of inhomogeneous heating in comparison to a conventional preform optimized process.

Only the final forging stages were compared during the parameter study. This is due to the fact, that the process chains consist of a varying number of stages—some have a preforming step while in others the final forging is undertaken directly after heating. For this purpose, a distinction is made between mandatory evaluation criteria, which must be fulfilled in order to obtain a successful forging process and which can only assume the values "True" or "False" and quantitative evaluation criteria. The mandatory evaluation criteria include the absence of folds and the form filling. The quantitative evaluation criteria are the amount of material required to obtain form filling, the forming force, and the die abrasion wear. For each of them, a minimum value is aimed for.

The simulations showed that no folds occur in any of the investigated process chains. The investigation of the mold filling revealed only a small process window in which a satisfactory process is possible. The inhomogeneously heated process chains, in particular, were very susceptible to the long initial waiting time of 20 s (see Fig. 6, left). In none of these simulated processes form filling could be achieved, while in homogeneously heated processes about 50% of all simulations reached form filling. For the short initial waiting time of 5 s, the chances for form filling were significantly higher. With a slight mass predistribution via flattening, all the simulations containing an inhomogeneous heating reached form filling. Without a preforming step, the proportion of form filling simulations was reduced to 75%. The same result was obtained for simulations with homogeneously heated billets. The size of the final geometry only had a small impact on form filling. The small size had a slightly higher rate of form filling than the bigger geometry. The most probable reason for this is that the billet designed for the bigger final geometry had a smaller flash ratio than the billets for the small geometry, meaning that for the small geometry the amount of material available to fill the form was higher, making it easier to reach form filling. The forming speed did not have any impact on the form filling. 60%

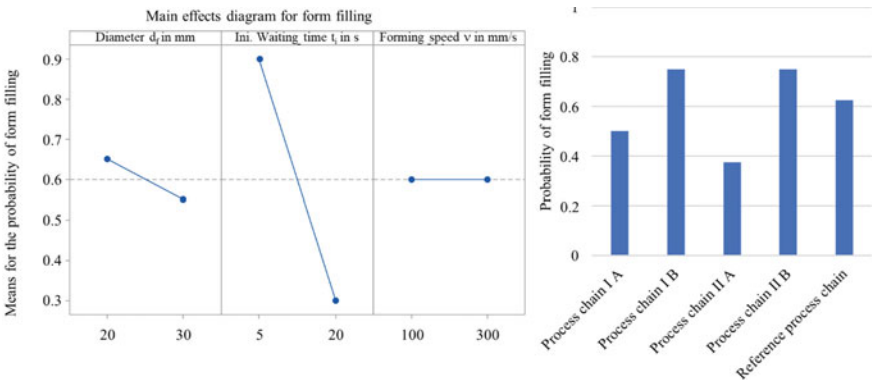

Fig. 6 The main effects for form filling under consideration of all parameter combinations (*left*) and comparison of the investigated process chains (*right*). (Color figure online)

of all simulations reached form filling for both investigated speeds regardless of the heating and preforming. In Fig. 6 on the left, the main effects for the form filling are shown under consideration of all parameter combinations. The right part of Fig. 6 shows the probability of a form filling process for the five investigated process chains.

For the amount of needed forming force, the most significant parameter was the size of the final geometry. The initial waiting time had only a small impact on the forming force, while the forming speed had none (see Fig. 7, left). For parameter combinations using an inhomogeneous heating, an increase in initial waiting time resulted in a decrease of forming force. The reason for the decrease in forming force was the compensation processes that led to a homogenization of the temperature profile. In these, the warm parts of the billet usually increased in temperature leading to a decrease in flow stresses and therefore to a decrease in the forming force. This

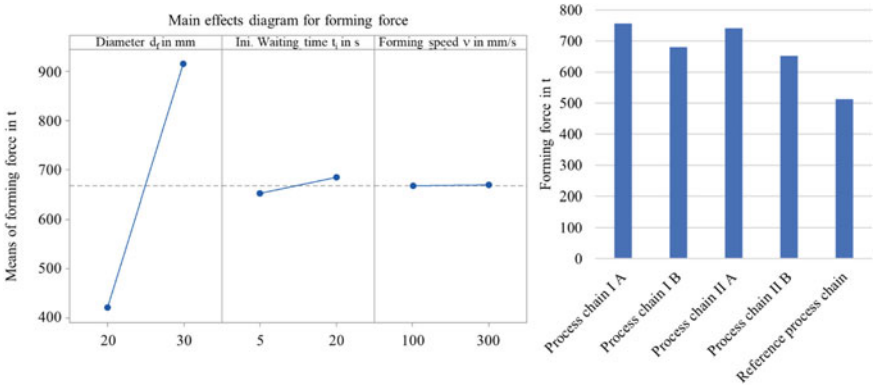

Fig. 7 The main effects for the forming force under consideration of all parameter combinations (*left*) and comparison of the investigated process chains (*right*). (Color figure online)

effect was higher in simulations without preforming since the flattening supports the compensation processes leading to a faster homogenization of the temperature profile. For homogeneously heated billets, the increase in initial waiting time led to an increase in forming force. Since no compensation processes took place and the billet cooled down homogeneously, the flow stresses also increased homogeneously leading to an increase in forming force. The main effects of the forming force, under consideration of all parameter combinations, are shown in Fig. 7, left. Overall, the forming forces were higher for processes with an inhomogeneous heating. In process chain I the inhomogeneously heated simulations showed a mean forming force of 755 t, while the homogeneously heated simulations reached a mean forming force of 680 t resulting in an increase of 75 t for inhomogeneous heating. Without preforming, the difference increases to 90 t with a mean forming force for homogeneous heating of 650 t and for inhomogeneous heating of 740 t. The reference chain showed a mean forming force of 510 t (see Fig. 7, right).

For the die abrasion wear, all parameter combinations qualitatively showed the same qualitative effects. The bigger size of the final geometry and the longer initial waiting time led to an increase in die abrasion wear, while the forming speed led to a decrease (see Fig. 8, left). When comparing the process chains, it becomes clear that flattening led to an increase in die abrasion wear (see Fig. 8, right). Also, an inhomogeneous billet heating led to an increase in die abrasion wear. However, the rate of change was about the same for both. An inhomogeneously heated billet led to an approximately 5% higher die abrasion wear compared to a homogeneously heated billet, while the flattening of the billet generated about 6% more die abrasion wear than a non-preformed billet.

Since not all of the simulations performed for the parameter study reached form filling, the flash ratio was compared using the initially designed processes described in Chap. 3.1 (see Fig. 4). Therefore, an investigation of the influence of the initial waiting time and the forming speed was not performed. The initial waiting time

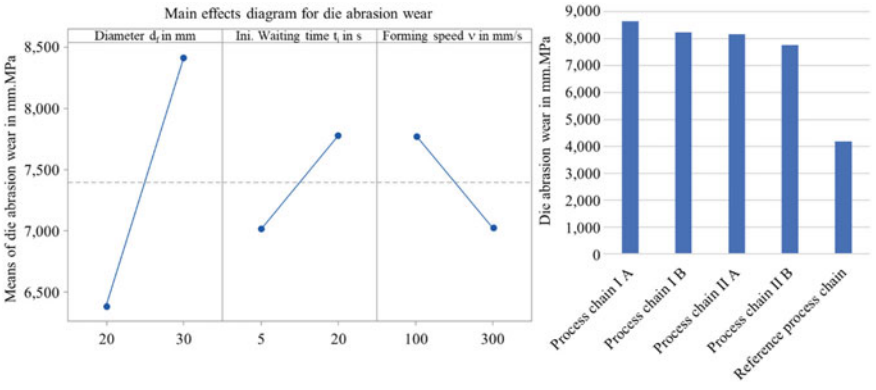

Fig. 8 The main effects for the die abrasion wear under consideration of all parameter combinations (*left*) and comparison of the investigated process chains (*right*). (Color figure online)

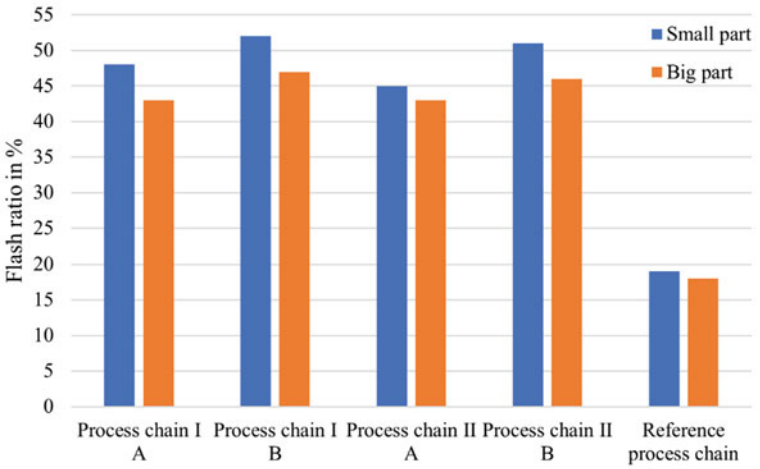

Fig. 9 Comparison of the investigated process chains regarding their flash ratio. (Color figure online)

would, of course, have had a significant influence on the flash ratio, but since the investigation of the form filling showed that the time window for a successful process is very small and clearly below 20 s, a variation of the waiting time would not have been effective. In addition, the forming speed showed no influence on the form filling at all. Therefore, it was found unnecessary to investigate these parameters in correspondence to their influence on the flash ratio. Figure 9 shows the comparison of the investigated process chains in regard to their flash ratio. At first glance, it is obvious that a larger final part results in less flash. This can be explained by the fact that they have less fineness, which made them easier to fill and which reduces the flash ratio. It can also be seen that the process chains containing flattening had a higher flash ratio than those without a preforming step. However, the most important observation that can be made is the reduction of the flash ratio in inhomogeneously heated process chains. The implementation of inhomogeneous heating in a process without a preform step led to a reduction of the flash ratio of 11.8% (6% points). In a process with a preform step, the reduction still corresponded to a reduction of 9.4% (5% points). This shows major potential for increasing the material efficiency of forging processes.

4 Conclusion and Outlook

This paper discusses an FE-based investigation of the influence of inhomogeneously heated billets on subsequent forging processes. The investigation was separated into two stages. In the first stage, the process chains that were investigated had to be designed. In the second stage, a parameter study was conducted to compare the

different process chains and thereby identify the influence of the inhomogeneous heating on them. In this stage, the influence of the forming speed, the initial waiting time on the size of the final geometry on the process chains, and the influence of an inhomogeneous billet heating on the form filling, the forming force, the die abrasion wear, and the flash ratio were studied.

For inhomogeneously heated process chains, a very small process window could be determined with regard to the initial waiting time. The longer the billet cooled down after an ideal inhomogeneous heating, the less likely it was that a form filling could be achieved. It was also found that flattening as a preforming step for inhomogeneously heated process chains is not effective, since compared to processes without preforming, it generally led to a deterioration of all evaluation criteria. The die abrasion and the necessary forming force increased due to higher flow stresses by inhomogeneous heating. An important finding, however, was the possibility of reducing flash by inhomogeneous heating of the billets. It was possible to reduce the flash ratio of an inhomogeneously heated process by 11.8% compared to an identical homogeneously heated process. This shows a high potential of inhomogeneous heating of billets in forging processes. It also shows the need for further investigations. Thus, it should be checked whether the combination of a preform optimized process, as it was carried out in the reference process chain, and an inhomogeneous heating also allows a reduction of the flash ratio.

In addition, the present investigations form the basis for experimental tests. For these, an inductive heating process must first be designed, which allows the smallest possible transition area between hot and warm temperature fields in the billets. Subsequently, forging tests can be carried out to verify the results of the present simulative study.

Acknowledgments The research project "Use of different flow stresses for forming inhomogeneously heated billets" (BE 1691/212-1) was funded by the German Research Foundation (DFG). The authors thank the DFG for its support.

Development of Automatic Design System for Closed Die Forging Process of Disk-Shaped Products

Yoshihiko Kobayashi, Eiji Sakamoto, and Tetsuya Yagami

Abstract When designing a closed die forging process, it is necessary to determine the process conditions with respect to various evaluation points such as forging load and shape accuracy. Two examples of process conditions are the number of stages and the die surface shape of each stage. It is particularly difficult to determine the combination of these two process conditions, which is called "process layout" in this paper, because there are numerous potential patterns that lead to a long development period for the design. Our objective is to generate a draft of the process layout for closed die forging. In this study, the authors focus on the forging process for disk-shaped products. To design a die surface shape with high flexibility, the authors propose a new method for die surface shape called the functional surface connection method and have developed an automatic design method for process layout by combining the proposed method with FEM and an optimization algorithm. The evaluation results showed that a process layout in which forging load restriction and forged shape accuracy were satisfied could be generated automatically.

Keywords Automatic process design · Multistage forging process · FEM · Optimization algorithm · Closed die forging · Disk-shaped product

1 Introduction

In the design of a closed die forging process, process conditions such as the number of stages, the die surface shape of each stage, the bottom dead center, and pressing speed need to be determined. These conditions are investigated by considering several evaluation points, including pressing load, forged shape accuracy, metal structure of forged workpiece, and die wear. Generally, these conditions are designed by FEM [1, 2, 3]. However, determining the proper conditions by trial and error is difficult because there is a lot of flexibility in the process design. In particular, the design of a multistage process is difficult. The multistage process is effective when forming in one stage

process is impossible [4], but as there are numerous combinations of the number of stages and the die surface shape of each stage (which is called "process layout" in this paper), the development period required for designing the process layout is very long. Reduction of the development period for process design is required in the production of many kinds of products.

In this study, the authors focus on the process in which a billet is forged into a disk-shaped product as an example of a closed die forging process. For a disk-shaped product, there are no clues for generating the die surface shape for each stage, so the process designer has to determine the proper die surface shapes from among various options. The conventional approach to die surface shape design has been trial and error based on the experience and intuition of the designer.

Many kinds of support technologies for process design have been developed to improve design efficiency for forging processes [5–8]. Several previous studies have focused on forging process design based on accumulated forging knowledge of a similar target shape. Although some of the previous studies have tried to generate proper process layout without any production rules, the die surface shape, which is important for the process layout design of disk-shaped products, cannot be appropriately determined. Other studies have examined the optimization of process layout or die surface shapes [9–13], but the forging processes were subjected to prerequisites in which the rough process layout and rough die surface shape of each stage were already known. In light of these aspects, a process design method that can generate a proper process layout and proper die surface shape at each stage without accumulated forging knowledge is still a technical challenge.

In this work, to generate a draft of the process layout for closed die forging, the authors investigated an automatic design method for disk-shaped products. Although there are various evaluation points (as mentioned above), as the first step of this attempt for automatic process design, the authors developed a prototype design system to generate process layouts for a net-shape forging part under the forging load restriction.

2 Automatic Design Method for Forging Process Layout of Disk-Shaped Products

2.1 Design of Die Surface Shape by Functional Surface Connection Method

The authors propose a functional surface connection method to generate a die surface. This method is based on the idea that each region of a die surface has its own function. With this method, the entire die surface shape is composed of connected partial die surface shapes that express different functions. These partial surfaces are called functional surfaces.

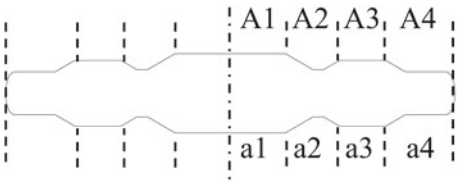

Fig. 1 Domain segmentation based on target shape

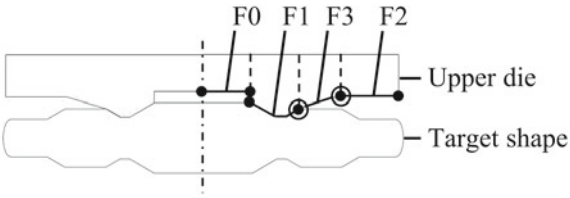

Fig. 2 Upper die shape represented by functional surface connection method

To generate the die surface by the proposed method, first, the authors introduce domain segmentation based on the geometrical features of the target forging shape, as shown in Fig. 1. In the example shown in the figure, domain segmentation is defined as A1 to A4 for the top surface and a1 to a4 for the bottom surface. The domain is divided into a concave shape of the target shape (A2, A4, a2, and a4) and others (A1, A3, a1, and a3). Second, various functional surfaces that express die surface function are assigned to each segment. Then, the entire die surface shape is generated by using four functional surfaces. Functional surface F0 means reducing the forging load by noncontact with the workpiece. Functional surface F1 means forming the workpiece to the target surface shape. Functional surface F2 means forming the workpiece to a flat surface shape. Functional surface F3 means forming the workpiece to a tapered surface shape. To express these functions, the following surface shapes are defined. F0 is a noncontact shape with the workpiece. F1 is the same shape as the target surface. F2 is a flat shape. F3 is a tapered shape. The taper angle of F3 (tapered shape) is set to 30° to the horizon. An entire die surface is generated by connecting these functional surface shapes as shown in Fig. 2, where an example of upper die generation is shown. In this case, the upper die surface is shaped by four connected functional surfaces (F0, F1, F3, and F2). The proposed method can generate various die surface shapes by means of this functional surface connection.

2.2 Automatic Design Flow for Process Layout

To design the process layout automatically, the authors developed the automatic design flow shown in Fig. 3. The design of a process layout depends on the number of stages. Accordingly, in the proposed design flow, the initial number of stages is assumed tentatively, and then the proper die surface of each stage is searched.

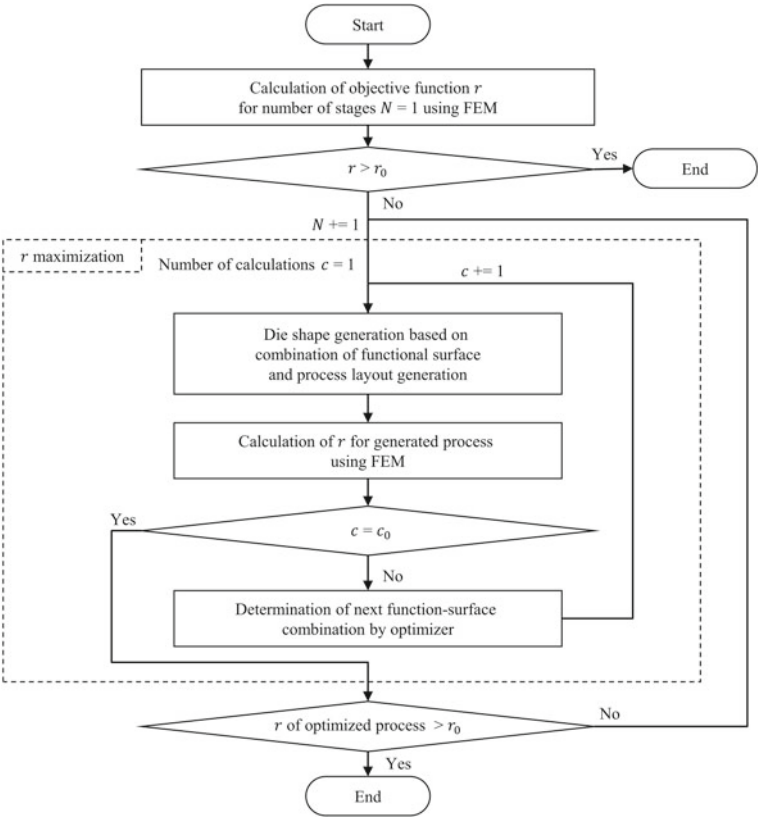

Fig. 3 Flowchart of automatic design for process layout

First, the number of stages is set to one. Objective function r is calculated on the basis of a FEM simulation result. In the FEM simulation, the shape of the entire die surface is the same as the target surface shape. r is given as $r = r_1 – r_2$, where r_1 is a shape concordance percentage between the forged workpiece and the target shape and r_2 is an excess percentage of the forging load compared with the forging load restriction. An r of 100% means that the shape error between the forged workpiece and the target shape is 0% and the forging load is less than the forging load restriction. After r calculation, it is determined whether r is greater than the restrictive value r_0 for objective function r.

If r does not reach r_0, the number of stages is increased before the process layout is searched. In the design of the process layout, the die surface of each stage is generated by the connection of functional surfaces F0 to F3, as shown in Fig. 2. To evaluate the generated process layout, r is calculated on the basis of the FEM result and maximized by repeated calculation using an optimization algorithm. To perform optimization of the process layout, all die surfaces of all stages are represented by a row of symbols that expresses functional surfaces in each segmented domain.

Functional surfaces F0 to F3 are converted into the symbol 0 to 3, respectively. For instance, the vertical symmetric shape; when the number of stages is 3 and the number of domain segmentation is 4 as shown in Fig. 1, the number of symbols which compose the row expressing process layout is 12. The example of this row is [1, 2, 2, 3, 2, 1, 3, 3, 1, 0, 1, 1], where the parts of [1, 2, 2, 3], [2, 1, 3, 3], and [1, 0, 1, 1] express each functional surfaces connections of the die surface shape in each stage. In the repeated calculation, this order of symbols is optimized to maximize the r value. This repetition is continued until the maximum number of available optimizations indicated by the number c_0 is obtained. After repeating calculations, it is determined whether r of the optimized process layout is greater than the restrictive value r_0. If the maximized r is greater than r_0, this process layout is considered to be proper and the design process is completed. On the other hand, if the maximized r is less than that of the previous value r_0, the number of stages is further increased and the search for the proper process layout is continued until maximized r exceeds r_0.

3 Verification of Automatic Design of Process Layout

3.1 Verification Target

In this section, the authors evaluate the effectiveness of the proposed automatic design method for generating the process layout. The method was applied to the target in Fig. 4, where (a) shows the workpiece before forging and (b) is the target shape. The material of the billet was SUS304.

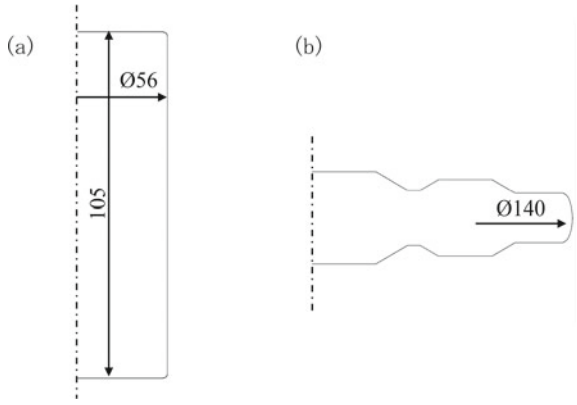

Fig. 4 Application target of the proposed automatic design method

3.2 *Implementation of Automatic Design Flow*

To perform the automatic design flow shown in Fig. 3, the authors developed a prototype system. Its functions include generating the die surface by the functional surface connection method, constructing a FEM model, executing FEM simulation, calculating objective function r, and maximizing r by an optimization algorithm. DEFORM 2D v11.2 was used as a FEM solver. Maximization of r was performed by a genetic algorithm. Load restriction and r_0 were set to 12 MN and 95%, respectively.

4 Results and Discussion

The process layouts in which objective function r became the largest of all the calculation conditions are shown in Fig. 5. The number of stages of these results ranged from one to four. In the case of one and two stages, forging load reached the forging load restriction, 12MN. In these cases, the obtained forged shapes had low accuracy due to an underfill at the outer region. In contrast, in the case of three stages, a process layout without forging load excess or underfill part was obtained. Automatic design calculation was also performed in a case with four stages as a reference. In this case, a process layout without forging load excess or underfill part

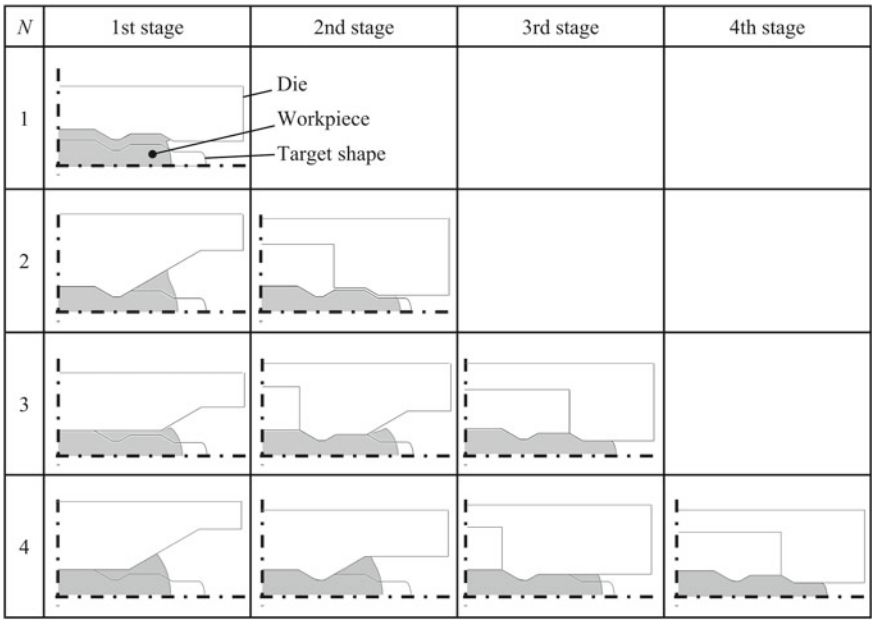

Fig. 5 Obtained processes for each number of stages

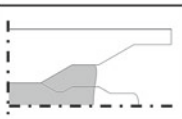
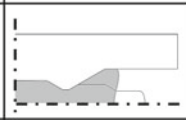
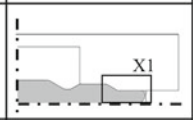
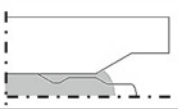
was obtained, the same as with the three-stage process. However, the authors found that with four stages, one of them was unnecessary, so the case with three stages is considered more proper. These results demonstrate that a process layout with a small number of stages can be obtained automatically by the proposed automatic design flow using the functional surface connection method.

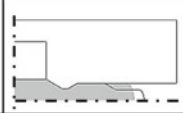
Next, the authors selected five process layouts from the 250 calculations for the process layout optimization of the three-stage process and compared them. These are shown in Fig. 6 and labeled as layouts i to v. In the figure, forging load is written as a relative value based on forging load restriction. Process layouts i and ii are any samples during the optimization process. In process layout i, the authors found forging load excess and a lap at the outer region (Fig. 7a), which is a defect of the forged shape, at the third stage. In process layout ii, forging load excess occurred at the second and third stages. In process layouts i and ii, various patterns of process layout were evaluated in the optimization process, which indicates that many combinations of the functional surface were calculated for all die shapes of all stages to search for the process layout by maximizing the r value. In addition, two similar process layouts,

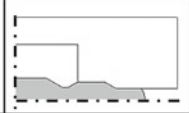


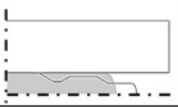


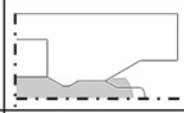


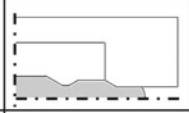


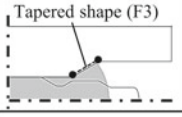


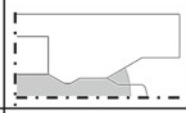


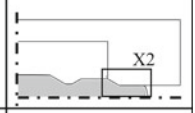


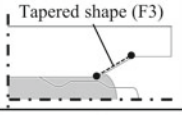


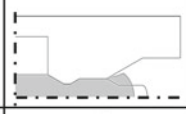


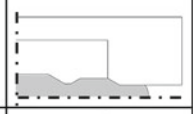












Sample number		1st stage	2nd stage	3rd stage
i	Process			
	Relative load [%]	−42	−39	+32
ii	Process			
	Relative load [%]	−11	+13	+40
iii	Process			
	Relative load [%]	+6	−19	−12
iv	Process			
	Relative load [%]	−38	−18	−13
v (the best result)	Process			
	Relative load [%]	−11	−19	−12

Fig. 6 FEM calculation results in optimization of three-stage process

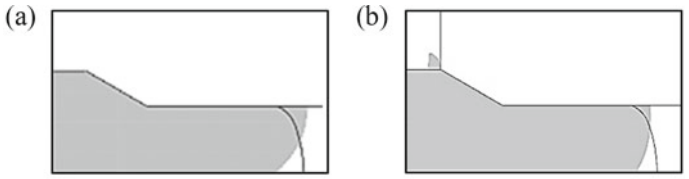


Fig. 7 Enlarged view around area **a** X1 and **b** X2 in Fig. 6

iii and iv, comparing with the process with most maximized r (as shown in Fig. 5) were selected. And then, these process layouts were compared with the process with the most maximized r in detail. The difference between these two process layouts and the process with the most maximized r is the die surface of the first stage.

Process layout v in Fig. 6 is the process with the most maximized r shown in Fig. 5. At the first stage of process layout iii, the die with the flat surface shape pressed the workpiece. The forging load at the first stage, 12.7 MN, exceeded 6% based on the forging load restriction. In contrast, at the first stage of process layout iv, the forging load did not exceed the forging load restriction. However, the shape accuracy of the forged shape became low because a lap at the outer region (Fig. 7b) was found after the third stage. As the examples of process layouts iii and iv, the die surface shape affects forging load and forged shape accuracy. In process layout v (which is the r maximized process), because the position of the tapered shape at the first stage was in the middle (between process layouts iii and iv), the authors could obtain a process layout in which both the forging load restriction and forged shape accuracy were satisfied. This demonstrates that the proposed automatic design method can determine the process layout automatically.

Previously, when there has been no accumulated forging knowledge to help with generating the process design, it is difficult to automatically design a die surface and process layout because these determinations have depended on the experience and intuition of the designer. The proposed method generates a process layout without any knowledge by searching for the proper die shape globally. Incidentally, optimizing the parameters of a die surface is effective when designing a process layout for a net-shape forging part under the forging load restriction. The proposed method can optimize the die surface parameters locally by changing the position of the functional surface. For example, in the case of process layouts iii to v in Fig. 6, the position of F3, which is a tapered shape at the first stage, can be changed and optimized to satisfy the forging load restriction and shape accuracy. Thus, the proposed method can express global and local optimizations.

5 Conclusion

In this work, the authors have proposed an automatic design method to automatically generate a draft layout for the closed die forging process of disk-shaped products.

The evaluation points of the forging process were forging load restriction and forged shape accuracy. Our work can be summarized as follows:

- The authors proposed a functional surface connection method based on die surface functions to generate die surface shapes of the closed die forging process. A prototype automatic design system was developed by combining the proposed die surface generation method with FEM and an optimization algorithm.
- To evaluate the proposed design method, verification was performed for a disk-shaped product. After various combinations of functional surface were evaluated, the proposed design method was able to automatically obtain a process layout with no forging load excess or underfill part.

In the future, the authors plan to investigate expanding application targets. The authors will also finetune the automatic design system so that it can consider additional evaluation points.

A FE Billet Model and a Spring-Mass-Damper Model for the Simulation of Dynamic Forging Process: Application to a Screw Press

Jean-François Mull, Camille Durand, Cyrille Baudouin, and Régis Bigot

Abstract In forging processes, the determination of blow efficiency is very important, as it quantifies the part of the stroke energy actually transmitted to the billet. Thus, forging processes should be deeply analyzed in order to better understand the stroke energy conversion, accurately estimate blow efficiency, and thus better predict process parameters. In this paper, a spring-mass-damper vibration model is proposed to describe forming operations of a screw press. Parameters specially adapted to the machine-tools system are identified, thanks to a stroke without billet. Thereafter, the experimental upsetting of a copper cylinder is realized, and two independent numerical simulations are performed. First, the billet upsetting is simulated by FE simulation with no consideration of the elastic and damping effect due to the machine-tools behavior in order to determine a relation between the load and the billet height. Then, forging load from the FE simulation is used to perform another simulation of the forging process with the spring-mass-damping model. Results show that the model is relevant to simulate load and ram displacement. Moreover, simulation can predict the distribution of the energy during the simulation and the blow efficiency can be calculated. This new way to obtain blow efficiency might improve productivity in process development and provide a better understanding of energy-driven machines.

1 Introduction

For energy piloted forging machines, the prediction of the energy actually transmitted to the billet for each blow is important in the conception of a forging sequence. Because it allows determining the number of necessary blows and thus optimizes the sequence. Therefore, a deep analysis is required to determine the distribution of the energy during the forging process and calculate the blow efficiency. For that, it is needed to consider billet and machine behavior. Different approaches were proposed to model energy-driven machines. For hammers, studies focused on the impact of the machine foundation [1] or the machine structure [2, 3]. But in every case, the dynamic models proposed were an association of springs, masses, and dampers with a different degree of freedom. In order to perform the simulation of the whole forging process, it is needed to couple the billet model and the machine model. For a hammer, Vajpayee et al. [4] realized simulations of the forging process by considering a press model constituted of one spring and two masses. Billet behavior was modeled by Siebel law allowing the calculation of the forging load during the simulation. The influence of process parameters as impact velocity and model parameters on the process efficiency and clash load was studied. This method is not time-consuming, but it does not allow using FE simulation for complex geometries and obtaining accurate predictions of billet behavior. Three different ways to couple the FE billet model and press model were defined for the forging process: offline coupling, model integration, and co-simulation [5]. Offline coupling simulates the machine and billet behavior in separate environments, the results of one of which is used for the calculation of the other. Model integration simulates the machine and billet behavior in the same environment allowing direct interactions. But simple machine model is required to keep a reasonable calculation time. Furthermore, the co-simulation is a mix of the previous methods, where the machine and billet behavior are simulated in different environments but linked with a third software that manages a synchronized cycle. Kroiß [6] developed an integrated model considering the interactions between billet, tools, and machine for a cold forging application. Optimization was realized on the die dimensions and punch position to obtain high workpiece accuracy. A coupled multibody-finite element simulation (MBS-FEM) for sheet metal forming application was developed [7]. From a 3D CAD of the press structure, the MBS model of a mechanical press was established after several assumptions on press part geometries. A mass was attributed to each element of the press and connection between each of them was defined. Then, the machine model was coupled with the FE simulation of the sheet upsetting to obtain a co-simulation of the whole forging process.

In this study, a spring-mass-damper vibration model is proposed to describe the forming operation of a screw press LASCO SPR400. The model parameters are identified with experimental measurement of load and impact velocity during a stroke without billet allowing to obtain parameters adapted to the machine–tools system. Then, the cold upsetting of a copper specimen is experimentally performed to validate the prediction of the model. Furthermore, two simulations are performed independently. First, a FE simulation of the copper upsetting is realized with no

consideration of the elastic and damping behavior of the machine and tools. This simulation provides a relation between billet height and forging load. Then, a second simulation with the spring-mass-damper model using the relation between load and billet height from FE simulation as input is performed. The results from the second simulation are compared with the experimental measurement concerning load and ram displacement and the simulated energy distribution during the forging process is studied.

2 Method

2.1 Definition of the Model and Identification of Associated Parameters

2.1.1 Experimental Protocol

The screw press of the study is the LASCO SPR400 from the Vulcain platform in Metz, France. The press has a portal frame structure and is equipped with a direct electric drive motor providing the forging energy. A load sensor constituting strain gauges is fixed on the lower toolholder of the press. The lower tool is directly screwed on the load sensor and the upper tool is fixed to the upper toolholder. In order to study the press behavior, a stroke without a billet is performed experimentally; in this case, the shock is generated by the collision between the upper and the lower tools. One stroke settled to reach 9% of the maximum press stroke energy is performed. Load signals from the sensor and ram displacement are recorded during the blow. The ram displacement is obtained with a magnetic coding system integrated into the machine (Fig. 1).

The ram velocity when the upper tool impacts the lower tool is deduced from the ram displacement. The numerical derivative of the ram displacement provides a large error for the evaluation of the ram velocity because of the short time period of the measurement (0.1 ms). One way to reduce this error is to fit the displacement curve with a differentiable function and derive it analytically to obtain velocity [8]. The 20 ms before the impact between the upper tool and the billet is considered. The displacement curve is fitted by a quadratic function with MATLAB® and the function *polyfit*. The derivative of the quadratic function is calculated and is evaluated at the moment of the contact between the tool and the billet. It provides an impact velocity equal to 0.20 m/s.

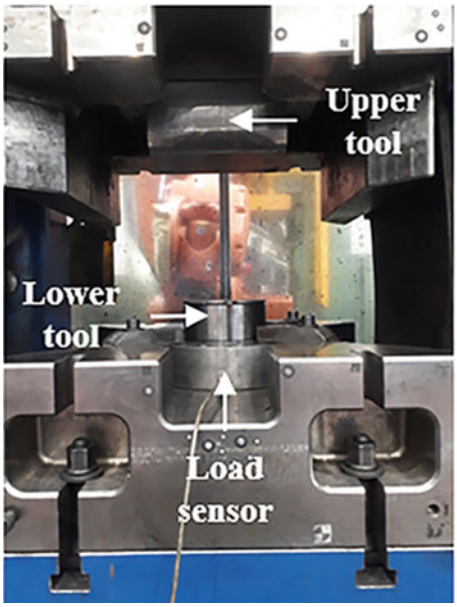

Fig. 1 View of the experimental assembly in upper dead point position. (Color figure online)

2.2 *Model of the Stroke Without Billet*

A two-degree-of-freedom spring-mass-damping vibration model is proposed to describe the press behavior during a stroke without billet (Fig. 2). This model constitutes two masses, two dampers, and three springs. The two masses represent the part in motion in the system (tools, toolholders, ram, screw, and flywheel). The spring k_{Moving} and the damper c_{Moving} link the two masses and model the elastic deformations and damping effects between the parts in motions in the system. The spring k_{Fixed} and the damper c_{Fixed} model the elastic deformations and the damping effects of the frame. During the experiment (cf. Sect. 2.1.1), a load sensor is placed on the stable of the press to be impacted by the upper tool. This sensor has an influence on the system behavior and needs to be considered. Hence, the spring k_{Sensor} is introduced in the model. This spring is linked to mass 1 and the fixed part.

The application of the fundamental principle of the dynamics to the mass 1 and the mass 2 provides the dynamic equations of the system as presented in Eqs. (1) and (2). The spring k_{Sensor} and the Kelvin-Voigt system consisted of the spring k_{Fixed} and the damper c_{Fixed} which are in series. Thus, the load applied to the spring k_{Sensor} and the Kelvin-Voigt system is the same. This equality is written in Eq. (3).

$$m_2\ddot{X}_2 = -k_{\text{Moving}}(X_2 - X_1) - c_{\text{Moving}}\left(\dot{X}_2 - \dot{X}_1\right) \tag{1}$$

$$m_1\ddot{X}_1 = k_{\text{Moving}}(X_2 - X_1) + c_{\text{Moving}}(\dot{X}_2 - \dot{X}_1) - k_{\text{Sensor}}(X_1 - X_{\text{Fixed}}) \tag{2}$$

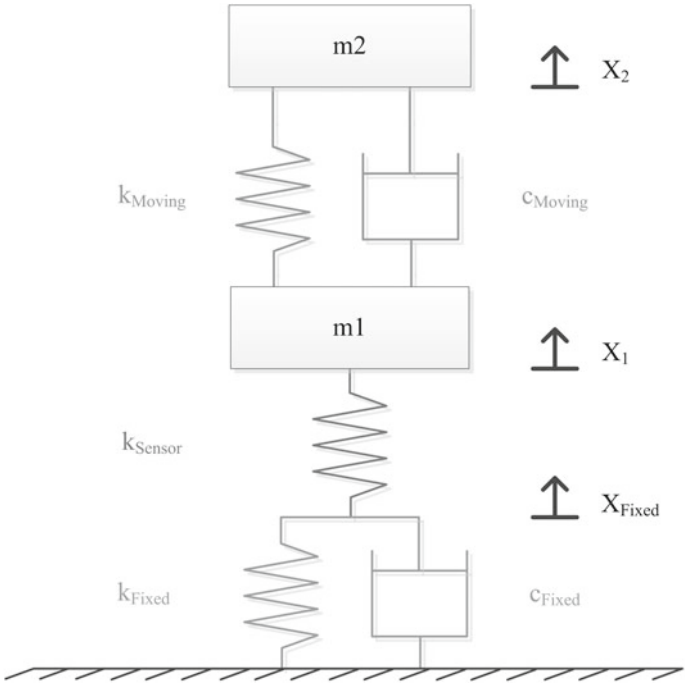

Fig. 2 Model of the screw press and load sensor system for a stroke without billet

$$-k_{\text{Sensor}}(X_1 - X_{\text{Fixed}}) = -k_{\text{Fixed}}X_{\text{Fixed}} - c_{\text{Fixed}}X_{\text{Fixed}} \tag{3}$$

where X_1 is the displacement of the mass 1, X_2 is the displacement of the mass 2, and X_{Fixed} is the displacement of the upper point of the spring k_{Fixed} according to their position at $t = 0$. The stiffness k_{Sensor} is obtained from the sensor manufacturer documentation and is equal to 6.67 GN/m. The initial velocity of the masses 1 and 2 is fixed to 0.20 m/s as in experimental conditions. The model is implemented in MATLAB SIMULINK and the numerical solution of the equations of the model is obtained with the fixed-step solver ode8 (Dormand-Prince method).

2.3 Parameters Identification

The identification of the model parameters is realized with the MATLAB module "Parameter Estimation". The load signal simulated at the spring k_{Sensor} is fitted to the load signal measured with the sensor during the experiment. The program starts to solve the model equations to obtain a numerical solution, and the squared error between the experimental signal and the numerical solution is calculated. This cost

Table 1 Model parameters

m_1	2471 kg
m_2	117 150 kg
c_{Moving}	1.51×10^5 N.s/m
c_{Fixed}	0 N.s/m
k_{Moving}	2.26×10^9 N/m
k_{Fixed}	4.86×10^9 N/m

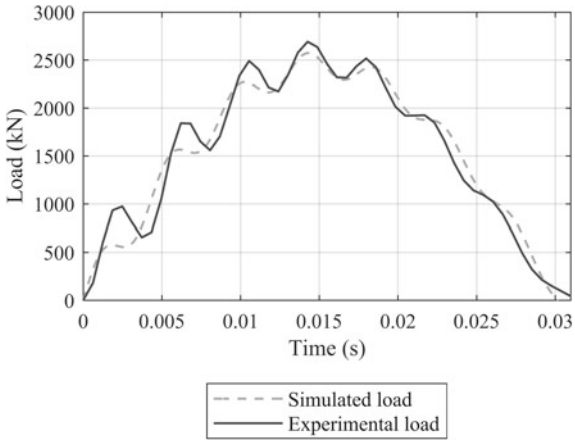

Fig. 3 Experimental and fitted load signals

function is minimized according to the trust-region-reflective algorithm and provides model parameters presented in Table 1.

The experimental load signal and the simulated load to the spring k_{Sensor} with parameters from Table1 are presented in Fig. 3.

2.4 Validation of the Predictive Capacity of the Model for Copper Cylinder Upsetting

2.4.1 Experimental Protocol

The experimental assembly is the same as presented in Sect. 2.1.1, but in this case the cold upsetting of a copper billet is performed. The specimen is a cylinder of 29.9 mm diameter and 59.7 mm length placed on the lower tool. No lubricant is used during the experiment. Concerning process settings, the velocity of the ram is regulated before the impact to provide 60% of the maximum press energy. The load from the sensor and the ram displacement are recorded during the stroke. The method presented in Sect. 2.1.1 is used to estimate the impact velocity equal to 0.51 m/s. The final billet height is measured and is equal to 19.8 mm.

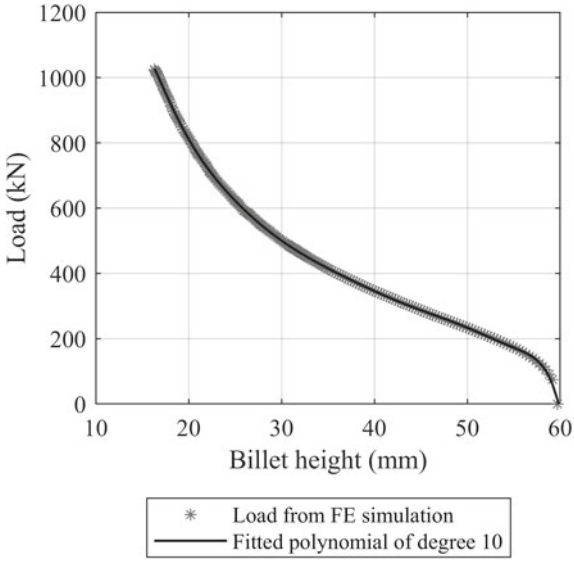

Fig. 4 Load as a function of the billet height from FE simulation and fitted polynomial of degree 10

2.4.2 FE Simulation for the Determination of the Forging Load as a Function of the Billet Height

The upsetting of a copper cylinder of 29.9 mm diameter and 59.7 mm high is simulated with the FE software Forge® NxT 2.1. The material behavior is described by a constitutive law of Hansel-Spittel whose parameters are selected from the database of the software. Friction behavior is modeled by Coulomb limited Tresca model. The friction coefficients are defined and are equal to $\mu/\overline{m} = 0.15/0.26$. Thermal exchanges with air and dies are considered. The associated heat transfer coefficients are, respectively, equal to 10 $W.m^{-2}.K^{-1}$ and 10 $kW.m^{-2}.K^{-1}$. A 2 mm size tetrahedra element is chosen for the mesh. Elastic and damping effects due to the machine–tools system are not considered in this simulation. Results from FE simulation allow obtaining the forging load as a function of the billet height for the interval from 16.3 to 59.7 mm. In order to use the simulated forging load with the spring-mass-damping model, it is required to express the forging load as a continuous function of the billet height. For this purpose, the load from the FE simulation is fitted by a polynomial of degree 10 noted as P (Fig. 4).

2.4.3 Billet-Interface-Machine (BIM) Model

For the simulation of billet upsetting, the spring-mass-damping model is completed as presented in Fig. 5.

The application of the fundamental principle of the dynamics to the mass 1 and the mass 2 provides the dynamic equations of the press system in Eqs. (4) and (5).

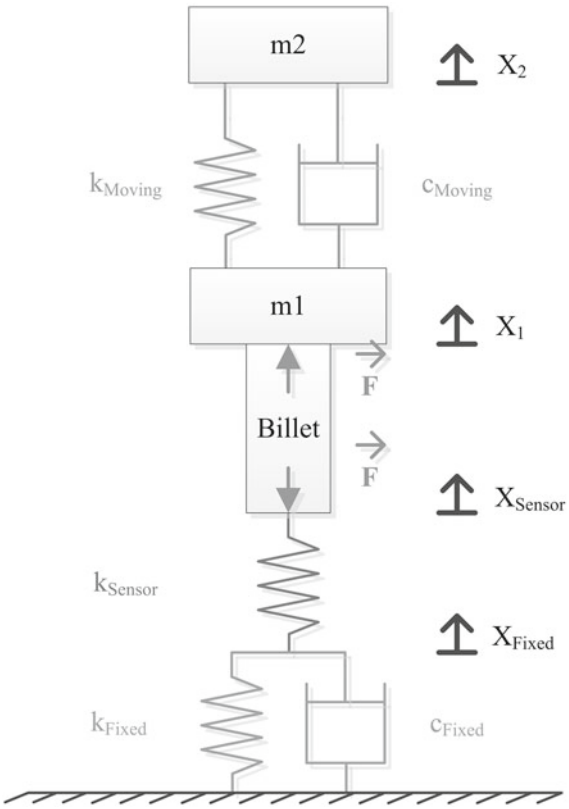

Fig. 5
Billet-Interface-Machine (BIM) model

The spring k_{Sensor} is directly linked to the billet, thus the forging load from the billet is directly applied to the spring, and the relation is written in Eq. (6). Equation (7) is obtained as explained in Sect. 2.2.

$$m_2\ddot{X}_2 + k_{\text{Moving}}(X_2 - X_1) + c_{\text{Moving}}\left(\dot{X}_2 - \dot{X}_1\right) = 0 \tag{4}$$

$$m_1\ddot{X}_1 - k_{\text{Moving}}(X_2 - X_1) - c_{\text{Moving}}\left(\dot{X}_2 - \dot{X}_1\right) = -F \tag{5}$$

$$-k_{\text{Sensor}}(X_{\text{Sensor}} - X_{\text{Fixed}}) = F \tag{6}$$

$$-k_{\text{Sensor}}(X_{\text{Sensor}} - X_{\text{Fixed}}) = -k_{\text{Fixed}}X_{\text{Fixed}} - c_{\text{Fixed}}X_{\text{Fixed}} \tag{7}$$

where X_1 is the displacement of the mass 1, X_2 is the displacement of the mass 2, X_{Sensor} is the displacement of the upper point of the spring k_{Sensor}, and X_{Fixed} is the displacement of the upper point of the spring k_{Fixed} according to their position at $t =$

0. As it can be seen, the reaction force from the billet F is required to perform the simulations of the billet upsetting. F is calculated for each increment of the simulation with the polynomial P identified in Sect. 2.3.2. At each moment, the billet height can be expressed by $X_1 - X_{\text{Sensor}} + h_0$ with h_0 the initial billet height. Thus, the load can be calculated such as $F = P\,(X_1 - X_{\text{Sensor}} + h_0)$.

The model is called "Billet-Interface-Machine" (BIM) model because it allows the coupling of these three aspects in simulation. The billet behavior and the impact of friction at the interface between material and tools are considered, thanks to the expression of the forging load from the FE simulation. Furthermore, the machine–tools behavior is described by the spring-mass-damping model which considers damping effects and elastic strains in the system. The BIM model is implemented on MATLAB® SIMULINK® with the parameters from Table 1. The simulation parameters are the same as presented in Sect. 2.2. The numerical simulation is realized by fixing the initial velocity of both masses to −0.51 m/s as in the experimental conditions.

3 Results and Discussion

The load measured by the sensor and the simulated load for k_{Sensor} are presented in Fig. 6. During the forging process, the simulation underestimates the load compared to the experiment before 0.06 s. Then, a slight difference can be noticed between

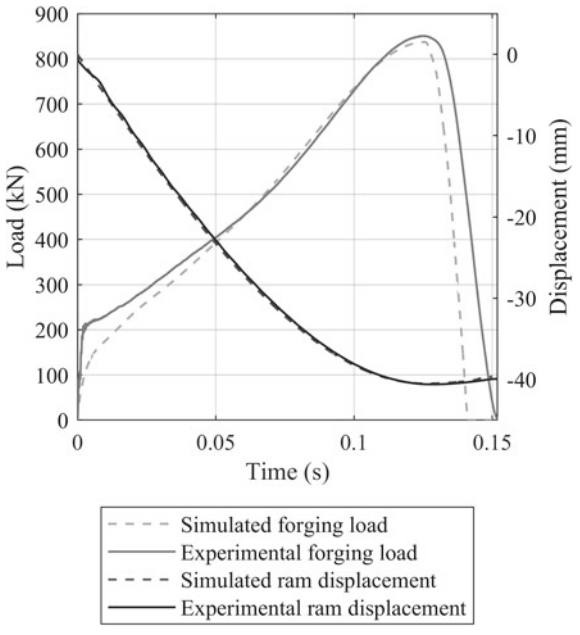

Fig. 6 Forging load and ram displacement measured with the load sensor and press displacement sensor, load in k_{Sensor}, and ram displacement simulated for the upsetting of copper cylinder upsetting

experimental and simulated load until reaching the maximum blow force with a maximum relative deviation of 2.5%. The maximum blow force predicted by simulation is 1.5% lower than the measured value. The forging time, defined as the time to reach the maximum blow force, is equal to 124.7 ms in the experiment and 125.8 ms in the simulation, giving a relative deviation of 0.01%. After reaching the maximum blow force, bigger differences are observed between simulation and experimental results. The simulated spring back time equal to 15.3 ms is smaller than the experimental spring back time equal to 27.8 ms. This means a relative deviation equal to 45%. Figure 6 also shows the ram displacement obtained by experimental measurement and by simulation. 0 corresponds to the initial contact between the tool and the billet. The ram displacement is accurately predicted by the simulation during the whole forging process. The minimum experimental and simulated displacements show a relative deviation of 0.3%. From the moment of the contact between the tool and the billet to 25 ms, damped vibrations can be observed on the experimental ram displacement. The amplitude of the vibration is very low compared to the global signal. No vibrations can be observed on the simulated signal. In the simulation, the final billet height is estimated to be 19.5 mm, meaning a relative deviation of 1.5% compared to the experimental result. It can be noted that the billet height simulated with the BIM model is always in the interval of identification of the polynomial *P*.

The distribution of the energy of the system for each blow is presented in Fig. 7. The model considers four types of energy: the kinetic energy of the masses, the elastic energy stored by the springs, the damped energy dissipated by the dampers, and the billet energy considering the plastic energy and the energy dissipated in the friction between the tools and the material. At the beginning of the stroke, all the energy is coming from the motion of the two masses. Thus, the energy is purely kinetic and can be calculated as $½.(m_1 + m_2).v_0^2$.

It can be observed from Fig. 7 that until reaching the maximum blow force the kinetic energy decreases during the forging process, whereas the billet energy and the elastic energy increase. Then, the billet energy remains constant while the kinetic energy increases and the elastic energy decreases. Concerning damped energy, it never exceeds 0.02% of the total energy. 98% of the initial kinetic energy is converted into billet energy at the end of the forging process. This value represents the efficiency of the stroke. During the blow, 2% of the available energy is turned into elastic energy. After reaching the maximum blow force, the elastic energy is turned again into kinetic energy in the acceleration of masses 1 and 2 in the opposite direction of the stroke.

Results have shown that the forging load and the ram displacement can be predicted by the simulation. The determination of the forging load with FE simulation and a fitted polynomial is suitable to simulate the whole forging process. The FE simulation allows obtaining the forging load in ideal conditions, i.e., with no consideration of the press behavior. Then, the second numerical simulation allows determining the part of the stroke energy transmitted to the machine–tools system and process variables associated with the operation.

In our case, the machine–tools system has a small impact on the forging process. Indeed, only 2% of the initial stroke energy is turned into elastic energy. The experimental study case corresponds to a soft blow, where most of the available energy is

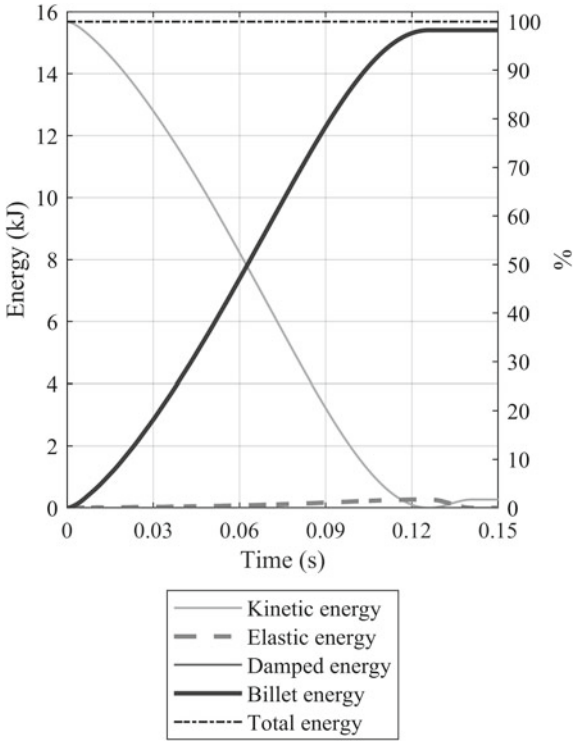

Fig. 7 Distribution of the energy for one simulated blow on a copper specimen

transmitted to the workpiece. For soft blows, small loads and large billet deformations are noticed [9]. Thus, the model provides a good representation of the energy distribution during the forging process. As the energy transmitted to the billet can be predicted by the simulation, it is possible to assess the efficiency of the blow.

It was noticed that the damped energy remains very low compared to the stroke energy. For this given forging operation, the damped energy can be neglected. As can be observed from Table 1, the damping effect is only caused by the relative displacement between the masses because k_{Fixed} is equal to 0. In the case of a soft blow, vibration modes are not activated enough and the relative displacement between the masses is too low to dissipate a significant part of the stroke energy in the damper. For hard blows [9], the damped energy might be more important and could become significant.

In this study, the forging operation is the cold upsetting of a copper cylinder. It simplifies the experimental protocol by allowing to neglect thermal effects, thus the measurement of the billet temperature and the transfer times are not required. Simulations of a more complex workpiece for hot materials could be intended. However, it is needed to keep an axisymmetric geometry for the workpiece because the press behavior is only considered for the vertical axis of the press in the model. Thus, this methodology brings a new way to cross the FE model and spring-mass-damper

press model without the need to couple two softwares. The consideration of the energy dissipated in the dynamic effects in the machine implies an improvement of the accuracy of the numerical simulations and a better prediction of the process variables.

4 Conclusions

This study presents an experimental methodology to model forming operations in the case of a screw press. Model parameters were identified with the measurement of the ram impact velocity and the load during a stroke without billet. Then, independent simulations crossing a FE model and the spring-mass-damper model for copper cylinder upsetting were performed. FE simulation allowed determining a relation between load and billet height used as an input of the simulation performed with the spring-mass-damper model. Experimental copper upsetting was led with the measurement of the load and ram displacement. Simulation results show a good agreement with experimental measurements. The following conclusions were drawn:

1. Measurements of the ram impact velocity and the forging load during a stroke without billet are enough to determine specially adapted model parameters for the screw press.
2. The use of FE simulation to predict the forging load required for the simulation of the forging process with a spring-mass-damper press model is suitable to predict the process variables. It provides a complete representation of the system without developing a coupling between two software.
3. The model of the whole forging process can predict the distribution of the energy in the system during the forging process. Thus, it is possible to determine the part of the stroke energy transmitted to the billet and calculate the blow efficiency for a given forging operation.

Acknowledgments The authors would like to express their sincere appreciation to Sebastien Burgun and Alexandre Fendler for their technical support in the realization of the experimental protocols. Moreover, they wish to thank MANOIR INDUSTRIES for their financial support in this research project.

Optimization of Open-Die Forging Using Fast Models for Strain, Temperature, and Grain Size in the Context of an Assistance System

Fridtjof Rudolph, Martin Wolfgarten, Viktor Keray, and Gerhard Hirt

Abstract Besides achieving the intended final shape, one main aim of open-die forging is the adjustment of the mechanical properties by transforming the cast structure into a fine-grained microstructure. To achieve this, the process needs to be designed in a way that ensures achieving all the required part properties, such as grain size, which up to now often requires a lot of operator experience. This paper presents the concept of a forging assistance system, since during forging small deviations from the previously designed pass schedule might add up to unacceptable errors. Such an assistance system requires the evolution of part geometry and surface temperature as input, which are captured with a thermographic camera. The assistance system then uses fast models for equivalent strain, temperature, and microstructure which allow calculation of these properties for the core fibre within seconds on the basis of semi-empirical and physical formulae. However, in the context of an assistance system, which gives real-time advice in case of process deviations, these calculation times are still fairly long, if the hundreds of iteration necessary for process optimization are taken into account. Therefore, three scenarios of deviations, which have to be solved within different time frames, are examined to explore the limits of the chosen classical optimization algorithm.

1 Introduction

The main goal of open-die forging besides achieving the desired geometry is to improve the mechanical properties by transforming the inhomogeneously solidified cast structure into a fine-grained microstructure. In order to guarantee excellent properties, the forging process must be designed in such a way that a certain temperature window is maintained during the process and a sufficiently large deformation needs to be introduced into the part to enable this transformation.

Nowadays, these part properties can be calculated and new open-die forging processes can be designed with the aid of either finite element analysis (FEA) or with fast models based on semi-empirical and physical formulae. FEA enables analysing of all parameters relevant for forming technology, but is very complex and time-consuming, while the fast models calculate only the most important process parameters in open-die forging for the core fibre of the workpiece in short calculation times.

However, in the case of unplanned process deviations, the previously designed process layout may be invalid and the desired properties can only be achieved by adjusting the pass schedule. In this paper, the application of fast models for temperature, equivalent strain, and microstructure in an assistance system is examined on the basis of three different process deviations. These show under which conditions the optimization still provides a satisfying adjustment of the pass schedule, which comprises the term assistance system in the context of this paper.

2 Assistance Systems

Over the last decades, several approaches for assistance systems for open-die forging have been developed. Siemer and Kopp [1] developed a fast model for offline and online calculation of open-die forging processes. The aim of this model is to design processes with a homogeneous equivalent strain distribution and to monitor the correct process sequence online. The calculation system consists of a specially developed spread model, a strain model, and a heat balance calculation. Press force, press velocity, temperatures, manipulator positions, as well as billet length were recorded in order to enable the online calculation of the equivalent strain. Temperature and microstructure are not taken into account.

In [2] and [3] Grisse and Heischeid present the model “Forge to Limit”, which was integrated into the control of a forging manipulator to demonstrate the online capability. The goal is to maximize the increase in length by minimizing the spread. In addition, the model can be used to optimize forging sequences with respect to a reduction of process time. Billet properties such as strain and temperature are not considered.

Elbadan [4] developed an automatic forging cell, which is able to design and implement the appropriate forging sequence inversely based on a defined target geometry.

During the process, a comparison between target and actual geometry is made by measurement with an end-effector after each stroke. If necessary, the process route is adapted fully automatically taking into account the technical boundary conditions. The online adaptation of the forging sequence is based on a fast model for geometry calculation using the upper bound method, therefore this system is limited to geometry adaptation.

The industrially available measuring system "LaCam" from Minteq Ferrotron Division [5, 6] has a fast calculation model for strain in the core for drawing out. The system is capable of displaying the current core consolidation per stroke and for the entire process using the billet geometry and the measurement data of the forging press. With regard to an assistance system, suggestions are made to the press operator as to where the next strokes should be positioned to ensure uniform equivalent strain over the entire length of the ingot. Temperature and microstructure are not taken into consideration.

Pelster and Blei [7] developed a fast model for the design and online monitoring of the geometry change, temperature, and microstructure for radial forging. The models are linked to the "ComForge" pass schedule calculation program. The 1D FEM temperature model is corrected by a heat balance calculation by Paukert [8]. The 2D equivalent strain model is also based on [8] and additional FEM simulations. The software calculates the equivalent strain distribution depending on the bite ratio and the true strain. For the microstructure calculation, the program MatILDa from GMT is used, which is integrated into the FEM software Simufact.

3 Fast Modelling in Open-Die Forging

Four of the presented assistance systems for open-die forging are limited to geometry and strain calculation. The fifth system for radial forging takes the microstructure into account but only for documentation purpose due to the long calculation times [7]. To close this gap for open-die forging, models for temperature, equivalent strain and microstructure with short computation times have been developed in the past. As these models build the foundation of the assistance system presented in this work, they are presented in more detail.

Rosenstock et al. [9] presented a temperature model for open-die forging based on the finite difference method (FDM), which can calculate the 3D temperature field for the entire process and workpiece geometry including cooling. The model takes all relevant phenomena into account: radiation, convection, heat conduction to tools and the environment, as well as dissipation.

One of the first fast models for the equivalent strain in the core fibre during forging was presented by Stenzhorn [10] and it allows the rough estimation of the strain distribution by linear approximation. An extended model was published by Recker et al., who used this model for the calculation of the equivalent strain for more than one pass for three-dimensional forging [11] based on FEM studies. The equivalent

strain for each stroke is described with a $\sin^2$ function which is superpositioned to obtain the distribution of the equivalent plastic strain for the whole process.

The semi-empirical program "StrucSim" for microstructure calculation was developed by Karhausen [12]. Using the input parameters such as temperature, equivalent strain, and equivalent strain rate, material properties such as austenite grain size and recrystallized fraction are calculated based on constitutive equations. The microstructure of the component is divided into a recrystallized and a non-recrystallized fraction at each time step according to the Johnson–Mehl–Avrami-Kalmogorov (JMAK) equation. For process such as open-die forging, the results of the fast models can be used to calculate the microstructure evolution in the core fibre for the whole process. The temperature and equivalent strain models were validated by comparison with results from a validated FEM model [13], while the microstructure model was validated directly with experiments [14].

4 Process Design Using Fast Models

The pass schedule calculation was implemented by coupling the above-presented models for temperature, equivalent strain, and microstructure with a geometry-based pass schedule calculation in MATLAB [11, 15]. This enables manual designing of pass schedules according to part properties. The procedure for process design is as follows.

First, the user defines the general process parameters (bite ratio, final workpiece geometry, material, etc.) as well as starting and boundary conditions (e.g. starting geometry and temperature as well as maximum press force), as is the case for conventional pass schedule calculation programs. Second, the software generates a pass schedule considering all input variables and provides the process sequence on a time axis for the fast models. Third, the fast models calculate the temperature and equivalent strain along with the process, which enables the calculation of microstructure for each stroke. Lastly, the results including a pass schedule and additional information are presented to the user in the graphical user interface (GUI), and the user can decide to repeat this process with different settings to manually optimize the process. As the calculation times for a conventional forging process with 8 passes and 170 strokes are less than 3 s (Intel Xeon E3-1240 v6), many of such cycles are possible in a comparatively small timeframe.

5 Process Monitoring

The fast calculation times allow for the process parallel calculation of temperature, microstructure, and equivalent strain in the core fibre from live measurement data. For this purpose, the change in length per stroke and the spatial billet position are needed as input for the equivalent strain model. Additionally, the surface temperature

is needed to calibrate the temperature model during the process to achieve maximum accuracy for the microstructure calculation. The software can be used either to document the forging process or as a decision support system for the operator by providing additional information or as necessary input data for an assistance system. As a proof-of-concept, Rosenstock et al. [14] connected the fast models via TCIP/IP with a "LaCam" forge system and performed two industrial forging processes. The model results were validated with metallographical grain size measurements of the finished forged billets.

For measurement a high-resolution thermographic camera can also be chosen, as it allows providing information about the elongation via edge detection algorithms and additionally generates surface temperature data to adjust the temperature fields. The measurement results are used as input for the fast models and the results are presented to the user in a GUI seen in Fig. 1. With this, detection and documentation of process deviations are possible, which consequently provides the basis for adjusting the ongoing process if deviations occur.

6 Process Optimization

A process optimization in the context of an assistance system is possible with the presented process planning and monitoring methods, as shown in Fig. 2. In case of a deviation from the planned process sequence, the models could be used to adjust the pass schedule online due to their short calculation time. The fast models may be used to calculate the current properties of the part during the forging process and to compare them with the expected properties of the previously specified pass schedule. Subsequently, in the event of a deviation, e.g. due to an operating error, the pass schedule can be adapted so that the desired properties can still be achieved despite the deviation. It is, however, unknown which process deviation can be solved within a certain time limit. Therefore, in this paper, an optimization approach is investigated regarding solvability and computing times for different process deviations.

Like the manual optimization described above, it is possible to use optimization algorithms for process layout and online optimization. The optimization loop follows the basic structure shown in Fig. 3. The user must provide the optimizer with a starting point and an upper and lower limit for the input parameters. The input parameters are the furnace temperature, transport time from the furnace to press, waiting time between passes, bite ratios as well as height reductions, press speed, and tool temperature. The non-variable process variables, such as start and target geometry, must also be specified. Lastly, the user defines the boundary conditions, e.g. maximum press force or maximum grain size. After a pass schedule is calculated, the corresponding equivalent strain, temperature, and microstructure are determined. After one loop, the algorithm evaluates the process and restarts the calculation with a new set of input parameters if the termination condition, e.g. time limit or finding of an ideal parameter set, is not fulfilled.

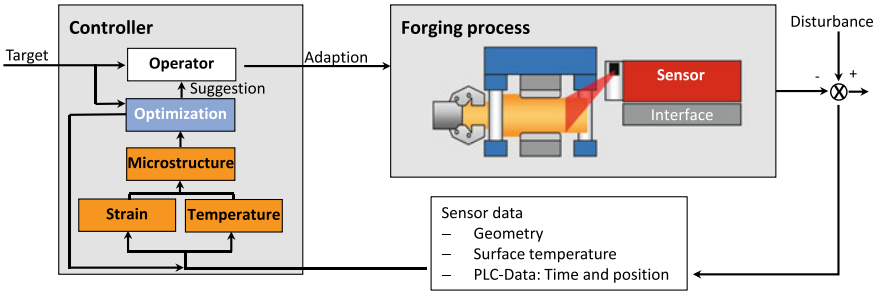

Fig. 2 Concept of an assistance system in open-die forging. (Color figure online)

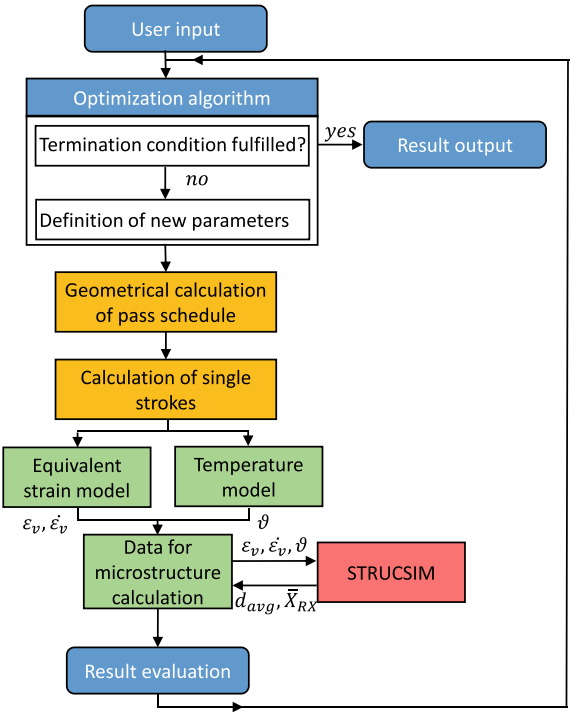

Fig. 3 Optimization loop for property-based pass schedule calculation. (Color figure online)

Since forging is an incremental forming process with up to many hundred forming steps, a single geometry can be achieved with an almost infinite number of process variants, which in turn leads to a very wide range of possible pass schedules. Additionally, the relationship between input parameters and their effect on the final workpiece properties is very complex, since a single parameter might influence the whole process. For example, the bite ratio b_w has an influence on the value as well as the homogeneity of the equivalent strain, press force, the recrystallization of the material, and process time. With a change in process time, the temperature changes

and influences the grain growth and recrystallization kinematic as well. Also, most input parameters such as height reduction, bite ratio, and press speed can be varied individually for each of them up to several hundred forming steps. Therefore, the optimization problem is characterized by the high complexity of open-die forging.

Due to the complex and unsteady transfer function between input and output parameters of the fast model, gradient-based optimization algorithms are not necessarily appropriate since they are fast, but often accept a local minimum as a solution too early. Therefore, the deterministic method "patternsearch" is used, which is integrated into MATLAB and offers a good compromise between solution speed and optimization quality. The method is based on the fact that with each iteration input variables are changed in the positive and negative directions by a step size within the upper and lower limits, and it is checked whether there is an improvement of the objective function. If this check is successful, the determined point is the starting point for the following iteration. If this iteration is not successful, the step size is reduced or increased. Termination conditions for the algorithm include a certain number of iterations, a time span, or if the search pattern falls below a specified minimum step size.

6.1 Definition of the Cost Function

Besides the basic structure of the optimization loop and the selection of the optimization algorithm, the result of the optimization is primarily dependent on the cost function, which was demonstrated for open-die forging in [14]. The cost function is divided into a target function, which assesses the quality of the result, and a penalty function, which punishes the violation of boundary conditions.

The selected targets and boundary conditions are listed in Table 1, where a low value symbolizes a better solution. The aim of the optimization is to achieve good and homogeneous part properties with respect to the microstructure and the equivalent strain as well as general process parameters, such as furnace temperature and process time. The individual terms of the target function are weighted so that parameters with low scalar values such as the equivalent strain are considered equally by the optimizer. The exact values of the different weights are chosen experience based on the user. The overall target function is the sum of the individual target terms. In contrast to a multiplicative operation, this has the advantage that converging a term towards zero does not result in the entire target function striving towards zero.

The possible solutions to the optimization problem are limited by the boundary conditions, which must not be violated. The boundary conditions are weighted with a pre-factor and an exponent. This ensures that the algorithm tries to keep the press limits, the forging temperature window, and the minimal workpiece properties to be achieved. Finally, the quality of the result is evaluated by the sum of the target and penalty function and depending on the result, the optimization is aborted or the next run of the optimization loop is started.

Table 1 Target values and boundary conditions

Target	Target term
High mean equivalent strain in the core fibre $\overline{\varepsilon}$	$c_1 = 1.000 \cdot \frac{1}{\overline{\varepsilon}}$
Low standard deviation of equivalent strain s_ε	$c_2 = 10.000 \cdot s_\varepsilon$
Low mean austenitic grain size in the core fibre $\overline{d}$ in µm	$c_3 = 10 \cdot \overline{d}$
Low standard deviation of austenitic grain size s_d in µm	$c_4 = 100 \cdot s_d$
Short process time t_S in s	$c_5 = t_S$
Low furnace temperature ϑ_F for the forging process depending on the allowed minimum temperature ϑ_{min} in °C	$c_6 = (\vartheta_F - \vartheta_{min})$
Boundary condition	*Penalty term*
Bite width b_w always smaller than tool width B in mm	$s_1 = \left(\sum_{i=1}^{n} \max\left\{\left(b_{w0,i} - B\right), 0\right\}\right)^4$
Surface temperature after forging $\vartheta_{n,O}$ larger than the allowed minimal forming temperature ϑ_{min} in °C	$s_2 = \max\left\{\left(\vartheta_{min} - \vartheta_{n,O}\right), 0\right\}^4$
Maximum ingot temperature during the whole process $\vartheta_{i,Feld}$ smaller than the allowed maximum forming temperature ϑ_{max} in °C	$s_3 = \max\left\{\left(\max\left\{\vartheta_{i,Feld}\right\} - \vartheta_{max}\right), 0\right\}^4$
Forging force F_i always smaller than maximum press force F_{max} in N	$s_4 = 10 \cdot \left(\sum_{i=1}^{n} \max\{(F_i - F_{max}), 0\}\right)^6$
Highest austenitic grain size after cooling d smaller than the maximal allowed grain size d_{max} in µm	$s_5 = 10 \cdot \max\{(\max(d) - d_{max}), 0\}^4$
Smallest equivalent strain ε larger than minimal allowed equivalent strain ε_{min}	$s_6 = 100 \cdot \max\{(\varepsilon_{min} - \min(\varepsilon)), 0\}^4$

6.2 Reference Process Without Deviations

At first, an industrial-scaled open-die forging process was numerically investigated. The chosen process parameters and boundary conditions are summarized in Table 2. As a material the most common tempering steel 42CrMo4/1.7225 was chosen due to its large industrial relevance. The material data, i.e. flow curve and microstructure model, were obtained by experiment, metallography and the remaining properties, such as specific heat capacity, conductivity, and Young's modulus were taken from the literature [16].

No time limit for the optimization algorithm was chosen since this reference pass schedule shown in Table 3 will be used to benchmark the quality of the adapted pass schedules, i.e. the quality of the reaction to process deviations. The maximum forging force limits the maximum available height reduction and bite ratio. Therefore, an average bite ratio of 0.32 and a height reduction of 12.2% were chosen by the algorithm. The total optimization time was 4.7 h.

Table 2 General parameters and boundary conditions for the investigated process

Ingot
Geometry of the ingot (h x w x l): 800 × 800 x 1200 mm
Target geometry (h x w x l): 470 × 470 x 3477 mm
Surrounding temperature: 25 °C
Emissivity: 0.85, Heat transfer coefficient to surrounding: 35 W/(m^2·K)
Forging dies
Assumed die temperature (constant): 300 °C; Press velocity: 100 mm/s
Heat transfer coefficient between forging dies and ingot: 4,000 W/(m^2·K)
Boundary Conditions
Die width: 2000 mm (Radius 200 mm on each side)
Assumed maximum forging force F_{max}: 25 MN
Assumed maximum ϑ_{max}/ minimum forging temperature ϑ_{min}: 1250/850 °C
Minimum allowed equivalent strain ε_{min}: 2.0
Maximum allowed grain size d_{max}: 175 µm

Table 3 Reference pass schedule

Input parameters	Pass									
	1	2	3	4	5	6	7	8	9	10
ε_h in %	12.4	12.1	12.4	12.1	12.3	12.0	12.5	12.2	12.4	12.1
s_{B_0}/h_0	0.31	0.33	0.31	0.33	0.30	0.33	0.30	0.32	0.31	0.33
Force F_i in MN	24.68	23.30	23.28	22.70	22.18	21.33	24.23	23.82	22.88	24.96

Using the target and penalty terms in Table 1, the cost values in Table 4 were calculated. The average equivalent strain is 2.10 with a very small standard deviation of 0.01. Similarly, the grain size is very homogeneously distributed with an average value of 165 µm and a standard deviation of 1.1 µm. The total process time without cooling is 872 s and the furnace temperature of 1034 °C was chosen. The total cost value q_{tot} is 3414 according to the cost function given in Table 1, where a lower value indicates a better optimization result.

All boundary conditions are fulfilled and lead to no penalty for the cost function, which has a high priority since any violation of the boundary conditions results in a very high penalty. A closer evaluation of the boundary conditions shows that each condition is only barely fulfilled. Therefore, the algorithm has very little freedom to adapt process parameters that are directly checked in the boundary conditions, e.g. the temperature.

Table 4 Results and corresponding cost values

	Result	Cost value
Boundary conditions s_1, s_2, s_3, and s_4		0
Mean equivalent strain $\overline{\varepsilon}$	2.10	$c_1 = 476.18$
Standard deviation of equivalent strain s_ε	0.01	$c_2 = 113.01$
Minimal equivalent strain $\varepsilon_{\min}$	2.06	$s_6 = 0$
Mean austenitic grain size $\overline{d}$ in µm	165	$c_3 = 1655.51$
Standard deviation of austenitic grain size s_d in µm	1.1	$c_4 = 113.91$
Maximal austenitic grain size $d_{\max}$ in µm	167	$s_5 = 0$
Process time t_S in s	871.6	$c_5 = 871.60$
Furnace temperature ϑ_F in °C	1034	$c_6 = 183.96$
Total target $\sum c_i$		3414
Total penalty $\sum s_i$		0

6.3 Different Process Deviations

The presented vision of an assistance system for open-die forging can observe the process deviations online during the process. There are many different possible deviations that need to be handled individually in the given timeframe. This means, however, that the assistant system must be able to differentiate the various deviations and chose appropriate optimization settings for each one. Therefore, three different process deviations of the above-optimized process are examined:

(a) Due to an error in one of the hydraulic pumps, the maximum press force is reduced by 20%. The error is known a few hours in advance and the optimizer has time for several thousand iterations. ($F_{\max} = 20$ MN, maximum calculation time: 4 h.)
(b) The manipulator control system crashes and it takes 20 min to fix the problem while the workpiece is already taken out of the furnace. (Transport time + 1200 s, maximum calculation time: 20 min.)
(c) The press operator chooses a height reduction of 8.4% in the third pass instead of 12.4%. The new pass schedule should be calculated as fast as possible since it is unrealistic to stop the process for a significant time. ($\varepsilon_{h,\text{pass3}} = 8.4\%$, calculation time: fastest possible.)

In Scenario (a), the above-presented optimizer can be used with an additional termination condition after 4 h of computing time. The results of the newly started optimization are shown in Table 5. The lower press force of maximal 20 MN is achieved by reducing the average bite ratio from 0.32 to 0.26. As a result, process time increases significantly, and all process objectives, such as minimum grain size, can be met. The calculation time is 3.9 h and the evaluation of the cost function is 3724, which is approx. 10% worse than in the reference process.

Table 5 Results and corresponding cost values for Scenario (a) and (b)

	Scenario (a)		Scenario (b)	
	Result	Cost value	Result	Cost value
Boundary conditions s_1, s_2, s_3 and s_4		0		1.87×10^6
Mean equivalent strain $\overline{\varepsilon}$	2.09	$c_1 = 479.25$	2.22	$c_1 = 450.99$
Standard deviation of equivalent strain s_ε	0.01	$c_2 = 141.53$	0.01	$c_2 = 104.65$
Minimal equivalent strain $\varepsilon_{\min}$	2.04	$s_6 = 0$	2.16	$s_6 = 0$
Mean austenitic grain size $\overline{d}$ in µm	168	$c_3 = 1679.49$	138	$c_3 = 1383.63$
Standard deviation of austenitic grain size s_d in µm	2.9	$c_4 = 285.71$	5.34	$c_4 = 533.91$
Maximal austenitic grain size $d_{\max}$ in µm	172	$s_5 = 0$	142	$s_5 = 0$
Process time t_S in s	942.4	$c_5 = 942.4$	1086	$c_5 = 1086.4$
Furnace temperature ϑ_F in °C	1045	$c_6 = 195.22$	1034	$c_6 = 183.96$
Total target $\sum c_i$		3724		3744
Total penalty $\sum s_i$		0		1.87×10^6

In Scenario (b), the optimization does not achieve a meaningful result in the short computing time. If the optimization is cancelled after 20 min, most of the boundary condition is not fulfilled and the total cost value is above 1×10^9. Therefore, the optimization scheme seen in Fig. 3 is slightly altered. In order to reduce the computation time, the optimization is first performed without calculating the temperature and microstructure. This leads to a pass schedule with a high and very homogeneous strain distribution in less than 180 s. This pass schedule is then used as a starting point for further optimization so that the optimization of temperature and microstructure is completed after 16.4 min.

When analysing the results in Table 5, it is noticeable that the achieved equivalent strain is larger and the grain size is smaller. The small grain size can be explained by the lower grain growth of the cooled billet. The equivalent strain in the core increases due to the pronounced temperature gradient in the forging part. The areas close to the surface have higher flow stress so that in comparison more deformation is introduced into the hotter and softer core. Two additional passes are required for forging, as the force limit of the press is reached due to the lower temperature. The total cost value without boundary conditions is 3744, which is slightly worse than the result without deviation.

Although one boundary condition is unfulfilled, the minimum surface temperature of 813 °C is lower than the lowest permissible forging temperature. This deviation leads to a penalty of 1.87×10^6. Overall, a forging process with the same results after this deviation was not found, and the user must decide whether a deviation from the minimum forging temperature of up to 37 °C in 4.4% of the component is acceptable or whether a new heat is necessary.

Table 6 Results and corresponding target values for Scenario (c) with 211 s and 883 s calculation time

	Scenario (c)—fast		Scenario (c)—slow	
	Result	Cost value	Result	Cost value
Boundary conditions s_1, s_2, s_3 and s_4		0		0
Mean equivalent strain $\overline{\varepsilon}$	2.08	c_1= 480.77	2.12	c_1= 471.83
Standard deviation of equivalent strain s_ε	0.01	c_2= 132.83	0.02	c_2= 212.55
Minimal equivalent strain $\varepsilon_{\min}$	2.03	s_6= 0	2.05	s_6= 0
Mean austenitic grain size $\overline{d}$ in µm	187	c_3= 1865.05	170	c_3= 1704.17
Standard deviation of austenitic grain size s_d in µm	2.15	c_4= 215.46	3.91	c_4= 390.81
Maximal austenitic grain size $d_{\max}$ in µm	189	s_5= 384,160	175	s_5= 0
Process time t_S in s	894.6	c_5= 894.61	890.3	c_5= 890.32
Furnace temperature ϑ_F in °C	1034	c_6= 183.96	1034	c_6= 183.96
Total target $\sum c_i$		3773		3854
Total penalty $\sum s_i$		387,933		0

Lastly, the optimization results of Scenario (c) with two optimization schemes with different calculation times are presented in Table 6. The first optimization was completed in 211 s using the same method for the speed up as in Scenario (b). The significantly shorter calculation time results from more stringent termination conditions and the reduced number of degrees of freedom since the start temperature and the first three strokes are already set. The optimization is successful without consideration of the boundary conditions with a cost value of 3773, but the desired grain size was not achieved and thus the disturbance could not be compensated, including the penalty term for the too height average austenite grain size the total value of the cost function is 387,933.

The failure of the previous optimization is due to the short optimization time limit. In an optimization time of 211 s, 83 full pass schedules including part properties can be calculated, which is too little to explore the complex optimization area. Only after a computation time of 883 s, a solution was found while considering all boundary conditions, which is rated at 3854 by the cost function. The results show that the chosen classical optimizer is suitable to find solutions for different process deviations. However, the computing time is still too long to react to deviations for short open-die forging processes within the concept of an assistance system, as even though

fast models are used to calculate workpiece properties, hundreds of iterations are necessary to achieve satisfying optimizations results.

7 Conclusion

The following conclusion can be drawn regarding optimization of open-die forging using fast models for strain, temperature, and grain size in the context of an assistance system:

- A cost function on the basis of process and optimization experience was developed, which allows evaluating the forging process under consideration of boundary conditions.
- The presented optimization method enables pass schedule modification in reaction to process deviations while keeping previously defined goals such as grain size or minimum equivalent strain.
- Optimization time of 15 min for industrial-scale open-die forging processes are achievable using classical optimization algorithms.

General Step Reduction and Enlargement Method for Knowledge-Based Process Planning of Totally Non-axisymmetric Forged Products with Blanking and Punching

Masanobu Umeda, Yuji Mure, Keiichi Katamine, and Kazuya Matsunaga

Abstract A forging process planning method, including blanking and punching, termed General Step Reduction and Enlargement (GeneSteR+E), is discussed for cold- and warm-forged products. It is applicable to non-axisymmetric forged products that consist totally of non-axisymmetric shape elements and can generate multiple process plans without relying on design cases. The shape of a forged product is split into outer and inner shapes, which are then split into axisymmetric and non-axisymmetric shape representation units termed basic elements (BEs) according to shape separation rules. Process plans are generated in reverse order from a final forged product by applying shape transformation rules that reduce the number of steps between BEs until a billet (or a blank) is obtained. The shape transformation rules are defined not only for forging, but also blanking and punching. An experimental knowledge base was implemented and applied to several non-axisymmetric forged products, such as an electrical connector. The results show that the GeneSteR+E method is applicable to the design of forging processes including blanking and punching of totally non-axisymmetric products and can generate satisfactory process plans comparable to those developed by an experienced engineer.

1 Introduction

Process planning for cold- and warm-forged products involves generating a process to form a final product from a billet (or a blank) using forging dies. It significantly affects the quality, cost, and delivery of the forged products. The planning is time-consuming and difficult, even for experienced engineers, because extensive knowledge and experience in plastic forming, forging, blanking, and punching are required. Improvements in the efficiency and quality of the process planning are thus important issues in the design and manufacturing of forged products.

Traditional rule-based approaches [1, 2, 4, 6, 7, 11] and case-based approaches [3, 5, 8] have been proposed for forging process planning. Most are limited to products similar to design cases or are mainly axisymmetric products. In contrast, the General Step Reduction (GeneSteR) method [9] for forging processes does not rely on design cases and is applicable to non-axisymmetric cold- and warm-forged products, such as hexagon-head bolts and universal joint yokes, that consist of axisymmetric and non-axisymmetric shape elements. However, the GeneSteR method is still limited to partially non-axisymmetric forged products that contain axisymmetric shape elements and is not applicable to totally non-axisymmetric products that consist of only non-axisymmetric shape elements.

In this paper, an extension of the GeneSteR method, termed General Step Reduction and Enlargement (GeneSteR+E), is shown to be applicable to totally non-axisymmetric cold- and warm-forged products, such as USB Type-C connectors, without losing GeneSteR generality. In addition, the GeneSteR+E method can support the process planning for blanking and punching, which are often used with forging. To clearly distinguish a non-axisymmetric forged product that consists of only non-axisymmetric shape elements from one that contains axisymmetric shape elements, this paper uses the terms ‘totally’ with respect to the former and ‘partially’ with respect to the latter.

The model representation of totally non-axisymmetric forged products in the GeneSteR+E method is described in Sect. 2. Essential ideas and details to generate process plans via the GeneSteR+E method are described in Sect. 3, and the design procedure for forging process plans is described in Sect. 4. The experimental results applied to several forged products using an experimental knowledge base that implements the GeneSteR+E method are shown in Sect. 5.

2 Model Representation of Forged Products

2.1 Basic Representation Unit of Forged Products

The GeneSteR+E method represents the shape of a forged product using basic shape representation units termed basic elements (BEs), as in the GeneSteR method.

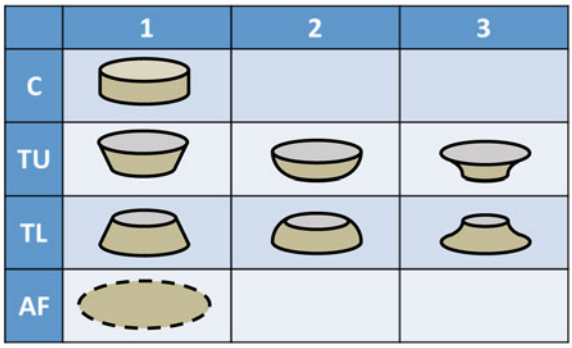

Fig. 1 Basic elements (BEs) for representing the shape of a forged product using shape representation unitsd. (Color figure online)

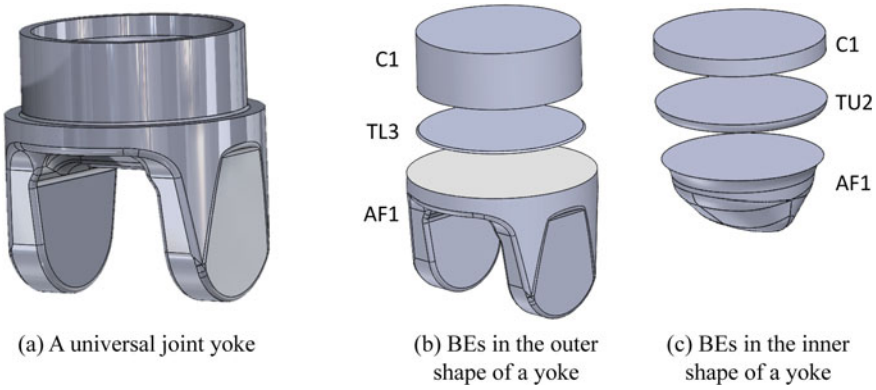

Fig. 2 Example of a partially non-axisymmetric universal joint yoke and its shape representations using BEs in the GeneSteR method. (Color figure online)

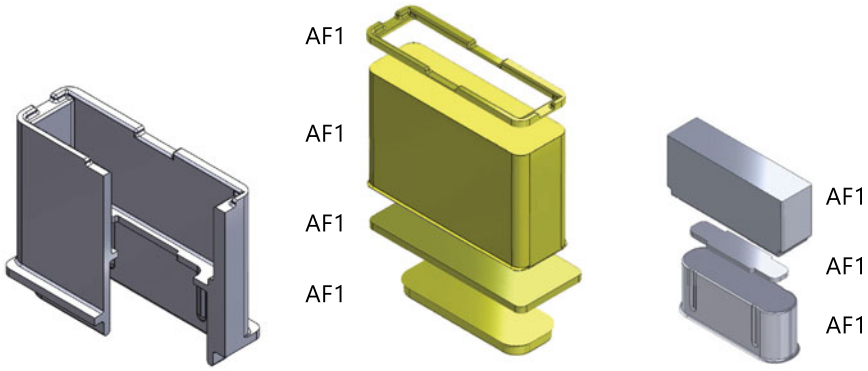
Figure 1 lists BEs, where row C and column 1 in the table is denoted C1. C2 defined in [9] was removed because it can be represented by using the pair TU2 and TL2.

Seven of the BEs, such as C1, have strictly defined axisymmetric shapes, such as a cylinder, whereas AF1 has no strictly defined shape and represents any non-axisymmetric shape. BEs have attributes characterizing their geometric outlines, with precise shapes specified by three-dimensional geometric models of a computer-aided design system.

The shape of a forged product is split into outer and inner shapes, which are then split into BEs by vertical planes to a forming direction. The design object model of a forged product represents its outer and inner shapes using two respective series of BEs. Figure 2 is an example of a universal joint yoke, that is partially non-axisymmetric, and its shape representations using BEs. In the GeneSteR method, successive non-axisymmetric shape elements in a forged product are represented using a single non-axisymmetric AF1.



2.2 *Representation of Totally Non-Axisymmetric Forged Products*

The GeneSteR method represents successive non-axisymmetric shape elements using a single AF1. Therefore, a totally non-axisymmetric forged product, such as an electrical connector shown in Fig. 3a, that contains no axisymmetric shape elements, is represented with a single AF1. In such a case, a process plan that consists of only a single forming step is generated, as described in Sect. 3.1, and is generally unrealistic due to design constraints, such as the limit of the forming load.

The GeneSteR+E method introduces new shape separation rules (SRs) to split successive non-axisymmetric shape elements of a forged product into several non-axisymmetric AF1s. The SRs are as follows:

SR1 A plane splitting a forged product must be vertical to a forming direction.
SR2 A plane must split a forged product into exactly two parts.
SR3 A plane must be located at inflection points of the second-order differential function of a cross section.
SR4 A plane must be located at discontinuous points of a cross section function.

Rule SR2 prevents a BE from being separated into isolated parts, as in the universal joint yoke that has a projecting joint structure at the bottom. The shape separation is essential for the process planning of a totally non-axisymmetric forged product like the electrical connector. Figure 3b, c, respectively, shows BEs of the outer and inner shapes of the connector.

3 General Step Reduction and Enlargement Method

3.1 Process Plan Generation by Step Reduction

As in the GeneSteR method, forged products, billets, and intermediate forged products in a GeneSteR+E process plan are all represented by BEs. Reversed forging process plans are generated by reducing the number of steps between successive BEs until a cylindrical or square billet is obtained. Step reduction is performed by simple step-by-step shape transformations over the BEs. Figure 4 illustrates a shape transformation and its corresponding forming step as the reverse operation of the shape transformation.

A forging process plan is generated by the following procedure. Starting from the forged product, one of the BEs of a post-formed product is selected as a key, indicated in red in Fig. 4. Then, one of the applicable shape transformation rules described in Sect. 3.2 is applied to the key. Several BEs are then selected as targets, which are indicated in blue in Fig. 4, according to an applied rule. The shape of a pre-formed product is created by substituting targets of a post-formed product with new BEs according to an applied rule. Because there are many candidates for a key, an applicable shape transformation rule, and targets, multiple process plans can be generated by an exhaustive search for them. In other words, a process plan consisting of a single forming step is generated if a forged product is represented using a single AF1.

3.2 Shape Transformation Rules

The shape transformation from post-formed to pre-formed products occurs according to simple rules defined for the outer and inner shapes. Figures 5 and 6 illustrate the shape transformation rules for the outer and inner shapes, respectively, and are extensions of those defined in the GeneSteR method.

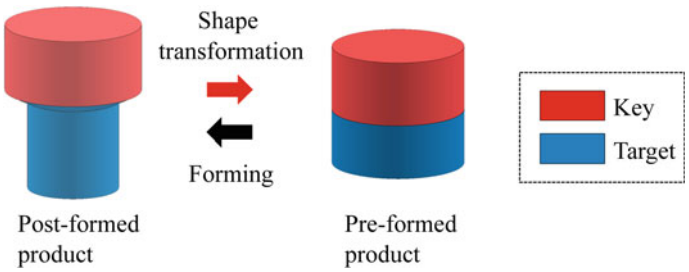

Fig. 4 Example of a shape transformation and the forming step of a process plan. (Color figure online)

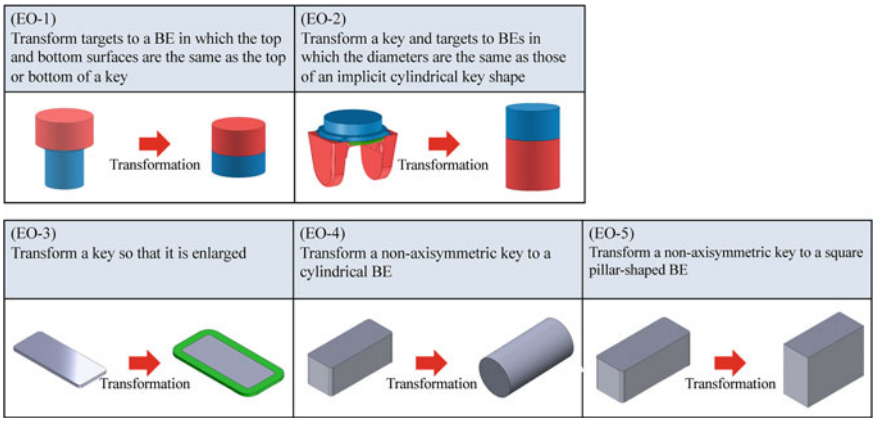

Fig. 5 Shape transformation rules for the outer shapes. (Color figure online)

Rule EO-1 for the outer shape adjusts the top and bottom surfaces of targets to the top or bottom surface of a key, which corresponds to forming via upsetting or forward or backward extrusion. Rule EO-2 adjusts the diameters of a key and targets to that of a cylindrical shape included implicitly in the key. EO-1 and EO-2 are similar to those defined for the GeneSteR method, whereas rules EO-3, EO-4, and EO-5 are new for the GeneSteR+E method. Rule EO-3 enlarges a key to a certain volume, which corresponds to cutting an edge off via blanking. Rule EO-4 restores to a cylindrical billet that is pressed in the direction perpendicular to its rotation axis, while rule EO-5 restores to a square billet.

Similarly, rule EI-1 for the inner shape is to adjust the top and bottom surfaces of targets to the top or bottom surfaces of a key, which corresponds to a forming via forward or backward extrusion. EI-1 and EI-2 are similar to those defined for the GeneSteR method, whereas, rules EI-4, EI-5, and EI-6 are new for the GeneSteR+E method. For example, rule EI-4 fills in a hole, which corresponds to cutting a hole via punching.

Rules O-1 and O-2 defined for the GeneSteR method are unified in rule EO-1 because the O-1 and O-2 geometric transformations are the same except for the surface shapes from an axisymmetric point of view. However, rule O-4 for design constraints regarding the limit of the forming load was eliminated because design constraints are considered in a later design phase as discussed in Sect. 4. A similar rule restructuring was also performed for the inner shapes.

4 Design Procedure for Forging Process Plans

Design constraints, such as the limit of the forming load, are not considered while transforming a shape according to the rules; therefore, some generated process plans may not be applicable to actual production. In addition, the forming steps in generated

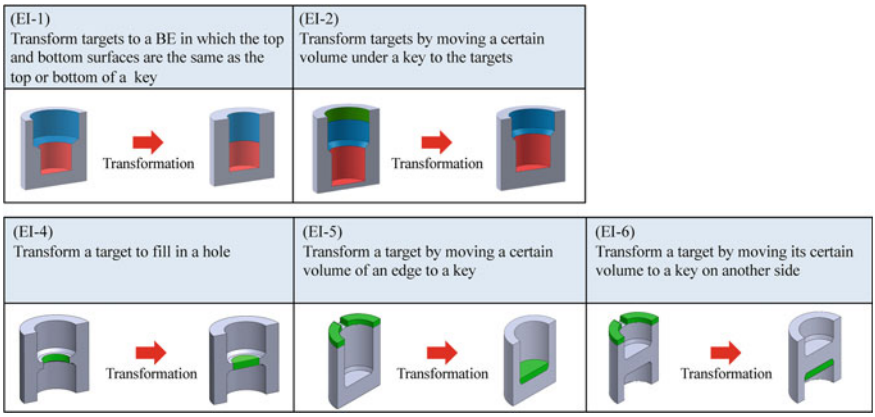

Fig. 6 Shape transformation rules for the inner shapes. (Color figure online)

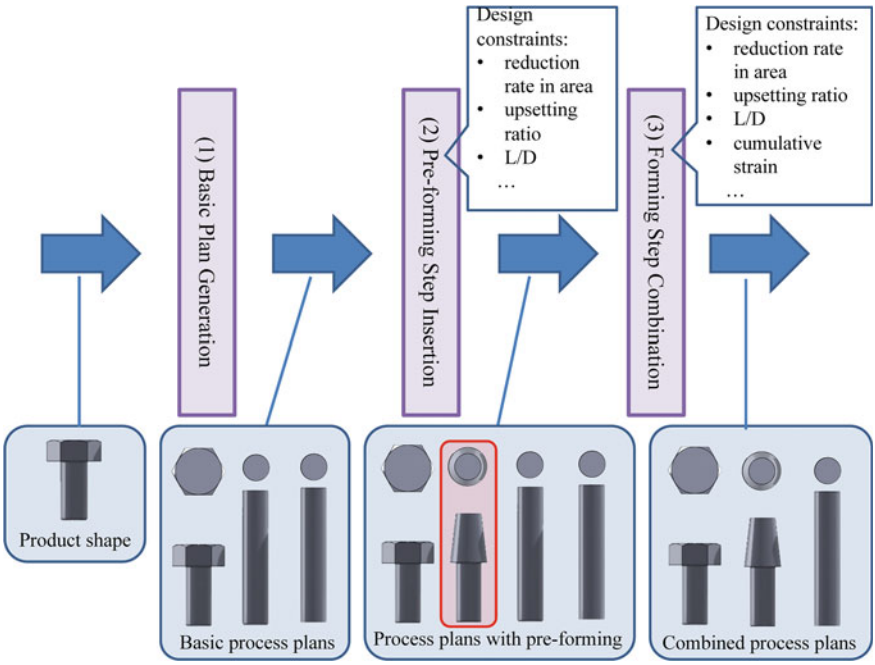

Fig. 7 Design procedure based on the GeneSteR+E method for forging process plans. (Color figure online)

plans may become too long to be practical because the rules are simple and the transformation is performed step by step. Therefore, the design procedure of the forging process is organized into three phases as shown in Fig. 7.

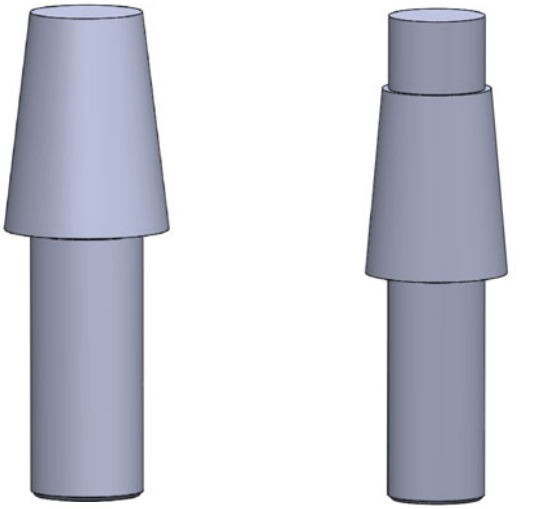

Fig. 8 Corn and bell shapes for preventing work material from being buckled by upsetting. (Color figure online)

First, basic process plans are generated by applying the GeneSteR+E method to a final forged product. The process plans generated in this phase may contain impractical forming steps because design constraints are ignored. Therefore, pre-forming steps are inserted into the plans in the second phase, considering design constraints, such as reduction rate in area, upsetting ratio, and L/D. Corn and bell shapes shown in Fig. 8 can be candidates for pre-forming steps inserted into process plans to prevent work material from being buckled via upsetting. Rule O-4 in the GeneSteR method was defined to prevent increases in the forming load by partly extruding work material forward and is realized in this phase as described in Sect. 3.2. Finally, multiple forming steps are combined into one by considering design constraints related to large shape changes in the third phase. The reduction in the number of forming steps will reduce production costs and lead time.

Because the shape transformation and the design constraints can be handled separately, unlike with the GeneSteR method, the management of the design knowledge becomes easier.

5 System Implementation and Experimental Results

The shape transformation rules are realized by using a set of basic shape operation functions that manipulate three-dimensional geometric models in SolidWorks through its OLE interface. New shape operation functions `CreateCuboid` and `ExpandByVolume` are added to the function set given in [9] for the new shape

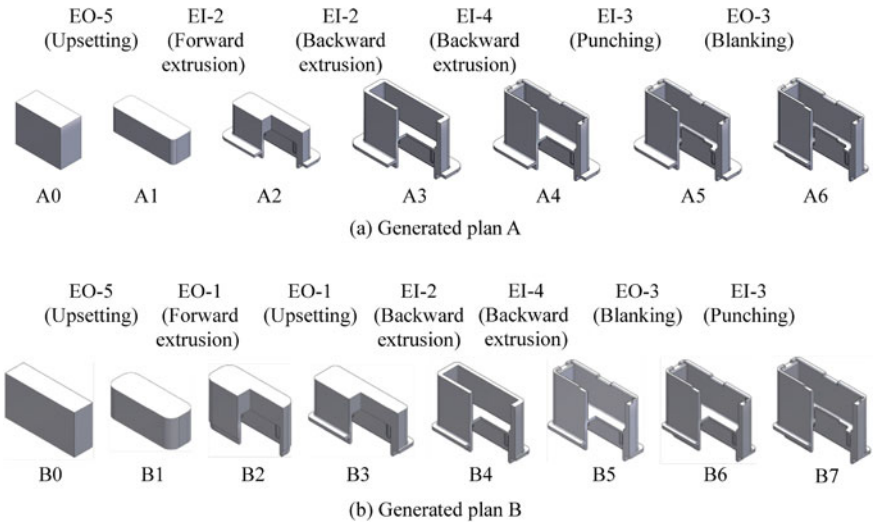

Fig. 9 Examples of generated process plans for an electrical connector. (Color figure online)

transformation rules. An experimental knowledge base, which implements the basic plan generation phase based on the GeneSteR+E method, is developed in the DSP knowledge representation language [10] using these functions.

The knowledge base was applied to cold- or warm-forged products, such as a hexagon-head bolt, a universal joint yoke, and an electrical connector. In the latter case, 162 process plans were generated in 6.55 h. Figure 9 shows two sample process plans generated via the knowledge base, while Fig. 10 shows one designed by an experienced engineer.

Plan A in Fig. 9 is similar to that of the engineer if it is modified by the next design phases described in Sect. 4. That is, the pre-forming step P2 is inserted between A2 and A3 for plastic deformability in the pre-forming step insertion phase, and the forming steps from A2 to P2 and from A3 to A4 are combined into single step to reduce the number of steps in the forming step combination phase. These results show that the GeneSteR+E method is applicable to forging process design, including blanking and punching, of totally non-axisymmetric products and can generate satisfactory process plans comparable to those by an experienced engineer. The execution time could be improved.

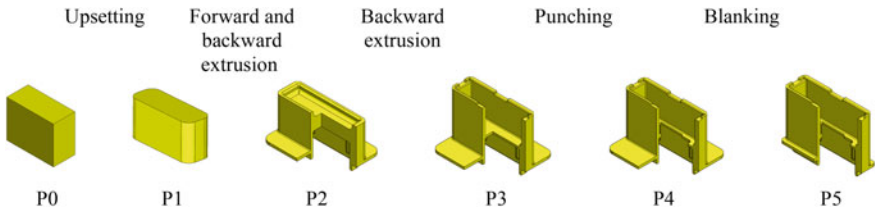

Fig. 10 Example of a process plan designed by an experienced engineer for an electrical connector. (Color figure online)

6 Conclusions and Future Work

This paper proposes a process planning method termed GeneSteR+E for totally non-axisymmetric cold- and warm-forged products that consist of only non-axisymmetric-shaped elements. It can generate plans for forging processes, including blanking and punching, for a forged product without relying on design cases.

An experimental knowledge base was implemented based on the GeneSteR+E method and applied to several forged products. The experimental results for an electrical connector had 162 generated process plans within 6.55 h. The generated plans included a plan comparable to one designed by an experienced engineer if the pre-forming step insertion and the forming step combination were applied to the comparable plan. These results show that GeneSteR+E is applicable to forging process design, including blanking and punching, of totally non-axisymmetric forged products.

The basic plan generation phase based on the GeneSteR+E method does not take care of design constraints; therefore, they have to be considered in the pre-forming step insertion and the forming step combination phases to produce deformable process plans. However, such design constraints have not been well systematized for non-axisymmetric forged products. Further research on this issue is essential to develop a practical knowledge base for forging process planning.

Acknowledgments The authors are grateful to Mr.Tateki Hamasaki who contributed to the establishment and evaluation of the GeneSteR+E method in the early research stage. This research was supported by the Strategic Core Technology Advancement Program by the Ministry of Economy, Trade and Industry, Japan.

Investigation of Failure Mechanisms of Cemented Carbide Fine Blanking Punches by Means of Process Forces and Acoustic Emission

Herman Voigts, Rafael Hild, Andreas Feuerhack, and Thomas Bergs

Abstract Due to the processing of high-strength materials in fine blanking, the lifetime of conventional high-speed steel punches decreases rapidly. Materials with higher wear resistance and compressive strength, such as cemented carbide, are investigated for use in fine blanking processes. However, cemented carbide punches often fracture during the stripping off phase due to the combined tensile and flexural stress collective. The understanding of fracture mechanisms and subsequent fracture prevention supports the application of cemented carbides. The fracture mechanisms during stripping off are mostly unknown. The objective is to identify fracture mechanisms of cemented carbide punches. The fracture mechanism of cemented carbide punches was metrologically monitored by means of acoustic emission (AE) and process forces. The fracture pattern was analyzed related to the measured signals. In order to interpret the AE signal, basic process analyses were performed. Subsequently, a punch fracture of cemented carbide was provoked with the high-strength steel 1.8974. Cemented carbide punches tend to fracture during stripping off as a cause of asymmetrical interactions with the scrap web.

Keywords Fine blanking · Cemented carbide · Acoustic emission · Stripping off

1 Introduction

1.1 Initial Situation

Ecological demands require emissions reduction in the mobility sector. As a result, the automotive industry faces challenges in terms of the application of lightweight solutions in structural and functional components and assemblies. Compared to 2016, the worldwide market volume for lightweight applications is expected to grow from €80 bn to €140 bn in 2020 [1]. In the field of metal processing, lightweight design

means integration of several functions in one part and structural lightweight design. Lightweight design leads to complex geometry and fine details of the blanked part as well as the processing of lightweight steel with high strength. Fine blanking is a highly productive manufacturing technology used for the manufacture of precise, functional lightweight system parts, e.g., for interior, mechanical, or safety components in combustion and electrical vehicles [2]. Both complex geometry with fine details and the processing of high-strength materials lead to high tool loads with local stress concentration in the punch. High local stresses lead to extensive wear or even plastification on the cutting edge of the punch. Tool failures occur suddenly due to chipping or by increasing abrasive and adhesive wear. Tool materials with higher compressive strength and wear resistance, such as cemented carbide grades, have a high potential for fine blanking of high-strength sheet metal. Nowadays, cemented carbides are successfully applied as tool materials for cutting, forming [3], and machining tools [4], where the high hardness, compressive strength, and wear resistance allow an improvement with respect to conventional tool steels.

1.2 State-of-the-art

In blanking of materials of higher strength and ductility, due to the hydrostatic stress state in the shearing zone, the springback of the sheet metal after the blanking phase causes high clamping forces [9]. The stripping force of high-strength TRIP steel with an ultimate tensile strength (UTS) of 850 MPa increases about the factor 10 compared to a bake hardening steel with a UTS of 320 MPa. The clamping mechanisms of the scrap web on the punch and the stripping force at fine blanking with cemented carbide punches have been investigated using a validated FE model [10]. Cemented carbide punches often fracture during fine blanking of high-strength steels in the stripping off phase. The scrap web clamps on the punch due to elastic springback. An analytic model for the description of the clamping and the stripping force was derived based on the approach of the shaft-hub connection theory. The stripping force increases for high UTS, elasticity, and sheet thickness. The UTS is interdependent on sheet thickness due to dissipated heat during shearing. The investigation was done for circular geometries.

AE has been used for fine blanking process analysis. Evaluation algorithms and signal characteristics in a three-step process, consisting of pre-punching, embossing, fine blanking, and upsetting have been investigated [11]. It was found that very complex interdependencies exist between the individual processes so that a direct correlation between a given signal and product quality is not immediately possible. Effects of workpiece errors on acoustic signals are found to be very small. Nevertheless, with a well-designed application, a process monitoring of the fine blanking process concerning the product quality based on the relative changing of acoustic signals is possible. Investigations for AE analysis of workpiece quality in fine blanking processes with compound dies [12] as well as progressive dies [13] were

published. AE has also been used for the detection of breakages as well as the chipping of cutting tools during machining [14]. Later, AE was used for the detection of catastrophic tool failure of drilling and cutting tools using root mean square (RMS) signals [15]. Tool fracture generates a significant burst of the measured AE signal.

A deep understanding of the interactions between the scrap web and the punch during stripping off can be used for the process design with a balanced load collective and compensated harmful stresses. This will allow for the application of cemented carbide for challenging processes and the processing of high-strength steels.

1.3 Objective

Fracture of the cemented carbide punch during stripping off is a cause of the interaction between the punch and the scrap web. The clamping of the scrap web on the punch as a result of elastic springback has been investigated. Further influence quantities from the cutting line geometry, geometric shape of the scrap web regarding the die roll, and stiffness of the scrap web are not comprehensively researched yet.

The main objective is to find the cause and effect relations between the scrap web and the punch during the stripping off phase in order to explain fracture mechanisms of cemented carbide punches. The evolution of fracture is analyzed using AE and force signals. The course of fracture is then explained with respect to the strip layout and properties of the sheared surface of the scrap web.

1.4 Methodology

AE and force analyses were conducted in order to identify the cause and effect interactions between the scrap web and cemented carbide punches during stripping off. Using a standard analogy geometry in a 2-up fine blanking tool, test strokes with a lower grade sheet metal were conducted. The characteristic of AE and punch force signal was analyzed for standard process settings. During the blanking phase, the scrap web is clamped on the punch. The critical load for cemented carbide punches is during the stripping phase. Both phases have been evaluated for Böhler S390 high-speed steel (HSS) punches with a hardness of 64 HRc. The blanked material was 1.7131 in soft annealed state with a sheet thickness of 6 mm and a UTS of approximately 400 MPa. In the second test, the HSS punches were replaced with a WC–Co cemented carbide grade with 8.5% binder content and submicron-fine average grain size. The sheet metal material was a micro-alloyed high-strength steel 1.8974 with a sheet thickness of 6 mm and a UTS of 715 MPa. This was done in order to provoke a punch face fracture of the cemented carbide punch. The fracture pattern was interpreted using punch force and AE signals in order to explain the fracture mechanisms. Finally, the scrap web was analyzed regarding geometry and

bridge widths. The fracture of cemented carbide punches was explained in context with the interactions between the punch and the scrap web. Elastic deformation of the scrap web during the relative motion with the punch leads to circumferentially uneven seizure and wedging.

2 Experimental Setup

The experiments were conducted on a servo-mechanical fine blanking press FEINTOOL XFT 2500 speed with a decoiler and leveler unit for automatic sheet metal supply. Figure 1a shows the cross-section of the fine blanking tool with the tool elements in the flux of force with the positions of the sensors for force and AE measurement. The fine blanking tool is a simple 2-up compound die producing two analogy geometries in one stroke. The strip layout is presented in Fig. 1b with two shifted and balanced arrow-shape geometries. During the shearing and stripping off phases, the active elements interact with the sheet metal, which is separated into two blanked parts and the scrap web. Hydraulic counter holder and blank holder forces introduce compressive stresses in the shearing zone which allows for larger forming grades during separation and therefore enables a high smooth-cut portion, see Fig. 1c [3].

Both the blanking and the stripping off phases are relevant for the analysis of fracture mechanisms. During the blanking phase, the interference fit of the scrap web and the punch is established, which is determined by the sheared surface quality characteristics. The interference fit leads to clamping and tensile stresses during stripping

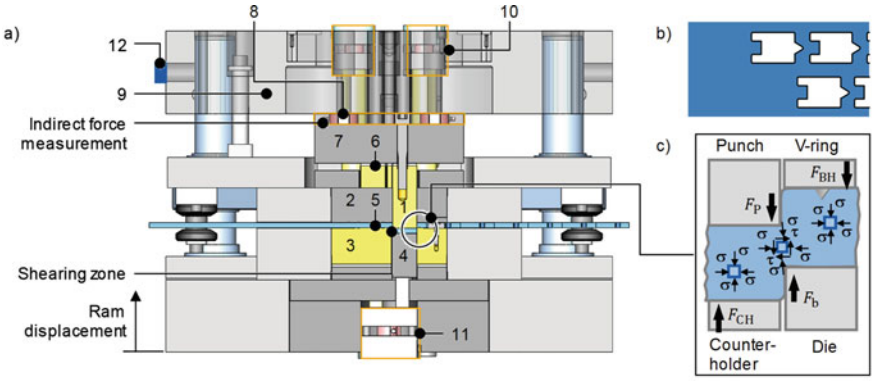

Fig. 1 Section through fine blanking tool with tool elements and positions of AE and force sensors (**a**), stress state in forming area and shearing zone (**b**), and strip layout (**c**). Legend: F_b—blanking force; F_{CH}—counter holder force; F_P—punch force; F_{BH}—blank holder force. (Color figure online)

off. Therefore, the complete fine blanking cycle is analyzed. Forming mechanisms are already known to emit structure-borne noise [12]. Fractures emit a burst in the AE signal [15]. It is also assumed that the tribosystem affects AE during the penetration of the sheet metal in the shearing phase and during the stripping off phase. AE has been used for the analysis of the tribosystem in gears using RMS signals [16]. Structure-borne noise is conducted from the punch through the tool components and measured outside the tool on the lateral top shoe. On each joint connection between components, noise is reflected [17]. Thus, a direct application of the sensor close to the punch is favorable. The only way to apply the sensor was on the top shoe. For the experiments, a sensor of the type KISTLER 8152C with a range of 400 kHz was used. The AE sensor was mounted using an M6-thread on the tool with a defined torque of 9 Nm. The contact surface for noise transmission on the tool surface was flat ground. The contact surface between the top shoe and the AE sensor was covered with ultrasonic transmission gel.

The process forces punch force F_P, blank holder force F_{BH}, and counter holder force F_{CH} were measured using piezo-electric load washers. The sensors were mounted in force shunts for indirect force measurement. Two tactile length gauges of the type HAIDENHAIN Specto with a system accuracy of ± 1 µm were used for the reference distances top shoe-ram and top shoe-guide plate. AE, forces, and displacement were measured in analogous with NATIONAL INSTRUMENTS LABVIEW software and saved in a TDMS format. The AE signal was measured with a sampling rate of 1 MHz which is twice the measuring range in order to avoid aliasing. Forces and displacements were measured with a sampling rate of 10 kHz.

Two experimental test series have been performed. In the first series, blanking strokes without tool fracture were conducted for a process analysis using HSS punches and 1.7131 sheet metal. The goal was the identification and quantification of characteristics in the AE and force signals. Due to the running-in of the fine blanking process, the blanking process was repeated 20 times in automatic mode of the fine blanking press. The 20th stroke was evaluated. The settings were set according to Table 1.

In the second test series, an overload of a cemented carbide punch was provoked using WC-Co cemented carbide punches and 1.8974 sheet metal. The stroke rate was set to 50 min^{-1} with a corresponding averaged blanking velocity v of 47 mm/s. The non-uniform transmission of the double toggle lever press provides for a mostly constant blanking velocity before top dead center (TDC) of the bottom-driven

Table 1 Process settings for fine blanking experiments

Parameter	Symbol	Unit	Value	Parameter	Symbol	Unit	Value
Stroke rate	h	min^{-1}	50	Counter holder force	F_{CH}	kN	300
Averaged blanking velocity	v	mm/s	47	Stripping off timing after TDC	t_{Strip}	mm	0
Blank holder force	F_{BH}	kN	350	Ejecting timing after TDC	t_{Eject}	mm	10

fine blanking press and stripping off velocity after TDC. The fracture surface was analyzed using light microscopy.

3 Results and Discussion of Waveforms of AE and Process Forces

First, the time–amplitude AE and force signals were analyzed with the displacement signals of the ram and the blank holder in order to get an understanding of the AE and force signals. Process variables have been varied in order to identify characteristics in the signals. Subsequently, the AE and force signal from a tool fracture due to material overload during stripping off was measured.

3.1 AE and Force Analysis of an Experimental 2-up Compound Die Fine Blanking Process

In correspondence with the ram and blank holder displacement curves, characteristics from the AE-signal were identified, see Fig. 2. Characteristic events during a fine blanking cycle became obvious.

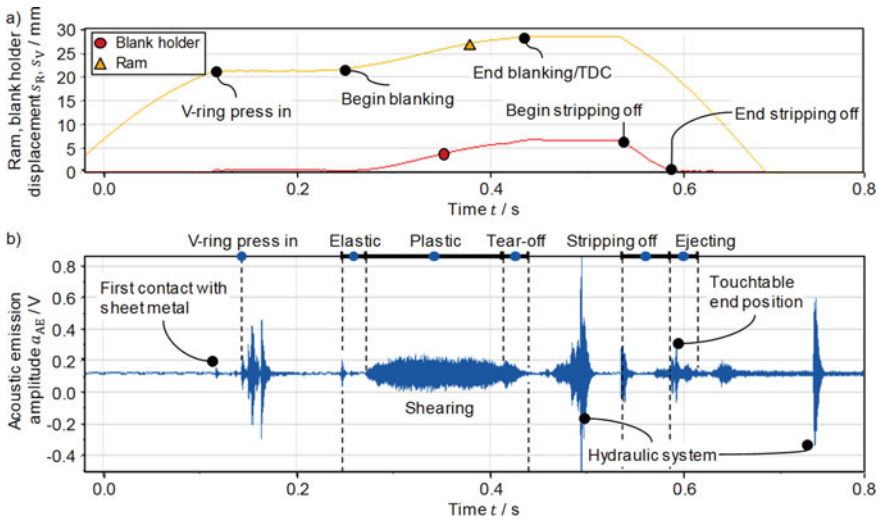

Fig. 2 Displacement (**a**) and AE signal (**b**) of a fine blanking cycle at stroke rate $n = 50\ \text{min}^{-1}$, blank holder force $F_{BH} = 350$ kN, counter holder force $F_{CH} = 300$ kN, stripping off at 0 mm after TDC, ejecting at 10 mm after TDC. (Color figure online)

The first contact between the V-ring and the sheet metal which is supported by the blank holder after the tool closes at 0.1 s is shown by a small peak before the V-ring is pressed into the sheet metal. The press-in of the V-ring and the clamping of the sheet metal while the touch table is moved is presented by peaks before 0.2 s. The plateau of the ram and blank holder displacement curves is due to the lifting of the touch table while the punch cannot apply a counterforce because the punch is not supported.

After the touch table reaches its end position, the punch is supported by the press body and the blanking phase begins. At the beginning of the blanking phase, the deformation is mostly elastic while die roll is formed which does not show high amplitudes in the AE signal. In the plastic portion of the shearing process, the amplitude increases which is due to dislocation movements during the forming operation. The amplitude during the shearing phase was observed to increase when the blank holder and counter holder force were increased according to [12]. Higher process forces induce a higher compressive stress state in the shearing zone, thus increase dislocation movement. At the end of the plastic forming when the cross-section and the forming zone and thus the AE amplitude decrease, the amplitude shortly increases which is explained by tear-off on the sheared surface. The torn-off surface height is about 5–10% of the sheared part thickness and occurs at a similar time compared to the AE peak.

The second plateau of the ram and blank holder displacement signals after reaching TDC at the end of blanking is due to the lowering of the touch table to its lower end position. The tool is opened at rapid traverse after the touch table reaches its end position. The stripping off is conducted immediately at the beginning of the opening of the tool. Peaks in a short distance at the beginning are explained with stick–slip behavior in the beginning. A higher amplitude at the end of the stripping off is observed which is expected to be based on the tribology between punch and scrap web. The amplitudes of the peaks are increased with higher stripping off velocity and decrease during the stripping phase while the contact surface between punch and the scrap web decreases linearly. Other peaks in the AE signal are explained with the behavior of the hydraulic system or reaching of end positions.

The process forces of the punch, blank holder, and counter holder were measured in correspondence to ram and blank holder displacement, see Fig. 3. The forces during the blanking phase are significantly higher compared to the stripping off and ejection phases. However, the stripping off phase is the more critical phase for fine blanking with cemented carbide punches because cemented carbide punches catastrophically fail in this phase [8].

Analogous to the AE analysis, characteristics from the blanking cycle are found in the force signals. When the press closes the tool and the strip is clamped, see Fig. 3a, the first amplitudes are seen in the punch and blank holder force in Fig. 3b. After the touch table is lifted to the end position, the blank holder and counter holder force build. The punch is set 0.1 mm back behind the blank holder such that the punch force builds slightly later than the blank holder force. At the beginning of the blanking phase, the punch force increases linearly. The increase in the punch force is to overcome the elastic deformation and the formation of die roll on the sheared part

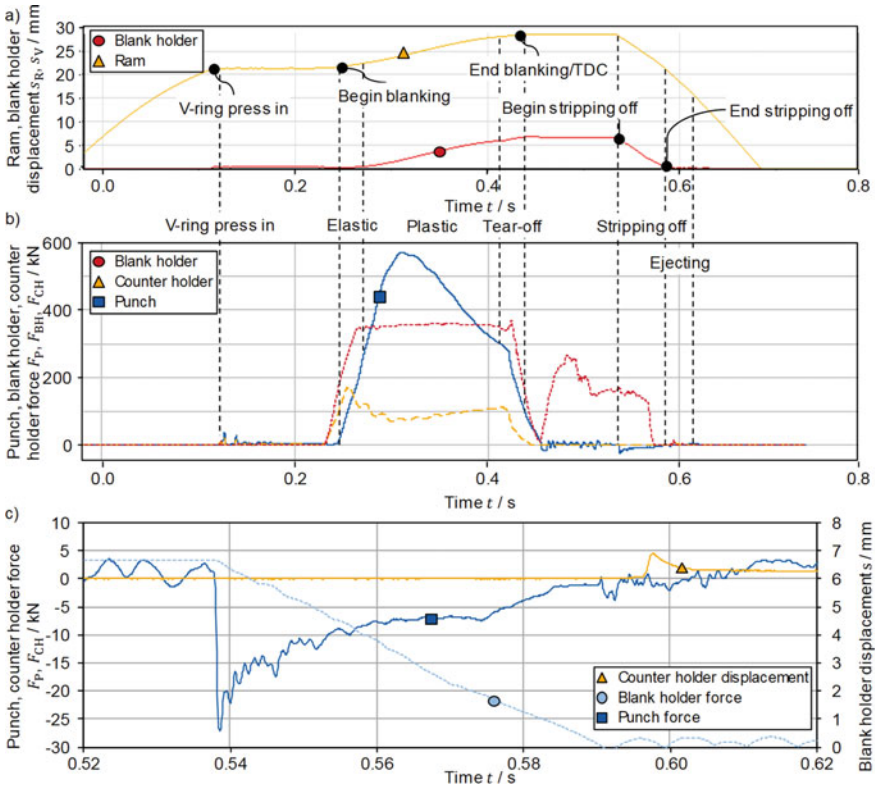

Fig. 3 Displacement (**a**), process force analysis of a fine blanking cycle (**b**), and force analysis during stripping off and ejection phase (**c**) at stroke rate $n = 50\ \text{min}^{-1}$, blank holder force $F_{BH} = 350$ kN, counter holder force $F_{CH} = 300$ kN, stripping off at 0 mm after TDC, ejecting at 10 mm after TDC. (Color figure online)

and the scrap web. The maximum punch force is registered after die roll formation is completed and the shearing zone is still large. After the punch force peak, when the shearing zone thickness decreases linearly with the ram displacement, the punch force decreases linearly correspondingly. At the end of the blanking phase before TDC, the punch force decreases rapidly which is explained by tear-off on the sheared surface of the sheared part and the scrap web. The process forces of the blank holder and the counter holder are controlled and the waveform depends on the hydraulic system. The volatile waveform of the counter holder is explained with the inertia of the hydraulic system.

The stripping off force at the punch and ejection force at the counter holder in Fig. 3c are small compared to the blanking forces. Stripping off timing was set to 0 mm after TDC in order to clamp the sheet metal between the guide plate and the die for better control of the stripping off and to avoid tilting of the scrap web. A tilted scrap web can cause uncontrolled stick–slip and flexural loads with increased

peaks on the punch. The punch tensile force increases rapidly at the beginning of the stripping off until the static friction is exceeded. Then the scrap web starts to slide off the punch with linear blank holder displacement. The punch tensile force decreases roughly linearly with the blank holder displacement as the contact area decreases linearly with the blank holder displacement. The punch force is close to zero before stripping off is completed which is explained with the die roll on the scrap web such that contact ends before the end of the stripping off phase. At the beginning of the stripping off phase, undulations are observed. The undulations increase when stripping off is delayed after TDC such that the scrap web is not clamped between the blank holder and the die. It is assumed that these undulations are due to a stick–slip behavior.

Ejection of the blanked parts from the die was set to 10 mm after TDC and is visualized by the counter holder force in Fig. 3c after the stripping off. Similar behavior compared to the punch during stripping off is observed without the undulations at the beginning and with a lower amplitude.

3.2 A Provoked Fracture of a Cemented Carbide Punch Due to Material Overload

A material overload of a WC–Co cemented carbide grade with submicron-fine average grain size and 8.5% binder content as punch material was provoked. The second punch in the 2-up fine blanking tool was made from HSS. Cemented carbides have high compressive strength but a low tensile and flexural strength compared to HSS [18]. This leads to material overload during stripping off phase in fine blanking of high-strength sheet metal S700MC with 6 mm sheet thickness. AE was measured during tool fracture and analyzed in Fig. 4. The blanking phase (Fig. 4a) is ordinary as with sharp punches. Fracture of the cemented carbide punch was registered as a burst after one-third of the stripping off path (Fig. 4b). The burst indicates catastrophic tool failure equivalent to drilling as investigated in [15].

The punch face was clamped and the face fragment remained in the scrap web. The assumed stripping off path from the measured signal until punch fracture correlated with the position of the face fragment in the scrap web. From the AE two cracks were observed. Two crack initiations were also observed in the fracture pattern on the punch face (Fig. 4c). The fractures confluence in the exposed vertical line close to the point of the second crack initiation.

The punch force during stripping off was analyzed in Fig. 5 analogous to Fig. 3c. Only the cemented carbide punch fractured due to overload. The HSS punch had sufficient ductility to withstand the load collective. Therefore, the force signal is formed by the fractured and the non-fractured punch. However, the force waveform gives information about the course of fracture.

The stripping force with the high-strength sheet S700MC and the cemented carbide punch increased to 70 kN compared to the softer sheet metal 16MnCr5

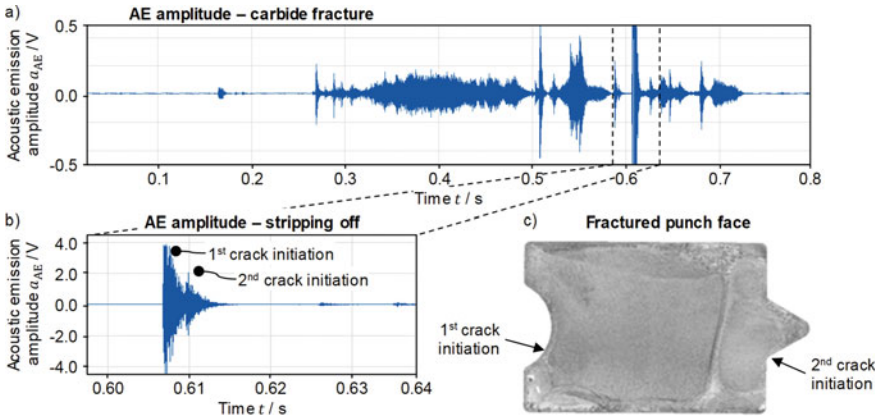

Fig. 4 AE of a fine blanking cycle with a provoked fracture of a cemented carbide punch (**a**), AE burst during stripping off phase (**b**), and fracture pattern of the punch face (**c**). (Color figure online)

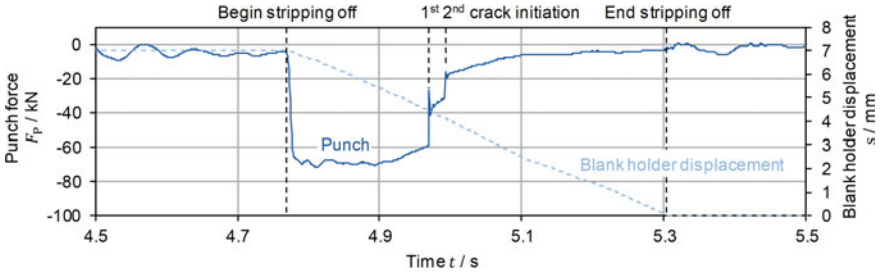

Fig. 5 Punch force of a provoked fracture of a cemented carbide punch during stripping off phase. (Color figure online)

with 25 kN. Instead of a decreasing stripping force, it remains constant for 1 mm of blank holder displacement before the stripping force starts to decrease. After one-third of the stripping path, first crack initiation is observed in the form of a sudden force drop. A second force drop occurred shortly after the first one.

4 Discussion of the Results

The fracture of the cemented carbide punch face during the stripping off phase caused a double peak in the AE signal and two punch force drops that were analyzed in Chapter 3.2. The sudden release of the strained punch after the fracture stimulated the acoustic eigenfrequency of the oscillation system of the punch and the joint tool elements. This caused a high amplitude of the measured AE signal, comparable to crack propagation according to [19].

The fracture pattern on the punch face is explained with the measured punch force and AE signal. On the fractured punch face, two opposing crack initiation points were identified. It is assumed that the punch was clamped on one end of the geometry where the first crack was initiated and flexural stresses were induced. The flexural strength was exceeded locally which led to the first crack initiation. The fracture leads to an asymmetric release of the punch which led to conversed clamping on the opposing side of the geometry. The same procedure occurred again at the point of the second crack initiation, see Figs. 4 and 5.

In previous investigations, the clamping of the scrap web on cemented carbide punches in fine blanking processes was described and explained with elastic spring-back of the scrap web for different materials and sheet thicknesses [10]. However, in industrial processes, the scrap web does not have constant circumferential stiffness at the cutting line due to relatively small bridge widths. Variable stiffness of the scrap web enables the material to locally unload the punch elastically, which results in variable clamping along the cutting line.

Moreover, the sheared surface of the scrap web varies along the cutting line. Different geometry elements are characterized by varying die roll and smooth cut portion as investigated in previous work [20]. This led to locally asymmetric contact areas between the punch and the scrap web on asymmetric cutting lines. Furthermore, the behavior of die roll during stripping off phase needs to be investigated.

Based on the stiffness and the die roll of the scrap web, two approaches for the explanation of fracture of cemented carbide punches in fine blanking have been established. Therefore, the scrap web is further analyzed.

Figure 6 shows the scrap web with the two cavities I and II and the holes from the previous blanking operation. Bridge widths are limited due to the distance to the previous hole of 10 mm and to the strip border of 7 mm. The scrap web right from the cavities and to the strip border is less stiff than on the infeed side. Thus, the clamping of the scrap web on the punch may relax where bridge widths are small. On the other side, the material in the strip on the infeed side has no ability to elude. The unbalanced clamping caused flexural loads in the punch during stripping off.

During the tests, the cemented carbide punch was mounted in cavity I. The scrap web of the provoked fracture experiment was measured with a 3D-sensor GOM

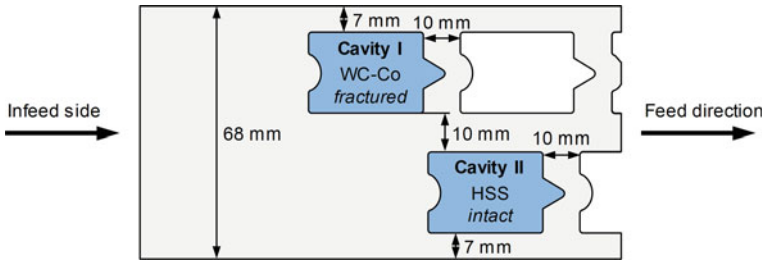

Fig. 6 Measures of the scrap web affecting its stiffness around cavities I and II. (Color figure online)

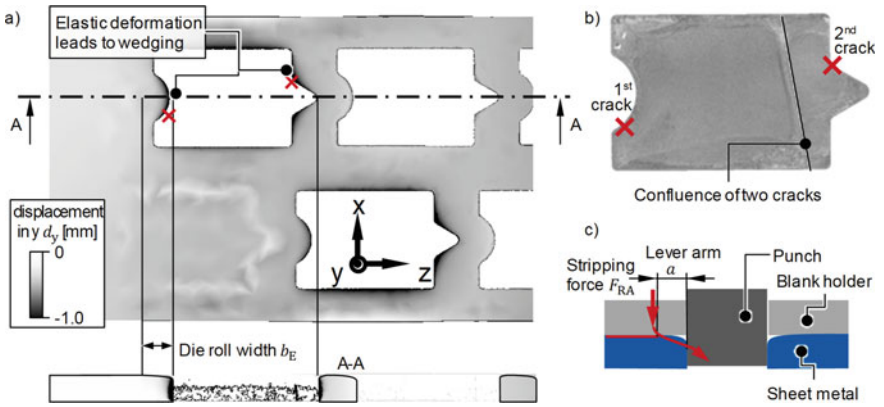

Fig. 7 Deformation of the scrap web in blanking direction (**a**), fracture pattern of the corresponding cemented carbide punch face (**b**), and wedging mechanism between scrap web with die roll and punch (**c**). (Color figure online)

ATOS and converted into an STL mesh. The STL mesh was compared with an ideal rectangular and plane CAD file of the scrap web using the software GOM INSPECT. Deviations in blanking direction (y) are presented in a false-color image in Fig. 7a.

Die roll in convexity radii of the geometry on the scrap side is clearly increased locally along the cutting line. There are convexity radii at the left-sided semicircular notch and right-sided next to the gear tooth, which shows an increased die roll. The die roll height is up to 0.7 mm which is 12% of the sheet metal thickness. The locally reduced die roll height results in lower friction force in convex geometry elements of the scrap web, assuming that the clamping force is constant along the cutting line. Together with locally reduced stiffness due to small bridge widths, concave geometry elements with larger bridge widths undergo larger friction during stripping off. In cavity I, the corner at the infeed side on the sheet metal center has a negligible die roll and large bridge width. However, the explanation with reduced friction due to die roll height is not sufficient for the explanation of crack initiation points.

In convex radii of the scrap web in the semicircular notch and besides the gear tooth, the die roll width is large with approximately 3 mm. The blank holder is used for stripping off the scrap web from the punch. In the die roll area, the scrap web cannot be supported by the blank holder. Thus, the stripping force is introduced into the scrap web over the die roll width as the lever arm as indicated in Fig. 7c. The elastic deformation of the die roll area in the scrap web during stripping off has been investigated in previous work [21]. Figure 8a shows von Mises stresses in a finite element model of the stripping off phase with a circular geometry with a diameter d = 30 mm. The simulation was run linear statical in Abaqus/Standard. The punch was modeled elastic as cemented carbide with Young's modulus E = 480 GPa. The sheet metal was modeled elastic-plastic using flow curves as high-strength steel 1.8974 was used in the experimental test. The non-supported scrap web deforms elastically in the die roll area during stripping off which leads to wedging with the punch as visualized

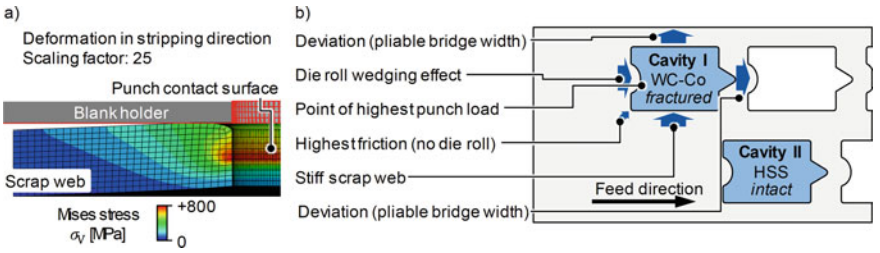

Fig. 8 Visualization of die roll wedging effect according to [21] (**a**) and asymmetric clamping mechanism leading to punch fracture during stripping off due to die roll wedging effect and asymmetric stiffness of the scrap web (**b**). (Color figure online)

in Fig. 8a. The die roll wedging effect results in increased contact normal stresses and subsequently to high stripping forces and clamping of the punch. The failure mechanism of the cemented carbide punch is explained in Fig. 8b. High stripping forces in the semicircular notch and the high stiffness of the sheet metal strip on the infeed side hold the punch back and introduce flexural stress into the punch. The small bridge width at the strip border, which results in lower clamping, enables the punch to slightly move to the strip border. As a consequence, the wedging in the notch was increased on the strip center side, where the first crack initiation point was identified.

5 Conclusion and Outlook

Punch fracture mechanisms during fine blanking of high-strength sheet metal have been investigated. The used tool was a 2-up compound die with an asymmetric geometry. One punch was made of HSS while the other one was made of tungsten carbide. The carbide punch fractured during the stripping off phase. Through process force and AE analysis, the course of fracture could be reconstructed. Two crack initiation points were identified in the measured signals and on the fracture pattern. As a consequence of the punch geometry and the strip layout, the punch was loaded with flexural and tensile stresses during the stripping off.

- Elastic springback due to the hydrostatic stress state in the shearing zone causes the scrap web to clamp on the punch during the stripping phase
- Small bridges in the scrap web are pushed away from the punch such that small bridges cannot hold the clamping force. This effect leads to asymmetric clamping if the scrap web is determined by asymmetric bridge widths. The strip has a high stiffness on the infeed side and small bridge widths in the scrap web. Moreover, the bridge width to strip borders is small.
- Die roll on the scrap web is not supported by the blank holder during stripping off such that the stripping force is introduced to the punch over a lever arm.

The non-supported scrap web in the die roll area deforms elastically. The elastic deformation finally causes a die roll wedging effect between the scrap web and the punch. With asymmetric cutting line geometries, different-sized die roll on opposing sides of the geometry results in a flexural load on the punch or in local exceedance of the material strength.

In future investigations, the stripping phase in a fine blanking cycle with asymmetric cutting line geometry needs to be simulated in order to quantify the observed effects. For example, the punch fractured after one-third of the stripping path. With the gained knowledge, asymmetric clamping of cemented carbide punches need to be compensated by an improved strip layout or die roll control.

Microstructural Evolution of Ti-55511 Titanium Alloy During Quasi-Beta Forging

Yu-Qiang Jiang, Y. C. Lin, and Guo-Dong Pang

Abstract The quasi-beta forging behavior of Ti-55511 alloy is systematically studied by hot compressive deformation experiments and electron back-scattered diffraction (EBSD) tests. The results show that the strain rates have obvious effects on the hot deformation behaviors of the studied alloy. With the increase of strain rate, the flow stress increases. At low strain rates, the work hardening rates hardly change until a critical strain, and then the work hardening rates slightly increase. At a medium strain rate (0.1 s^{-1}), the work hardening rate gradually decreases until a critical strain, and then the work hardening rate shows little variation with strain. However, at high strain rates (1 s^{-1}), the positive work hardening rate indicates the obvious work hardening at the initial deformation stage, and the work hardening rates change to negative and then to positive with strain when the strain rate is further increased to 10 s^{-1}. The main soften mechanism of β grain is DRV. With the increase of strain rate, the fraction of DRX grains and the sub-grains decrease. Too high strain rate leads to the formation of flow localization.

Keywords Microstructural evolution · Ti-55511 alloy · Quasi-beta forging

1 Introduction

Admired for their excellent high specific strength and fracture toughness, titanium alloys are widely used in aircraft industries [1, 2]. However, the narrow TMP parameter ranges and complicated mechanical/microstructural evolution restrict the forming qualities of the titanium alloys [3, 4]. So, the hot deformation behaviors of high-strength titanium alloys were pursued by many authors [5, 6].

According to the relationship between the forging temperature and beta transition temperature, the forging of titanium alloys is split into β and α + β forging. For the α

+ β forging, the initial grain size, strain, strain rate, and temperature have important effects on the dynamic evolution of the α phase [7–9]. When the temperature is higher than the β transition temperature, namely the β forging, the DRX and DRV of β phases will happen [10, 11]. The processing parameters, such as strain, strain rate, and deformation temperature, also have a remarkable influence on the evolution of β phases [12, 13].

For the high-strength beta alloy, the quasi-beta forging (the deformation temperature slightly exceeded the beta transfer temperature) is put forward to control the β grain size [14, 15]. In this work, the quasi-beta deformation behaviors of Ti-55511 alloys and the microstructural evolutions are systematically studied by the EBSD method. The effects of strain rates on the deformation behavior and microstructural evolution of the studied alloy are investigated. Meanwhile, the deformation mechanism of the studied alloy is discussed.

2 Material and Experiment

A near beta titanium alloy, Ti-55511, was used in this study. The beta transition temperature of the studied alloy is 1148 K obtained by optical examination [16, 17]. Cylindrical specimens (ϕ8mm × 12mm) were prepared from the wrought bar. To get the single beta phase, the specimens were heat-treated at 1173 K for 60 min followed by water quenching. The initial microstructure obtained by the authors of the specimens after heat treatment is shown in Fig. 1. The hot compression tests were conducted at 1163 K on Gleebe-3500 thermal simulation test machine, and strain

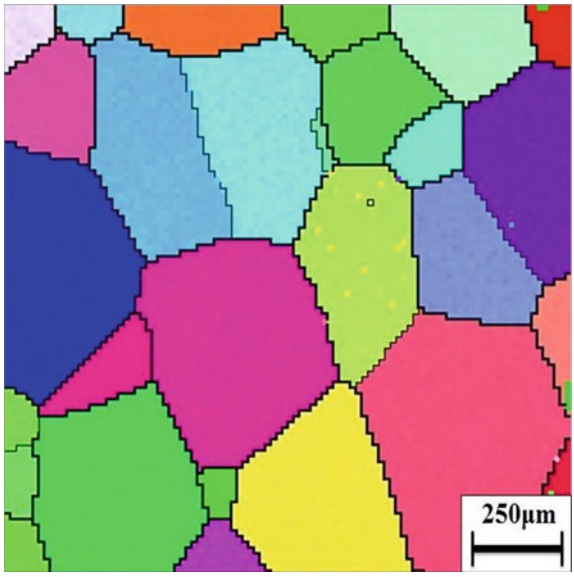

Fig. 1 The initial microscopy image of the studied alloy. (Color figure online)

rates of 0.001, 0.01, 0.1, 1, and 10 s^{-1}. After the hot deformation, the specimens were water quenched for the following EBSD observation.

Prior to the hot deformation, the specimens were heated to the target temperature at 10 K/s, and then kept for 300 s to minimize the differential temperature. After the hot deformation, the specimens were water quenched for the following microstructural observation. Then the specimens were sectioned parallel to the compression axis and prepared for the EBSD observation. The samples for EBSD observation were electrochemical polished in corrosive liquid of 5 ml $HClO_4$ and 95 ml CH_3COOH for 30 s at the voltage of 50–55 V. The step size during the EBSD observation is 10 μm because of the large grain size and to reduce the scanning time.

3 Results and Discussion

3.1 The Quasi-Beta Deformation Behavior

Figure 2 shows the quasi-beta deformation behaviors of the studied alloy. It can be found from Fig. 2 that the strain rates have obvious effects on the hot deformation behavior of the studied alloy. Generally, with the increase of strain, the stress first increases and then almost keeps stable when the saturation stress is reached, which shows the typical DRV feature [4]. Moreover, increasing the strain rate can largely increase the stress. There is enough time for the DRV and DRX, and the relative low flow stress can be found at a low strain rate. However, the short deformation time restrains the DRV and DRX process, and the flow stress is increased at a high strain rate.

Figure 2b shows the relationships between the work hardening rate ($\partial\sigma/\partial\varepsilon$) and true strain. It can be found from Fig. 2b that the coupling between strain and strain

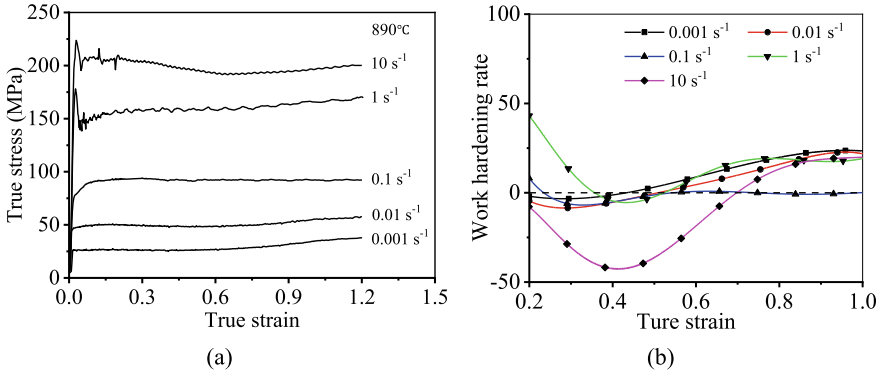

Fig. 2 The quasi-beta deformation behavior of the studied alloy: (**a**) The true stress true strain curves; (**b**) Work hardening rates. (Color figure online)

rate has remarkable effects on the flow stress of the studied alloy. At low strain rates (0.001–0.01 s^{-1}), the work hardening rates hardly change until a strain of 0.6, and then the work hardening rates slightly increase, as shown in Fig. 2b. At a medium strain rate (0.1 s^{-1}), the work hardening rate gradually decreases until the true strain of 0.3, and then the work hardening rate shows little variation with strain. However, at high strain rates (1 s^{-1}), the positive work hardening rate indicates the obvious work hardening. When the strain rate is further increased to 10 s^{-1}, the work hardening rates change from negative to positive, as shown in Fig. 2b.

During the hot deformation of the studied alloy, the strain rate sensitivity factor ($\partial \ln \sigma / \partial \ln \varepsilon$) lies in the range of 0.19–0.23, and the deformation activation energy ranges from 180 to 220 kJ/mol, which is slightly greater than the self-diffusion activation energy of the beta titanium (153 kJ/mol) [18]. So, the main deformation mechanism of the studied alloy is the slip and cross-slip of the dislocation, and the soften mechanism is DRV [19, 20].

3.2 *Microstructural Evolution*

During quasi-beta deformation of Ti-55511 alloy, the complicated microstructural evolution leads to the versatile hot deformation behaviors. In the following parts, the complicated microstructural evolution is discussed and the relationship between microstructural evolution and hot deformation behavior is revealed.

3.2.1 Effect of Strain

Figure 3 shows the inverse pole figures (IPFs) of the studied alloy deformed at true strains of 0.3, 0.6, and 1.2, and the arrows show the compressive direction. In Fig. 3, the LAGBs and HAGBs are marked by thin-gray and thick-black lines, respectively.

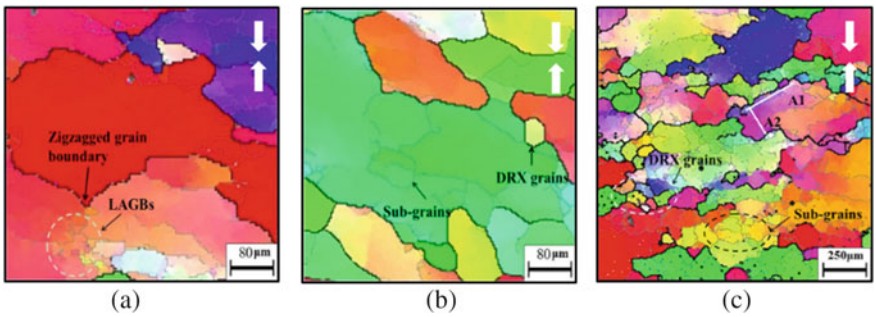

Fig. 3 The IPFs of Ti-55511 alloy deformed at 0.001 s^{-1} and strains of **a** 0.3; **b** 0.6; **c** 1.2. (Color figure online)

It can be found from Fig. 3 that the strain has obvious effects on the evolution of β phases of Ti-55511 alloy. At a relatively low strain (0.3), the initial β grain is slightly elongated, and the β grain boundaries are irregularly zigzagged. Meanwhile, there are plentiful LAGBs in the initial β grains, as shown in Fig. 3a. When the strain is increased to 0.6, some DRX grains are formed in the zigzagged initial β grains, and sub-grains are also formed in the initial β grains, as shown in Fig. 3b. However, when the strain is further increased to 1.2, a great deal of DRX grains are formed in the initial β grains. Within the initial β grains, the number of sub-grains is increased, as shown in Fig. 3c.

3.2.2 Effect of Strain Rate

Figure 4 shows the IPFs of the studied alloy deformed at different strain rates, and the arrows show the compressive direction. It can be found from Figs. 3c and 4 that the strain rates have tremendous effects on the evolution of the beta phase. At a relatively low strain rate (0.001–0.01 s^{-1}), the initial beta grain boundaries are irregularly zigzagged, and some DDRX grains and sub-grains are formed (Fig. 3c). Figure 5a, b illustrates the variations of the local and cumulative misorientations along the lines labeled in Fig. 3c. As indicated in Fig. 5a, b, the local misorientation (point to point) which is greater than 10° is scarcely observed, and the cumulative misorientations (point to origin) along grain boundary, as well as from grain boundary to grain interior, are larger than 15°, which indicates that the DRX is under development stages. Meanwhile, the misorientation mutation can be found in Fig. 5a, b, which indicates the occurrence of sub-grains and the development of DRV.

When the strain rate is increased to 0.1 s^{-1}, the initial beta grains are elongated, and the degree of grain boundary zigzagging is decreased. Meanwhile, the number of DRX grains and sub-grains decreases, as shown in Fig. 4a. The cumulative misorientations along grain boundary, as well as from grain boundary to grain interior, are no more than 10° (Fig. 5c, d), indicating the slow evolution of the DRX process. In

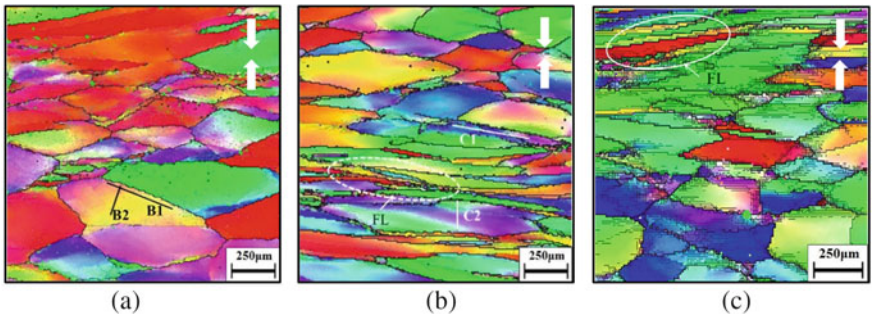

Fig. 4 The IPFs of the studied alloy at a strain of 1.2 and strain rates of **a** 0.1 s^{-1}; **b** 1 s^{-1}; **c** 10 s^{-1}. (Color figure online)

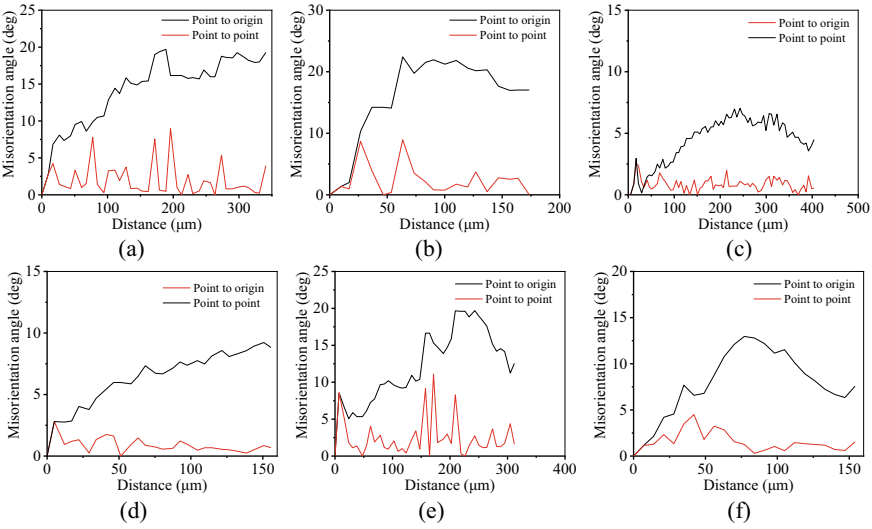

Fig. 5 Evolution of misorientation angles along the lines labeled in Fig. 3c and Fig. 4: **a** A1; **b** A2; **c** B1; **d** B2; **e** C1; **f** C2. (Color figure online)

addition, dense, small sub-grains are formed at the initial β grains boundaries, and the misorientation mutation occurs more frequently (Fig. 5c).

When the strain rate is increased to 1 s^{-1}, the initial beta grains are further elongated, and less irregular zigzagged grain boundaries are formed, indicating the lower degree of DRX, as shown in Fig. 4b. The cumulative misorientations along grain boundary exceed 15°, while the cumulative misorientations from grain boundary to grain interior are no more than 15°, as displayed in Fig. 5e, f. However, with the increase of strain rates, the deformation is accumulated at the local area, and obvious deformation gradient and flow localization are formed (Fig. 4b). When the strain rate is further increased to 10 s^{-1}, more obvious flow localization (FL) and elongated initial beta grains are found, as shown in Fig. 4c. Yamanaka et al. [21] also found the flow localization at high strain rates (1 s^{-1}).

3.3 The Deformation Mechanism of Ti-55511 Alloy

Due to high stacking fault energy, the DRV of β phases is apt to happen. The soften mechanism of β phases is DRV, and only small DRX grains emerged at the initial β grain boundary, as shown in Figs. 3 and 4. Figure 6 shows the kernel average misorientation (KAM) maps of the studied alloy at different strain rates. It can be seen from Fig. 6a that there are many LAGBs within the initial β grain, which indicates the high dislocation density. The high-density dislocations impede the deformation of the studied alloy, and the flow stress is gradually increased, as shown in Fig. 2.

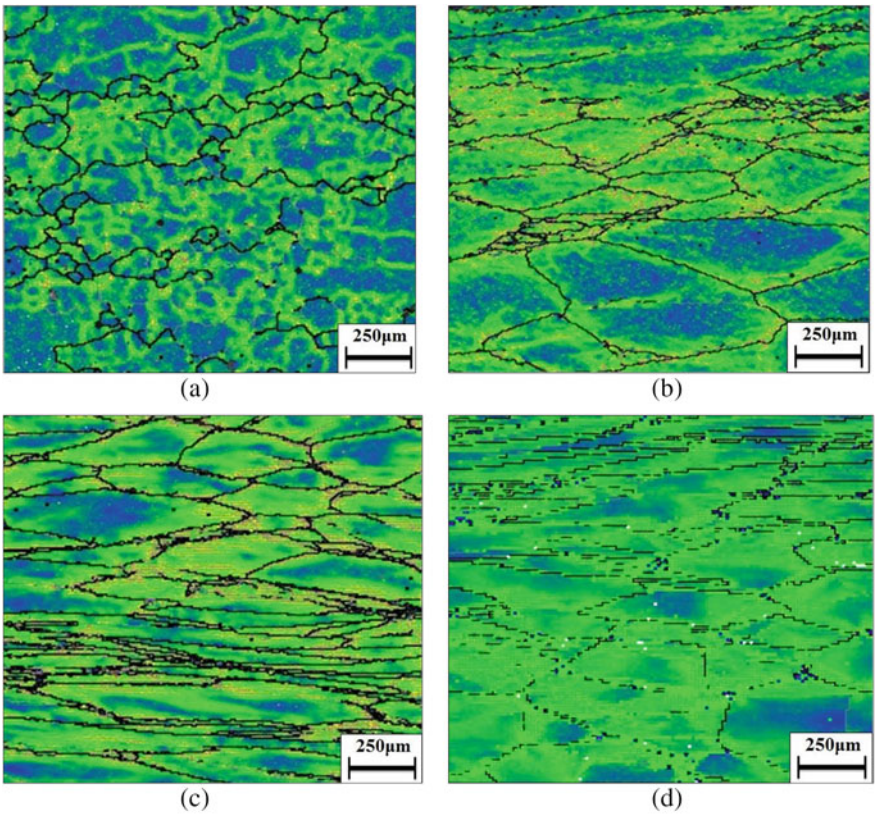

Fig. 6 The KAM maps of the studied alloy deformed at a strain of 1.2 and strain rates of **a** 0.001 s^{-1}; **b** 0.1 s^{-1}; **c** 1 s^{-1}; **d** 10 s^{-1}. (Color figure online)

When the strain rate is increased to 0.1 s^{-1}, many sub-grains are formed at the initial beta grain boundary due to DRV (Fig. 6b) and the balance between work hardening and DRV is obtained. So, the flow stress is almost unchanged with the strains, as shown in Fig. 2. However, when the strain rate is increased to 1 s^{-1}, more dislocations and tiny sub-grains are accumulated at the initial β grain boundary, as shown in Fig. 6c. The deformation of β grain is impeded by the tiny sub-grains and LAGBs, and the flow stress is increased gradually, as shown in Fig. 2. When the strain rate is further increased to 10 s^{-1}, the DRV is further improved, and many tiny sub-grains are formed in the beta grains. The short deformation time restricts the growth of sub-grains, and the DRX grains are seldom found (Fig. 4c). Due to the formation of tiny sub-grains, the degree of dislocation entanglement is increased, and the flow stress is increased with strain (Fig. 2).

Figure 7 shows the schematic diagram of the deformation mechanism of the studied alloy. Due to the work hardening, the dislocations are accumulated within the initial beta grains. With the increase of strain, the DRV is promoted, and some

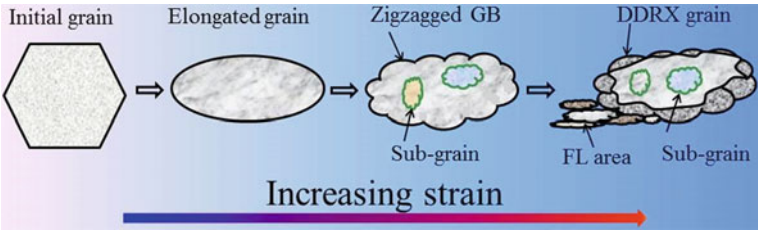

Fig. 7 The deformation mechanism of the studied Ti-55511 alloy. (Color figure online)

sub-grains are formed in the initial beta grains. At the same time, the initial beta grains are elongated and boundaries are zigzagged. On further increasing the strain, the DRX grains are formed at the zigzagged grain boundaries, and the number of sub-grains is increased.

4 Conclusions

The quasi-beta deformation behavior and microstructural evolution of Ti-55511 alloys are systematically studied, and the main conclusions are summarized as follows:

(1) The strain rates and strain have obvious effects on the flow behaviors of Ti-55511 alloy. With the increase of strain rate, the flow stress increases. The coupling between strain and strain rate has remarkable effects on the flow stress of the studied alloy. At low strain rates, the work hardening is not obvious, and work hardening and dynamic softening are the main flow characters at high strain rates.

(2) The main soften mechanism of beta grain is DRV. With the increase of strain, the initial beta grain boundary is zigzagged, and the DRX grains and sub-grains are observed. With the increase of strain rate, the fraction of DRX grains and the sub-grains decrease. Too high strain rate leads to the formation of flow localization.

High Speed and Impulse Forming

High-Speed Material Characterization Using an Instrumented Forging Hammer

Julen Agirre, David Abedul, Angel Oruna, Nagore Otegi, and Lander Galdos

Abstract Hammer forging is a widely employed manufacturing process to produce parts with excellent mechanical properties. Although the rheological behavior and the microstructural transformation phenomena of metals under hammer forging conditions are of great industrial interest, few materials have been tested in such intermediate strain rates ($10–10^3$ s^{-1}) due to the lack of laboratory machines for intermediate speed testing. With the objective of addressing that gap, this paper presents a novel automatic forging simulator comprising an instrumented forging hammer capable of performing intermediate speed deformations, up to 5 m/s. Three data acquisition approaches were evaluated to select the most appropriate approach and obtain valid rheological data from intermediate strain rate tests performed on the developed hammer. First, the data obtained by both a high-speed camera and a load cell was combined to calculate reference flow curves. Then, two additional data monitoring approaches were then analyzed, employing independently first the high-speed camera and then the load cell data. It was concluded that flow curves obtained utilizing only the load cell data offered accurate results without the need for an expensive and complex high-speed camera.

1 Introduction

Hammer forging is a widely employed technology that produces parts with superior mechanical properties and with minimum material waste. The initial billet, which usually has a simple geometry, is plastically deformed in one or more operations to produce parts with complex final geometries. The process is attractive from an economic standpoint when a large number of parts must be produced and/or when superior mechanical properties are required [1]. Frequently, such exceptional mechanical properties are achievable only by a hammer forging process.

The most significant characteristic of hammer forging is the high deformation speed, and thus the high strain rates reached when forming the material. Although in other manufacturing processes such as machining operations the material is subjected to higher strain rates (10^3–10^6 s^{-1}) than those reached in hammer forging operations (10–10^3 s^{-1}), deformation speeds in hammer forging are much higher than those of press forging [2]. In the case of mechanical presses, this variable can reach a maximum of only 30 s^{-1}, and no more than 10 s^{-1} in hydraulic presses [2, 3].

Although the rheological behavior and the microstructural transformation phenomena of metals under hammer forging conditions are of great industrial interest, few studies have been carried out, and few materials have been tested in such intermediate strain rates. One of the main reasons is that there are not many commercial experimental facilities that allow testing under such conditions [2]. Conventional servo-hydraulic testing machines are commonly utilized for quasi-static strain rate testing ($\leq$10 s^{-1}), and high strain rate tests (>10^3 s^{-1}) are generally performed in split Hopkinson pressure bar (SHPB) testing machines [2]. However, there is a lack of laboratory testing facilities to perform tests in the gap between quasi-static and high strain rates. Numerous researchers have developed testing machines for intermediate strain rate testing, such as servo-hydraulic machines or modified SHPB systems. However, excessive acquisition noise or limited achievable strain levels are the main drawbacks of these machines [2]. Furthermore, very few of these testing facilities are equipped with a heating system, resulting in a lack of machines capable of performing tests at both intermediate strain rates and high temperatures.

This paper presents a novel automatic forging simulator developed to address this gap. This laboratory-scale testing machine is able to reproduce a wide range of real cold and hot industrial forging conditions, from low strain rates in an isothermal hydraulic press up to intermediate strain rates in an instrumented forging hammer. Additional forging strategies can also be tested, including intermediate heating cycles and combined strain rate deformations. Moreover, by modifying the sample geometry and the tooling of the forming modules, several loading conditions, such as compression, tension, or shear, can also be tested.

As regards the instrumented forging hammer, data acquisition in the intermediate to high-speed range is crucial to obtain valid and representative results. There exist a number of high acquisition-rate techniques to measure the kinematics and

load in these speed ranges. For kinematic data acquisition, non-contact measurement techniques are often used, e.g., high-speed cameras with digital image correlation (DIC), laser displacement sensors, or customized extensometers. The load applied to the specimen is typically measured by a Hopkinson bar or by a piezoelectric load cell connected to an amplifier and an oscilloscope [2]. The instrumented hammer presented in this paper is equipped with two of the aforementioned acquisition devices: a high-speed camera with DIC, and a piezoelectric load cell with an amplifier and an oscilloscope. These two techniques were selected as they offer a good compromise between cost, versatility, and robustness.

In the present paper, three acquisition approaches are evaluated so as to select the most appropriate approach and to obtain valid rheological data from intermediate strain rate tests performed on the instrumented forging hammer. For this purpose, the instrumented hammer was employed to perform cold uniaxial upsetting tests at four intermediate strain rates. The uniaxial compression test is a widely known method to determine the flow stress of a metallic material as a function of the strain applied, by compressing a cylindrical sample between two flat dies [4]. In this case, the tested material was S235JR structural steel.

First of all, data obtained by both the high-speed camera and the load cell was combined to calculate reference flow curves. With the aim of simplifying the data acquisition setup of the instrumented hammer, two additional data monitoring methods were then analyzed. These were data acquired solely by the high-speed camera to analytically calculate the flow curves, and data acquired by only the load cell to calculate the same stress–strain curves.

The suitability of each monitoring technique was evaluated in terms of the correctness and the sharpness of the acquired rheological data as well as the simplicity of the monitoring setup. Results of the three acquisition approaches were compared and evaluated and the most appropriate acquisition technique for the novel instrumented forging hammer was selected. This work forms the basis for future studies in intermediate strain rate testing, not only for flow data acquisition at these underexplored strain rates but also for the study of microstructural transformation phenomena of metallic materials at these strain rates and under cold to hot conditions.

2 Experimental Procedure

2.1 Instrumented Forging Hammer

Very few commercial laboratory machines are capable of testing materials at hammer forging strain rates (up to 300 s^{-1}). To address that problem, a novel automatic forging simulator was developed and constructed (Fig. 1). This automatic forging simulator was designed to perform compression, tension, and shear tests, in addition to crash tests. It comprised four main sections: a heating furnace (max. 1350 ºC), an isothermal hydraulic press, an instrumented hammer and a quenching medium.

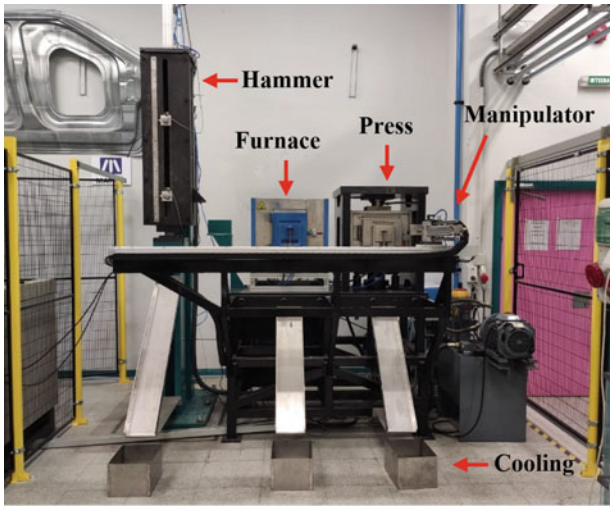

Fig. 1 Overview of the developed experimental forging simulator. (Color figure online)

To minimize human error and optimize manipulation times, the machine is fully automated, and sample manipulation is carried out by an electro-pneumatic system.

In the present paper, we focus on the instrumented hammer, as it was the only deformation module employed in the study. The hammer is pneumatically actuated and capable of performing high-speed deformations, up to 5 m/s. Such elevated speeds mean that upsetting tests at strain rates of up to 300 s^{-1} can be carried out (depending on the geometry of the tested sample), thus covering the range of strain rates commonly reached in industrial hammer processes. In a conventional uniaxial upsetting test, the strain rate at which the sample is deformed is calculated by the following equation (Eq. 1):

$$\dot{\varepsilon} = \frac{v}{h} \tag{1}$$

where v and h are the instantaneous deformation velocity and instantaneous sample height, respectively. As an example, if a strain rate of 300 s^{-1} is sought in a conventional uniaxial upsetting test with an initial deformation velocity of 5 m/s, an initial sample height of 16.67 mm would be needed. If a constant strain rate is required during the straining, a decreasing deformation velocity would need to be applied to the sample.

In the instrumented forging hammer presented in this paper, the sample is deformed by kinetic energy, propelling the upper die downward with a high-pressure pneumatic cylinder. Speed variation is accomplished by modifying the falling height of the upper die; the greater the falling height, the higher the deformation velocity, and thus, the higher the deformation energy. The weight of the upper die is 92 kg, and hence the maximum applicable deformation energy is 1.15 kJ.

2.2 Uniaxial Upsetting Tests and Data Acquisition Setup

With the objective of selecting the most appropriate acquisition approach to generate valid flow data at elevated strain rates, cold uniaxial compression tests were performed with the instrumented hammer at four different speeds (3.3, 4, 4.7, and 5 m/s) which correspond to four different strain rates (150, 200, 235, and 260 s^{-1}, respectively). Cylindrical samples (Ø13,5 × 20 mm) of S235JR structural steel were employed for the tests.

Although correct lubrication is necessary to obtain accurate compression flow data, in the present work neither lubrication nor Rastegaev-type samples were utilized. This is because the aim of this study was not to obtain accurate flow curves of S235JR but to evaluate different acquisition approaches. For the same reason, neither barreling nor temperature corrections were applied.

As regards data monitoring, two techniques were utilized to acquire load and displacement experimental data. For the measurement of the kinematics of the upper die, a Photron Fastcam-APX RS250K high-speed camera with appropriate illumination lamps was used (Fig. 2). This camera offers recording rates of up to 250,000 fps. In this study, experimental measurements were taken at 15,000 fps. Random point patterns were generated in the upper (moving) and lower (static) dies, and the deformation kinematics were obtained with the DIC software GOM Correlate (Fig. 3). For safety reasons, the deformation of the sample was carried out inside a cavity located on the lower side of the upper die. Therefore, for the strain calculation of the sample, the linear displacement of the upper die was taken into account. The upper die was considered rigid, and consequently, the motion of the upper die was determined to be equal to the deformation kinematics of the sample. To acquire the impact force, a piezoelectric load cell connected to an oscilloscope was employed (Fig. 2). This force sensor was mounted directly inside the lower static die of the hammer, and the acquisition frequency was 300 kHz.

3 Results and Discussion

In this section, the experimental results are presented. First of all, reference flow curves are discussed, which were generated combining the kinematics obtained by the high-speed camera and the force measured by the load cell. Next, the two analytically calculated flow curves are presented, one using the data obtained by the high-speed camera, and the other is the data acquired by the force sensor. Finally, the flow curves generated by the three acquisition approaches are compared.

Henceforth, the lowest tested strain rate (150 s^{-1}) is referred to as case 1, the strain rate of 200 s^{-1} as case 2, the next higher strain rate (235 s^{-1}) as case 3, and the highest tested strain rate (260 s^{-1}) as case 4. Three repetitions were performed for each of the four velocities and a very low deviation was observed in all cases. Mean values were calculated for each case. As the test was automated, this undoubtedly enhanced the repeatability of the results.

3.1 Reference Curves

Reference flow curves were generated by combining the motion data obtained from the high-speed camera and the force measured by the load cell. As for the high-speed camera results, Fig. 4 shows the DIC technique employed for the acquisition of the kinematics of the upper and lower dies. A mean value of all the measured points was calculated in each of the dies. The displacement and velocity data of the four tested strain rates is presented in Fig. 5. As expected, it is observed that the higher the impact speed, the greater the sample deformation. A velocity peak can be seen at the beginning of each speed curve, at the instant in which the upper die makes

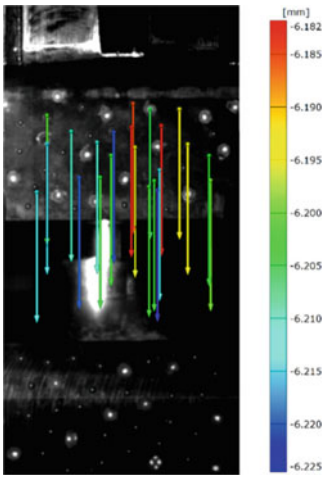

Fig. 4 Displacement of the upper die calculated with GOM Correlate DIC software. (Color figure online)

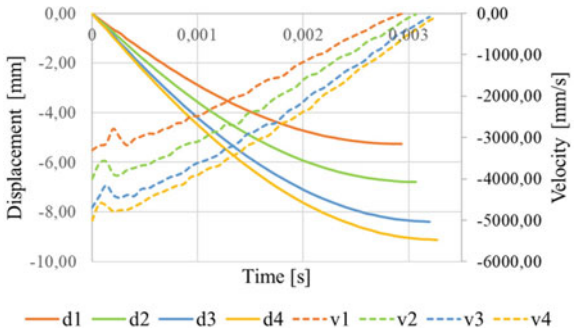

Fig. 5 Displacement and velocity of the upper die acquired with a high-speed camera. (Color figure online)

contact with the sample. This is likely due to the lack of lubrication between both surfaces, and thus the use of lubrication may smooth those peaks. It is also observed that the speed curves follow a relatively linear tendency.

It is important to highlight that only the motion data of the upper die was employed to generate the flow curves, disregarding the displacement of the lower die. In the most unfavorable case, that of the highest velocity, the maximum displacement of the lower die was 0.32 mm, while the maximum displacement of the upper die was 11.67 mm. In this case, the displacement of the lower die is 2.74% of the displacement of the upper die. Figure 6 shows the acceleration of the upper die during the high-speed deformation. Although the tendency is similar from case to case, high levels of noise and significant variations in acceleration values can be observed.

True strain values were calculated taking into account the displacement of the upper die measured by the high-speed camera (Eq. 2). Once true strain was calculated, true strain rate values were also obtained (Eq. 1). With respect to the evolution of strain rates during the uniaxial upsetting tests, once the upper die comes into contact with the sample, the die starts decelerating with a linear trend (Fig. 5). Figure 7

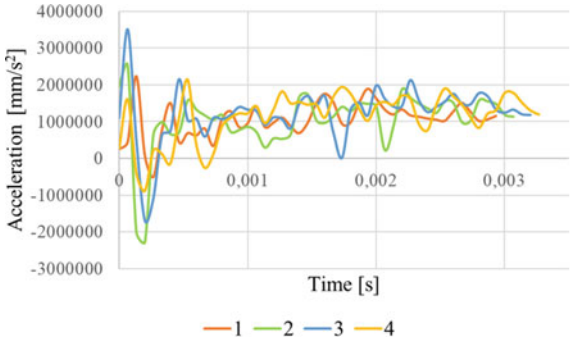

Fig. 6 Acceleration of the upper die acquired with a high-speed camera. (Color figure online)

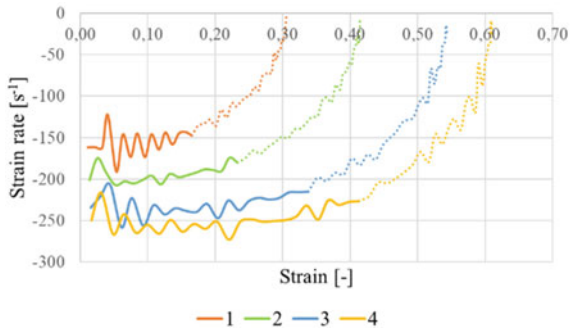

Fig. 7 Strain rates acquired with a high-speed camera. (Color figure online)

shows that the strain rate remains relatively constant up to a certain strain level, and this strain level is higher in the case of the highest deformation speed. Taking this into account, if a constant strain rate is sought, a criterion is needed to specify the strain level until which the test can be considered as strain rate constant. In the case of this work, a constant strain rate was considered until the strain rate dropped below 90% of the initial strain rate value. The constant strain rate ranges are marked as solid lines in Fig. 7 and the non-constant ranges as dotted lines. The figure shows that at the highest speed, strain rates of 250 s^{-1} are reached. In industrial hammer processes strain rates of up to 200 $s^{-1}$are attained, and thus the tests performed with the instrumented forging hammer covered the range of strain rates found in the industry.

As for data obtained by the load cell, Fig. 8 shows the force acquisition during the compression tests. It can be seen that the higher the strain rate, the higher the force needed to deform the material. As in the case of the velocities acquired by the high-speed camera, a peak is observed at the beginning of the force curves. This can be attributed to the first contact between the upper die and the sample and could be smoothed by applying lubrication between both surfaces.

Figure 9 sets out force vs displacement curves generated by combining the displacement captured with the high-speed camera, and the force acquired with

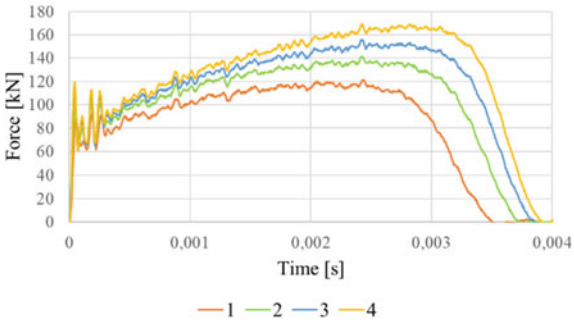

Fig. 8 Force data acquired with load cell. (Color figure online)

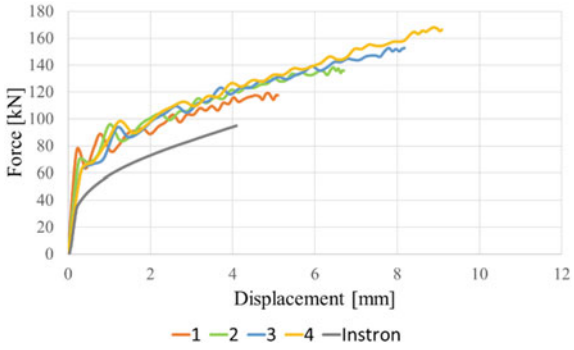

Fig. 9 Reference force versus displacement data. (Color figure online)

the load cell. Additionally, a force vs displacement curve obtained from a quasi-static compression test performed in a universal electro-mechanic drive Instron-4206 testing machine is shown. Compression tests in this standard testing machine were performed at a strain rate of 0.001 s^{-1}, significantly lower than the strain rates of the instrumented forging hammer, hence the difference in force.

To generate a typical stress–strain curve, displacement values were converted into true strain values by Eq. 2, and the force values were converted into stress values using Eq. 3:

$$\varepsilon = \ln\left(\frac{h}{h_0}\right) \tag{2}$$

$$\sigma = \frac{\vec{F}}{A} \tag{3}$$

where h is the height of the sample at each point of the test, h_0 is the initial height; and F and A are the force and transversal area at each point of the test, respectively. The instantaneous transversal area of the sample was calculated based on the following assumption (Eq. 5):

$$V_0 = V \tag{4}$$

$$A = \frac{A_0 \cdot h_0}{h} \tag{5}$$

where A_0 and h_0 are the initial area and initial height of the sample, respectively, and h is the instantaneous height of the sample measured by the high-speed camera. In cases of considerable barreling, this assumption can lead to errors. Little barreling was observed in the uniaxial upsetting tests performed in the current work, and therefore the assumption can be considered as valid (Fig. 10).

Reference true stress vs true strain flow curves is presented in Fig. 11. Interestingly, a maximum valid true strain of 0.42 was achieved at the highest strain rate. Intermediate strain rate flow curves show some noise which could be mathematically smoothed if needed. Quasi-static tensile and compression curves of tests performed in the aforementioned universal Instron testing machine are included in the figure as a reference.

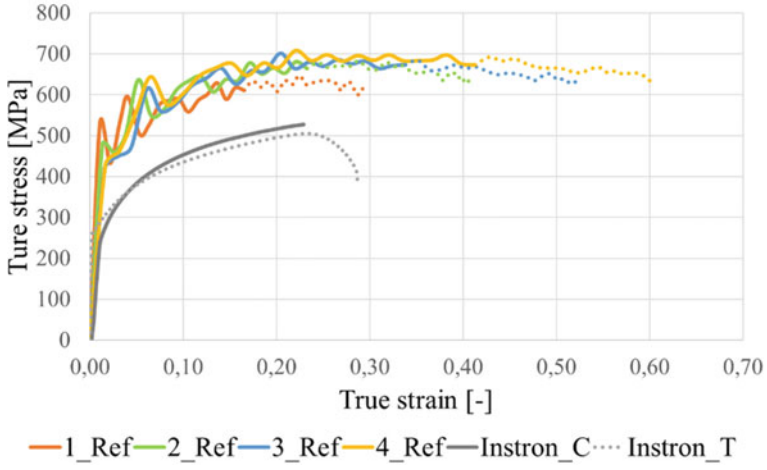

Fig. 11 Reference medium strain rate flow curves, and Intron compression (C) and Instron tensile (T) curves. (Color figure online)

3.2 Curves from High-Speed Camera Data Only

Once the reference flow curves were obtained by combining high-speed camera data and load cell data, a second approach was used to evaluate its ability to calculate valid flow data under hammer forging conditions. For this second approach, stress vs strain curves were generated by employing only data acquired by the high-speed camera. As the kinematics of the upper and lower dies can be directly acquired by the high-speed camera, the true strain is obtained. To analytically calculate the force data from the motion data measured by the high-speed camera, Newton's second law was followed (Eq. 6):

$$\vec{F} = m \cdot \vec{a} \tag{6}$$

where m is the total mass of the moving elements and $\vec{a}$ is the acceleration acquired by the camera. The mass of all the moving elements in the upper die was measured at 92 kg. As an example, in case 3 force acquired by the load cell and the force analytically calculated from camera data is shown in Fig. 12. Although the calculated curve follows the tendency of the reference load cell data, significant noise and a lack of sharpness can be distinguished. Moreover, at the beginning of the curve, at small strains, the calculated curve does not represent the reference curve.

By analytically calculating the force in all the cases (Eq. 6), and converting it into stress (Eq. 3), stress vs strain curves were generated from only the high-speed camera data (Fig. 13). Each case is presented separately as the noise makes differentiation difficult. Although the calculated flow curves follow the reference force tendencies measured by the load cell, significant noise is discernable in all cases. In addition, this monitoring technique is unable to represent the beginning of the flow curve at small strains.

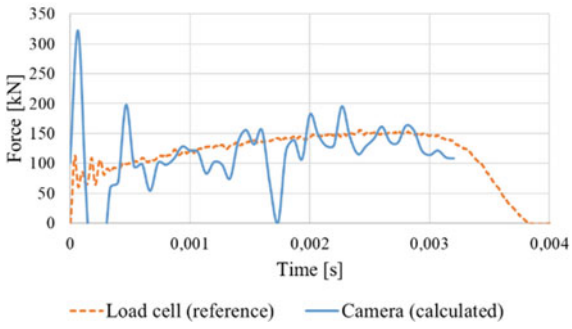

Fig. 12 Load cell (reference) force versus camera (calculated) force for case 3. (Color figure online)

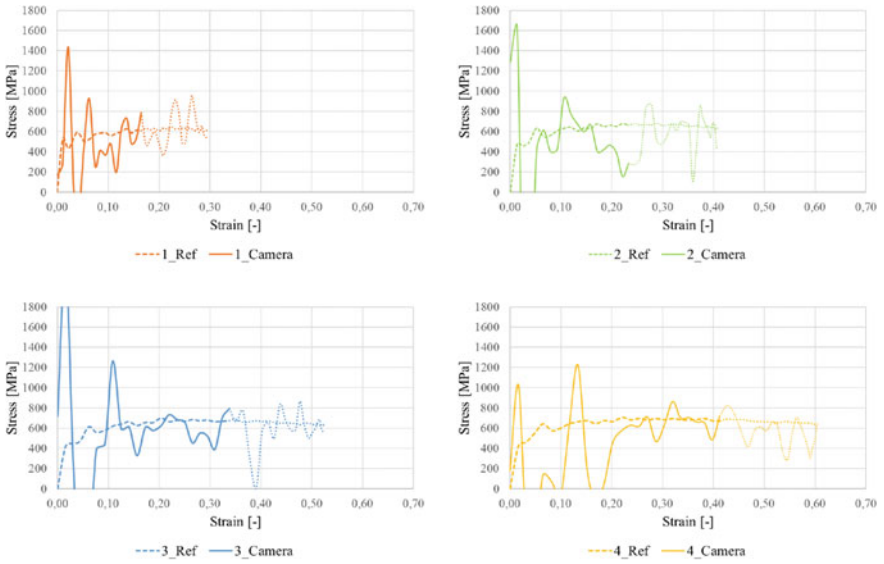

Fig. 13 Reference flow curves versus calculated (camera) flow curves for all tested velocities. (Color figure online)

3.3 Curves from Load Cell Data Only

Finally, a third acquisition approach was analyzed, in which medium strain rate flow curves were generated by only employing data acquired by the load cell. Deformation forces were directly acquired by the load cell, and to extract strain and stress data, acceleration was first calculated with Newton's second law (Eq. 7):

$$\vec{a} = \frac{\vec{F}}{m} \tag{7}$$

where m is the total mass of the moving elements and $\vec{F}$ is the force acquired by the load cell directly. It was known that the mass of all moving elements was 92 kg. Taking case 3 as an example, acceleration acquired by the high-speed camera and acceleration analytically calculated from load cell data is presented in Fig. 14. It can be clearly seen that the calculated acceleration follows the reference tendency. Furthermore, the calculated acceleration signal is significantly smoother and sharper than the acceleration acquired by the high-speed camera.

Once the acceleration was calculated, the equation of an accelerated linear motion was employed to calculate the position of the upper die at each point of the test (Eq. 6):

$$\vec{s} = \vec{s}_0 + \vec{v}_0 \cdot t + \frac{1}{2} \cdot \vec{a} \cdot t^2 \tag{6}$$

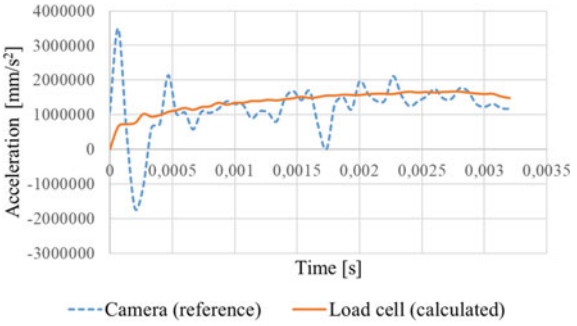

Fig. 14 Camera (reference) acceleration versus load cell (calculated) acceleration for case 3. (Color figure online)

where $\vec{s}_0$ is the initial position of the upper die, $\vec{v}_0$ is its initial velocity, $\vec{a}$ is its acceleration, and t is the time. To calculate position data using this equation, the initial velocity is the only variable that cannot be measured or analytically calculated from load cell data. Thus, in this case the velocity of the upper die just before the impact measured by the high-speed camera was used. However, as a future line, to analytically calculate the displacement of the upper die without employing an expensive and complex high-speed camera, the idea is to equip the hammer with a simple velocity measuring setup. To do so, two electrical switches separated by a known distance and connected to the same oscilloscope of the load cell will be utilized. The two switches will detect the upper die just before impact. Knowing the time difference between the two detectors and the distance between the two switches, the velocity of the upper die just before the impact will be calculated by Eq. 7:

$$\vec{v} = \frac{d}{\Delta t} \tag{7}$$

where d and Δt is the distance between the two detectors and the time difference between the two detections, respectively. By calculating the displacement in all cases (Eq. 6) and converting it into stress and strain data (Eqs. 2 and 3), flow curves were generated utilizing only the load cell data (Fig. 15).

The analytically calculated flow curves utilizing solely data acquired by the load cell and the reference flow curves show very good agreement. Similar noise is discernable in both cases and the deviation between them is minimum.

4 Conclusions

In this study, a novel automatic forging simulator comprising an instrumented forging hammer capable of performing intermediate speed deformations is presented. Three data acquisition approaches were evaluated so as to select the most appropriate

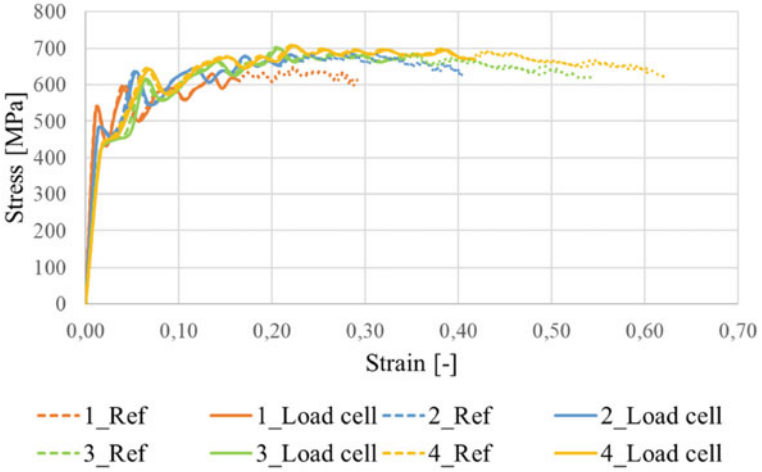

Fig. 15 Reference flow curves versus calculated (load cell) flow curves for all tested velocities. (Color figure online)

technique and obtain valid rheological data from intermediate strain rate upsetting tests. The main conclusions are set out as follows:

- Flow data calculated by employing only the high-speed camera was not sufficiently accurate and significant noise was discernable in all cases.
- Although analytically calculated forces followed reference force tendencies measured by the load cell, this monitoring approach was not sharp enough to precisely represent the beginning of the curve at small strain values.
- Stress vs strain data calculated by only employing data acquired by the load cell showed very good agreement with the reference flow curves without the need for an expensive and complex high-speed camera. Similar noise is discernable in both cases and the deviation between them is minimum. Moreover, no time-consuming DIC post-processing was required, and thus the flow data calculation is considerably faster.
- Based on these conclusions, it was determined that this acquisition approach will be implemented in the instrumented forging hammer for future material behavior analysis at medium strain rates.

Advancements in the Simulation of Magnetic Pulse Forming Processes with FORGE®

José Alves, François Bay, Ugo Ripert, Julien Barlier, and Nicolas Poulain

Abstract In this work, the latest developments on the electromagnetic (EM) module of FORGE® and the derived improvements for simulating the magnetic pulse forming process are presented. The following aspects are covered: advanced material description for high-intensity magnetic fields where coupling with the material database software JMatPro® is extended to account for the EM phenomena; integration of the forming limit diagrams (FLD) for analysis of thin sheets forming; improved meshing/remeshing for large displacements in the fully immersed multi-objects approach, where a particular focus is given to the fields transfer stage, showing how the overall CPU time can be reduced by half or more; and introduction of an advanced second-order time-stepping integration method based on an asynchronous interpolation that was previously developed for thermal-shock problems and is now extended to the computation of EM fields showing excellent convergency and stability properties.

1 Introduction

The interest in high-speed forming processes and especially magnetic pulse forming (MPF) continues to grow due to the benefits these processes bring to forming metallic alloys that show low formability under regular forming conditions when compared to conventional steels. This is the case for aluminum alloys, copper alloys, and in some cases magnesium alloys. For some materials, it has been shown that deformation at high strain rates improves the formability limits [1]. A debate is still ongoing on the exact mechanisms responsible for such phenomena. It is argued that at such strain rates the internal available energy enables a viscous almost fluid-like flow. It is also argued that shock waves traveling within the bulk of the material allow for a very efficient release of elastic deformation and residual stresses [2]. These improvements in formability are not systematically found and thus there is continuous research on the description of material properties. In the case of MPF, it is also necessary to consider the presence of large magnetic fields. For instance, Li et al. [3] recently showed the influence of high pulsed magnetic fields at low strain rates on an Al7055 alloy. In that work, it was shown that between 0 and 3 T the forming limit increases by up to 20%, and the residual stresses decrease by a factor of 10. Beyond that point, and up to 7 T the forming limit decreases with respect to 0 T, and the residual stresses are found at the same levels. In a typical MPF process, the magnetic field can reach values beyond 10 T that, even if for a short period of time,[1] can contribute to the activating movement of dislocations affecting the mechanical behavior during forming and the in-use properties afterward.

Due to the complex multi-physical interactions in this process, it is not obvious how to properly quantify the influence of each physical phenomenon. As experimental research continues to bring more information on the behavior of several kinds of materials, it is also necessary to improve the existing mathematical and numerical models which are the tools for interpreting the underlying phenomena and help in the decision-making process for optimizing energy consumption, material usage, and so on.

In this work, some of the latest developments done within the numerical simulation software FORGE® and its electromagnetic module FORGE®\Induction are presented. After a review of the fundamental physical principles, it is shown how the material data software JMatPro® can be used to obtain a first approximation of rheological and physical properties to carry out complex numerical simulations. Furthermore, the possibility of evaluating forming limit diagrams for high strain rate data is presented. In the following sections, numerical aspects related to time-step integration of the electromagnetic problem, automatic time-stepping on the mechanical side when dealing with impact conditions in MPF, and improvements to the data communication stages needed for the coupling of the several physics involved in the simulation are covered.

[1] A medium-size MPF machine delivers between 5 and 20 kJ of energy which is about the same energy stored in a modern smartphone battery. This energy is delivered in a time laps of less than 100 μs in order to release the power required to plastically deform the materials.

2 Multi-Physical Model

The computational model is based on a loose coupling between a thermo-mechanical dedicated solver and an electromagnetic dedicated solver (Fig. 1).

2.1 Thermomechanical Model

The solid mechanics model takes into account the conservation of linear momentum Eq. (1) and the mass conservation equation for compressible media:

$$\begin{aligned} \nabla \cdot \underline{\underline{\sigma}} + \vec{f} &= \rho \frac{D\vec{v}}{Dt} \\ \nabla \vec{v} &= \frac{1}{\rho}\frac{d\rho}{dt} \end{aligned} \tag{1}$$

where $\underline{\underline{\sigma}}$ denotes the Cauchy stress tensor, ρ the material density, $\vec{f}$ the volumetric force density vector in which the external loadings such as gravity or the Lorentz body forces are defined. Temperature evolution in the workpiece is determined by solving the heat transfer equation:

$$\rho C_p \frac{\partial T}{\partial t} - \nabla \cdot k \nabla T = \dot{Q} \tag{2}$$

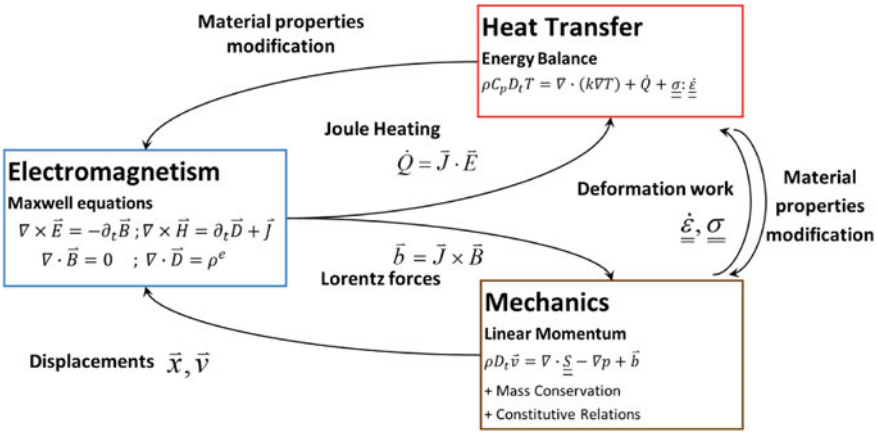

Fig. 1 Global interaction scheme of the physical models for electromagnetically-driven processes. (Color figure online)

where C_p represents the specific heat and k the thermal conductivity. The volumetric heat source term $\dot{Q}$ is made up of the sum of the dissipated heat due to plasticity and of the induced Joule power.

2.2 Electromagnetic Model

The electromagnetic model is based on the quasi-static state approximation of Maxwell equations expressed in the scalar-vector potential form:

$$\begin{aligned} &\sigma \frac{\partial \vec{A}}{\partial t} + \frac{1}{\mu_0} \nabla \times \frac{1}{\mu_r} \nabla \times \vec{A} = -\sigma \nabla \phi \\ &\nabla \cdot \sigma \nabla \phi = 0 \end{aligned} \tag{3}$$

where $\vec{A}$ is the magnetic vector potential, ϕ represents the scalar electric potential, σ denotes the electric conductivity, μ_0 the magnetic permeability of void space, and μ_r the material relative permeability.

2.3 Spatial Discretization

The 3D finite element discretization is carried out using tetrahedral finite elements which have the advantage of enabling automatic and fast remeshing strategies for any complex geometry. This basic geometry is declined in different linear formulations depending on the physical field to be computed as shown in Fig. 2.

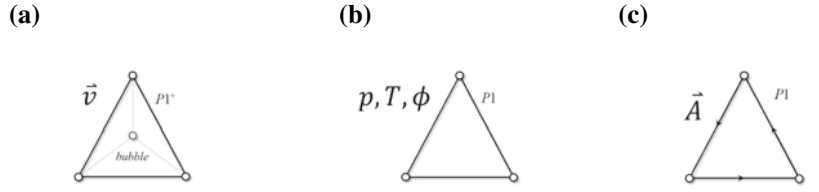

Fig. 2 Type of linear elements used in FORGE®. **a** Bubble linear element for the velocity field. **b** Regular P1 element for pressure, temperature, and electric potential fields. **c** Edge or Nédélec [5] element for the magnetic potential

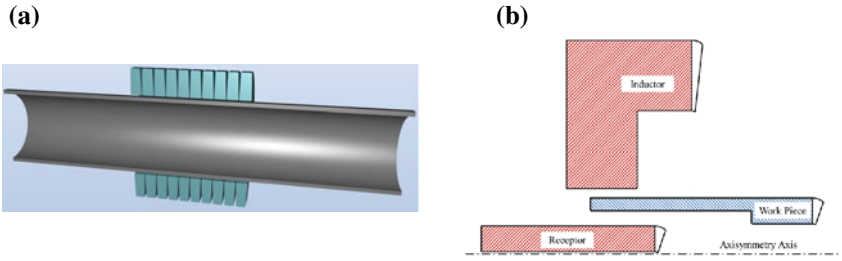

Fig. 3 **a** Free compression test of an Al6066-T6 tube [6]. **b** Magnetic pulse crimping of an aluminum Al2024 tube with a copper cylinder [7]. (Color figure online)

2.4 Test Cases

In order to test the different developments proposed in the following, two formerly introduced test models were used. The first case corresponds to a free compression test case (Fig. 3a)—courtesy of the I^2FG group. The second one consists of a magnetic pulse welding simulation of an aluminum alloy with a copper bar (Fig. 3b)—courtesy of BMAX.

3 Complex Material Behaviors and Strain-Rate-Dependent Forming Limit Diagrams

In order to define a useful material description, it is not only important to consider all the electromagnetic and thermo-mechanical interactions but also to choose the scale at which such interactions are to be represented/analyzed. At the macro-scale either phenomenological behavior laws or homogenization approaches can be used to describe the material behavior with sufficient accuracy and reasonable computational times. From a phenomenological approach, it is common to use rheological behavior models adapted to high strain rates such as the Johnson–Cook model. The disadvantage of such approaches is the need for large experimental tests to fit the model parameters. The advantage is that once fitted these models enable very accurate results within the range of loading conditions at which they were obtained.

Another additional approach typically used as a first estimate for the material description when no experimental data is available or neither possible to obtain is the application of software such as JMatPro® or Thermo-Calc®. These allow generating material behavior models for a large range of physical properties. For instance, within the FORGE® framework, all material parameters are defined as thermo-dependent, i.e., density, heat capacity, thermal conductivity, electrical resistivity, Young's modulus, etc. Furthermore, the magnetic permeability is defined as a function of the magnetic field as well as the temperature $\mu_r = f\left(T, \vec{H}\right)$ within

Table 1 Mean chemical composition of an Al6066-T6 aluminum alloy

Component	Al	Cr	Cu	Fe	Mg	Mn	Si	Ti	Zn
wt%	93.15	0.4	1.2	0.5	1.4	1.1	1.8	0.2	0.25

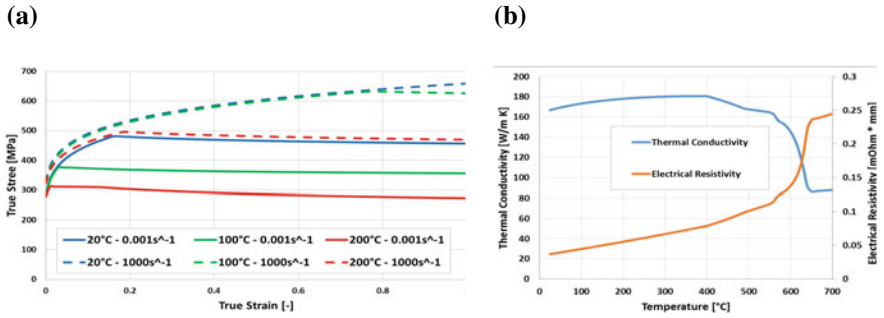

Fig. 4 Rheological data and physical data for the Al6066-T6 as generated by JMatPro® v11. (Color figure online)

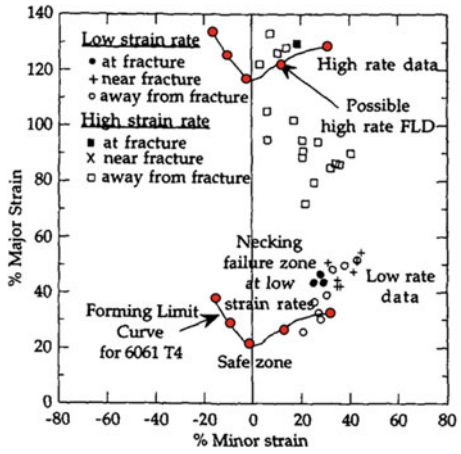

the electromagnetic module.[2] A compressible elasto-viscoplastic (EVP) model is applied for the mechanical representation of the stress–strain interaction in solid mechanics. All these properties can be found for several types of alloys from JMatPro® by entering the chemical composition as input. An example is shown for the Al6066-T6 alloy in Table 1 and Fig. 4.

As mentioned at the beginning, one of the key interests in MPF technologies is the possibility to access increased formability regimes for difficult-to-form materials. It is common practice to characterize formability using forming limit diagrams (FLD) in applications with thin metal sheets or thin tubes. Within this approach, the strain state is projected to a principal reference frame in which it is assumed that only two of the three components are necessary to fully characterize the formability. The third component is assumed to correspond perfectly to the deformation in the thickness direction of the part and to be uniform.

An example of an FLD as reported from the literature is shown in Fig. 5. Here it is shown how the formability of an Al6061-T4 alloy is increased at high strain rates. Nevertheless, it is important to highlight that it is also reported that this behavior is not necessarily incremental, i.e., below some unknown strain rate threshold value no improvements are observed. As this field continues to evolve, the possibility to define experimentally obtained FLDs was introduced in the software allowing the use of simulation for validation/verification purposes.

In order to use 3D volume elements in this context, the total strain tensor is projected on all external surfaces (triangles) of the mesh. The tensor is rotated on a space orthogonal to the normal direction of each surface. Two principal strain components parallel to the surfaces are computed from this rotation. These values

[2] At large magnetic field conditions it is usual to assume full magnetization of the material ($\mu_r = 1$).

$$\varepsilon_I = f(\varepsilon_{II}, T, \dot{\varepsilon})$$

Piece-wise linear file data-base

Fig. 5 Forming limit diagram of Al6061-T4 aluminum alloy as reported in [1]. (Color figure online)

are then used to compute how far away a surface element is from the forming limit curve, giving a factor between (0 and 1) if the element is below the FLC and in the "safe" region or (>1) if the element overpasses the FLC. An example is shown in Fig. 6 where the FLD is computed using a piecewise linear description as shown by the red dots in Fig. 5.

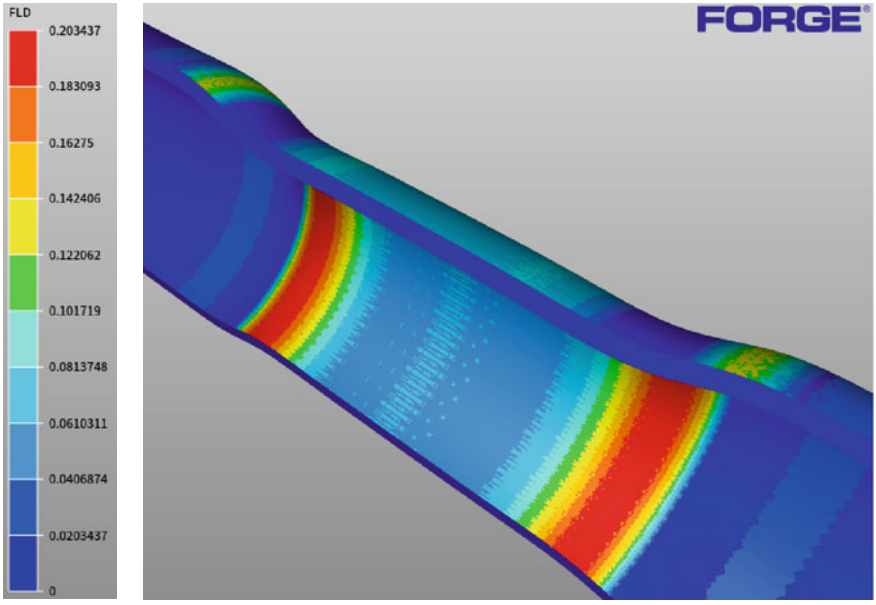

Fig. 6 Distribution of the forming limit criteria for the tube compression test. (Color figure online)

4 Robust Second-Order Time-Stepping

One of the key aspects in modeling evolution problems is how to properly discretize the time dependency. It is needed to have a robust, stable, and consistent method to minimize the divergence between the numerical approximation and the "real" solution. In this work, the use of a family of second-order methods presented previously is introduced in the software FORGE® for the thermal problem and extended to the electromagnetic problem, as described in Eq. (3). A detailed description can be found in [8, 9]. In the following, a brief summary of the method is given:

A system of ordinary differential equations is given as:

$$C\frac{\partial X}{\partial t} + KX = Q \tag{4}$$

It is required to compute X at a future time t_{n+1} assuming all state and input fields are known at the current time t_n and a past time t_{n-1}, where $t_{n+1} > t_n > t_{n-1}$, $\Delta t = t_{n+1} - t_n$ and $\Delta t_0 = t_n - t_{n-1}$ are the current and previous time-steps. An asynchronous time is also introduced as shown in Fig. 7.

The discretization and equilibrium are established at a virtual time as follows:

$$t^* = \alpha_1 t_{n-1} + \alpha_2 t_n + \alpha_3 t^a_{n+1}; \alpha_1 + \alpha_2 + \alpha_3 = 1 \tag{5}$$

$$X^* = \alpha_1 X_{n-1} + \alpha_2 X_n + \alpha_3 X^a_{n+1} \tag{6}$$

$$\frac{\partial X^*}{\partial t} = (1-\gamma)\frac{X_n - X_{n-1}}{\Delta t_0} + \gamma\frac{X^a_{n+1} - X_n}{\Delta t_a} \tag{7}$$

$$C^*\frac{\partial X^*}{\partial t} + K^* X^* = Q^* \tag{8}$$

The assembly of the linear system is written as:

$$\left[C^* + \frac{\alpha_3}{\gamma}\Delta t_a K^*\right]X^* = \frac{\alpha_3}{\gamma}\Delta t_a Q^* + C^*\left(\alpha_2 + \frac{\Delta t_a}{\Delta t_0}(\gamma - 1)\frac{\alpha_3}{\gamma} + \alpha_3\right)X_n$$

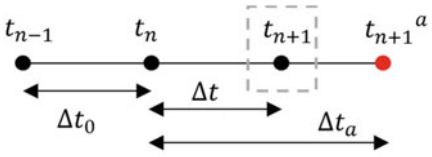

Fig. 7 Discretization of time in the asynchronous time-integration approach. (Color figure online)

$$+\left(\alpha_1 - \frac{\Delta t_a}{\Delta t_0}(\gamma - 1)\frac{\alpha_3}{\gamma}\right)X_{n-1} \tag{9}$$

And the actual solution at t_{n+1} is re-interpolated by:

$$X_{n+1} = \frac{\Delta t}{\alpha_3 \Delta t_a}X^* + \left(1 - \left(1 + \frac{\alpha_2}{\alpha_3}\right)\frac{\Delta t}{\Delta t_a}\right)X_n - \frac{\alpha_1}{\alpha_3}\frac{\Delta t}{\Delta t_a}X_{n-1} \tag{10}$$

For practical purposes $\Delta t_a = \Delta t$ is used, meaning that there are four numerical parameters to define the integration scheme. The method is defined:

- unconditionally stable if

$$\gamma \geq \frac{1}{2}; \alpha_1 > \frac{1}{2}(1 - \gamma)$$

- and consistent if

$$\alpha_2 = 1 - \alpha_1 + \left(\frac{1}{2} - \alpha_1\right)\frac{\Delta t_a}{\Delta t} - \frac{\gamma}{2}\left(1 + \frac{\Delta t_a}{\Delta t}\right)$$

$$\alpha_3 = \left(\alpha_1 - \frac{1}{2}\right)\frac{\Delta t_a}{\Delta t} + \frac{\gamma}{2}\left(1 + \frac{\Delta t_a}{\Delta t}\right)$$

In order to respect both conditions, there are only two free numerical parameters from where to choose α_1 and γ. Otherwise, the consistency condition can be violated as is the case for the classical Euler-implicit method (Table 2).

To evaluate the influence of the integration method on the resolution of the electromagnetic problem, the evolution of the active power (Joule heating) during the discharge using the test case 1 was investigated. The comparison is done by selecting different levels of refinement of the time-step applied to the electromagnetic problem: in this case $dt = [0.1, 0.5, 1]\,\mu$s. As shown in Fig. 8, for the Euler-implicit method the active energy is underestimated as the time-step grows, implying that for a reliable computation it would be necessary to use systematically small time-steps. For the Dupont-implicit method, the estimations are almost identical enabling larger time-steps with higher confidence in the results.

Table 2 List of some known time-integration schemes that can be derived from the proposed method

Name	γ	α_1	α_2	α_3	Observation
Euler-implicit	1	0	0	1	Stable but not consistent
Crank-Nicolson	1	0	1/2	1/2	
Dupont-implicit	3/4	0	0	1	The multiplying factors are the same as the QSSC method previously tested in [4]
Lees	1/2	1/3	1/3	1/3	

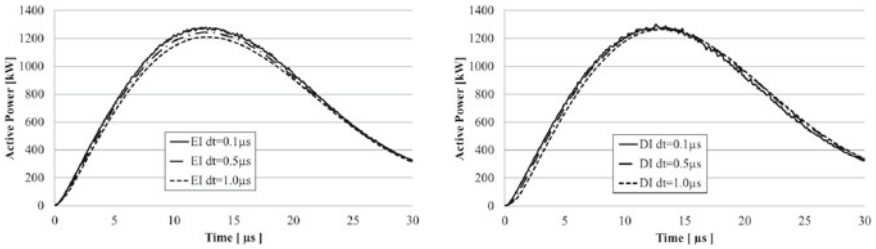

Fig. 8 Comparison of the numerical convergence for three time-step refinements of the active power in the electromagnetic model. (Left) Euler-implicit method. (Right) Dupont-implicit method

5 Field Transport Optimization

Several improvements have been introduced in the meshing/remeshing step necessary to enable the following large displacements and deformations within the resolution of the electromagnetic problem. In the following, some of the strategies that have been adopted and the improvements on the overall computational time are presented.

When talking about numerical computation, one of the key aspects is the fact that communicating information is more computationally costly than executing an algebraic computation. This is also the case for finite element simulations in which it dealt with different meshes to represent different physical phenomena and the communication between the different meshes is mandatory. Within the framework of electromagnetic simulation in FORGE®, there are four stages in which information must be communicated between different meshes. The first one will not be covered here being placed within the thermo-mechanical computation during remeshing. The other three stages (Fig. 9) correspond to (1) the communication from the electromagnetic module to the thermo-mechanical module, (2) the update of the electromagnetic model from the thermo-mechanical one, and (3) the recovering of a previously computed increment within the electromagnetic module if the mesh is modified.

Since a single mesh containing all solids is used in our numerical approach for electromagnetic computation, in some cases the communication between the two stages can be computationally costly. This is especially true in stages (1) and (3). The most time-consuming aspect is to build the acceleration structure which can be thought of as an index that allows a fast look up of a given point within a source mesh. There are several techniques that can be used to build this structure like octrees or the bounding volume hierarchy method. The latter is used with a bottom-up strategy (build containing cells from small to big) in order to build a precise and optimal search tree. However, the computational cost is far from negligible.

In order to reduce the CPU time dedicated to this stage, the notion of filters within the acceleration structure creation phase was introduced. These filters enable using the existing methodologies with minimum modification of the original algorithms. The basic idea is to include a label on elements/nodes from the source mesh during

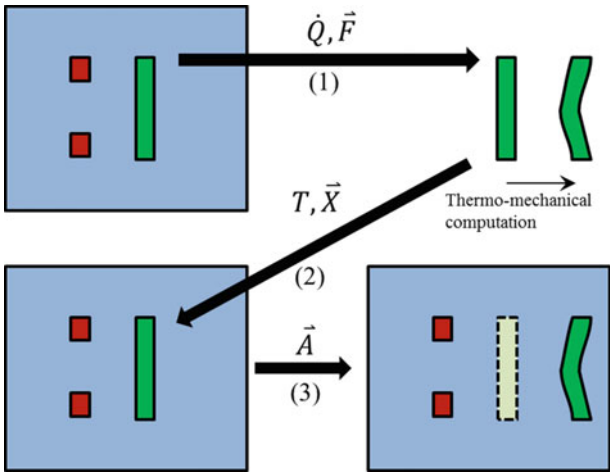

Fig. 9 Main communication stages between the electromagnetic solver and the thermo-mechanical solver. (1) Transfer of Joule heat term and Lorentz forces. (2) Transfer of temperature and displacements. (3) Transfer of magnetic vector potential from the previous time-step, if remeshing of the electromagnetic mesh (Color code: blue = air, red = coil(s), green = billet). (Color figure online)

Table 3 Comparison of CPU time burden of field transport operations (notation: EMAG—electromagnetic module, MECA—thermomechanical module)

	(1) EMAG to MECA	(2) MECA to EMAG	(3) EMAG to EMAG
Without filter	~14 s	~800 ms	~20 s
With filter	~0–150 ms	~800 ms	~2 s

the creation of the search tree in order to skip them. In this particular case, the filter is applied to all elements "labeled" as belonging to the air and the coil.

In the following example, case 1 will be considered as a coupled configuration as in [6]. The electromagnetic model contains 281,265 elements and 58,883 nodes, while the thermo-mechanical model of the aluminum tube contains 66,895 elements and 12,696 nodes. The computation runs until a stop time of $100\mu s$ with a coupling time-step of $1\mu s$. In this case, a single electromagnetic increment requires 9 s.[3] When running the simulation without the filters, the total CPU time amounts to 1 h, while it is reduced to 0.5 h when including the filters. This reduction by a factor of 2 is caused by the optimization of the transport operation in stage (1). As seen in Table 3, stage (1) takes 14 s on average without filters and almost 25 min in total (100 couplings). This communication time is reduced enormously by applying the filter, making it almost negligible. A large reduction is also attained for stage (3) but since remeshing

[3]Computations done on 8 processors of an Intel® Xeon® CPU E5-2630 v3 @ 2.40 GHz on a Windows7 OS.

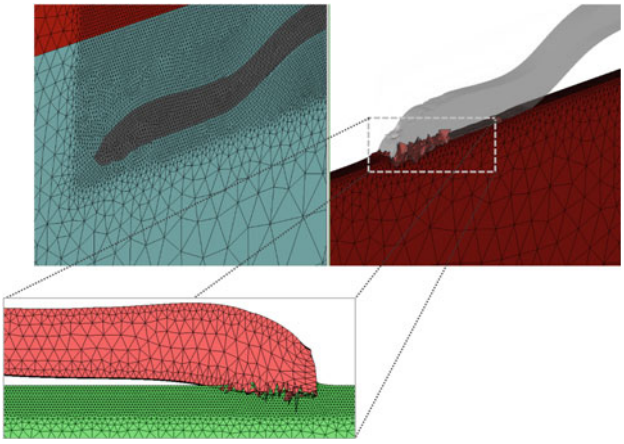

Fig. 10 Numerical defect at impact condition (mesh interpenetration between colliding bodies) if constant mechanical time-step is used [2]. (Color figure online)

of the electromagnetic mesh is done just once[4] it doesn't have a big impact on the overall computing time.

6 Automatic Thermo-Mechanical Time-Stepping

It was reported in [2] that one of the weaknesses of the established simulation strategy was the requirement of using a constant time-step for the mechanical computation, mainly to enable a proper update of the electromagnetic mesh. As a consequence, there was a certain lack of flexibility in dealing with impact conditions (see Fig. 10). This problem could be bypassed by simply restarting the simulation stage just before the impact and then enable automatic time-step adaptation. Such an approach is nonetheless cumbersome to enable ease of use and generality of the numerical approach. In order to fix this issue, the information that is recovered by the electromagnetic solver was modified. The previous approach was based on the transport of the current velocity field. In the new approach, the total cumulated displacements added to the storage of the initial configuration of the system are used instead. While demanding more memory to allocate an additional field information (initial configuration), this cost is totally negligible, and the change of mesh update paradigm allows for a greater flexibility.

The new approach was tested using test case number 2. A constant time-step for communication between the solvers ($0.5\,\mu$s) was established but the thermo-mechanical solver was allowed to automatically adapt the time-step to loading conditions. As seen in Fig. 11, the time-step decreases in order to enable correct conver-

[4] For the other increments a nodal relocation algorithm is used allowing to reuse a given mesh longer.

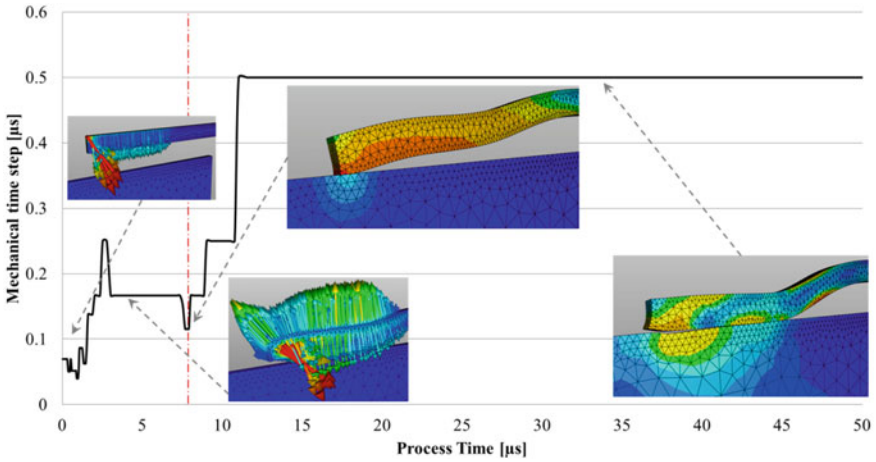

Fig. 11 Automatic adaptation of the mechanical time-step. (Color figure online)

gence of the nonlinear iterative algorithm at the beginning of the mechanical computation. The time-step increases as the simulation advance because a regular evolution path is found. A drop occurs when approaching contact in order to enable proper impact without interpenetration of the meshes. After impact, an almost steady-state is reached allowing for the time-step to reach the maximum value ($0.5\,\mu$s).

7 Conclusions and Perspectives

In this work, the state-of-the-art regarding the simulation of induction-driven processes and particularly for MPF simulations within the FORGE® framework was reviewed. It was presented how to make use of external material databases to define complex material behaviors. All these developments are the result of cross-related needs in different technological domains which have pushed the software forward to enable faster computations with reliable, robust, and easily parallelizable algorithms. A recent development introduced in the software is the possibility of defining experimentally obtained FLDs. This option was also rendered depending on additional fields such as strain rate in order to enable studying processes such as magnetic pulse forming which show increased formability within certain loading conditions.

Models with increasing complexity can be computed, as the simulation software regularly increases its computational capability and enables to reduce computational time.

The definition of material behavior is one important aspect undergoing great advances. Besides describing complex rheological paths, it is also possible to include

metallurgical aspects such as by-phase behavior. Enabling this approach will allow increased accuracy in material behavior modeling.

Another ongoing project devoted to error estimation and adaptive remeshing will enable using mesh adaptation techniques based on error estimator for the electromagnetic computation.

The High-Speed Deformation Behavior of High-Strength Lightweight Al-Li Alloy Sheets

Ali Abd El-Aty, Shi-Hong Zhang, Xunzhong Guo, Yong Xu, Ma Yan, Dayoung Chen, and Jie Tao

Abstract Since high-strength lightweight Al-Li alloys gained much attention recently, investigating the dynamic behavior of high-strength lightweight AA2060-T8 sheets is crucial because of their outstanding mechanical properties. Thus, uniaxial tensile tests were performed under high strain rate conditions using universal testing machines and split Hopkinson tensile bars. The ductility of AA2060-T8 sheets was improved under HSR deformation because of the adiabatic softening with increasing strain rate and the inertia effect, which may diffuse necking, slow down the necking development, and delay the onset of fracture. The present study results can efficiently develop a new manufacturing route based on impact hydroforming technology (IHF) to manufacture sound thin-walled-complex shape components from high-strength lightweight Al-Li alloy sheets at room temperature.

Keywords Al-Li alloys · AA2060-T8 · High-speed deformation · Impact hydroforming

1 Introduction

In recent years, Al-Li alloys have acquired much attention for their weight and stiffness-critical structures used in aircraft, military, and aerospace because of their superior outstanding properties, such as low density and high specific strength, than

those of commercial Al alloys. The exceptional properties of Al-Li alloys are principally attributed to the added Li, which impacts the elastic modulus and weight reduction, where 1 wt.% of Li increases the elastic modulus by approximately 6% and reduces the resultant Al alloy's density by approximately 3% [1–3]. Based on the production date, Al-Li alloys are classified into three generations: first-generation Al-Li alloys such as AA1420, AA1421; second-generation Al-Li alloys such as AA8090, AA2090; and third-generation Al-Li alloys such as AA2050, AA2060 [2, 3].

AA2060-T8 is one of the newest candidates in the family of the third-generation Al-Li alloys launched by Alcoa Inc. in 2011 to replace AA2024-T3 and AA7075-T6 for upper and lower wings and fuselage structures [1, 3, 4]. The challenges associated with using AA2060-T8 sheets with conventional forming technologies are (1) poor formability because of the micro-voids and micro-cracks during processing; (2) anisotropic tensile properties, which caused serious issues during press forming; (3) and wrinkling and springback, which, in turn, adds to the cost of the die and the final products because of the try-out time. The aforementioned issues of AA2060-T8 restrict its broad applications [2, 3].

For the reason that AA2060-T8 was launched a few years ago, few studies on understanding the mechanical behavior, deformation mechanism, and anisotropic response of this alloy, notably at elevated temperatures, have been accomplished. For instance, Abd El-Aty et al. [5] studied the mechanical behavior and the texture evolution of AA2060-T8 during the bending process using PRM. Abd El-Aty et al. [6] learned the dislocation boundary structures of AA2060-T8 during the bending process, and they found that three types of microstructures were formed during bending. Ou et al. [7] revealed the deformation behavior of AA2060-T8 under hot forming conditions. Gao et al. [8] used their outstanding results [7] to investigate the feasibility of manufacturing aircraft components from AA2060-T8 using the HFQ process. Abd El-Aty et al. [4–6] proposed a computational method-based crystal plasticity modeling to link the mechanical response of AA2060-T8 sheets with their microstructural states and predict their deformation behavior at room temperature and different strain rates. Later, Abd El-Aty et al. [3] investigated the mechanical behavior of AA2060-T8 sheets at room temperature and a wide range of strain rates.

From the discussion mentioned above, it is evident that the quasi-static and high-speed deformation behavior of high-strength lightweight AA2060-T8 Al-Li alloy sheets and the constitutive relations which describe the flow behavior of AA2060-T8 sheets under high strain rate conditions are not investigated. The flow behavior of Al-Li and Al alloys under high strain rate deformation is complicated because they depend on several factors, such as the deformation mode, strain, and strain rates [9]. These factors control the strain hardening and dynamic softening, which affects the flow behavior and formability of these alloys [10–12]. Thus, characterizing the quasi-static and high-speed deformation behavior of high-strength lightweight AA2060-T8 Al-Li alloy sheets is meaningful to describe their mechanical response at various deformation conditions.

2 Experimental Procedures

The material used in this study was rolled AA2060-T8 sheet. HSR tensile tests were done using SHTB apparatus at room temperature to investigate the dynamic behavior of AA2060-T8 sheet at RD and strain rates of 1733, 3098, 3651, and 3919 s^{-1}. The sample orientations in HSR tensile tests were not considered since the sample orientations significantly impacted the case of quasi-static strain rates rather than HSR [1, 3]. The experimental setup of the SHTB apparatus and the details of the tensile specimen used in this test are depicted in Fig. 1. The HSR experiment was supposed to be started once the tensile sample was placed between the incident and the transmitter bars. However, the material being studied was rolled sheets with 2 mm thickness. Thus, a novel gripping method (clamp) was designed to integrate it in the SHTB apparatus for providing adequate clamping forces to avoid the tensile specimens from slipping during the experiments and introducing a low mechanical impedance to prevent the distortion of the waves. Once the novel clamp was implemented in the SHTB apparatus, the tensile specimen was placed between the incident and transmitted bars; thereafter, the striker situated on the incident bar impacted the flange, leading to the generation of a tensile wave (incident wave) that propagated along the incident bar, as depicted in Fig. 2. The strain gauge located on the incident bar recorded the incident wave ($\boldsymbol{\varepsilon_I}$) once it passed. Once the incident wave ($\boldsymbol{\varepsilon_I}$) hits the specimen, it is partly reflected ($\boldsymbol{\varepsilon_R}$) through the incident bar and partly transmitted ($\boldsymbol{\varepsilon_T}$) through the tensile specimen and the transmitted bar, as shown in Fig. 2. These reflected and transmitted waves were recorded by the strain gauges (using a high-velocity acquisition system, i.e., an oscilloscope) situated on the incident and transmitted bars, respectively. A schematic and a real set of waves detected during the SHTB experiment are depicted in Figs. 3 and 4. The progress of the HSR tensile

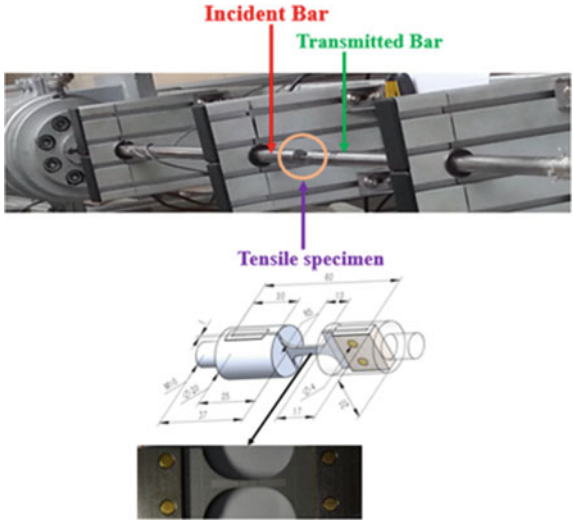

Fig. 1 The actual setup of the SHTB apparatus. (Color figure online)

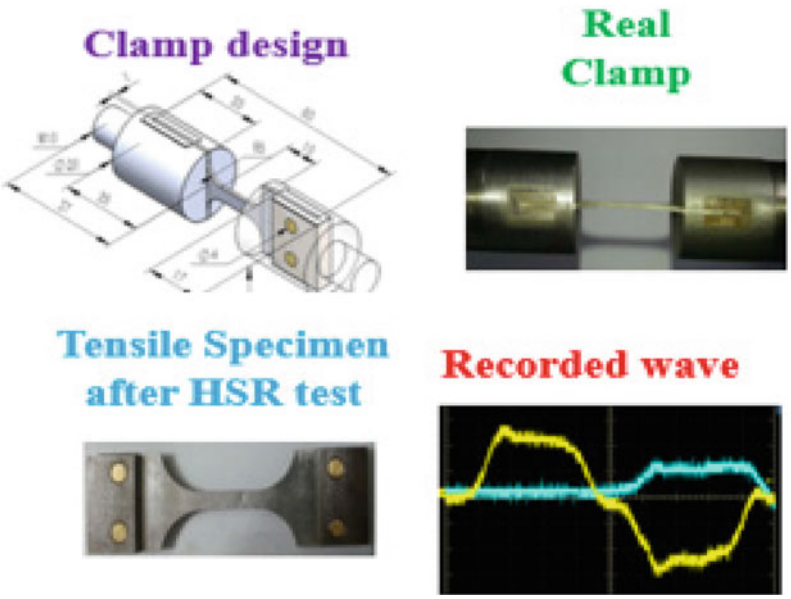

Fig. 2 The final version of the novel clamp used to avert the specimens from slipping during the test. (Color figure online)

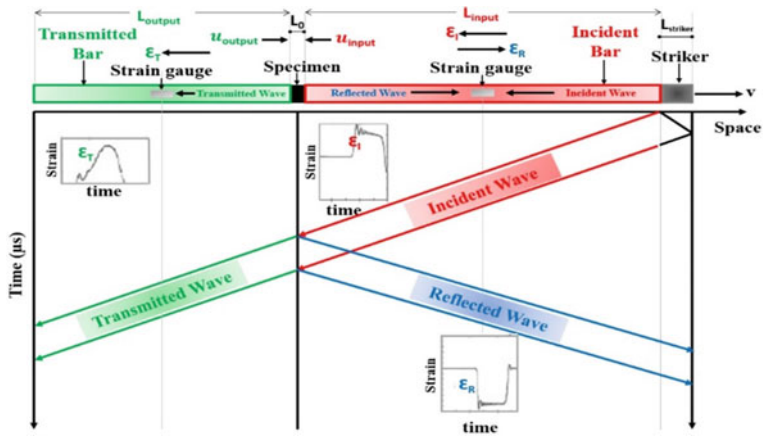

Fig. 3 The schematic representation of stress waves propagation in the bars. (Color figure online)

specimen during HSR tensile testing is illustrated in Fig. 5.

For simplicity, it was assumed that the equilibrium condition was verified during all the test, thus the mean strain and mean stress are generalized as:

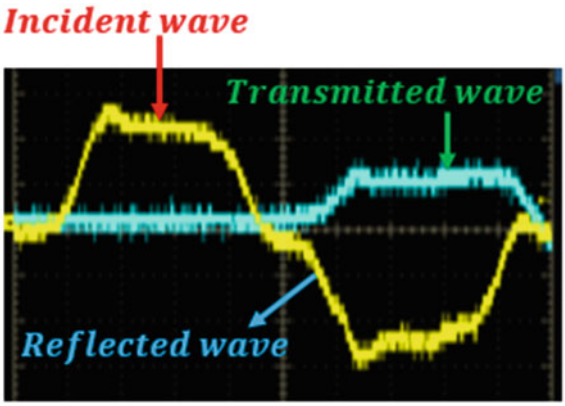

Fig. 4 The waveforms recorded by the oscilloscope during the HSR test. (Color figure online)

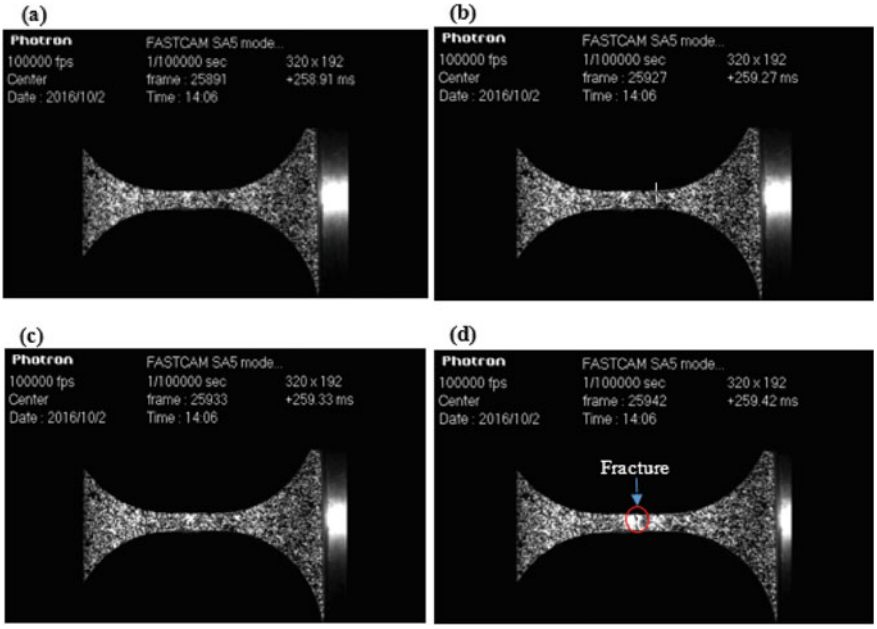

Fig. 5 The HSR tensile specimen **a** at the beginning of HSR tensile testing; **b** after 36 μs; **c** after 41 μs; and **d** after 51 μs from the beginning of HSR testing, in which the tensile specimen was broken. (Color figure online)

$$\varepsilon(t) = -\frac{2C}{L_0}\int_0^t \varepsilon_R(t)dt \tag{1}$$

$$\sigma(t) = E\frac{A}{A_0}\varepsilon_T(t) \tag{2}$$

The promptly axial strain rate ($\dot{\varepsilon}$) in the tensile sample was calculated from the first derivative of Eq. 1, so it can be written as

$$\dot{\varepsilon}(t) = \frac{v_{\text{input}}(t) - v_{\text{output}}(t)}{L_0} = -\frac{2C}{L_0}\varepsilon_R(t) \tag{3}$$

From Eq. 3, it could be perceived that with the SHPB equipment, the tests are not performed precisely at a constant strain rate. Only in the ideal case of the perfectly rectangular reflected wave, i.e., an entirely plastic response of the specimen, the strain rate is constant during the whole specimen deformation. In practice, this is almost impossible to observe and, generally, the nominal strain rate (average value of the effective strain rate) which used to indicate the strain rate of tests performed on the Hopkinson bar apparatus. Thus the HSR experiments were accomplished at strain rates of 1733, 3098, 3651, and 3919 s^{-1}.

3 Results and Discussion

3.1 Stress–Strain Behavior

The (σ_e, e) curves of AA2060-T8 sheets under HSR conditions are shown in Fig. 6. The work hardening behavior observed in HSR testing is more prominent than that

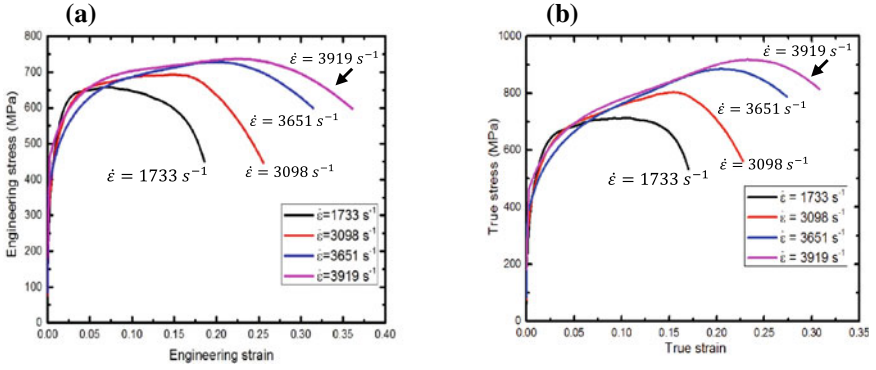

Fig. 6 **a** Engineering, and **b** true stress–strain curves of AA2060-T8 sheets at RD and HSR zone (i.e., $\dot{\varepsilon} = 1733s^{-1}$,$\dot{\varepsilon} = 3098s^{-1}$, $\dot{\varepsilon} = 3651s^{-1}$, and $\dot{\varepsilon} = 3919s^{-1}$). (Color figure online)

detected in QSR and ISR testing [1–3]. Thus, the yield, flow, and ultimate tensile stresses at HSR were higher than their QSR and ISR counterparts, which are generally attributed to the increased strain rates. Notwithstanding, the strain hardening rate observed in HSR testing was lower than that in QSR and ISR testing. This is attributed to the competition between the strain hardening and thermal softening due to adiabatic temperature rise with increasing strain rate. Thus, adiabatic softening influence is significant in HSR deformation and leads to abnormal mechanical behavior [34–37]. The strain rate increased to 1733, 3098, 3651, and 3919 s^{-1} (i.e., strain rate changed from QSR to HSR). The elongation to fracture of AA2060-T8 sheets in the HSR zone was simultaneously improved by increasing the strain rate, which is an appealing feature in HSR deformation. This enhancement is attributed to the adiabatic softening with increasing the strain rate and the inertia effect, which may diffuse necking, slow down the necking development, and delay fracture onset.

3.2 Design and Manufacturing a Novel Machine Based on IHF Technology

Based on the results mentioned above and the results obtained from Ma et al. [13], a new manufacturing route based on HSF was developed and denoted as IHF. Based on this new manufacturing route and principle of IHF, an advanced IHF machine was designed and manufactured, depicted as Fig. 7. There are four zones in this machine. Power zone can provide very high acceleration to the projectile, which is as high as 3200 m/s^2. The acceleration zone supplies the acceleration distance for the projectile and the release rig. The dynamic resistance reduction technology is implemented by controlling the air and adopting a special structure to reach high impact velocity.

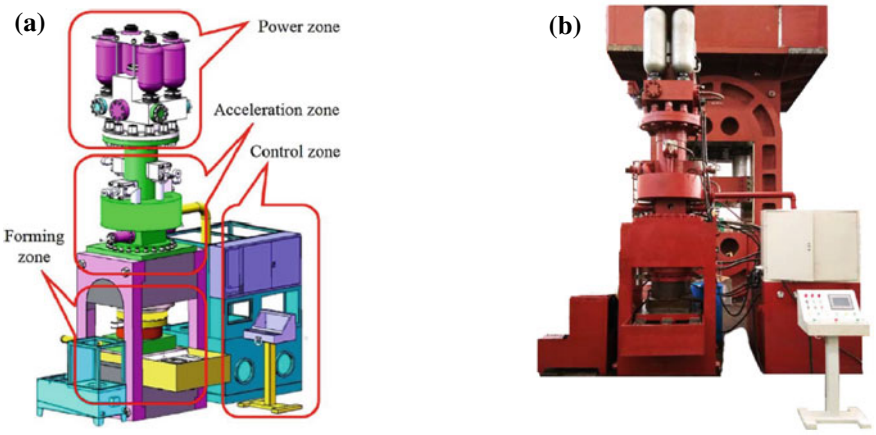

Fig. 7 (**a**) The schematic description, and (**b**) actual setup of IHF machine. (Color figure online)

Forming zone supplies the liquid chamber, binder hydraulic cylinder, and moveable working table. The control zone supplies the control function to all of the hydraulic valves to control the equipment's action. And the machine can run both under manual and automatic mode by inputting the code to the control board. The current research equipment's power source is the hydraulic-driven system, which can provide higher forming energy. For previous works, the power source is a pneumatic or explosive material, and their projectile is a solid cylinder that can freely move in the acceleration tube. The projectile of the current equipment is connected and controlled by a driven rod, capable of realizing more precise control. Furthermore, this equipment is more automatically run, which is suitable for industrial applications. The projectile's mass and the impact velocity and impact energy of the designed IHF machine are 60 kg (changeable), 10–80 m/s, and 3–200 kJ, respectively. The diameter and the volume of the liquid chamber are 250 mm (changeable) and 3–9 L. The dimensions of the working table are 800×800 mm, the max blank holder force is 250 T, and the binder hydraulic cylinder can be opened up to 400 mm.

3.3 Bulging Test

This novel IHF machine was used in this study to conduct a hydro-bulging test to investigate the formability of AA2060-T8 sheets under IHF loads and compare these results obtained from the bulging test under conventional hydroforming (quasi-static loading) loading. The specimens used in the bulging test were machined from AA2060-T8 sheets, and the radius of these samples is 83.6 mm.

Since the IHF machine's impact energy is 3–200 kJ, the impact velocity can be reached up to 80 m/s. As depicted in Fig. 7, the test specimen placed on the lower and upper dies was fixed on the master cylinder of the IHF machine by the fixing ring. The locating ring was used to guide the upper die to the right position along the axial direction. After the upper die contacted the test specimen with suitable clamping pressure, the high-speed hammer accelerated the liquid (Projectile). Thereafter, the test specimen was formed by the liquid with high energy in the shock wave. The velocity sensor was set in the chamber's lateral wall, whose position was near the liquid's upper surface to detect exactly the final velocity of the accelerated hammer. Each test condition was investigated at least three times to ensure consistency and repeatability.

The bulge height (h_B) of each test specimen was measured as depicted in Fig. 8 to assess the IHF loading effect on the formability of AA2060-T8 sheets and build up a window to describe the relationship between the impact energy (E_I) and the corresponding bulge height. This window is denoted as bulge height–impact energy (h_B–E_I) window, as presented in Fig. 9. The impact energy was used in this study instead of the pressure because the projectile's speed and mass mainly decide the impact energy. Furthermore, it is easy to calculate it compared to the pressure, especially under IHF conditions. As shown in the (h_B–E_I) window, under the IHF loading, the bulge heights of the test specimens were increased by increasing the impact energy

Fig. 8 The measurement tool used to measure the bulge height of each test specimen. (Color figure online)

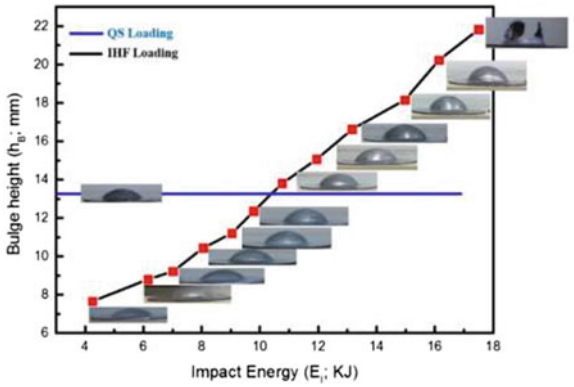

Fig. 9 Bulge height–impact energy (h_B–E_I) window describing the relation between the impact energy (k_J) and the corresponding bulge. (Color figure online)

up to 16.2 kJ; beyond this value, the test specimens were ruptured. The max bulge height obtained from IHF loading before rupture was 20.23 mm; however, the max bulge height obtained from conventional hydroforming loading using max pressure of 28 MPa was 13.3 mm as depicted in (h_B–E_I) window. This means and proves that the developed IHF technology can improve the formability of AA2060-T8 sheets at room temperature.

3.4 Manufacturing Aircraft Frame Part by IHF Technology

To investigate IHF technology's feasibility to fabricate thin-walled complex-shaped components, a complicated aircraft frame part was selected as a case study. The details of the aircraft frame part are depicted in Fig. 13. As shown in Fig. 13a, the aircraft frame part consists of eight convex shapes, outer surfaces, two concaves (concave 1 and concave 2), with drawing ratios (DR) of 3.88 and 3.52, respectively.

The ***DR*** in this study was calculated from Eq. 4 as:

$$DR = \frac{\textbf{blankarea}}{\textbf{concavearea}} \tag{4}$$

Because of the complexity of the shape of the aircraft frame and high ***DR*** compared to the common DR limit of steel sheets, 2 or many redrawing steps were required to reduce the DR for each step. The convex zones between the two concave zones are relatively easy to crack, as depicted in Fig. 10b since the strain is easy to exceed the forming limits. Furthermore, there are many small fillets (2 mm) at the outer surfaces and the concaves' bottoms. These small fillets increase the difficulties of forming this component. According to the theories of hydroforming, the smaller the radius, the higher the pressure, since it is challenging to supply the material to the radius zone because of the frictions under the high pressure, and form the material which already contacted the surface of the die and supply the material to the radius zone because of the friction under this increased pressure.

In the beginning, actual trials were performed to investigate the feasibility of forming the aircraft frame part using a quasi-static sheet hydroforming process (QS-SHF). As depicted in Fig. 11a, b large crack has appeared, and the outer surface of the frame part has a wrinkling tendency. This is because there is not enough material flowing to the fillet area to achieve the feeding effect. The rounded material's plastic deformation ability cannot meet the forming requirements, thus causing large area cracking. Therefore, the IHF technology was used to address the issues mentioned

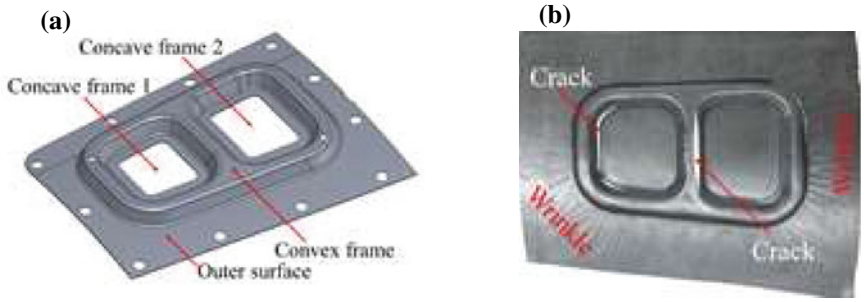

Fig. 10 **a** The aircraft frame part's details, **b** The actual aircraft frame part with wrinkle and crack formed by sheet hydroforming process (SHF). (Color figure online)

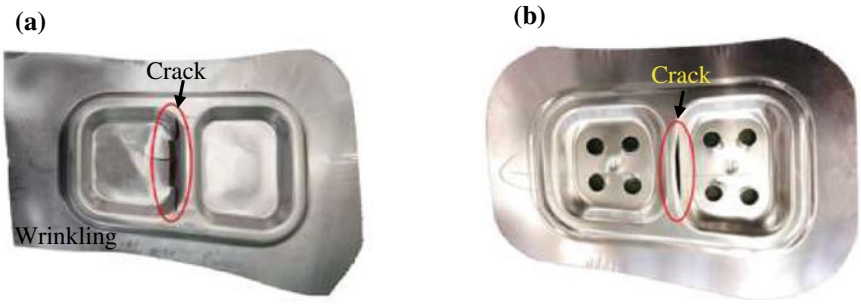

Fig. 11 Actual trials to produce the frame part by one step **a** QS-SHF, **b** IHF. (Color figure online)

above of QS-SHF. It is observed that the formability of the AA2060-T8 sheets was improved under the HSR condition. Furthermore, the cracking tendency and wrinkling were reduced compared to QS-SHF. However, the final product still has a small crack, as depicted in Fig. 11b. By analyzing the results obtained from both one-step QS-SHF and IHF, as shown in Fig. 11, it is challenging to manufacture the frame part by the one-step forming process. This is attributed to the high ***DR*** of concave 1 and concave 2. Thus, multi-step forming processes were used to overcome the limitations of the one-step forming process.

First, the pre-forming stage was accomplished using QS-SHF. The pre-forming stage improved and controlled the flow and the distribution of the material during the deformation. After that, to investigate and compare the effect of forming process on the formability and the crack tendency, the second forming stage was performed using either QS-SHF or IHF. Based on the original design of the frame part, the pre-formed parts were proposed as depicted in Fig. 12, since the rounded part of the inner side of the two cavities was increased from 2 to 20 mm. Furthermore, the width of the eight convex shapes is also increased.

After successfully carrying out the pre-forming stage, many trials were performed using both QS-SHF and IHF as a second forming stage. It is observed that the cracks still exist in the frame part produced by QS-SHF. However, no cracks were detected,

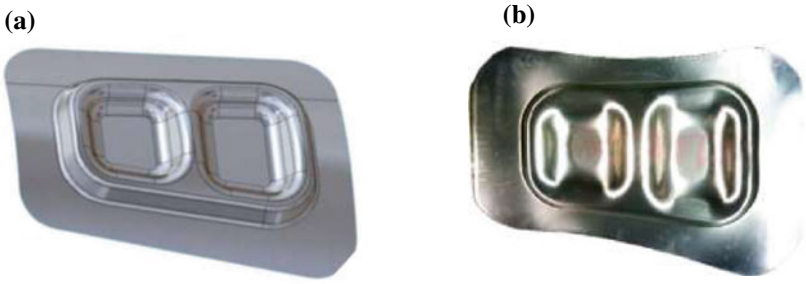

Fig. 12 **a** The CAD model, and **b** the actual trial of the pre-formed frame part. (Color figure online)

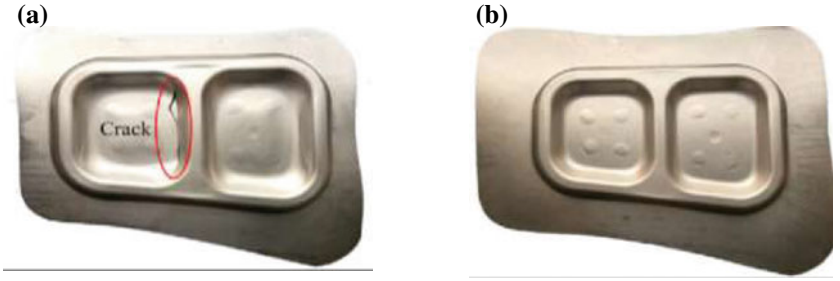

Fig. 13 The frame part was produced by **a** QS-SHF, **b** IHF after pre-forming. (Color figure online)

and the wrinkling was reduced in the frame part produced by IHF, as depicted in Fig. 13.

4 Conclusions

The main conclusions of this investigation can be deduced based on the achieved results as follows:

1. The work hardening behavior observed in HSR deformation is more prominent than that detected in QSR deformation. Thus, the YS, flow stress, and UTS at HSR were higher than their QSR counterparts. The strain hardening rate observed in HSR deformation was lower than that in QSR deformation, which was attributed to the competition between the strain hardening and thermal softening due to increasing the adiabatic temperature with increasing strain rate. The ductility of AA2060-T8 sheets was improved under HSR deformation because of the adiabatic softening with increasing strain rate and the inertia effect, which may diffuse necking, slow down the necking development, and delay the onset of fracture.
2. These results obtained from this study were efficiently used to develop a new manufacturing route called impact hydroforming technology (IHF). The IHF technology can improve the formability of lightweight metals and manufacture thin-walled complex-shaped components from Al-Li and Al alloys.

The Effects of the High-Velocity Shearing Speed on the Sheared Edge Quality and Edge Cracking

J. Gu, F. Alamos, D. Schoch, J. Bornhorst, and H. Kim

Abstract High-speed shearing was studied to potentially improve the sheared edge quality of advanced high-strength steels. The AIRAM pneumatic press can provide significantly higher speed than a conventional press, up to 1.5 m/s depending on equipment setup at a low energy cost. The study evaluated the pneumatic press that could increase the slide speed up to 1.5 m/s. Various grades of AHSS steel, DP780 and GEN3-980, were sheared using the pneumatic press with two different operating pressure levels as well as using a conventional press with 0.2 m/s with the same tooling. The edge quality of the sheared blanks was evaluated using half-specimen dome test (HSDT) and microhardness tests. The effects of high-speed shearing are discussed in this paper.

Keywords Edge cracking · Pneumatic press · Advanced high-strength steel (AHSS) · High-velocity shearing

1 Introduction

As the lightweight steel demand has been increasing in the automotive industry, more advanced high-strength steel (AHSS) has been considered for the automotive body structure. However, the edge cracking issue of the AHSS has been a challenge. Many research programs have been conducted to evaluate and improve the sheared edge quality.

(a) The effect of shear die clearances on the edge formability has been reported by Konieczny and Henderson [1] and Lee et al. [2].
(b) The critical parameters that influence the edge local formability were investigated by Pathak et al. [3].

(c) Shearing with different punch configurations was conducted by Shih et al. [4], to improve the sheared edge quality.
(d) Interestingly, a recent study on the high-speed impact cutting process by Fraunhofer IWU has shown that the adiabatic softening effect creates a smooth edge finish [5].
(e) However, little research has been done to investigate the effect of speed on the edge local formability.

Therefore, a study to evaluate edge formability by the effect of shearing speed was conducted by EWI. This study also considered the effect of different shear clearances on edge quality. The edge local formability was evaluated by the failure strain from the half-specimen dome test (HSDT).

2 Approach

Two AHSS materials, DP780 and GEN3-980, were selected for this study. The material properties are given in Table 1. Shear testing with different speeds and clearances was conducted on both materials. The edge quality created by different speeds and clearances was evaluated by the HSDT, microhardness testing, and optical microscopy.

2.1 Shear Test

Both materials were sheared with four different speeds from an AIDA 300-ton servo-press and AIRAM 12-ton pneumatic press as shown in Fig. 1. Two press motions, silent deceleration and crank motion, were used in the servo-press. The crank motion imitates the conventional mechanical press motion, while the silent deceleration motion slows the ram down to one-tenth of the overall velocity before the tool contacts the blank. The press load and press speed were measured and exported from the servo control module. The pneumatic press was used to create shearing speed up to 1.8 m/s with the shear test tooling, and the speed can be adjusted using different press operating pressure settings. The instantaneous shearing speed was measured using a laser sensor. Thirty psi and 50 psi pneumatic press settings were considered, which provided approximately ten times higher shearing speed than a mechanical press.

Table 1 Material properties of the selected sheet materials

Material	Thickness (mm)	Yield strength (MPa)	Tensile strength (MPa)	Total elongation (%)
DP780	0.9	499	855	18.0
GEN3-980	1.2	609	1022	22.1

Fig. 1 Servo-press (left), pneumatic press (middle), and shear test tooling (right). (Color figure online)

2.2 Die Clearance

The tooling clearance of the shear die was adjusted using shims. At each speed, each material was tested in four different clearances except one condition that corresponds to DP780 material 15% shear clearance with crank motion. The test matrix is shown in Table 2. The sample was cut into 100 by 200 mm, with the interested sheared edge on the 200 mm side.

The shear clearance is calculated with Eq. 1:

$$\text{Shearclearance}\% = \frac{\text{Dieclearance}}{\text{Materialthickness}} * 100\% \tag{1}$$

2.3 Half-Specimen Dome Test (HSDT)

As an alternative test to evaluate the sheared edge stretchability, HSDT was extensively used by Kim et al. [6] and Gu et al. [7]. HSDT can evaluate the straight sheared

Table 2 Test matrix of the shearing test

DP780	GEN3-980		Repetition	
Shear clearance (%)		Shearing speed	Shearing	HSDT
9	9	4	Minimum 5	Minimum 3

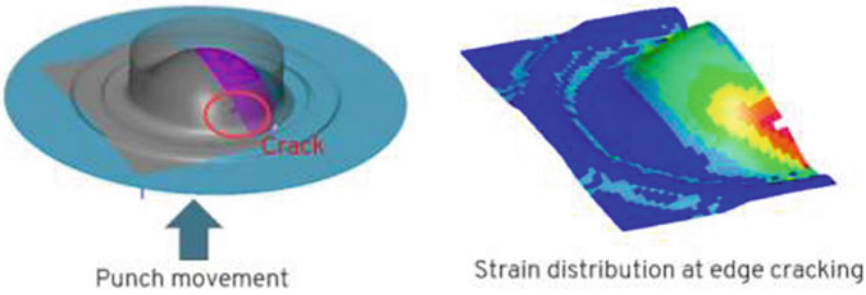

Fig. 2 HSDT experiment setup [7]. (Color figure online)

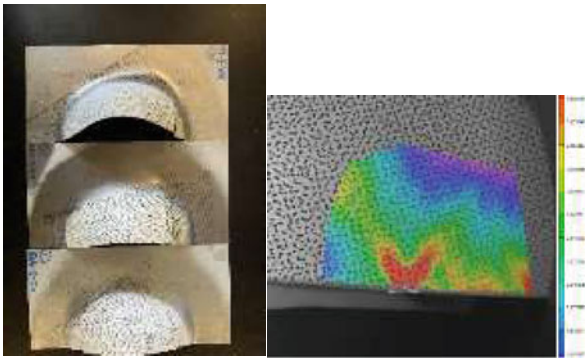

Fig. 3 HSDT sample and strain contour measured by DIC. (Color figure online)

edge, instead of punched holes for hole expansion test. HSDT uses a 100 mm diameter dome punch to stretch the sheared edge, and the die ring has a knurl pattern to prevent any material draw-in in the flange area. The tooling setup is illustrated in Fig. 2. The punch moves up to stretch the sheared edge and creates a uniaxial tension failure in the area between the punch and the die ring. The edge local formability was evaluated using the DIC measured failure strain as close to the edge as possible. The tested sample and digital imaging camera (DIC) post-processing result is shown in Fig. 3. At least three test repetitions were conducted for each sheared edge condition.

2.4 Microhardness and Optical Microscopy

The change of hardness-induced during shearing was measured by microhardness test and the measured hardness on the sheared edge was compared with the base metal hardness. The sheared edge was cut with an abrasive saw, mounted, and polished for the Vickers microhardness measurement. Ten indentations were made starting from the edge horizontally across the shear-affected zone for each shearing condition. The starting point of the indentation at the sheared edge is indicated in Fig. 4. The

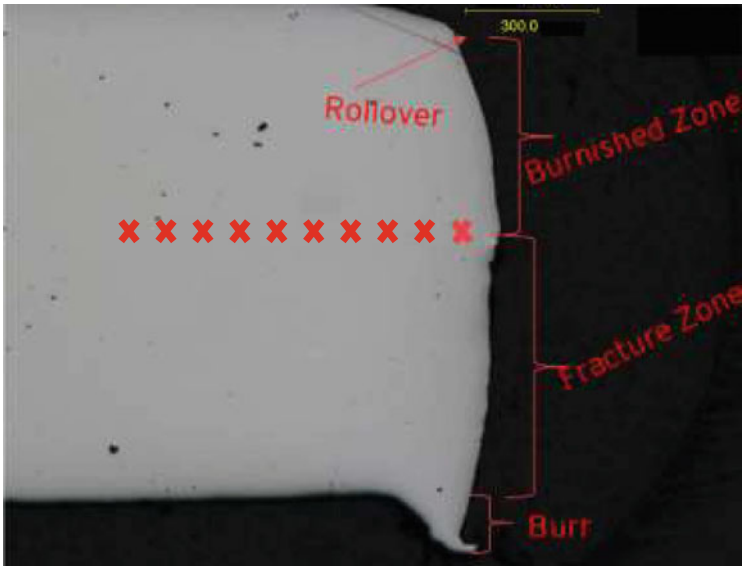

Fig. 4 Starting point selection of hardness test. (Color figure online)

starting point was selected at the transition of the burnished zone to the fracture zone, where the highest hardness value is normally measured along the vertical sheared edge surface.

3 Results

Two different press speeds and position profiles of the servo-press motions created from the servo-press control module are shown in Fig. 5. Instantaneous shearing speed was measured at the initial contact of the shearing die to the blank. The kinetic

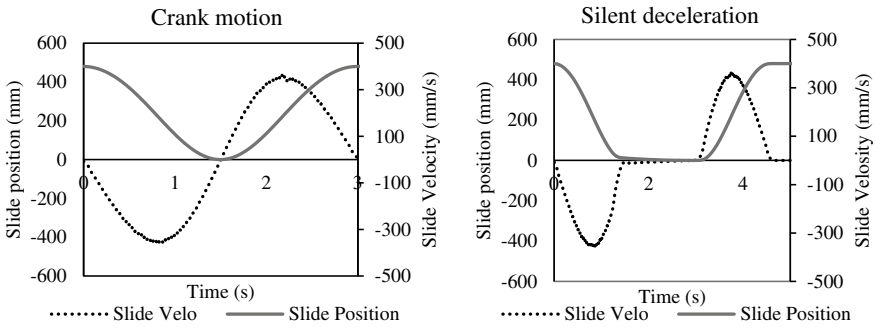

Fig. 5 AIDA servo-press speed and position versus time of crank motion and silent declaration

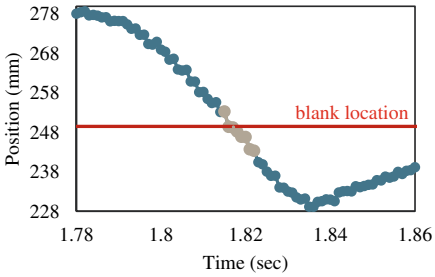

Fig. 6 AIRAM pneumatic press position versus time. (Color figure online)

energy created by the pneumatic press is very high, so the die velocity was high enough that the press speed was not reduced during the shearing operation. The AIRAM pneumatic press displacement–time curve is given in Fig. 6.

3.1 Shearing Speed

The shearing speed from the different types of press motions is summarized in Table 3 and Fig. 7. The four press settings provide four different speeds from 0.012 to 1.8 m/s. Note that the 1.8 m/s velocity conditions of the pneumatic press is over 100 times higher than the silent deceleration speed of the servo-press. Also, the silent deceleration has one-tenth the speed of the crank motion, and the pneumatic press motion has approximately ten times the speed higher than the crank motion. The higher pressure setting of the pneumatic press provides a higher shearing speed. However, the increase in speed is not as significant as in the two servo-press motions.

Table 3 Shearing speed obtained from different press motions

	Press motion	Speed (mm/s)	St. dev
Servo-press	Silent deceleration	12.7	0.3
	Crank motion	144.7	1.6
Pneumatic press	30psi-AIRAM	1283.1	142.2
	50psi-AIRAM	1810.7	245.8

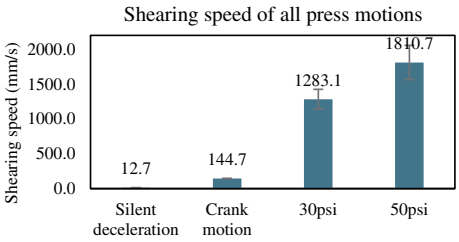

Fig. 7 Shearing speed obtained from different press motions. (Color figure online)

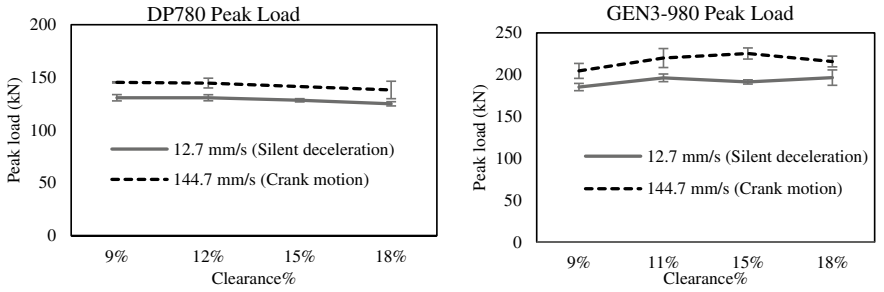

Fig. 8 Press peak load in the different shearing speeds of DP780 and GEN3-980

3.2 Press Peak Load at Shearing

The press load in the servo-press is measured by the servo load analyzer. For both materials, at each clearance, the slower silent deceleration speed (12.8 mm/s) shows a significantly lower shearing peak load than the speed of conventional mechanical press motion (144.7 mm/s), shown in Fig. 8. For DP780, the average peak load between silent deceleration and crank motion shows about 14 kN difference, while for GEN3-980, the average peak load changed about 24 kN between two different press speeds. It appears that the slow speed creates less impact loading the tooling, which can be beneficial to increase tool life.

3.3 Half-specimen Dome Test Result

Half-specimen dome tests were conducted on both materials. The equivalent strain before edge cracking was recorded using a DIC system. The higher failure strain means the larger local formability of the sheared edge. The equivalent failure stain is compared for various conditions in Fig. 9. With the same shear clearance, the higher shearing speeds of the AIRAM pneumatic press, creating velocities of 1283.1 mm/s and 1810.7 mm/s show larger equivalent failure strain compared to the other two relatively lower speeds of the servo-press. Overall, the lowest speed of 12.7 mm/s of the servo-press showed a slightly worse result compared to 144.7 mm/s crank motion that represents conventional mechanical press speed.

3.4 Microhardness Measurements

The microhardness data of DP780 and GEN3-980 are shown in Fig. 10. The other hardness data for different shear clearances and speeds showed similar trends with Fig. 10. The hardness at the sheared edge has the maximum value and as the measurement location approaches the base metal, the hardness decreases and becomes equal

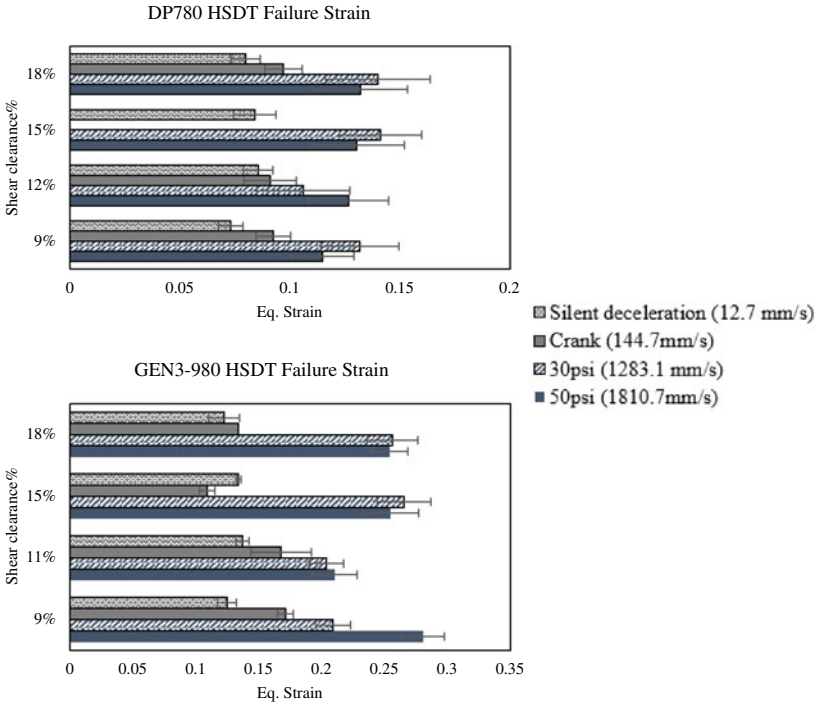

Fig. 9 HSDT equivalent failure strain of each speed with available clearances. (Color figure online)

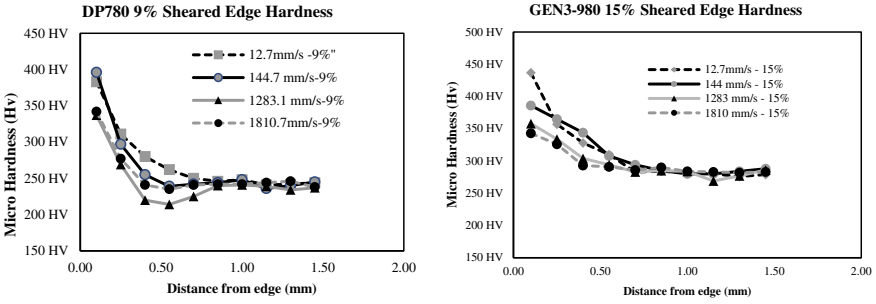

Fig. 10 Hardness measurements result of DP780 sheared with 9% clearance and GEN3-980 with 15% clearance. (Color figure online)

to the hardness value of the base metal. The first hardness measurement which is closest to the sheared edge represents the critical hardness of the sheared edge. The critical normalized hardness is calculated by Eq. 2. The normalized critical hardness closer to 1 indicates less hardness increase and less damage to the edge during shearing.

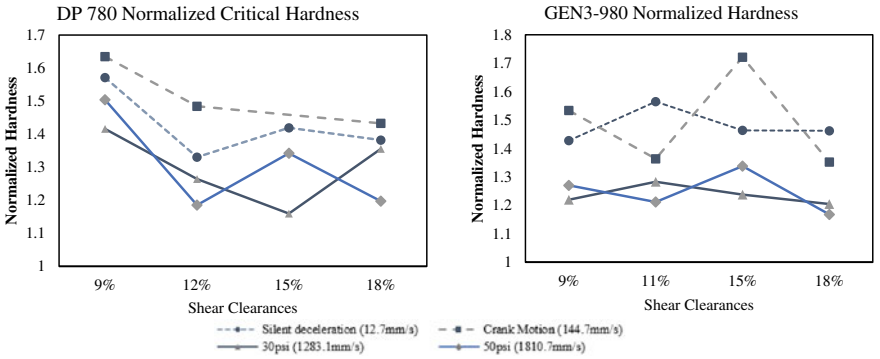

Fig. 11 Summary of the normalized critical hardness of DP780 and GEN3-980. (Color figure online)

$$\text{NormalizedCriticalHardness} = \frac{\text{Criticalhardness}}{\text{Basemetalhardness}} \tag{2}$$

Figure 11 compares the critical normalized hardness for different press speeds. The lower normalized hardness indicates less work-hardening during shearing and a significant preferred edge condition. For both materials, the normalized critical hardness is lower for the two higher speeds produced by the AIRAM pneumatic press (i.e., 1283.1 and 1810.7 mm/s) for each shear clearance. However, the shearing conditions to obtain the lowest normalized hardness (i.e., preferred result) varies with shear clearance and press speed.

3.5 Optical Microscopy

The optical microscopic image of the sheared edge was taken to qualitatively evaluate the edge quality. The lowest speed setting shows the largest burnished zone of all. Most samples from the two high-speed shearing conditions produced with pneumatic press show negligible rollover height, smooth shear zone transition, smooth fracture zone, and negligible burr. Example images of DP780 sheared edges with different shearing speeds and 11% shear clearance are compared in Fig. 12.

4 Conclusions

The following conclusions can be drawn from this study:

- The high-speed shearing velocities produced by the pneumatic press improved local formability.
- The preferred shearing conditions for DP780 and GEN3-980 are:

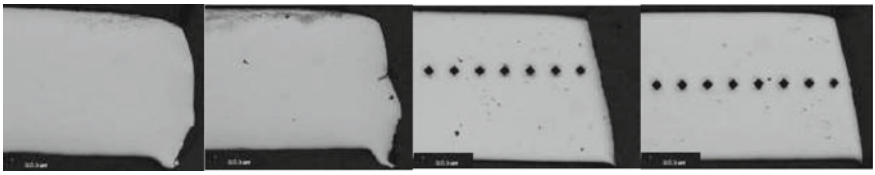

Fig. 12 Sheared edge of DP780 with the different shearing speeds with 11% shear clearance

- DP780: 15% clearance with 1283 mm/s shearing speed, which is 92% higher failure strain than that of crank motion average
- GEN3-980: 9% clearance with 1810 mm/s shear speed, which has 50% higher failure strain than that of crank motion average
- The effect of shear clearance on local formability varies with the press speed. Therefore, at the higher press speeds, the sensitivity of different shear clearances to the sheared edge quality is reduced.
- Regardless of shear clearances, two higher speed sheared samples show the better edge quality compared with the lower speed.
- The better edge conditions produced by the pneumatic press high-velocity shearing should produce less microcrack conditions and thus a higher resulting strength part with higher reliability.

Local Microscopic and Integral Macroscopic Analysis of Magnetic Pulse Welds and Deformations for Dissimilar Metal Joints

Frank Huberth, Balaji Ragupathi, Christian Scheffler, Verena Psyk, and Johannes Preußner

Abstract Magnetic pulse technology is used for high-speed forming as well as for joining. Joining by magnetic pulse welding (MPW) is the combination of high-speed forming, impact, and a resulting weld in the collision zone of the accelerated flyer and the impacted target. This MPW process allows the welding of dissimilar metals, like aluminum and steel for lightweight construction or aluminum and copper for E-mobility applications. Investigations showed up scattering in binding strength and failure for comparable welds. The effects leading to the bond formation and the reasons for the quality variation are not fully understood until now. For further understanding, a combined experimental investigation of integral and local mechanical weld properties supported by simulations and microstructure analysis was performed considering dissimilar metal joints of aluminum EN AW1050 H14/24 and copper Cu DHP R240 for different configurations and impact energies. Lap shear tests served for quantifying integral mechanical properties, while local mechanical properties were determined by microtensile tests on samples prepared in the thickness direction of the welded metal sheets and microstructural analysis. These local microscopic testing and analysis results provide information about the weld strength distribution. These investigations give new hints on the bond-forming mechanisms and local process depending on material effects.

1 Introduction

Magnetic pulse welding (MPW) is a technology providing high potential for the metallic bonding of dissimilar metal materials without largely heating and melting them [1]. The connection of multi-material joints has been a key technology for different applications for multiple years. Joining aluminum and steel for hybrid lightweight constructions [2] or electromobility is essential for further developments in hybrid lightweight construction [3]. This concerns structural applications as well as the electric connections for the power supply [4].

Many joining technologies reduce the performance of the components beneath the level of the weakest part in the load path. This is well investigated in the literature [5]. The authors resumed that the combination of EN AW 1050/ Cu-ETP R240 MPW "provided joints with the highest mechanical properties" [5]. Combining the advantages of distributed force transmission, which is characteristic for adhesive bonding with the processing speed of the dynamic welding process, the magnetic pulse welding (MPW) process provides both good load-bearing capacity and short processing interval. MPW is a solid-state metal joining process. This means that it can join metallic materials generating a true metallurgical weld. The main advantage of these processes is that no heat affects the components and materials with very different melting temperatures can be welded. The most extended current overview for these processes is given in [6].

During the investigation presented in this paper, a combination of aluminum EN AW1050 H14/24 and copper Cu DHP R240 was welded by MPW and analyzed by mechanical test at different scales. Numerical simulations using FEM were performed for the process to derive supporting information. The simulations were used to determine the local conditions for the impact angle and velocity.

Detailed microstructure investigations were performed. The correlation of local microstructural investigations and micro test is discussed in detail here and a first hypothesis is developed for the strength distribution.

2 Methods

This paragraph describes the MPW process and explains the integral macroscopic analysis via lap shear tests. Furthermore, information about the sample preparation and the test execution of the local microscopic analysis via microtensile is given.

3 Process and Process Parameters

For the welding process the flyer and target blank must be positioned with a small gap (approx. 0.5–2.0 mm) in-between them and close to a so-called tool coil as

illustrated in Fig. 1. The coil is electrically connected to a pulsed power generator, which is the forming machine of this process that provides the energy for the process as capacitatively stored electrical energy. A sudden discharge of a capacitor battery via the tool coil causes electromagnetic forces in the flyer, which accelerate it toward the target and cause an impact of flyer and target with impact velocities in the range of several hundred meters per second and varying impact angle α_{impact}. If the collision properties are within a material-specific parameter window, the impact results in a partial weld in the impact zone. MPW is welding in the cold, solid phase with large local deformations at extremely high strain rates. A detailed description of the process is given in [7].

Together with other important parameters such as the capacitor charging energy or geometrical parameters of the tool coil and the joining partners, the gap significantly influences the collision parameters and thus the resulting weld properties [8]. Fraunhofer IWU developed a trident-shaped working coil described in [9], which is used for the welding experiments in this study. Two different setups indicated in the start configuration of the setup shown in Fig. 1 are regarded. The first setup is a symmetric one with a completely overlapping flyer and target and the weld seam positioned in the middle of the sheets. Exemplary welded parts are shown in Fig. 2 on the right side. The second setup is asymmetric. This means that the flyer and

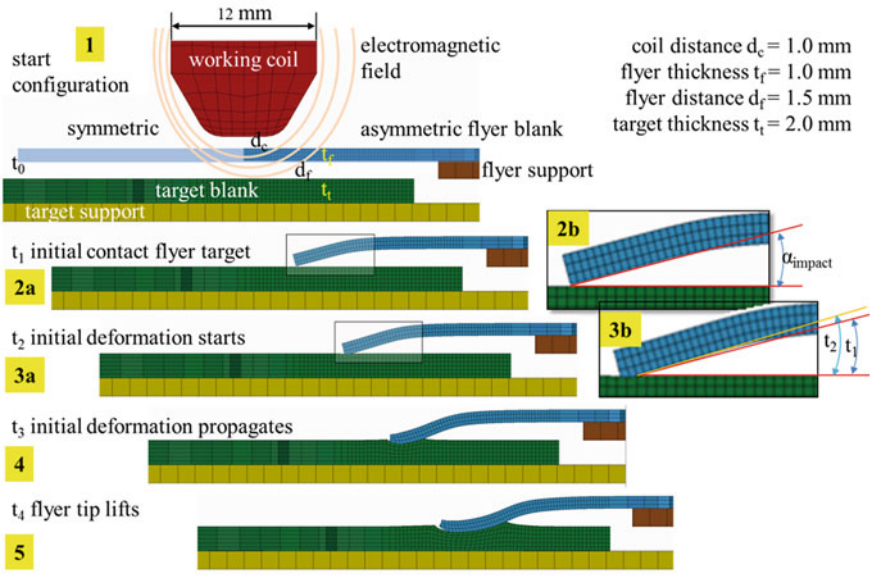

Fig. 1 Schematic MPW process for different time steps 1 to 5 based on a FE simulation using LS-DYNA and modeled with solid elements (0.3 mm), material model *MAT_PIECEWISE_LINEAR_PLASTICITY, and contact type *CONTACT_AUTOMATIC_SURFACE_TO_SURFACE. For the process the FEM–BEM electromagnetic solver of LS-Dyna is used coupled to the mechanical domain [14]. The detailed illustrations 2a and 2b show the definition of the impact angle α_{impact} at two time steps t_1 and t_2. (Color figure online)

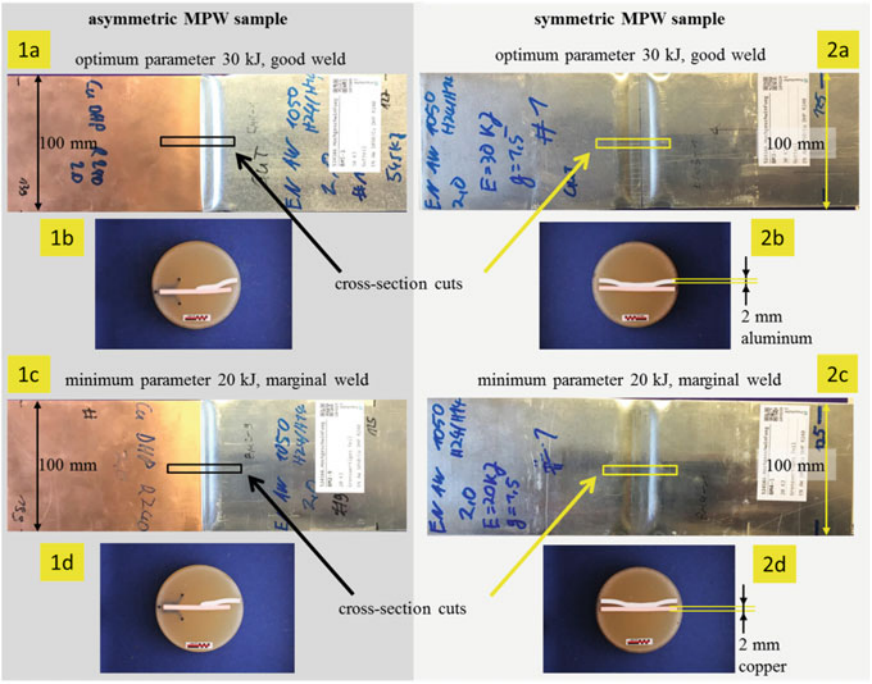

Fig. 2 MP welded samples, symmetric (1 a–d) and asymmetric variant (2 a–d), with optimum parameters (a, b) and minimum parameters (c, d); cross-section cuts for each variant (b, d). For the MP weld 1, the used parameters were 30 kJ, 544kA, and 22.2 kHz; for weld 2 reduced to 20 kJ (Pulsar MPW 50/25). (Color figure online)

target overlap each other only partially and the edge of the flyer sheet is welded to the target as shown in the different forming stages presented in Fig. 1.

An exemplary welded part with the asymmetric setup is presented in Fig. 2 on the left side. In order to achieve similar collision parameters for the transient impact velocity and consequently similar weld quality, the symmetric setup required slightly higher capacitor charging energy, when keeping all other process parameters, the coil and flyer distance, constant. The reason is that the deformation process is completely different. In the case of the asymmetric setup, the flyer edge is bent toward the target (see Fig. 1) resulting in a one double-bent deformation zone between the contact area of the flyer and target and the undeformed area (see Fig. 2 left). In the case of the symmetric setup, the middle section of the flyer moves toward the target resulting in two double-bent deformation zones between the contact area of the flyer and the target and the undeformed areas (see Fig. 2 right). Additionally, in the case of the symmetric setup, the true length of the flyer slightly increases due to the deformation leading to very different strain states in the sheet. Therefore, depending on the setup different energies were applied leading to similar weld quality. Precisely, two different energies were regarded for each setup. The first one was chosen just high enough to lead to

welding. In the following, this is referred to as "marginal weld". The second one was chosen significantly higher so that high-quality welds characterized by failure in the base material when being tested in macroscopic lap shear tests are expected. In the following, this is referred to as "good weld". Exemplary samples and cross-section cut for each variant are shown in Fig. 2.

During the process the local conditions in the contact zone change continuously. This is illustrated in Fig. 1 by the zoomed parts for t_1 and t_2. Different local conditions result in different local weld properties ranging from high weld strength over low weld strength up to no established weld at all. Figure 3 shows an exemplary process window for welding the specific material combination considered here. This means that it indicates the combinations of normal impact velocity v_{normal} and the impact angle α_{impact} leading to welding as green dots and the collision conditions leading to no weld as red crosses. This process window corresponds to the one determined in [8] but it is extended by some more detailed data. In the boundary area between the separation of the green region from the red one, the weld conditions are critical. This means that the process is not robust and already slight changes in the process parameters, e.g., due to material or positioning tolerances can lead to non-welded specimens. Additionally, the welds manufactured with these critical weld parameters typically show minor weld quality characterized by early failure in mechanical tests such as lap shear tests.

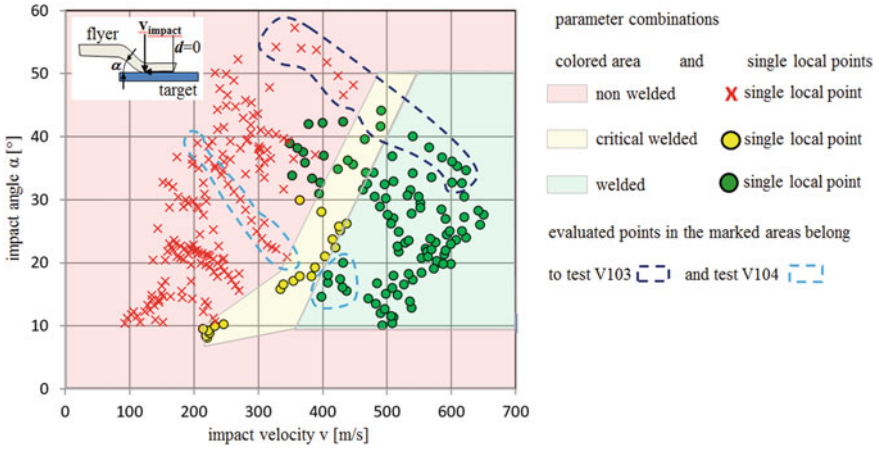

Fig. 3 Process parameters impact velocity v and impact angle α for established weld (green), transition area with critical conditions (yellow), and no weld (red) based on a combined approach of experimental and numerical results. Experimental results are compared with the simulation by the resulting MPW connection at the process conditions for two samples shown here, V103 and V104 in the marked area, as well as for simulation of each test [14]. (Color figure online)

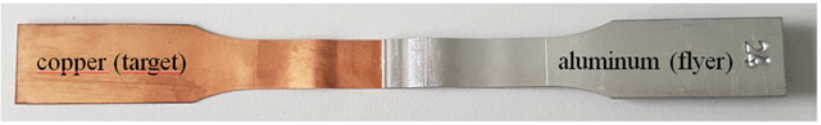

Fig. 4 MPW-lap shear sample, machined from the asymmetric variant of the weld samples (Fig. 2, left). (Color figure online)

4 Integral Macroscopic Analysis

The welded samples were machined to dumbbell-shaped lap shear samples as exemplarily shown in Fig. 4. For the machining process, the samples are clamped in a way that a load on the weld is prevented and during the milling process the sample is cooled. By this process, the end parts of the welding zone were eliminated and the results represent pure weld strength without edge effects. Typical edge effects and this approach with machined samples to avoid them are described in [10]. Edge effects are initiated by the run-out zones of the MPW process in lateral directions. Lap shear tests were performed on samples prepared from good and marginal asymmetric welded samples (Fig. 2, left). The tests were performed analog to tensile tests in a universal testing machine. The integral axial force was measured via the integrated load cell, while the total sample elongations were recorded via the traverse path sensor during the tests. This elongation measurement features only limited accuracy, but as the main intention of the lap shear tests is to characterize the weld quality by quantifying the maximum transferable force of the hybrid sheet and to identify the failure type (failure in the weld vs. failure in the base material), this limitation of the very simple test setup is accepted here.

5 Local Microscopic Analysis

To get access to the local strength distribution of the weld, local microtensile tests were performed at small dumbbell-shaped samples with the interface region in the waisted sample center. The segmentation of the weld zone by stripes and the sample contours were machined in a specifically developed process by wire-electro discharge machining, polishing, and micro water jet cutting in different steps. A similar approach to sample extraction is described in [10]. There, different cutting techniques were used. The welding zone is identified via light microscopy. For each variant of the welded samples, a separate extraction plan was prepared to extract the stripes as shown in Fig. 5 for the good asymmetric sample. As the welded region for the marginal samples is smaller, fewer stripes are extracted. The positions of the stripes are shown in the results paragraph by micrographs.

The tests are performed at the IWM using the DynMicro testing machine (Fig. 6). This machine allows testing at different tensile speeds. The concept of dynamic

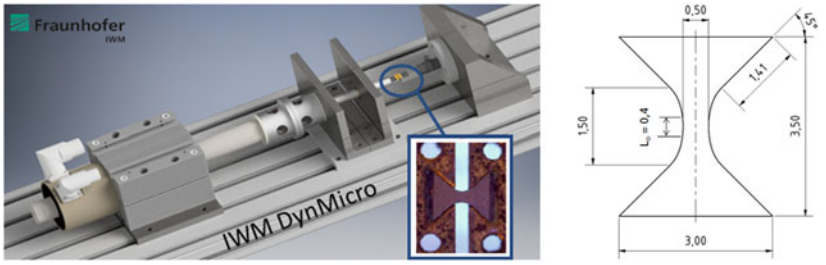

Fig. 6 Sketch of the micro testing machine IWM DynMicro with a detailed view of the sample in the clamps and a technical drawing with the sample geometry (right). (Color figure online)

microtesting is described in general in [12] and [13]. Force measurement is realized by a fixed 5 kN piezo sensor scaled down to the calibrated range of 500 N. Displacement analysis is done by digital image correlation (DIC) on the sample. To get the images for DIC with a high time resolution high-speed camera Photron SA5 with microoptics is applied to the setup. The natural surface texture of the prepared samples is sufficient for DIC. Two image series of the tests are shown in Figs. 9 and 11.

6 Results and Discussion

The results of the different test series with samples from different process conditions are shown and discussed for the integral macroscopic and local microscopic approaches.

6.1 Integral Testing for Different Process Parameters

The lap shear tests on samples with good and marginal asymmetric welds are discussed in this paragraph. The results of the lap shear tests are shown for these two variants in Fig. 7. As the samples showed a mixed deformation of bending and tension, it is not possible to calculate reliable stress–strain curves or flow curves. Therefore, only the measured force over total sample elongation is shown. However, the width and initial sheet thickness of the samples were equal, and the results are absolutely comparable with each other. As expected, the marginal welded samples reached a lower maximum load compared to the good welded samples. Moreover, the variation in the maximum transferable load measured for the three individual specimens shown in Fig. 7 is higher, which confirms the expected lower robustness of the process in the case of critical weld parameters. Regarding the elongation, the comparison of the curves shows that similar values can be achieved for marginal and good welds, and also this parameter can vary remarkably due to unstable conditions in the case of marginal welds. To evaluate the results tensile tests were performed on the weaker base material (i.e., EN AW1050 H14/24) using comparable sample size in order to allow direct comparison of the force–elongation curves for the lap shear

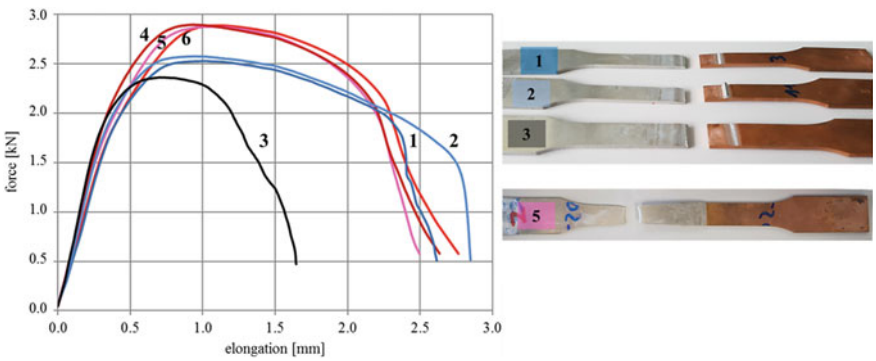

Fig. 7 Force and sample elongation diagram on the left side for MPW-lap shear tests for good (red curves 4–6) and marginal (1, 2—blue and 3—black curves) welded samples. The black curve (3) represents the minimum loading capacity tested. Different failure modes for the corresponding samples 1–3 and a representative failure of sample 5 with tensile failure in the aluminum section at the right side. (Color figure online)

tests and the tensile tests. Figure 8 clearly demonstrates that the maximum transferable force is similar for both specimens. This proves that the weld can transfer the same forces as the weaker base material. Even the weakest MPW-lap shear sample (sample 3) reached a maximum force comparable to that of the tensile sample (Fig. 8). For the other marginal and good MPW samples, the measurements suggest an even higher load-bearing capacity than the base material, which is surprising at first glance. However, these measured higher forces in the lap shear tests compared to the forces measured during tensile tests on the pure aluminum can be explained by the different stress state in the shorter and bended aluminum section of the welded sample compared to the uniaxial stress state in the tensile sample. The elongation measured during the lap shear and tensile tests is not comparable here as the MPW samples were bended during the tests.

The microsample was extracted from a good symmetric welded sample in stripe 3 at position 9. (Color figure online)

6.2 Local Strength Distribution and Process Correlation

The micro tests for different samples showed two different failure types. The first one is characterized by deformation and failure in the aluminum section. The development of this failure type is shown in the image series in Fig. 9. The second failure type is characterized by failure in the bonding zone. The corresponding deformation states are illustrated in the image series shown in Fig. 10. The samples were taken for the same sample position in the lateral direction (position 9) at different distances to the initial impact (stripe 1, Fig. 9 and stripe 3, Fig. 10).

As shown in the image series in Figs. 9 and 11, the different failure modes occurred in the symmetric welded samples. In the following, the results for the asymmetric welded samples are discussed and compared to the macroscopic tests. For the samples extracted from the good and marginal welded samples, the same two failure types were observed, depending on the position of the stripe along with the propagation of the contact point during the joining process (longitudinal sample direction). As only the good welded samples allow more than one stripe to be extracted, the influence of the position was investigated for this variant only. Figure 11 shows a typical micrograph of a good weld. Here the positions 1 and 3 are marked and the diagram in Fig. 11 shows stress–strain curves determined in micro tests on samples taken from these positions. Precisely, the samples were taken at positions 5, 7, and 9 in the lateral direction from these two stripes. At position 1, next to the initial impact position, the samples show a reproducible stress–strain curve for all positions. For samples extracted from the stripe position 3, the results are significantly different. The stress level and the strain show a significantly larger scatter. Sample 9 reached maximum stress of 150 MPa. Samples 5 and 7 didn't reach the average stress of 130 MPa for position 1.

These two samples failed in the bonding zone as shown in Fig. 13. All samples related to position 1 failed in the aluminum. For the marginal weld, tests were performed only at position 1. The results are shown in Fig. 12. The micrograph

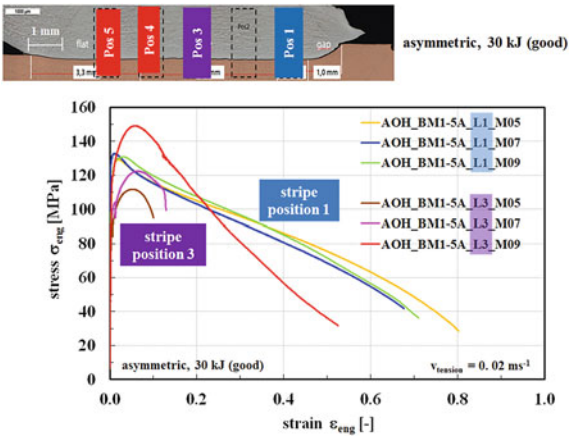

Fig. 11 Illustrated micrograph of the weld cross-section of an asymmetric good weld with marked positions for stripe positions 1 to 5 and diagram of the stress–strain curves for the microtensile tests with samples. (Color figure online) taken from stripe L1 at position 1 and L3 at position 3. Stripes at positions 4 and 5 (red) failed during processing or had no connection; at position 2 the stripes are not cut to sample shape. The complex sample code gives full information on the sample extraction position. (Color figure online)

shows the positions of the stripes. The stripe at position 2 had such a weak bond between the two sheets that it failed after extraction (Fig. 13).

The samples tested from this marginal asymmetric variant for position 1 failed in the aluminum comparable to the good one. But the stress level shown in the diagram of Fig. 12 is lower for the marginal weld. The maximum stress for these tests is 105 MPa on average compared to 130 MPa for the good weld. This different stress level must be influenced by the different deformation histories and the correspondingly different strain hardening effects leading to variations in the resulting strength of the aluminum

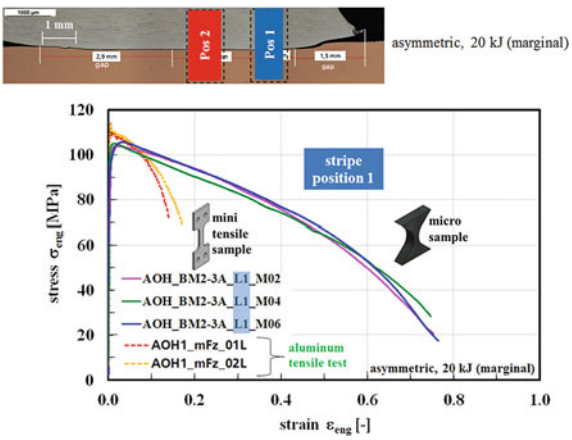

Fig. 12 Illustrated micrograph of the weld cross-section of an asymmetric marginal weld with marked positions for stripe positions 1 and 2 (red, failed) and diagram of the stress–strain curves for the micro tensile tests ($L_0 =$ 0.4 mm) with samples taken from stripe $L1$ at position 1 and the stress–strain curves of tested mini tensile samples ($L_0 = 14$ mm) taken from the base material (dotted curves). (Color figure online)

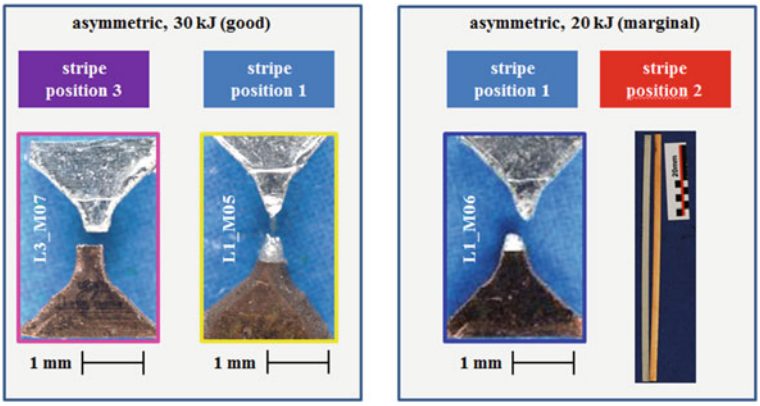

Fig. 13 Different failure modes for the stripe positions taken from a good weld (left) and a marginal weld (right). For the marginal weld at position 2 the failed stripe is shown. The box colors are the graph colors in the diagrams. (Color figure online)

for the two process variants. In the region of the initial impact high deformation rates occur, and for the good weld at 30 kJ higher velocities are applied compared to 20 kJ. This is supported by the results for the mini tensile test on larger samples taken from the sheet material shown in the diagram in Fig. 12. The maximum stress for the two tests is 110 MPa. Considering the different sample geometries, potential damage in the microsample, and other potential effects, this is a comparable stress level for the marginal weld and the aluminum base material. A high stress level of 130 MPa for the good weld with failure in the aluminum indicates a local strain hardening of the material. This observation is supported by microhardness measurements in the aluminum next to the bonding zone with an average value of 58 ± 4 HV0.001 compared to a reference value of 51 ± 4 HV0.001 in the uninfluenced base material.

The observation that the samples at position 1 failed all in the aluminum indicates high local weld quality for the region next to the initial impact. This finding is supported by the process window shown in Fig. 3, where it is shown that smaller joining velocities lead to weaker bonding. As the lower impact energy for the 20 kJ process is exhausted after a short distance from the initial impact, the stripe at position 2 already showed a critical weld with very weak bonding. At higher impact energies of 30 kJ, the welding area is increased, but the strength and thus the quality of the connection decreases with increasing distance to the initial impact zone. As both the impact angle (see Fig. 1 for t_1 and t_2) and the impact velocity decrease during the process, the actual process parameters are shifted to the yellow and finally toward the red zone of Fig. 3. This is illustrated by the single points in the boxes for V103 and V104 in Fig. 3.

7 Summary and Conclusions

The combined approach of process variation, macroscopic integral characterization, and local micro characterization lead to a better understanding of the MPW performance and mechanisms. The principal method shows a high potential for characterization of other welding or bonding processes.

The micro tests support the process window initially developed on the basis of macroscopic lap shear tests and the inhomogeneous failure observed for the marginal welded samples. The good samples showed an improved load-bearing capacity based on combined mechanisms of the larger welded zone and local strain hardening. Further investigations in combination with microsimulations based on smoothed particle hydrodynamics (SPH) and high-resolution microstructure analyses are ongoing and will promote a deeper understanding of the joining mechanisms on small length scales. The test results discussed in this paper enable the local and global calibration of the simulation models.

Computational Modeling of Magnetic Pulse Dissimilar Alloys Welding: Aluminum Alloy 6082-T6 and HC420LA Steel

N. Rodriguez-Barrio, E. Iriondo, D. Jouaffre, and F. A. Girot

Abstract The use of lightweight materials such as high-strength steel, aluminum alloys, and composites is increasing. The joints of dissimilar alloys as the aluminum alloy 6082-T6 and the HC420LA steel are studied in this work. The selected joining process is the magnetic pulse welding (MPW) which enables welding of these two alloys, being non-joinable by other traditional welding technologies. The technology involves a strong electromagnetic–mechanical–thermal interaction. The investigation will be developed mostly on computational modeling by means of using LS-DYNA software, taking into account the key process parameters and their influence. The work includes experimental results for validating the numerical analysis. All the analyzed cases showed welding of the blanks, which was confirmed by metallographic characterization. The simulations show the same deformation behavior as experiments.

1 Introduction

Reducing the weight of structures for transport, whether for the aeronautical, automotive, naval, or railway sectors, has been a strategic objective for product and component manufacturers. The ability to design and manufacture light, durable, and economically profitable structures is essential to maintain competitiveness and advance in minimizing energy consumption and emissions into the atmosphere. An

advanced strategy for achieving this is the use of different materials based on the specifications to be met by each component.

The assembly of the subsystems whose components have been manufactured in dissimilar materials can become a limiting aspect due to the fact that conventional joining technologies are not capable of welding certain combinations of materials. The joining of dissimilar materials by means of conventional fusion welding processes is not possible in certain cases, due to the differences existing between both materials in terms of melting point, thermal conductivity, specific volumetric heat, and coefficient of thermal expansion. Electromagnetic joining, also called magnetic pulse welding (MPW), offers the possibility of welding dissimilar materials, allowing manufacturers and designers to improve their designs and productive results. This will permit the integration of components manufactured by light and resistant combined materials.

The use of electromagnetic driving forces is one of the variants that characterize MPW with respect to other impact welding technologies, where the welding of two different materials occurs through the high-speed impact of both alloys, by means of a controlled acceleration. The magnetic forces, produced between the electromagnetic coil and the moving element to be joined, provide the acceleration force to the moving work element and are the reason for the formation of a solid-state cold weld [1–3].

2 Magnetic Pulse Welding (MPW) of AA 6082-T6 and HC420LA Alloys

Solid-state welding depends on the pressure between the elements to be welded and this pressure can be applied in different ways. The present study focuses on the application of pressure through a high-speed impact. In the particular case of MPW, the impact is created by an electromagnetic pulse (see Fig. 1) and could be applied to both flat and cylindrical parts [4].

Figure 1 shows schematically the three stages that occur in a magnetic pulse welding operation. In the lower part of the system, the electromagnetic coil will be located through which a high amount of current of tens of kiloamperes will be discharged in a short period of time—approximately 100 μs. This discharged primary

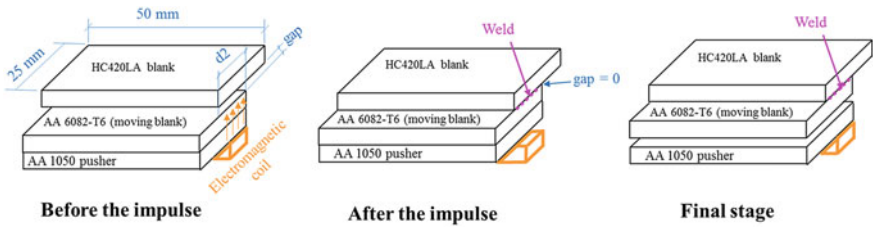

Fig. 1 Stages of the experimental magnetic pulse welding tests. (Color figure online)

current will induce an electromagnetic field in the sheet adjacent to the coil. In this case, a pusher plate made of AA 1050 aluminum alloy of the same dimensions as the moving plate is introduced, due to its lower electrical resistivity, 0.028×10^{-6} Ωm compared to 0.038×10^{-6} of the AA 6082-T6 alloy. The use of the pusher improves the energy efficiency of the pulses. The moving elements of this study will be the pusher and the moving plate of AA 6082-T6.

The two moving blanks are placed on the electromagnetic coil. On the top of the AA 6082-T6 plate, some positioning gauges made of G10 material are set. This is a laminated material made with fiberglass and epoxy resin, whose most outstanding properties for the present application are its high mechanical resistance and good electrical insulation. The gauges, in addition to maintaining the clearance or necessary distance between the HC 420 LA steel plate and the mobile AA 6082-T6, fix the overlap distance (d2) of the pusher and moving plate above the coil. The clearance between the two plates is what allows the moving plate to accelerate and reach a higher impact velocity, which is transformed into a higher mechanical impact pressure.

The second stage of Fig. 1 presents the state after the discharge of the capacitor bank through the coil. This discharge creates an oscillating electromagnetic field that induces currents in the nearby conductive material (pusher plate in the case of the present study). The currents in the piece or moving material are those that react with the oscillating electromagnetic field generating the Lorentz forces, which are the ones that create the deformation of the piece. In the same way that Lorentz forces are generated, the material is also heated instantly by the Joule effect, but the sheet as a whole does not, at any time, approach the melting temperature or undergo any metallurgical transformation [5, 6].

The pusher blank is repulsed with respect to the coil and pushes the AA 6082-T6 plate, accelerating it until it impacts the HC 420 LA steel blank. This impact is what generates significant pressure and the solid-state union.

The third stage, or final situation, reproduces the state of the system after the impact. The two plates that have impacted have been permanently joined and the pusher remains in its deformed shape, but it is not joined to the AA 6082-T6 blank.

3 Finite Element Modeling of the Process

The operations carried out by means of magnetic pulses require a multiphysics solution with electro-magneto-thermo-mechanical interactions [7]. Most of the studies carried out in the field of modeling magnetic pulse operations have assumed that most of the material deformation occurs after the first electromagnetic pulse [8]. This assumption results in the separation of the physical phenomena that are part of the process, to the electromagnetic and mechanical response of the problem, and they are proposed to be solved sequentially.

LS-DYNA [9] is an advanced nonlinear finite element multiphysics software capable of simulating highly complex real problems. It is useful for analyzing

phenomena with large deformations, models of sophisticated materials, or complex contact conditions. Forming and metal welding is one of the most important applications of LS-DYNA because it is capable of simulating many of the phenomena that occur in these processes. This software integrates an electromagnetic module that is very useful for electromagnetic impact welding since mechanical/thermal/electromagnetic simulations can be coupled [7]. This module allows introducing the source of electric current in solid conductors and to compute the resulting electromagnetic field and the induced currents. The generated fields are solved with Maxwell's equations. These equations are solved in turn using the finite element method and the boundary element method. This module allows the coupling of different solutions of both electromagnetic and thermo-mechanical simulations.

3.1 Model Specifications

The present research work aims to model the welding of dissimilar materials using magnetic pulses: the aluminum alloy AA 6082-T6 and the steel alloy HC 420 LA. The materials used are widely applied in the automotive industry. Table 1 shows the main mechanical properties, in addition to the electrical resistivity of both materials.

Once the materials with those which validate the MPW method have been selected, the experimental setup is defined. The aluminum alloy is chosen as the mobile element of the system, due to its lower electrical resistivity. The lower the electrical resistivity, the less discharge energy will be required to generate the same induced current, or what is the same, to generate the same level of acceleration in the moving material or sheet.

The size of the blanks is 50 × 25 × 1 mm and they are completely overlapped longitudinally at a certain distance between them and it is in this overlapping area that the weld will be generated. The distance between the plates is a process variable.

The finite element (FE) model consists of a coil, a tool, the HC420LA steel blank, the AA6082-T6 blank as the moving part, and finally, an AA 1050 aluminum alloy plate that acts as a pusher for the moving plate. The pusher is placed in the closest position to the coil.

The mesh used in both materials has been the same. The total number of cells of each blank is 8000 and it has been made with cells in the form of 1 × 0.5 × 0.25 mm hexahedrons. The duration of the calculations for each simulation has been approximately 2 h.

Figure 2 shows the configuration of the model including all the elements that

Table 1 Mechanical properties and electrical resistivity of the studied materials

Properties	AA 6082-T6	HC 420 LA
Yield strength (MPa)	289	475
Ultimate strength (MPa)	331	547
Electrical resistivity (Ωm)	0.038×10^{-6}	1.585×10^{-7}

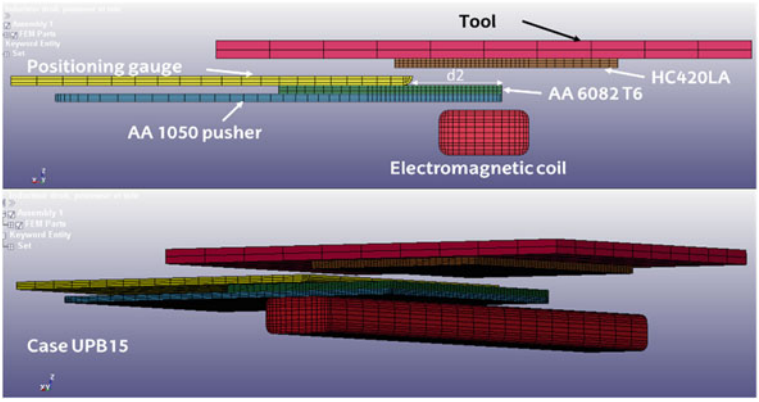

Fig. 2 LS-DYNA model. (Color figure online)

take part in the simulation. The elements that will be used during the experimental validation are simplified in the case of simulations, for example, limiting the geometry of the coil to its active zone.

To describe briefly the configuration of the elements of the models, four elements are observed in each of the models. The electromagnetic coil is the element that is in the lower position and on it is positioned the AA 1050 aluminum alloy pusher used to improve the efficiency of each impulse. On the pusher is the moving plate that impacts and will be welded with the plate positioned on it. The element positioned at the top is the tool that stops the movement of the two sheets: AA6082-T6 and HC420LA. The angle of impact, see Fig. 3, is the angle formed by the materials at the point of contact. At the first point of contact, or impact point, a shock wave is created between the two materials in the radial direction due to the high value of the generated impact velocity. This shock wave creates the jet of air that cleans the surface to be welded of oxides and other particles, favoring the joint.

Four different cases have been simulated: UPB15, UPB17, UPB28, and UPB41. The energy conditions and the design distances are shown in Table 2. The parameters

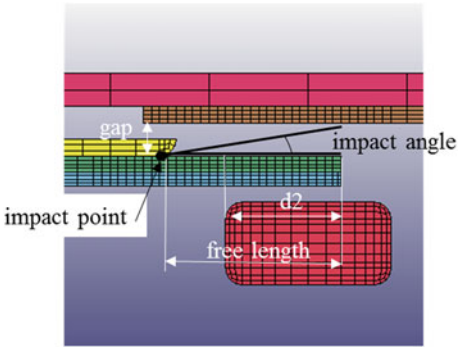

Fig. 3 LS-DYNA model detail: impact angle and impact point. (Color figure online)

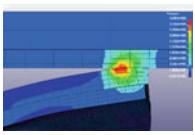
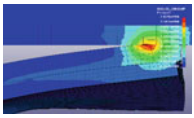
Table 2 Model conditions

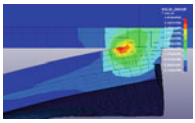
Case	Energy (kJ)	Gap (mm)	d2 (mm)	Impact angle (°)
UPB15	22	2	7	11
UPB17	19.4	2	7	11
UPB28	25	2	6	13
UPB41	25	1	8	5

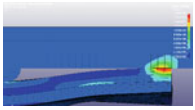
that have been calculated are: plastic deformation, previous speed at the instant of impact, and impact pressure.

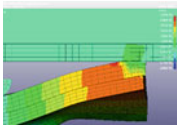
3.2 Computational Modeling Results

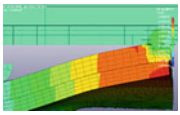


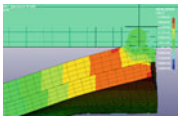


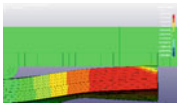


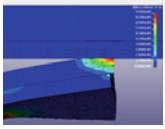


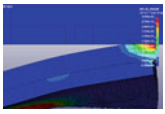


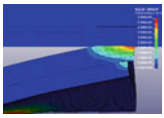












The results obtained from the simulations carried out are shown in Table 3, where the maximum values of impact pressure developed between the blanks to be welded, the velocity at the previous instant to the impact, and the plastic deformation suffered after the welding are displayed. The analysis to carry out will be done based on the maximum values obtained from these parameters due to their inherent relevance for MPW technology.

The maximum impact pressure values are within the range of 1–15 GPa, and this range being considered valid for mechanical welds [10]. The maximum values of the impact pressure appear at the point where the impact occurs (see Table 4). The highest pressure level is achieved at the UPB15 case. On the other hand, it is observed that with the same arrangement of the blanks and when the value of the applied energy decreases, the value of the maximum pressure also decreases. However, when the blank configuration changes, the increase in the applied energy does not lead to an increase in the pressure achieved. The last-mentioned case occurs in the UPB41 test, as can be seen in Table 3. In this case, the discharge energy level has been the maximum (25 kJ); however, by drastically reducing the impact angle to 5°, the maximum pressure reached has decreased by 41% compared to UPB 15 (22 kJ and 11°).

Table 3 Maximum values obtained from the four modeled cases

Case	Energy (kJ)	Impact angle (°)	Pressure (GPa)	Velocity (m/s)	Plastic deformation
UPB15	22	11	3.09	537.6	0.35
UPB17	19.4	11	2.63	504.9	0.3
UPB28	25	15	2.91	576.8	0.5
UPB41	25	5	1.85	329	0.06

Table 4 Images of maximum values of simulation parameters. (Color figure online)

CASE	Pressure (GPa)	Velocity (m/s)	Plastic deformation
UPB15			
UPB17			
UPB28			
UPB41			

The velocity of the moving plate, at the previous instant to the impact, behaves in a similar way to the maximum pressure achieved. The most remarkable thing is that the higher the energy applied for the same arrangement, the higher the speed is. Using the same configuration, when lowering the energy value the velocity of the blank also decreases. However, when using another arrangement, such as UPB41, the increase in energy does not translate into a rise in velocity.

The maximum velocity obtained in the UPB41 case simulation is 39% lower than the UPB15 case, with the energy discharged being practically the same.

With regard to plastic deformation, this parameter continues the same trend as the previous two.

4 Experimental Validation

The experimental tests were carried out on the Innovaltech platform (Saint-Quentin, France). The equipment used to develop the tests consists of a capacitors bank, a circuit in which there will be an electromagnetic coil specifically designed to carry out these experiments, and the blanks to be welded. The capacitor bank used is a PULSAR, with a maximum capacity of 25 kJ/9 kV (690 μF) and the pulse frequency was 17 kHz.

The used electromagnetic coil is flat (see Fig. 4) due to the nature of the joint to be

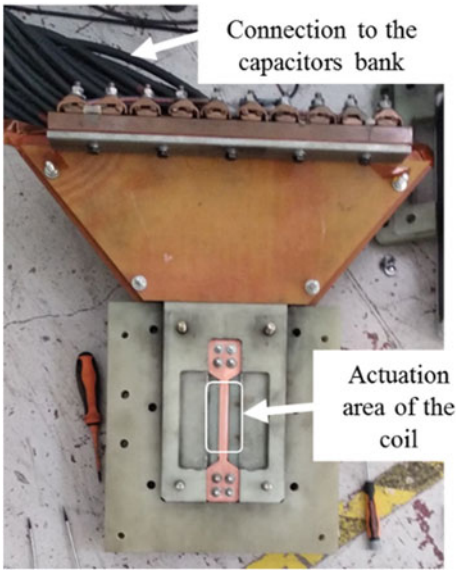


Fig. 4 Flat electromagnetic coil and the connections to the capacitors bank. (Color figure online)

made. To isolate the current discharged through the coil, with respect to the metallic elements of the system (joining elements, blocks to stop the impact, and the press used to contain the different components), the electromagnetic coil is embedded in a block of G10 as shown in Fig. 4. This figure also shows the connections required by the coil for its coupling to the capacitor bank and the actuating area of the coil: the area where the coil induces currents on the pusher and the Lorentz forces are generated. The mobile plates are placed on the actuation area of the coil, where the magnetic pulse will be generated.

In Fig. 5 the pusher blank is not shown, which would be located on the coil and this is covered with Kapton tape. This wrap is also called polyamide tape with silicone

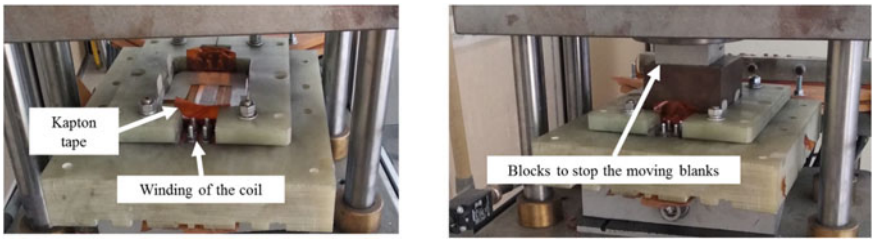

Fig. 5 Experimental setup. Left: after positioning the blanks to be welded on the coil. Right: final position of the setup elements before the electric discharge of the capacitors bank. (Color figure online)

adhesive, being an electrically insulating adhesive tape that is highly resistant to high temperatures, up to 250 °C.

Figure 5-Left shows the Kapton tape placed on the coil. The main function is to protect the coil from electrical arcs that may be created during the electrical discharge: between the coil and the other metallic elements of the system, such as the blanks to be welded or the joining elements such as screws. If the elements that configure the experimental setup are not electrically isolated, currents can be derived and electric arcs could be generated with catastrophic results for the coil and other elements of the test [11].

The tests have been carried out with a voltage between 7 and 8.5 kV. The distance between the moving and the fixed blanks has varied, increasing from 1 to 3 mm. The third parameter to evaluate was the superposition of the moving blank (AA 6082-T6) in regard to the coil, varying between 6 and 8 mm.

4.1 Experimental Validation Results

After welding, the joint is generally 20 mm long and 2 mm wide, as shown in Fig. 6.

The UPB15 and UPB17 tests were carried out with the same geometry, but applying different energy levels, 22 kJ and 19.4 kJ, respectively. In both cases, the welding is achieved.

In the UPB28 test, the overlap distance between the moving blank and the coil changes from 7 to 6 mm, the impact angle goes from 11 to 13° and the energy is set at 25 kJ. In this case, the welding is also considered acceptable. Finally, to carry out the UPB41 test, the energy used is 25 kJ, the distance between the two blanks changes from 2 to 1 mm, and the overlapping distance between the moving plates and the coil is increased to 8 mm, obtaining an impact angle of 5°. In this last-mentioned case, the weld is considered correct.

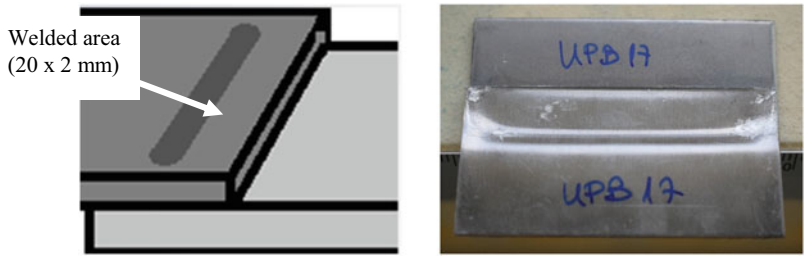

Fig. 6 Left: Rendering of the weld area. Right: Image of the experimental sample UPB17. (Color figure online)

5 Metallurgical Characterization

Hereunder, the results of the metallurgical characterization performed on the four welded specimens by magnetic pulses are shown. The cross-sections of the specimens have been analyzed. The specimens have been polished and etched following a standard procedure and the images were captured using a Leica confocal microscope. Figure 7 shows the images obtained for UPB cases 15, 17, 28, and 41. In the upper part is the steel blank and in the lower part the aluminum base. The bond between them is distinguished in the central area of the image.

It has been observed that the morphology of the joint varies by means of the modification of the parameters of the magnetic welding process. For example, Fig. 7d shows the influence of the impact angle on the morphology. The UPB41 case has an impact angle of 5° compared to 11° for the UPB15 and UPB17. Continuing with the analysis of this case, UPB41, it is observed that the bonding has a lower continuity than the other cases studied, and the start of the weld does not start at the point of the impact and shows a slight curvature in this area, while in the other cases the start of the welds is closer to the point of the impact.

It is observed that the higher is the angle of impact of the experimental setup, the higher levels of plastic deformation are reached.

Regarding the microstructure of the bonding, the characteristic sinusoidal or wavy shape of MPW [12] has been observed (see Fig. 8). However, the joints do not show homogeneity in their cross-section.

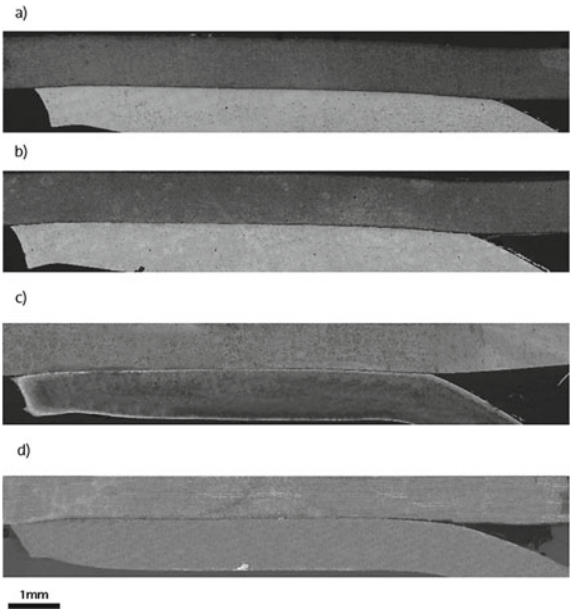

Fig. 7 Optical images of the cross-section of **a** UPB15, **b** UPB17, **c** UPB28, **d** UPB41 specimens

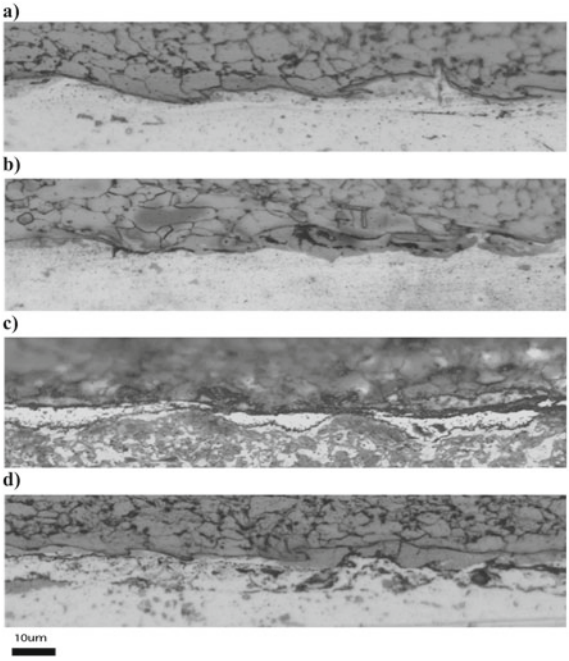

Fig. 8 Micrographs of the weld interfaces **a** UPB15, **b** UPB17, **c** UPB28, **d** UPB41

In the metallurgical analysis carried out, it has been observed that the microstructure varies with the process parameters tested. An increase in the angle of impact has a direct influence on the deformation of the material, being this higher, as bigger is the angle. The welds do not have a uniform morphology and show a characteristic wavy-interface configuration of MPW.

6 Concluding Remarks

After developing the present research work, whose main hypothesis was the determination of the feasibility of welding dissimilar materials, the main conclusion reached confirms that MPW is capable of joining dissimilar materials, such as steel and aluminum alloys. In the experimental validation carried out, using different test conditions, it was possible to bond the two blanks of HC420LA and AA 6082-T6.

LS-DYNA software has been capable to simulate processes like those analyzed in this study. The simulations carried out reveal approximate information on the process parameters, such as pressures, speeds, and maximum plastic deformations. From the impact pressures obtained from the simulations, it can be concluded that a greater amount of experimentally tested case modeling is required to conclude that a simulation is a valid tool to accurately predict the behavior of the joint.

Metallurgical characterization has been performed to verify that the joints made through this process produce good welds. The morphology of the transverse bond of the tested specimens has been studied and the four cases studied have presented favorable results that confirm the existence of the weld. The micrographs have shown the deformations generated, as well as the influence that the process variables exert on them.

Influence of Ultrasonic Assistance on the Forming Limits of Steel

Manuel Jäckisch and Marion Merklein

Abstract Since Blaha discovered the beneficial effect of superimposing high-frequency oscillations to the metal forming process, the occurring force and stress reduction are well-known phenomena. Leading to an immediate flow stress reduction, the so-called ultrasonic assistance is a promising approach to enable forming with reduced process forces. While the achievable force reduction has been investigated intensively, only a few analyses have been conducted in the context of the impact of ultrasonic superposition on the forming limits. The latest investigations state earlier material failure due to localized forming with recurrent high strain rates. Within this paper, the influence of superimposed vibrations on the forming limits of C35E is investigated with regard to distinct oscillation amplitudes and press velocities. It was found that superimposed 20 kHz oscillations of 10 and 20 μm cause considerable earlier material failure. In comparison to conventional testing, the crack initiation, as well as the shear zone formation, is alternated due to the ultrasonic assistance.

Keywords Ultrasonic · Forming · Failure · Steel

1 Introduction

The global goal to reduce CO_2 emissions affects almost every industrial sector. In the European Union (EU) 21% of the overall CO_2 emissions are caused by road transport [1]. Consequently, lightweight construction offers a high potential to reduce emissions and comply with critical limits. A common measure is the use of high-strength steels, which allow a significant reduction of wall thicknesses, and therefore lead to a decrease of component weight. High flow stresses as well as limited formability limit the application of conventional manufacturing processes for these materials. Therefore, there is a demand for innovative production methods. One approach is the superposition of high-frequency oscillations to the forming process. In this way, the so-called ultrasonic assistance enables a substantial reduction of the forming

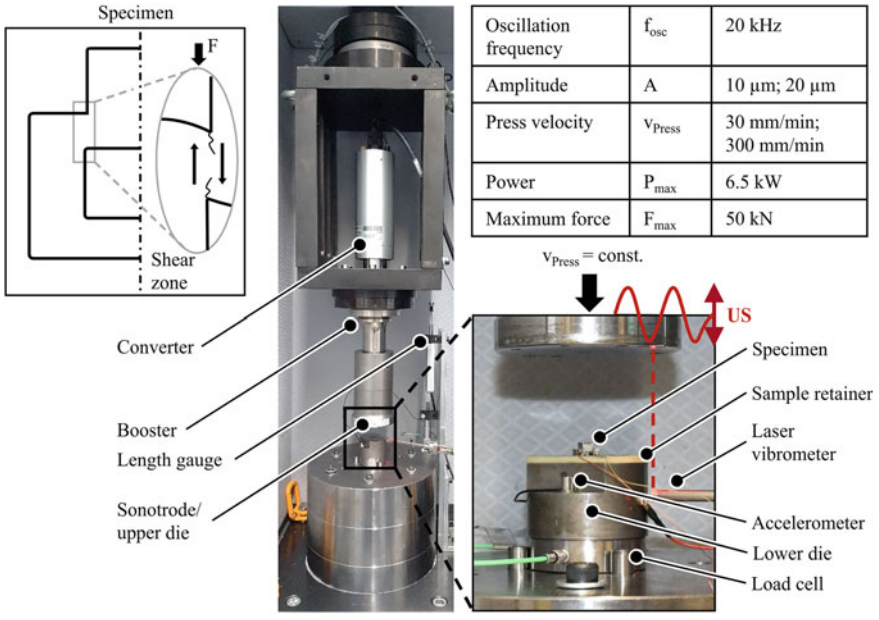
forces. The ultrasonic-based softening, which is also known as the Blaha effect [2], has already been confirmed for several processes such as deep drawing, wire drawing, and forging, as well as for various materials like copper [3], aluminum [4], and mild and high-strength steel [5]. However, most investigations focused on the achievable force reduction and the process characteristics. Only a few analyses dealt with the influence of high-frequency oscillations on the forming limits of metallic materials.



In order to investigate the ultrasonic-based influence on material failure under shear loading, Michalski et al. [6] superimposed hat-shaped specimens with a 20 kHz oscillation and amplitudes of 10 and 20 μm. In comparison to conventional shear tests without vibrational influence, they found earlier material failure due to crack initiation as well as reduced maximum shearing loads because of the superimposed oscillations. These findings were confirmed for cast aluminum, mild steel and high-strength steel. Moreover, the superimposed oscillation caused transversal cracks. Schmauder et al. [7] investigated ultrasonic-induced effects on the forming limits under torsional loading. Therefore, torsion tests were superimposed with 22 kHz oscillations in the axial direction. It was found that the forming limits of mild steel and nickel silver were extended, whereas a reduction occurred for aluminum. Independent of the material, the vibrational effects were weakened with increasing strain rates. Wittauer et al. [8] conducted ultrasonic-assisted blanking tests with aluminum. They presumed enhanced material plasticity due to the high-frequency vibration since increasing oscillation amplitudes caused decreasing fracture zones. In contrast, analyses of oscillation-induced effects with compression and tension testing indicate a material-dependent reduction of the formability for high-strength steels and titanium alloys [9]. Nerubai ascribed this behavior to damaged crystal structures. Wen et al. [10] also conducted tension testing with superimposed vibration. For an oscillation frequency of 15 kHz and amplitudes up to 1.5 μm, an enhanced material formability was found for AZ-31. Greater amplitudes of 2.7 μm resulted in earlier material failure. They assumed different predominant dislocation movement mechanisms for the contrary findings.

Regarding the influence of ultrasonic assistance on material failure, the present studies indicate varying findings as well as material dependencies. Moreover, for mild steel both reduced [6] and enhanced [7] material formability was determined. Therefore, this experimental analysis aims for a systematic investigation of vibrational induced effects on the forming limit of steel and a more in-depth analysis of characteristic process states in comparison to previous investigations. For this, a common bulk-forming steel C35E is used, which has a well examinable microstructure. Based on the methodology in [6], hat-shaped specimens are formed by two distinct press velocities of $v_{Press} = 30$ mm/min and $v_{Press} = 300$ mm/min with superimposed longitudinal 20 kHz oscillations of 10 and 20 μm oscillation amplitude A. As a reference, conventional testing without superimposed vibration, equivalent to 0 μm oscillation amplitude, is carried out. On the basis of the force–displacement curves, substantial process influences are investigated and material failure is determined. The shear zones are evaluated by means of qualitative and quantitative metallographic analyses. Moreover, stepwise shear testing is conducted and the crack initiation and propagation is investigated by microsections.

2 Experimental Setup

The specimen geometry for ultrasonic-assisted shear testing is derived from high-speed shear testing [11]. The hat-shape enables a predominantly homogenous stress state in the shear plane and has already been successfully applied for ultrasonic-assisted shear tests [6]. The C35E specimens are precisely cut by electrical discharge machining with an AgieCharmilles CUT2000. As depicted in Fig. 1 the samples are mirror-symmetric with two identical 10.0 mm long, 1.0 mm high, and 0.1 mm wide shear zones.

The experimental investigations on the impact of ultrasonic assistance on the forming limits of steel are carried out on a universal testing machine Walter + Bai LFEM 300. An individual tool that enables the superposition of high-frequency oscillations to the constant feeding rate is mounted to the testing machine. The testing rig for ultrasonic-assisted forming, introduced in [12], consists of a fixed lower and a moveable upper tool and is depicted in Fig. 1. The moveable upper tool is mounted to the traverse of the testing machine and comprises a converter, a booster, and a sonotrode, which also functions as the upper die. To superimpose ultrasonic oscillations to the forming process, the converter is fed with a high-frequency AC voltage. Based on the inverse piezoelectric effect, the converter transforms the electrical voltage into a mechanical oscillation of the same frequency. Due to the booster's geometry and the interaction with the sonotrode, the oscillation amplitude is amplified by a specific ratio. This way, the constant feed of the testing machine is

Oscillation frequency	f_{osc}	20 kHz
Amplitude	A	10 µm; 20 µm
Press velocity	v_{Press}	30 mm/min; 300 mm/min
Power	P_{max}	6.5 kW
Maximum force	F_{max}	50 kN

Fig. 1 Specimen geometry and experimental setup. (Color figure online)

superimposed with a high-frequency oscillation of 20 kHz and amplitudes of 10 and 20 µm. A length gauge is used for measuring the tool displacement and controlling the ultrasonic system. Moreover, the lower tool is shown in detail in Fig. 1. Besides the lower flat die, where the samples are positioned in a retainer, measurement instrumentation for process control is included. A piezoelectric force transducer directly underneath the die gauges the dynamic forces. Since the dynamic behavior of the load cell and the whole lower tool is frequency-dependent, the transfer function is determined by means of the approach proposed in [13]. This way, oscillating forces are assessed correctly and the true maximum oscillatory forces are identified. A laser vibrometer and an accelerometer are utilized to monitor the oscillation of the upper and lower tool, respectively. All signals are sampled with 1 MHz.

3 Results

Material failure is determined based on the force–displacement curves. As proposed in [6] the displacement at failure initiation is analyzed by the gradient of the mean process force. Therefore, the derivative of the mean process force with respect to the displacement is calculated. Since the derivative's zero-crossing indicates the decline of the process forces, this position marks the material failure. The respective maximum oscillatory process force is the force at failure. In Fig. 2 the force–displacement curves are depicted for conventional and ultrasonic-assisted shear testing with 20 kHz oscillation frequency and 10 and 20 µm amplitude. For each parameter combination, three valid repetitions are conducted. The results for the press velocity of 30 and 300 mm/min are separated in two diagrams. Essentially, the force–displacement curves are similar for the distinct press velocities. After the initial steep rise, which indicates the elastic range, the process forces increase moderately until material failure occurs. With continuing plastic shear deformation the process forces decrease. For 30 mm/min press velocity the respective process forces are lower and the ultrasonic-based force reduction is more pronounced than for 300 mm/min. These findings are in accordance with the investigation of the ultrasonic-based force

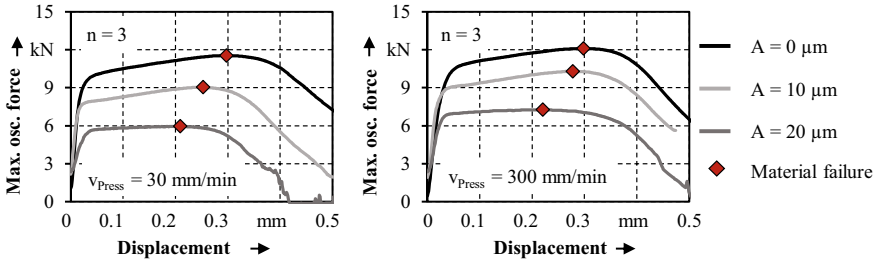


Fig. 2 Force–displacement curves for conventional and ultrasonic-assisted shear testing with 30 and 300 mm/min press velocity. (Color figure online)

reduction in compression tests with the identical material [14]. The increased force reduction is explained by the enhanced vibrational energy input due to the greater oscillation amplitude. Additionally, the lower press velocity, leading to an extended process duration, further increases the energy input.

For a quantitative analysis of the displacement and force at failure, the respective results are plotted in Fig. 3. Without superimposed oscillation failure occurs for 30 and 300 mm/min press velocity at a displacement of 0.30 mm. Thus, the evaluated strain rate range has no influence on the displacement at failure. A press velocity of 30 mm/min and ultrasonic assistance with 10 and 20 µm amplitude lead to considerable earlier failure at 0.25 and 0.21 mm displacement, respectively. For higher press velocity, the points of crack initiation under oscillation superposition are determined later; however, the deviations in comparison to 30 mm/min press velocity are insignificant. Regarding the force at material failure, similar behavior is detected. Maximum shear forces are 11.54 and 12.11 kN for conventional forming with 30 and 300 mm/min, respectively. Superimposed oscillations of 20 µm amplitude lead to a maximum force reduction of 5.59 and 4.85 kN for the respective process velocities. The force reductions due to the lower forming velocity and the higher oscillation amplitudes are consistently significant. In conclusion, the oscillation amplitude has the most prominent influence on the ultrasonic-based force reduction and therefore on the force at failure. Since these outcomes are in accordance with investigations on the ultrasonic-based force reduction under compressive stress [14], it can be assumed that the findings are applicable to a shear stress state.

In order to evaluate the crack initiation and propagation precisely, for each parameter combination at the lower press velocity, six characteristic microsections of stepwise shear tests are illustrated in Fig. 4. The upper row depicts the process states for conventional shear testing, equivalent to A = 0 µm. Up to 0.25 mm feed plastic forming leads predominantly to a rollover. As initial cracks occur, the rollover formation is interrupted at 0.26 mm displacement. This behavior is similar to conventional shear cutting. During the following process stages the cracks grow smoothly in the axial direction and a defined shear zone is formed. Superimposing a 20 kHz oscillation of 10 µm amplitude results in the crack formation presented in the middle

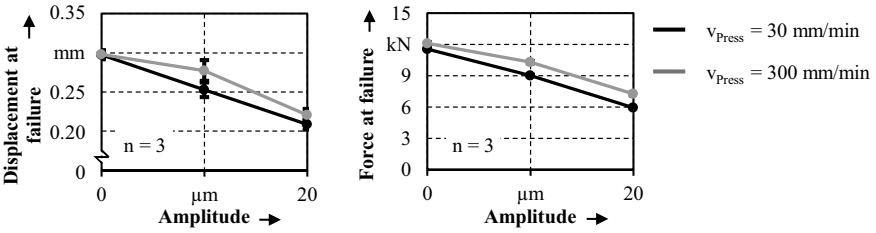

Fig. 3 Material failure displacement and force for conventional and ultrasonic-assisted shear testing. (Color figure online)

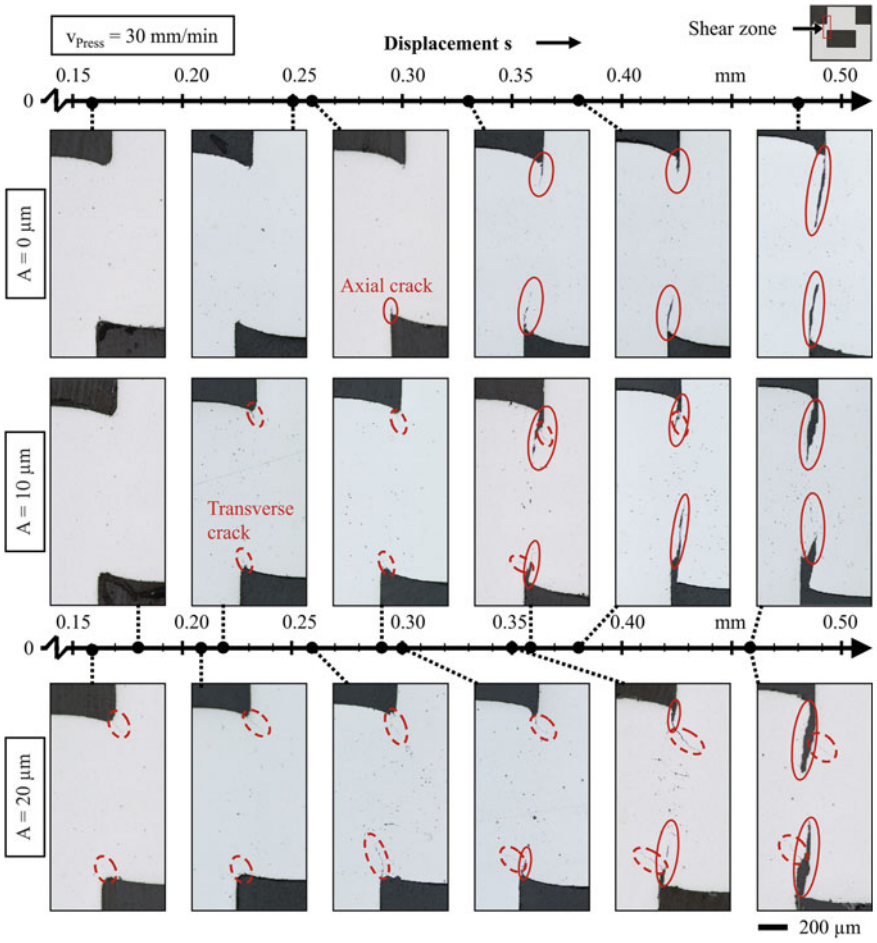

Fig. 4 Crack initiation and propagation at characteristic process states for shear testing with v_{Press} = 30 mm/min and oscillations amplitudes of 0, 10, and 20 µm. (Color figure online)

row. First cracks are identified at 0.22 mm displacement. In contrast to conventional forming, the cracks are also transverse-orientated. According to [6], this transverse crack formation is caused by cyclic high frequent stress alternation as well as stress concentration at the edges. Further deformation results in the formation of a pronounced upper and lower axial crack with smaller transverse cracks. Consequently, the final shear fracture is more rugged. As indicated by the microsections in the last row, superimposed vibration with 20 µm amplitude results in a similar crack propagation as oscillations of 10 µm amplitude. Nevertheless, the effects are more severe. Initial transverse cracks are detected at 0.16 mm stroke. At first, crack growth is predominantly orientated transversal before the axial crack propagation

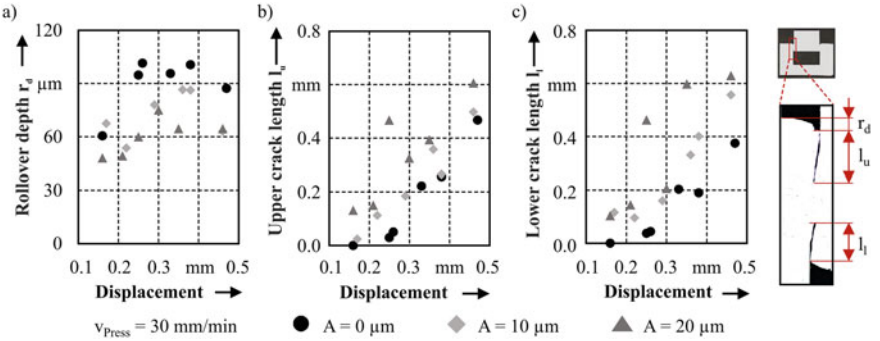

Fig. 5 Quantitative analysis of **a** rollover depth as well as **b** upper and **c** lower crack propagation for shear testing with $v_{Press} = 30$ mm/min and superimposed oscillations of 0,10, and 20 µm amplitude. (Color figure online)

becomes dominant. In conclusion, ultrasonic assistance causes both earlier and transverse crack growth. Moreover, fine microcracks occur for all evaluated parameter combinations in earlier process states than previously determined on the basis of the force–displacement curves.

In addition to the qualitative mircosections, a quantitative evaluation of the rollover depth and the crack growth from the upper and lower edge of the shearing zone is carried out for the respective process states. Each data point in Fig. 5 represents the mean of the left and right shear zone of a single sample. Figure 5a presents the rollover depths r_d for conventional and ultrasonic-assisted shear testing with 30 mm/min press velocity. The most considerable rollover occurs for conventional shearing. The maximum rollover depth is already reached at a process state of 0.25 mm stroke. Since the continuing stroke leads to substantial crack propagation, further rollover is inhibited. Similar behavior is identified for vibration superimposed shearing tests with 10 and 20 µm amplitude. The maximum rollover depth develops until the deformation results predominantly in axial crack propagation. This process state is attained at about 0.3 mm displacement for both amplitudes. Furthermore, the maximum occurring rollover depth reduces with greater oscillation amplitudes. These findings indicate reduced plasticity due to ultrasonic assistance. Moreover, the effect is promoted by greater amplitudes. The analysis of crack lengths growth is plotted in Fig. 5b, c. Regarding the upper crack l_u, the largest cracks occur due to high-frequency oscillations with 20 µm amplitude. Additionally, cracks are formed at earlier process states. Reducing the oscillation amplitude to 10 µm results in both later crack initiation and shorter cracks. This trend is enhanced for conventional shear testing with 0 µm amplitude. Essentially, mainly steady crack growth is measured for all the analyzed parameter combinations, which correlates with the linear increasing displacement. Similar behavior is detected with respect to the crack propagation emerging from the lower edge. However, superimposed oscillations of 20 µm amplitude appear to lead to unsteady crack formation. The results indicate an interruption of the rollover formation due to the axial crack initiation. Regarding ultrasonic-assisted shear testing,

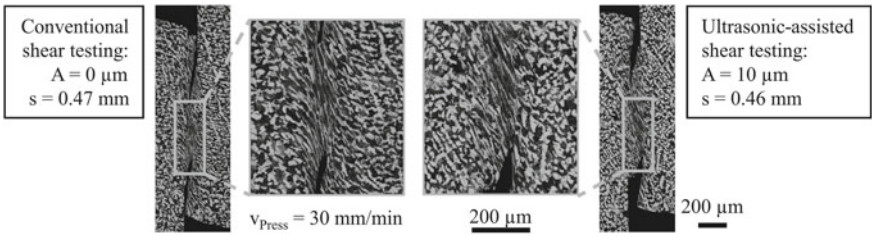

Fig. 6 Comparison of the microstructure due to conventional and ultrasonic-assisted shear testing

axial cracks develop from the initial transverse cracks. Hence, these initial cracks are crucial to the early material failure under the ultrasonic influence.

Considering the identified points of material failure based on the force–displacement curves and the qualitative and quantitative evaluation of the microsections, slight deviations are present. Even though initial fine cracks occur prior to the calculated point of crack initiation, the deviations are similar for the various process parameters. Thus, the methodology is appropriate to determine the influence of ultrasonic assistance on the material failure. Since these fine cracks are apparently insignificant to the process force, the formation cannot be directly measured. Nevertheless, qualitative and quantitative results verify reduced material formability due to superimposed oscillations. Michalski et al. [6] explained this effect by the formation of adiabatic shear bands. Therefore, Fig. 6 compares the microstructures of deformed specimens after conventional and ultrasonic-assisted shear testing with 10 µm amplitude. The etched microsections of both parameter combinations reveal narrow shear bands with highly deformed grains close to mainly undeformed microstructure. Even though this formation is characteristic to adiabatic shear bands [15], in this case, it is addressed to specimen geometry, which promotes a narrow shear zone. Moreover, the precondition of very high strain rates due to the high-frequency oscillation is not fulfilled for the conventional shear tests. Considering the similar microstructures of conventional and ultrasonic-assisted shear tested specimens, adiabatic shear bands are unlikely for the steel C35E. Consequently, other causes for the reduced shear formability are present. The experimental findings prove a promoted crack initiation at early process stages due to the superimposed oscillations. Thus, the instantaneous cross-section in the shear zone is decreased and stress concentration at the crack tips occurs. Hence, it can be assumed that the initial material failure is a crucial cause for the reduced shear formability.

4 Summary

Within this investigation, the influence of ultrasonic assistance on the material failure was analyzed. Conventional and ultrasonic-assisted shear testing with 20 kHz oscillations and 10 and 20 µm oscillation amplitude was carried out for C35E. Based

on the force–displacement curves material failure was determined by means of the mean forming force derivative with respect to the stroke. It was found that the forming forces are considerably reduced by superimposed oscillations. This behavior accords with the usual influence of ultrasonic assistance on forming processes. Moreover, material failure occurred earlier and at lower process forces. The oscillation amplitude predominantly influenced this behavior, while distinct press velocities and thus the process duration had minor effects. Conducting stepwise shear tests, the formation and propagation of the shear zone were investigated. Mircosections at characteristic process states revealed smooth crack formation for conventional forming and transverse crack growth as well as rugged shear zones due to ultrasonic assistance. Quantitative analyses of the shear zone geometry confirmed the findings. Crack initiation and size were promoted by superimposed oscillations and correlated with the amplitude's magnitude.

Design and Fabrication of a High-Performance Magnetic Actuator for Magnetic Pulse Welding of Metal Tubes with Large Diameters

Xiaoxiang Li, Quanliang Cao, Zhipeng Lai, Yiliang Lv, Siyuan Chen, Yi zhang, Xiaotao Han, and Liang Li

Abstract Magnetic pulse welding (MPW) is a high-speed joining process that uses pulse electromagnetic force to achieve welding. It is a clean welding process and it can be applied to dissimilar metals welding, which has a wide range of application prospects. However, this technology is currently mainly used for welding small-diameter thin-walled tubes. This is because the energy and electromagnetic force required for welding increase significantly as the tube size increases, which consequently places strict requirements on welding tools, including pulsed power and coil. To solve this issue, this work developed a two-dimensional (2D) axial-symmetry finite element model to optimize the tube welding process and designed a high-performance magnetic actuator with a high-strength coil to generate a strong enough electromagnetic force. On this basis, both numerical and experimental studies were performed to investigate the welding behavior of a 6061 aluminum alloy tube and a 304 stainless steel tube with 110 mm diameter and 3 mm thickness. Finally, a mechanical test and scanning electron microscope (SEM) were used to verify the joining quality, and the results show that the metallurgical bonding occurred between the two tubes. The presented optimization method and tool design could be of significance to the practical applications of MPW technology.

1 Introduction

Magnetic pulse welding (MPW) is an advanced and clean technology, which can translate electric power into kinetic energy of metallic tubes or sheets and achieve welding by high-speed impact. Compared with traditional fusion welding, MPW is a kind of solid-state welding process. Without an obvious welding seam, the shortcoming of a heat-affected area can be avoided. In addition, the joining of dissimilar materials is impossible for the conventional fusion welding process due to huge differences in melting point, thermal conductivity, volumetric specific heat, and coefficient of thermal expansion [1]. As MPW can achieve atomic diffusion of two materials by high-speed impact, this method can be used to join dissimilar materials and achieve lighter and stronger material combinations. Other high-speed welding technologies, like explosive welding, laser impact welding, and vaporizing foil actuator welding are mainly applied to sheet welding. MPW has significant advantages in tube welding because of the axisymmetric structure of the coil actuator.

At present, MPW technology is mainly used for tubes with a diameter of less than 50 mm and thickness thinner than 1 mm, like automotive space frame and cable connector, as in [2]. To the best of our knowledge, the largest diameter of magnetic tube welding research latest reported is 80 mm [3]. Welding large and thick tubes needs more input energy to generate high driving pressures between magnetic actuator and tubes in a short acceleration time. The lack of high-energy power supplies or the low efficiency of welding actuators makes the energy input unsatisfactory. Furthermore, high driving pressures can also lead to shorten the longevity of the actuator or even damage the equipment which makes it difficult to weld large diameter tubes [4]. To solve these problems, a necessary task is to optimize the welding system via an effective simulation model, which can be used to improve the utilization of magnetic energy. As the MPW system is not a perfect two-dimensional axial-symmetry system, the existing simulation models are mainly based on the 3D model [5, 6]. Although these models can analyze the whole MPW process accurately, it is complex and low efficiency to achieve optimization work. Yu et al. 2005 established a 2D model by ANSYS to explore the effect of field shaper on magnetic pressure distribution in electromagnetic modules [7]. But the MPW is a multi-physics coupling process and the optimization of detailed parameters of magnetic actuators is rarely mentioned. In addition to optimization work, how to increase the structural strength of the coils used in the MPW process is also critical, which is the key to ensuring that a sufficiently strong electromagnetic force can be generated. In this regard, our group has done some related research. For example, the high-field pulsed magnet manufacturing technology has been introduced to increase the coil strength in the field of electromagnetic forming [8]. A new discharge circuit configuration with a crowbar circuit was proposed to reduce the Joule heating of the coil [9]. A dual-coil system was developed to improve the forming ability of sheet and tube processing [10, 11].

This paper provides an effective two-dimensional model for the optimization of design of the MPW process by simplifying the boundary conditions in COMSOL.

Aiming at welding aluminum tubes with 110 mm diameter and 3 mm thickness, the effects of actuator parameters such as the coil turns and the structural parameters of the field shaper on the magnetic pressure are analyzed in detail, and a high-strength coil has been designed and fabricated. Furthermore, a variable-size, multi-function MPW experimental platform is developed and a series of experiments are carried out to achieve the high-quality welding between the AA6061 and SS304 tubes. Finally, some mechanical and metallography tests are performed to evaluate the welding quality.

2 Simulation

For tube welding, a magnetic actuator is placed outside the two tubes and energized with a capacitor bank. The interaction between the generated magnetic field and the induced eddy current in the outer metal tube will trigger a strong Lorentz force that induces the high-speed impact of two tubes, as shown in Fig. 1a. Field shaper (FS) is an important part that has an effect on the distribution of the magnetic field. The magnetic actuator is not a perfect two-dimensional axial symmetry model and a slot exists in the FS. Through this slot structure, the magnetic field generated by the coil can access the area near the outer tube, as shown in Fig. 1b. In the FS region, the slot cuts off the current in the hoop direction, and the FS can be regarded as a single-turn secondary coil [12]. In COMSOL software, the model can be treated as a 2D axial symmetry model by defining the FS region as a coil characteristic and making its total current to zero all the time.

A 2D axial symmetry finite element simulation model has been built by the COMSOL Multiphysics software package. In the time domain, five physical modules are solved by the unity coupling mode: (1) the "global ordinary differential equations (ODEs) and differential algebraic equations (DAEs)" module; (2) the "magnetic fields" module; (3) the "solid mechanics" module; (4) the "Heat transfer in solid"

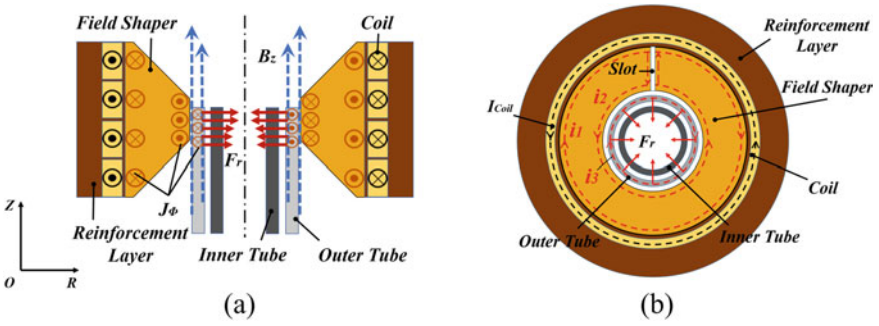

Fig. 1 Schematic diagram of the MPW process: **a** The front view and **b** the top view. (Color figure online)

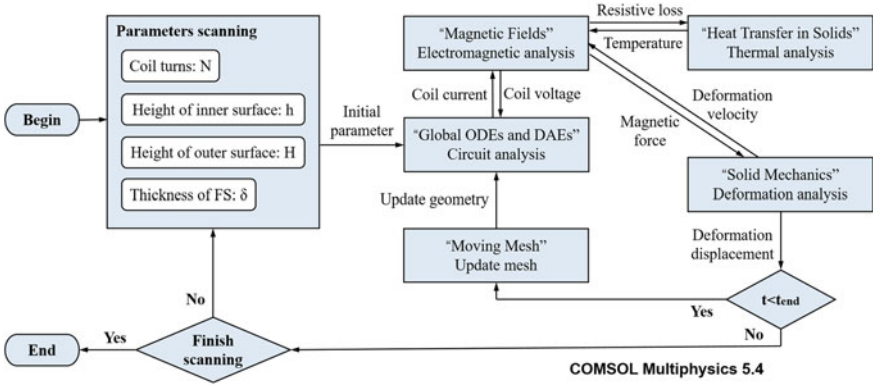

Fig. 2 Flowchart of the implemented algorithm. (Color figure online)

module; and (5) the "moving mesh" module. A flowchart of the simulation process is shown in Fig. 2.

Higher impact velocity means more likely to achieve welding in MPW. The maximization of impact velocity of the outer tube is regarded as an optimization objective. COMSOL has an outstanding ability to solve multi-physics coupling problems and very convenient to use its built-in optimized model. As the simulation model is based on the finite element method (FEM), the air region is required to calculate the electromagnetic field and to define the boundary of the whole area. Considering the air mesh will be distorted when solving the above coupling physical fields, the "Moving Mesh" model is applied to update and redraw the air mesh to ensure high-precision simulation. Note that the air resistance was not considered in this optimization design model. To get the optimized parameters, combining the results of magnetic pressure calculated by "magnetic fields" model and the velocity which is calculated by "solid mechanics" model can be more convincing. The diagram of mesh subdivision is shown in Fig. 3. The magnetic pressure represents the magnetic field energy density, which can be calculated by Eq. (1) based on the magnetic field intensity near the tube:

$$p_m(t) = \frac{1}{2}\mu\left(H_o^2(t) - H_i^2(t)\right) \tag{1}$$

where H_o represents the magnetic field intensity between FS and tube, and H_i represents the field intensity inside the tube [13]. The second method is to take the line integral of the Lorentz force on the wall thickness of the workpiece, as shown in Eq. (2):

$$p_m(t) = \int_{r_{in}}^{r_{out}} f_m(r,t)dr \tag{2}$$

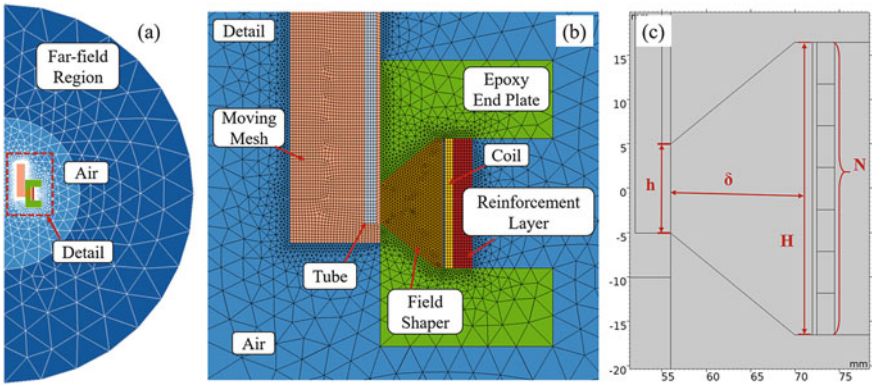

Fig. 3 Finite element mesh for the MPW system and a schematic diagram of the simulation model. (Color figure online)

where f_m represents the Lorentz force, r_{in} and r_{out} are the inner and outer diameter of the tube, respectively. The two methods mentioned above are both feasible. As this paper mainly analyzes the velocity of the tube end, the second method was adopted.

3 Experiment

3.1 Experimental Configuration

The actuator with optimized parameters is made according to the simulation results. Figure 4 shows the experimental configuration. An aluminum alloy tube (AA6061) with a diameter of 110 mm and thickness of 3 mm was welded to steel tubes with

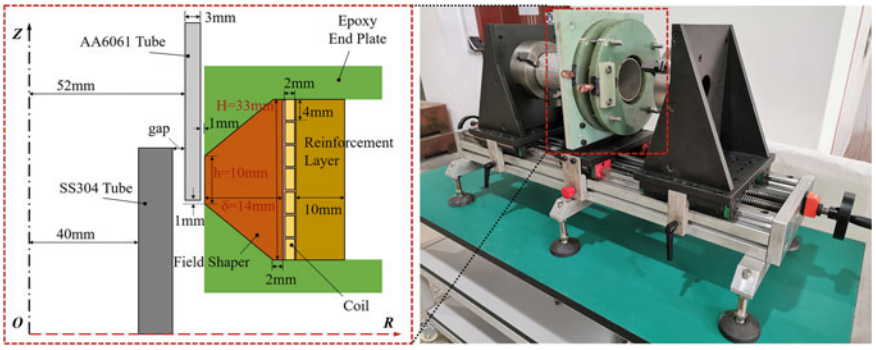

Fig. 4 Geometric model of the experimental configuration and experimental platform. (Color figure online)

different diameters. In order to improve the magnetic energy utilization, the multi-turn coil structure was chosen and the field shaper was wound by copper wires with rectangular cross-section directly. The copper wires were covered with polyimide film to ensure a high degree of insulation between turns. This design makes the distance between the coil and the field shaper only 0.5 mm, and reduces the stray losses significantly. In addition, decreasing the length of the overlap between the tube and the FS working area can reduce the non-effective connection [14]. In the experiment and optimization design, there is an uncovered distance between the end of the tube and the inner surface edge of the FS along the axial direction to enhance the electromagnetic force, and the distance is set to 1 mm. The reinforcement layers are very important for improving the strength of the coil. High-tensile strength material (Zylon) was used to increase the strength of the reinforcement. The detailed system parameters are shown in Table 1.

To adapt to tubes with different diameters, two three-jaw chucks were used to fix the outer and inner tubes. And the actuator was coaxially placed with two three-jaw chucks. The horizontal position of chucks is controlled by two screw rods with a position indicator. This design makes the repetitive experiment of different-sized tubes become realizable. Our laboratory, the Wuhan National High Magnetic Field Center, has developed several sets of pulse capacitance supplies for MPW, and the parameters of the discharge circuit are shown in Table 2.

Table 1 System parameters used in this experiment

Parameters	Description	Value
Coil (Copper conductor)		
ρ_c	Mass density	8.9×10^3 kg/m^3
E_c	Young's modulus	110 GPa
v_c	Poisson's radio	0.34
σ_{y0c}	Initial yield stress	135 MPa
E_c^T	Tangent modulus	0.4 GPa
Reinforcement (Zylon fiber)		
ρ_z	Mass density	1.56×10^3 kg/m^3
E_z	Young's modulus	3/230/3 GPa
v_z	Poisson's radio	0.34/0.0148/0.0148
Coil frame (Epoxy resin board)		
ρ_e	Mass density	2.6×10^3 kg/m^3
v_e	Young's modulus	22 GPa
E_e	Poisson's radio	0.34
Stycast W19		
ρ_s	Mass density	2.4×10^3 kg/m^3
E_s	Young's modulus	22 GPa
v_s	Poisson's radio	0.34

Table 2 System parameters used in this experiment

Parameter	Description	Value/category
C	Capacitance	150 μF
L_l	Line inductance	2.6 μH
R_l	Line resistance	18 mΩ
U_c	Charging voltage	0–20 kV
S	Switch	Self-breaking spark gap switch

3.2 Experimental Design

First, a series of discharge experiments were performed to explore how the discharge voltage and accelerate gap influence the welding quality. The discharge voltages range from 8 to 17 kV for the interval 1 kV. The gap distances between the two tubes range from 2 to 6.5 mm, and the interval is 1.5 mm. Since the surface treatment of the two tubes has a significant impact on the mechanical properties of weldments [15], the roughness of the outer surface of the steel tube was controlled at 0.65 ± 0.15 μm. During the welding process, the discharge voltages and currents were measured by a high-voltage probe and a Rogowski coil. After discharge experiments, the weldment was processed to mechanical testing samples by wire-electrode cutting. Peel tests and tensile tests were used to evaluate the quality of joining. Finally, scanning electron microscopy (SEM) is used to observe the distribution of elements. The results can be used to judge whether the metallurgical bonding occurs between the two dissimilar materials tubes.

4 Results and Discussion

4.1 Distribution of Magnetic Pressure and Stress

Figure 5a shows the current and voltage curves of the coil from discharge voltage to be 15 kV. The experimental curves are consistent with simulation results, demonstrating that the simulations accurately reflected the experimental process. The distribution of magnetic field and pressure is shown in Fig. 5b. FS can concentrate the pressure on the tube surface effectively and the distribution of pressure is the same as the results calculated by Yu et al. [7]. As the maximum discharge capacity of our equipment is 20 kV, the von Mises stress in the radial direction of the coil and reinforce parts were calculated at 20 kV situation. The results are shown in Fig. 5c. The coil is reinforced by Zylon fiber composite, whose ultimate tensile strength is about 3.5 GPa. When the thickness of the reinforcement is 10 mm, the maximum von Mises stress in the Zylon is 3.5 GPa. In practice, the maximum discharge voltage of our experiments is 17 kV, lower than the maximum discharge voltage. So, the 10 mm thickness of the reinforcing layer to ensure safety is enough.

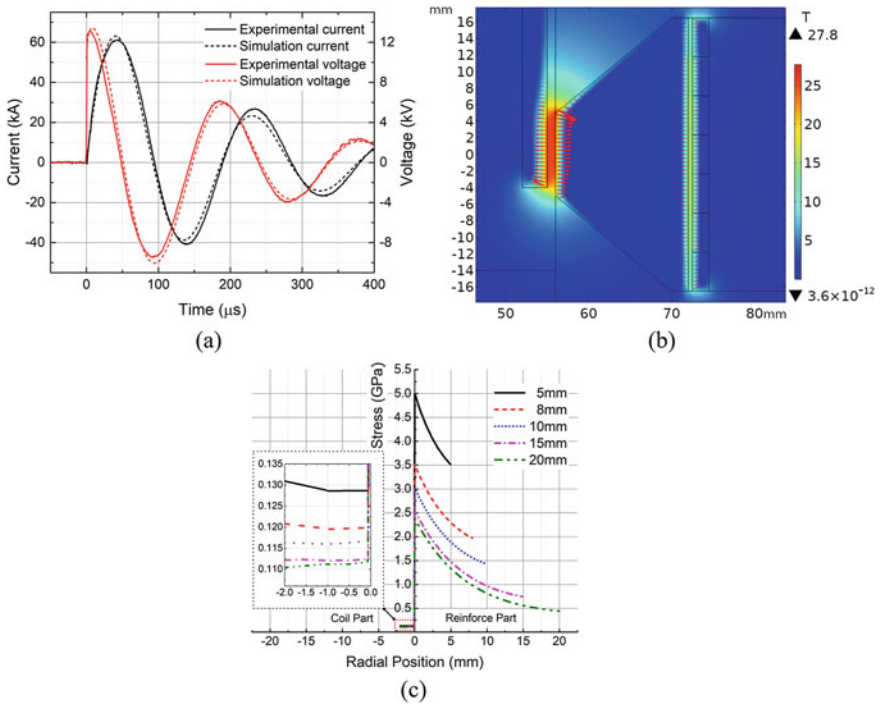

Fig. 5 Simulation results: **a** current and voltage curves compared with experimental results, **b** the distributions of magnetic field and pressure, and **c** the von Mises stress of coil and reinforce parts. (Color figure online)

4.2 Optimization Results of Coil and FS

The optimal results of coil turns N, height of FS inner surface h, height of FS outer surface H, and FS thickness δ are presented in Fig. 6. The velocity and pressure increase first and then decreases with increasing coil turns N can be found in Fig. 6a. According to Biot-Savart law, it can be derived that the magnetic flux density B is proportional to ampere-turns NI. As coil current I decreased with N increasing, there is a maximum value of NI and B. Figure 6b presents that magnetic pressure and velocity are monotonically decreasing with the height of inner surface h. It can be explained that the smaller the inner surface is, the magnetic field can be more concentrated. However, the welding area should not be too small for comprehensive consideration, and $h = 10$ mm was selected.

To explore the universal laws of the size effect, the ratios of FS thickness and outer surface height to inner surface height are defined as two coefficients to reflect the relative dimension. The influence of the coefficient of the thickness ($k_\delta = \delta/h$) and the outer surface height ($k_H = H/h$) both have the same variation trend, which is increased first and then decreased, as shown in Fig. 6c, d. It is speculated that this

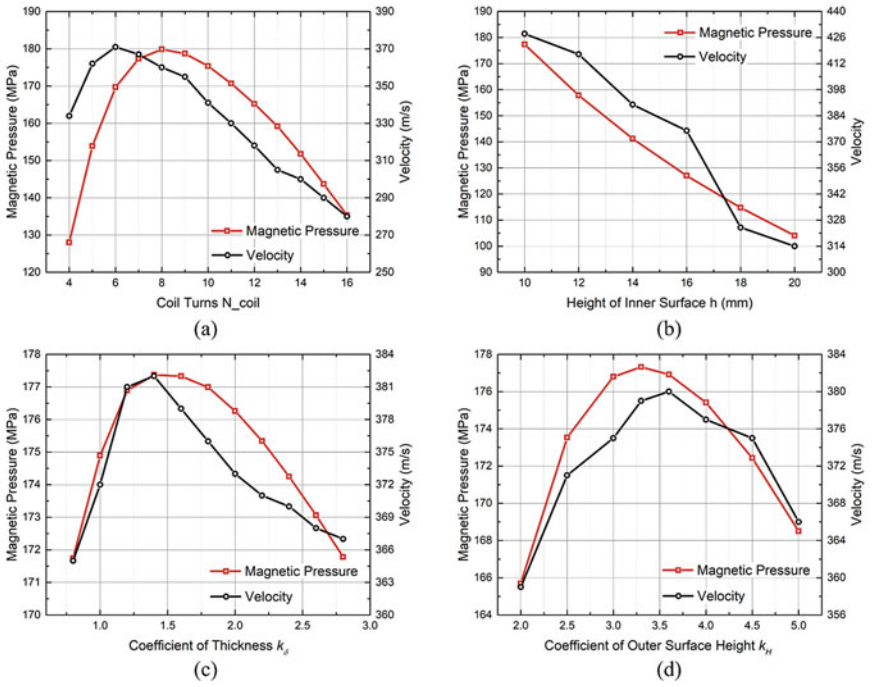

Fig. 6 Magnetic pressure and velocity variation curves with **a** coil turns, **b** height of inner surface, **c** coefficient of thickness, and **d** coefficient of outer surface height. (Color figure online)

change in trend is related to the energy utilization rate. The change of FS thickness and outer surface height leads to variety of impedance and inductive reactance of the load. As the energy is consumed in the circuit part and load part, this variety will affect the energy transformation ratio eventually.

For synthesis, considering the optimal results of magnetic pressure and velocity, the parameters of coil and FS were chosen finally. The details are shown in Fig. 4.

4.3 Mechanical Testing and Welding Windows

The results of welding characteristics and quality were obtained by peel testing and tensile test. According to the tensile test methods on the weld and deposited metal (GB/T 2652-2008), the tensile samples were designed and processed by wire-electrode cutting. As the welding joint is thick and long (both more than 10 mm), it is difficult to keep the direction of tensile force on a fixed line, and therefore two improvement measures were carried out. First, a metal block with a thickness of steel tube was placed on the aluminum side, while another metal block with a thickness of aluminum tube was placed on the steel side. Second, an epoxy splint was used

to avoid the bending of samples' working areas. Considering the influence of the FS slot, two positions of weldment of each tube were tested: the positions near or opposite the slot of the FS. And the results of characteristics can be classified into three types: (1) No falling off at two positions, the situation was regarded as **fully weld**, (2) only one position bonding, the situation was regarded as **part weld**, (3) both two positions falling off, this situation was regarded as **no weld**.

Further, the tensile test was done on fully weld samples to evaluate the welding quality. If a sample fracture at the base material or the tensile force is greater than 3200 N (corresponding to 90 MPa stress), it can be regarded that the strength of the weldment is stronger than the aluminum base material, and it can be defined as a high-strength combination. If the fracture occurs at the weld joint and the tensile force is less than 3200 N, it means that the strength of the weldment failed to obtain promotion.

Considering the results of the two positions as mentioned above, the welding quality can be divided into three categories: (1) when high-strength combination occurs at two positions, the situation is regarded as **high-quality weld**, (2) when high-strength combination occurs at only one position, this situation is regarded as **medium-quality weld**, (3) when no high-strength combination occurs at these two positions, the situation is regarded as **low-quality weld**. The welding window of a large diameter metal tube was obtained and drawn in Fig. 7. The results show that there are some differences and correlations between welding boundary and high-quality welding boundary.

For each fixed gap, an increasing voltage can improve the welding quality. As the radial deformation is fixed, the energy lost to overcome the deformation of the material is the same. So, more energy input from the actuator means more kinetic energy can be translated into the outer tube. Higher impact velocity makes it easier to achieve welding and improve the welding quality. Moreover, both welding boundary and high-quality welding boundary have optimal welding gap and lowest discharge

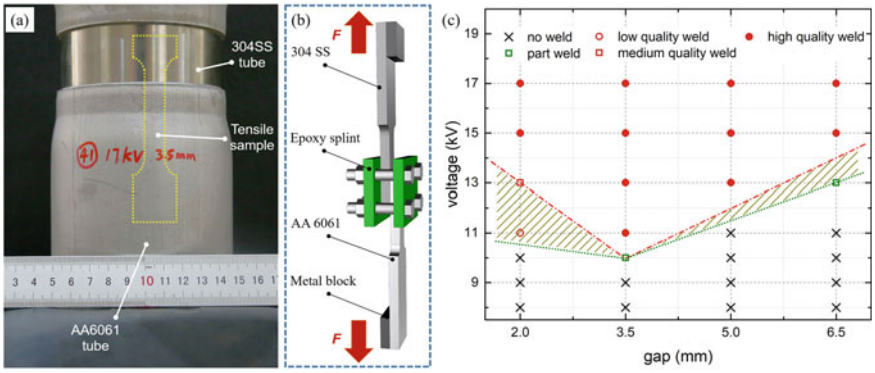

Fig. 7 The welding window of large diameter metal tubes: **a** The result of 17 kV voltage and 3.5 mm gap discharge conditions, **b** schematic diagram of tensile test, and **c** welding window. (Color figure online)

voltage. It is supposed that when the gap distance is small, increasing the gap can increase the acceleration space so that more kinetic energy can be loaded on the metal tube. As the gap continues to increase, more energy is needed to overcome the plastic deformation of the tube, resulting in the reduction of kinetic energy.

4.4 Metallographic Analysis

The test results of the welding sample using SEM and energy dispersive spectrum (EDS) under the conditions of 17 kV discharge voltage and 3.5 mm gap distance are shown in Fig. 8. It can be clearly found that the diffusion process occurred between Al and Fe. As a result, an obvious element transition layer is formed at the weldment area. Also, the dimension of the transition layer is about 10 μm. Considering the SEM image of the interlayer characteristics, the temperature was enough to melt the whole interface due to the high collision velocity under this discharge condition [16]. A large volume of mixtures of Al and Fe were formed at the interface under the high-pressure condition. These results demonstrate the metallurgical bonding occurring between the two dissimilar materials tubes.

5 Conclusions

In this paper, the optimal design and experimental study for magnetic pulse welding of dissimilar metal tubes with large diameters were analyzed in detail. Some conclusions can be summarized as follows:

(1) An effective two-dimensional simulation model for the optimization of the design of MPW was built by COMSOL, and the results obtained from the simulations are consistent with the experimental observations, providing an efficient approach for MPW system design.
(2) Some optimization parameters were analyzed how to influence the magnetic pressure and tube velocity. These principles are helpful to understand the operating principles of the magnetic actuator and provide a practical basis for further numerical model building.
(3) By the experimental method, the welding windows of gaps and discharge voltages were built up. The experimental results also prove that the magnetic welding of tubes with 110 mm diameters and 3 mm thickness became reality, and the strength of the welding area can be stronger than the basic material.
(4) By using SEM, the element diffusion phenomenon was observed between Al and Fe. This result also demonstrates the metallurgical bonding occurring between the two dissimilar materials tubes.

Deformation Behavior in Magnetic Pressure Parallel Seam Welding

Takashi Ichimura, Yusuke Ito, Makoto Miyazaki, and Akira Hatta

Abstract Magnetic pressure seam welding has attracted attention as a new joining method for aluminum sheets. Magnetic pressure seam welding is a collision welding process for producing metallic bonds of similar and dissimilar materials, utilizing electromagnetic force as the acceleration mechanism. Pressure seam welding is a method of abruptly adding a high-density magnetic flux around a metal material and utilizing the generated electromagnetic force to deform the sheet at high speed and pressure welding. This paper deals with the deformation behavior of aluminum sheet with single and parallel coils. The sample used for this analysis is assumed to be a sheet made of aluminum and composed of quadrilateral elements of plane strain. Numerical analysis of the dynamic deformation process of the metal plate is performed by the finite element method. As a result, it was shown that the collision point velocity is very fast at the initial collision point, but decreases continuously during welding. In addition, the thinner the sheet, the wider the gap length for obtaining higher equivalent stress and frictional stress. The initial collision point velocity, equivalent stress, and friction stress at the time of collision in the parallel coils showed the same tendency as in the single coil.

1 Introduction

The development of a new welding method for dissimilar materials is strongly required for the weight reduction of automobiles. Several joining methods, such as diffusion bonding, explosive bonding, and rolling welding have been attempted so far. However, it is known that a sound welding with acceptable strength cannot be obtained mainly because a brittle layer is formed at the bonding interface [1].

Aluminum has higher electrical conductivity and thermal conductivity than iron, so welding is difficult due to low heating efficiency. In previous studies, there is a report on the magnetic pressure seam welding method [2–12]. Magnetic pressure seam welding is a collision welding process similar to explosive welding and utilizes electromagnetic force as an acceleration mechanism. In magnetic pressure seam welding, the central area of the lower sheet (flyer sheet) bulges radially and collides with the upper sheet (parent sheet).

When the impulse current from the capacitor bank passes through the single coil, a magnetic flux is instantly generated under the flyer sheet. When this magnetic flux intersects the flyer sheet, an eddy current is induced in the flyer sheet. Due to the eddy current, the flyer sheet receives a large upward electromagnetic force. This electromagnetic force causes the flyer sheet to deform toward the parent sheet. In addition, the surface oxide of the metal interfaces is disrupted due to the jet action, and metallurgical bonding is achieved between clean surfaces.

The purpose of this paper is to discuss the dynamic deformation behavior of magnetic pressure seam welding of aluminum sheets.

2 Welding Principle

The welding principle is shown in Fig. 1. Magnetic pressure seam welding uses electromagnetic force to accelerate aluminum sheet (flyer sheet) against another stationary aluminum sheet (parent sheet). When a large current flows through the coil, a high magnetic field $\boldsymbol{B}$ is suddenly generated. Then, the magnetic field intersects the flyer sheet, and an eddy current (current density $\boldsymbol{i}$) is generated. The current density $\boldsymbol{i}$ and magnetic flux density (high magnetic field) $\boldsymbol{B}$ are given, as shown in Eq. 1. As

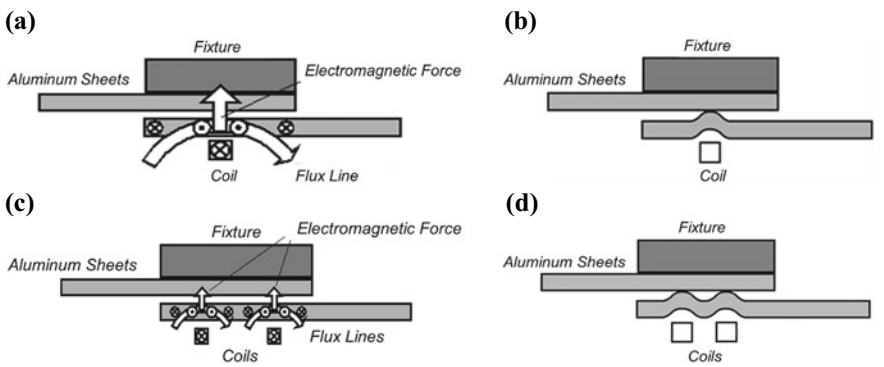

Fig. 1 Schematic illustrations of welding principle (cross-sectional view). **a** Single coil (before welding), **b** single coil (after welding), **c** parallel coils (before welding), **d** parallel coils (after welding)

a result, the electromagnetic force $\boldsymbol{f}$ given by Eq. 2 mainly acts on the flyer sheet, accelerates away from the coil, and rapidly collides with the parent sheet [13].

The eddy $\boldsymbol{i}$ and joule heat Q are calculated by the following Eq. 3. κ and $\boldsymbol{B}$ are electric conductivity and magnetic flux density of aluminum sheet.

$$\mathrm{rot}\, \boldsymbol{i} = -\kappa \frac{\partial \boldsymbol{B}}{\partial t} \tag{1}$$

$$\boldsymbol{f} = \boldsymbol{i} \times \boldsymbol{B} \tag{2}$$

$$Q = \frac{\boldsymbol{i}^2}{\kappa} \tag{3}$$

3 Numerical Analysis

The analysis was made by nonlinear structure–analysis program (MARC 2018). An element division model and boundary condition are shown in Fig. 2. The sample used for this analysis is assumed to be a sheet made of aluminum (A1050-H24, 100 mm length, 0.5 and 1 mm thickness) and composed of quadrilateral elements of plane strain. The gap length between the flyer sheet and the parent sheet varied from 0.5 to 1.5 mm. The relationship between true stress σ and true strain ε is given by the following Eq. 4. Since the effect of the strain rate of aluminum is smaller than that of other materials such as iron, the experimental results are almost in agreement with the FEM analysis [14, 15].

$$\sigma = F\varepsilon^n \tag{4}$$

Material properties obtained by a static tension test are shown in Table 1 [15]. The deformation of the aluminum sheet is reported to end with the first discharge waveform [16].

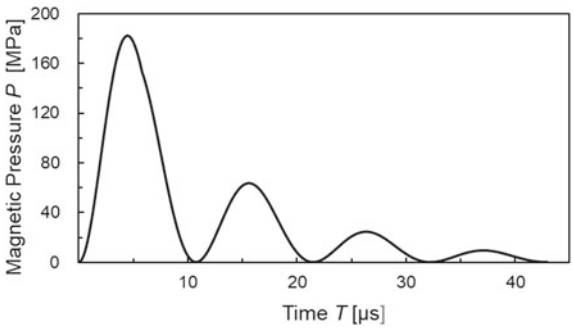

Fig. 3 Relationship between time T and magnetic pressure P (discharge energy 1.0 kJ)

In the analysis, the calculation time was 10.8 μs, and the calculation step was 5000. The time integration method was a single-step method of the implicit solution method. The relationship between the magnetic pressure P and the measured magnetic flux density B is given by Eq. 5. The parameters t, μ, and δ are the thickness of aluminum sheet, magnetic permeability, and surface depth, respectively. The surface depth is calculated by the following Eq. 6. At this time, ω represents the frequency at which the magnetic flux changes periodically.

Figure 3 shows the relationship between time T and magnetic pressure P. In the analysis, the discharge energy was set to 1.0 kJ.

$$P = \frac{B}{2\mu}\left\{1 - \exp\left(-\frac{2t}{\delta}\right)\right\} \tag{5}$$

$$\delta = \sqrt{\frac{2}{\omega\kappa\mu}} \tag{6}$$

4 Results and Considerations

The analysis in this study was examined from the initial collision point to the outside (directions +x). The collision angle and collision point velocity relations are given as follows [17]:

$$\upsilon_p = 2\upsilon_c \sin\frac{\beta}{2} \tag{7}$$

$$\upsilon_p = \sqrt{\upsilon_x{}^2 + \upsilon_y{}^2} \tag{8}$$

where β, v_c, v_p, v_x, and v_y are collision angle, welding velocity (collision point velocity), collision velocity, x-direction element of v_p, and y-direction element of v_p, respectively. Spatial relationships of v_p, v_c, and β are shown in Fig. 4.

Figure 5 shows the schematic diagram of the collision behavior between the flyer sheet and the parent sheet. The point where the flyer sheet and the parent sheet first collide is called the initial collision point. The collision point moves outward (directions +x) at the same time as the pressure welding. The speed at which this collision point moves is called the collision point velocity. The distance from the initial collision point is defined as shown in Fig. 6.

It has been reported that the joint start of electromagnetic magnetic pressure seam welding is affected by the collision angle and the joint end is affected by the collision point velocity [18]. In addition, above the speed of sound that can be transmitted through aluminum, metal jets are generated. The velocity of the metal jet is 1000–2000 m/s [19]. When the surface layer of the aluminum sheet is released as a metal jet, a strong metal bond is established [20]. Since the emission of the metal jet changes depending on the collision point velocity and the collision angle, it is considered to be related to the collision friction stress.

Therefore, in this study, in addition to the collision point velocity, the collision frictional stress and the equivalent von Mises stress after the completion of deformation are examined.

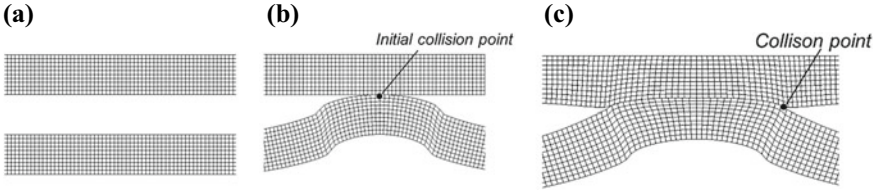

Fig. 5 Schematic diagram of the collision behavior between the flyer sheet and the parent sheet. **a** Before deformation, **b** initial collision, **c** after deformation

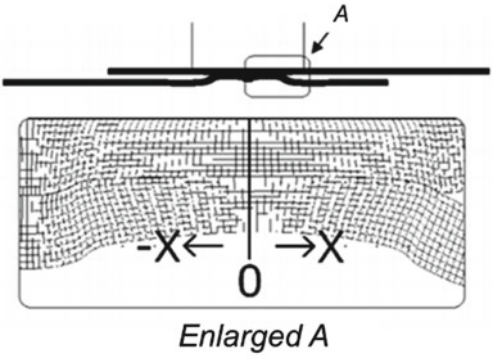

Fig. 6 A model of magnetic pressure parallel seam welding

4.1 Collision Point Velocity

Figure 7 shows the relationship between the distance from the initial collision point and the collision point velocity. The velocity of the collision point is very fast near the initial collision point but decreases continuously during welding. There was no difference in these trends even if the sheet thickness changed. When the thickness is

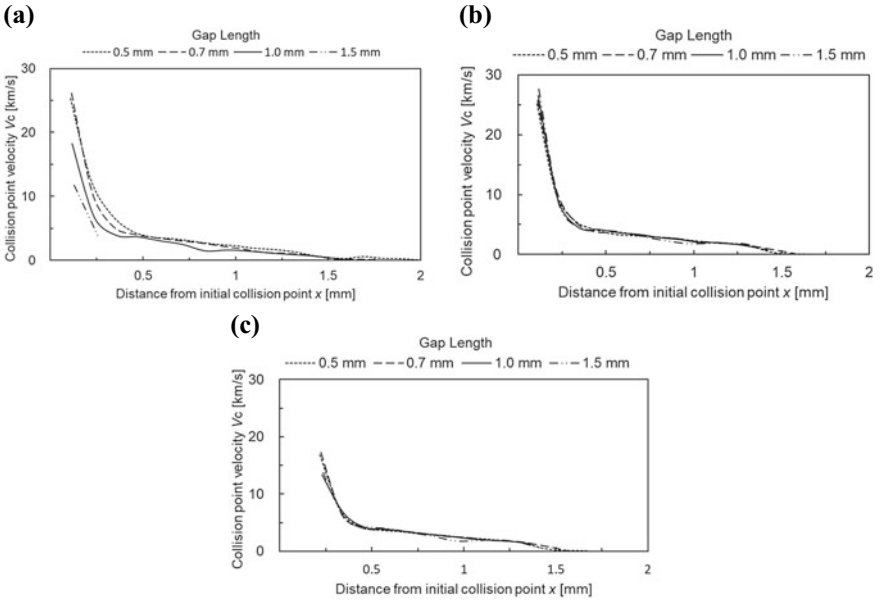

Fig. 7 Relationship between distance from initial collision point x and collision point velocity v_c **a** 1.0 mm thickness (single coil), **b** 0.5 mm thickness (single coil), **c** 0.5 mm thickness (parallel coils)

1.0 mm, the collision point velocity largely depends on the gap length. However, by reducing the thickness, the influence of the gap length on the collision point velocity is reduced.

The tendency of the analysis results of the parallel coils from the initial collision point to the outside was the same as that of the single coil. However, the collision point velocity of the parallel coils was slower than that of the single coil.

4.2 Collision Frictional Stress

Figure 8 shows the relationship between the distance from the initial collision point and the collision frictional stress. The collision frictional stress was very small at the initial collision point and increased during welding. It also reached its maximum at a certain distance from the initial collision point and slowed down from there. When the sheet thickness was 1.0 mm and if the gap was increased, sufficient collision could not be obtained, and the deformation behavior was close to that of stretch forming. Therefore, the experimental data with a gap length of 1.5 mm is unsuitable and is excluded. The frictional stress at the time of collision between the single coil

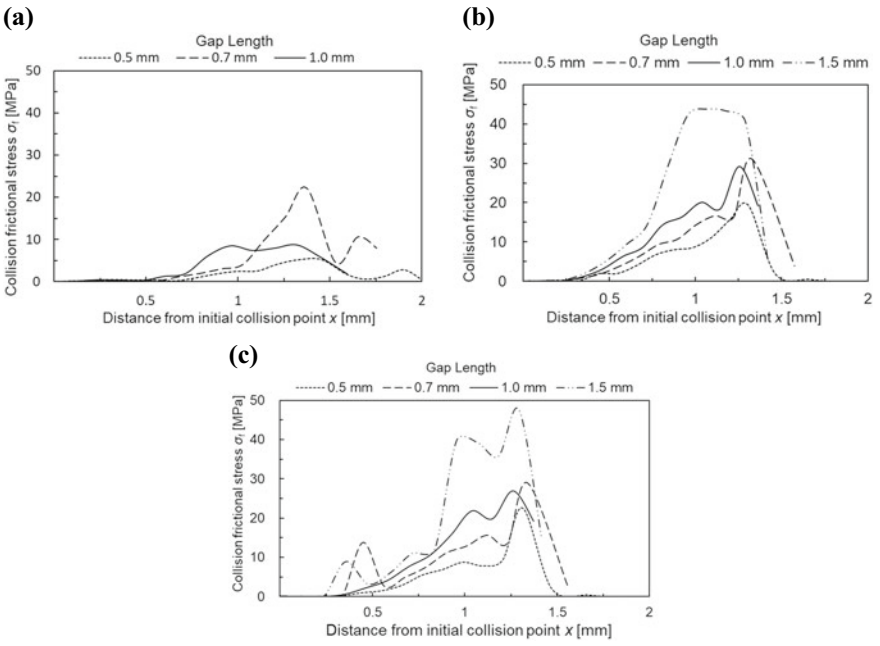

Fig. 8 Relationship between distance from initial collision point x and collision frictional stress σ_f **a** 1.0 mm thickness (single coil), **b** 0.5 mm thickness (single coil), **c** 0.5 mm thickness (parallel coils)

and the parallel coils was maximum when the position was 0.75–1.5 mm. It is known that these are determined by the collision point velocity and the collision angle. The collision point velocity and collision angle are determined by the influence of the sheet thickness and the gap length [18].

From the analysis results, it is considered that a larger collision frictional stress can be obtained by reducing the sheet thickness. There is no definite value for the optimum value of the gap length, and there is a local optimum value. In other words, the optimum gap length for obtaining high collision frictional stress depends on the thickness of the sheets. In addition, the thinner the sheet, the wider the optimal gap length. It is known that the optimum gap length is about 1.0 mm when the sheet thickness is 1.0 mm. However, the optimal gap length has only been empirically clarified. In this study, it was found that the optimum gap length for a sheet thickness of 0.5 mm is about 1.5 mm.

The collision frictional stress of the parallel coil was not much different from that of the single coil in the analysis result from the initial collision point to the outside (directions +x).

4.3 Equivalent von Mises Stress

Figure 9 shows the relationship between the distance from the initial collision point and the equivalent von Mises stress. By reducing the sheet thickness, the equivalent von Mises stress near the initial collision point was reduced. The collision point velocity near the initial collision point is faster than the speed of the metal jet. Therefore, the equivalent von Mises stress became unstable due to the non-coupling region near the initial collision point. In other words, if the initial collision point velocity exceeds the metal jet generation speed, it indicates that the metal jet is confined.

In the position where the collision point velocity is slower than the speed of the metal jet, the collision frictional stress and equivalent von Mises stress begin to increase in the range of 0.5–1.0 mm. Therefore, it can be said that the collision frictional stress and equivalent von Mises stress are important parameters related to the joint state.

5 Conclusions

(1) In the parallel coil, the tendency of the analysis result from the initial collision point to the outside was the same as that of the single coil.
(2) In the case of parallel coils, collision point velocity near the initial collision point tends to be slow.

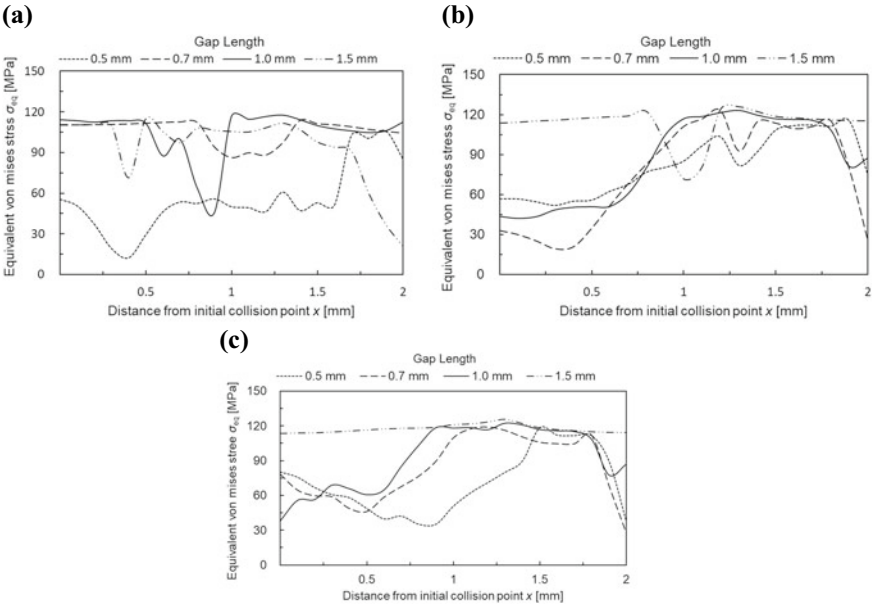

Fig. 9 Relationship between distance from initial collision point x and equivalent Von mises stress σ_{eq} **a** 1.0 mm thickness (single coil), **b** 0.5 mm thickness (single coil), **c** 0.5 mm thickness (parallel coils)

(3) The optimum gap length for obtaining high collision frictional stress depends on the thickness of the plate. Also, the thinner the plate, the wider the optimum gap length.
(4) Collision frictional stress and equivalent von Mises stress are important parameters related to the joint state.
(5) Knowledge of the effects of certain parameters such as plate thickness and gap length is essential to obtain high equivalent von Mises stress.

Shaping of Sharp-Edged Design Elements by Electromagnetic Forming

Verena Psyk, Christian Scheffler, Albrecht Stalmann, and Martin Goede

Abstract Modern car body design includes parts with sharp-edged elements, which are challenging for conventional sheet metal forming technologies. This is especially critical when implementing aluminum parts in order to consider lightweight design requirements. Applying high strain rates allows increasing formability for numerous materials, including typical aluminum alloys used in the automotive industry. Therefore, integrating high-speed forming into a conventional process can help to extend forming limits. The feasibility of locally sharpening a deep-drawn radius by integrated electromagnetic forming was proved in the literature, but up to now, the investigated target radii were much larger compared to the sheet thickness. The presented paper shows that target radii in and below the size of the sheet thickness are possible by this process combination. Based on a simplified 2D component geometry, complementary experimental and numerical investigations served for developing different variants of a modular test tool and analyzing the influence of important process and tool parameters on the forming result.

who were planning to buy a new car or a year-old car stated that the vehicle design was a reason for their choice. Environmental friendliness, on the other hand, is an essential criterion for only 25% of these interviewees [1]. In another survey conducted between 2015 and 2018 by several market research institutes in Germany, the most important criteria are safety, reliability, and value for money, but for more than 70% of those surveyed, design is an important criterion when buying a car, too. Here, this criterion is almost on par with environmental friendliness and low CO_2 emissions. This prioritization has remained constant over the last few years [2]. According to these trends, the automotive industry may not neglect design-oriented developments, although current political initiatives set a focus on promoting and funding developments related to resource efficiency and environmental friendliness for a good reason.

Over the years, automotive design has changed dramatically. While the early car bodies in the 1930s and 1940s had a more round (e.g. Adlerwerke Type 10) or shell-shaped design (e.g. Porsche 356), later on, the favored designs comprised clear lines, trapezoidal (e.g. DKW F12) and box shapes (e.g. Peugeot 604), or wedge shapes (e.g. Lamborghini Countach). In modern design, aerodynamically modeled edges such as the so-called Tornado line shall lend the car elegance and make it look longer. Here, the aim is to achieve edges as sharp as possible. However, the limited formability in conventional forming processes, e.g. deep drawing, restricts the possible geometries, which is especially true for modern body-in-white materials such as aluminum alloys. The radii achievable via deep drawing of aluminum parts typically lie in the range of 2 mm, while radii of 0.5 mm are mostly desired. Therefore, new technologies are required for enabling extended forming limits in order to increase the freedom of design. One principle approach to extend forming limits lies in adapting the strain rate and/or the forming temperature. Either very low or very high values of these parameters can be beneficial, depending on the material. For typical automotive aluminum alloys, e.g. EN AW-6111, high-speed forming processes such as electromagnetic forming (EMF) are suited to extend the formability significantly [3].

EMF uses the energy density of pulsed electromagnetic fields to exert forces on electrically conductive workpieces, thus forming them. In contrast to deep drawing processes, a so-called tool coil or inductor replaces one active element of the tool set (usually the punch), while the counterpart (the die) is retained and serves as a form definition for the process. Depending on the geometry and arrangement of the workpiece and the tool coil, it is possible to compress or expand tubes and hollow profiles and form flat or curved sheet metal [4]. The setup for EMF consists of the forming machine (pulsed power generator), the tool coil (possibly including a field shaper), the workpiece, and application-dependent tool components such as cutting tools, forming dies, or joining partners. Charging and then discharging the capacitor of the pulsed power generator starts the process. As a result, a damped sinusoidal current pulse flows through the coil with maximum values of up to several hundred kiloamperes and typical rise times between 10 and 100 μs. This time-dependent current induces a corresponding magnetic field with local field strengths of up to several 10 T. Moreover, if an electrically conductive workpiece is located in the direct vicinity of the inductor, a second current in the opposite direction to the

inductor current results in this workpiece. Due to the interactions of the currents and magnetic fields, Lorentz forces arise, which accelerate and deform the workpiece. It is possible to transform these volume forces mathematically in an equivalent surface load, the so-called magnetic pressure. In EMF, the motion of the workpiece is always directed away from the tool coil. Depending on the other tool components and their interaction with the workpiece, it is possible to execute forming, cutting, and joining operations [5].

In addition to its use as a single solution, EMF has special potential for extending forming limits in combination with conventional forming processes. Ideally, the respective process-specific advantages complement each other so that process-specific limits can be extended. The technological feasibility and the benefits have already been demonstrated for the following process combinations:

- Deep drawing with integrated EMF (e.g. [6])
- Combined bending, EMF, and hydroforming [7]
- Combined joining by EMF and hydroforming [8]
- Combined extrusion and EMF [9]
- Combined bending and EMF [10]
- Combined roll forming and EMF [11].

The process of deep drawing with integrated EMF is most relevant with regard to the calibration of sharp-edged design elements in automotive body-in-white components. In this context, Vohnout showed in fundamental tests that combined quasi-static pre-straining and subsequent EMF can extend the overall forming limit of EN AW-6061. The gain is greater if the forming capacity is already exhausted as far as possible after deep drawing. Vohnout also demonstrated the applicability of the process combination of deep drawing and EMF for car body components. In particular, he sharpened the corner radius of an inner door panel from approx. 50 mm after deep drawing to approx. 10 mm [6]. Similarly, Imbert and Worswick sharpened a preformed 20 mm radius in a v-shaped part to 5 mm by EMF [12]. Burden et al. investigated the EMF of a door handle cavity in deep-drawing parts and showed that homogeneous pressure distribution has a positive effect on the forming result [13]. Psyk et al. and Risch et al. integrated an EMF step into a conventional deep-drawing process by incorporating the tool coil into the punch [14] and into the die [15], respectively. In another variant of the process combination, Vohnout et al. use numerous small pulses during the deep-drawing process to achieve a more homogeneous strain distribution, thus extending the forming limits and reducing the number of forming steps [16]. Studies that are more recent deal with the numerical simulation and mathematical optimization of the process combination. For these basic investigations, simple geometries are used such as cylindrical cups [17] or cross-shaped cups [18].

This clearly shows that deep drawing with integrated EMF offers technological advantages regarding formability and corner filling with small target edge radii. However, the implemented radii always amount to a multiple of the sheet metal thickness (i.e. approx. 5–10 times the sheet thickness or more), while so far there have been no reports aiming at forming of sharp-edged design elements such as the Tornado line with radii in or even below the magnitude of the sheet thickness.

From the point of view of forming technology, this is an important change because the process can no longer be considered a conventional sheet metal forming process. However, it is a process of so-called "sheet-bulk metal forming" or "solid sheet metal forming". According to [19], this class of processes comprises forming technologies with three-dimensional stress and strain states within the sheet metal. The aim of the presented studies was to prove that electromagnetic forming is applicable for calibrating sharp-edged design elements with radii, which are smaller than the sheet thickness. Moreover, recommendations for the design of tool coils suitable for this kind of manufacturing task are given.

2 Regarded Forming Task

In a cooperative project, the Fraunhofer Institute of Machine Tools and Forming Technology IWU and Volkswagen AG investigated the potential of mechanical preforming with integrated EMF for manufacturing components with sharp design edges for outer body parts. The focus of the investigation was on processing EN AW-6016 material with a thickness of 1.2 mm, an aluminum alloy typically used for body-in-white components. However, some tests were performed on other semi-finished parts in order to prove the transferability of the results and to analyze the influence of workpiece-dependent properties.

The investigations considered a 2D geometry (see Fig. 1b), which was based on an industrial fender geometry featuring two distinct design edges (see Fig. 1a). In order to generate the 2D shape, the middle cross-section of the fender was geometrically extruded to a length of 280 mm. Due to this simplification, strictly speaking, the preforming is no longer a deep-drawing operation but a bending process. However, the advantage of this approach is that it allows comparative tests on different material thicknesses without elaborate adaptation of the tooling, e.g. in order to adjust the

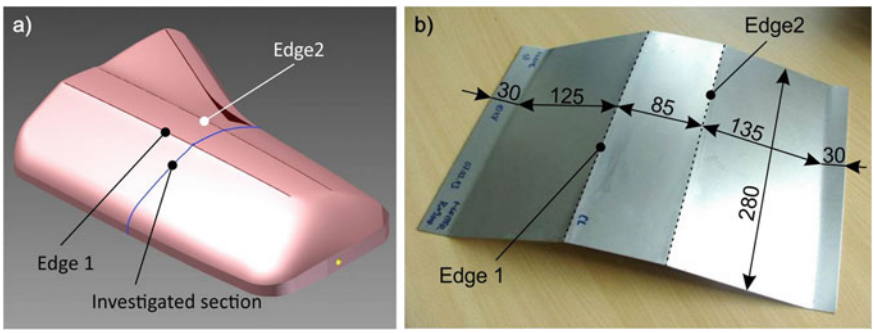

Fig. 1 **a** Basic punch geometry of 3D-fender; **b** simplified 2D part geometry for laboratory tests. (Color figure online)

drawing gap. Thus, the transferability of the results can be easily verified and principal correlations can be identified.

3 Tool Design

The tooling for the combined process includes the punch incorporating the tool coil and the forming die. Manufacturing sharp-edged concave geometries is a challenge for milling processes due to the tool radius. In a conventional deep-drawing process, this is usually solved by a cut out in the die, since the resulting radius of the formed part is determined by the convex radius of the deep-drawing punch and the thickness of the material, while the local die geometry is of minor influence. Contrary, in the investigated case, the die radius limits the minimum radius achievable in the electromagnetic calibration process. In order to work around the problem, the die geometry was separated at the two edges; the three segments of the die were manufactured individually and mounted onto a base plate. Thus, manufacturing a sharp-edged concave geometry was possible.

The punch features a modular setup, which allows implementing different coil variants and analyzing the respective influence on the forming result. The coil design concerns the conductor winding as well as the housing. The major function of the coil winding is to conduct the current, thus shaping the magnetic field and the corresponding magnetic pressure required for the forming process. Here a highly efficient energy transfer is desired in order to realize the forming task with minimum energy input, consequently operating at minimum equipment load. Therefore, different conductor variants were drafted based on a numerically assisted design using a harmonic 2D magnetic field simulation by David Meeker [20]. This simulation provides the magnetic field in the gap between the tool coil and sheet metal workpiece H_{gap} and the penetrated magnetic field at the workpiece surface facing away from the tool coil H_{pen}. These field distributions and the magnetic permeability μ make up the input data for analytically estimating the magnetic pressure according to Eq. 1.

$$p = \frac{1}{2} \cdot \mu \cdot \left(H_{\mathrm{gap}}^2 - H_{\mathrm{pen}}^2 \right) \tag{1}$$

Figure 2 shows the calculated maximum of the magnetic pressure course (i.e. the magnetic pressure as a function of time) as a function of the coil current for different frequencies of the discharging current and for different coil conductor variants. It compares conductor variants with one single turn, three parallel turns, and five parallel turns. As indicated via the sketched cross-sections, the turns are concentrated on the two calibration areas beneath edges one and two. The current direction in each bundle of turns is uniform but opposed to the current direction in the other bundle. For the five-turn variant, the turns are arranged in two layers in order to find a compromise between the limited extension of the calibration area and the required

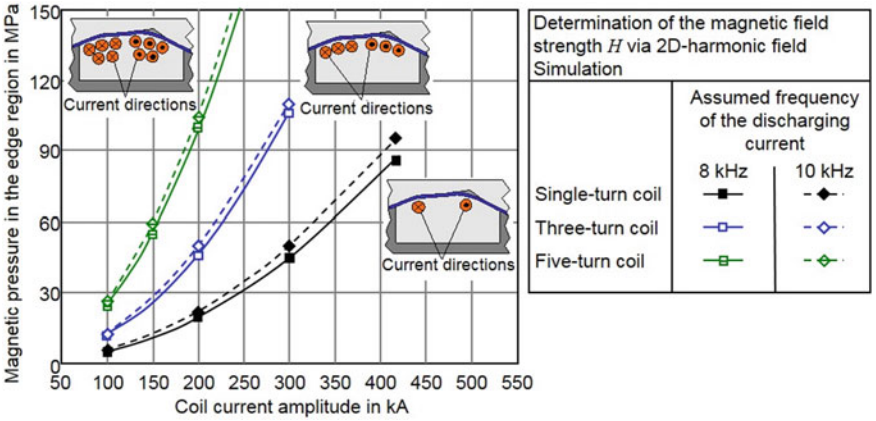

Fig. 2 Magnetic pressure as a function of coil current amplitude and discharging frequency for different coil conductors. (Color figure online)

space for dimensioning reasonable conductor cross-sections and insulation distances between the individual turns. As expected, the pressure maximum increases squarely with the coil current for all coil variants. Furthermore, it is obvious that for a higher number of turns, a significantly lower coil current is required in order to reach a defined pressure.

This simple calculation approach suggests that the five-turn coil is the most promising one. However, it neglects the influence of the number of turns on the electrical parameters of the oscillating circuit, especially on the resistance R and the inductance L. These influences are described via fundamental electrotechnical equations, which are summarized in [5]. Amalgamating these equations leads to Eq. 2, which describes how these parameters affect the course of the discharging current $I(t)$. This means that in order to have the same current course in different coil variants, these influences must be compensated by varying the other electrical parameters of the oscillating circuit, i.e. the capacitor, the charging voltage U, and the capacitance C. However, the latter is a property of the pulsed power generator and can only be adjusted in discrete steps, if possible at all. Therefore, adjusting the same current course for different conductor variants is hardly possible in practice so that a more sophisticated evaluation of the different coil types is necessary, taking into consideration the described correlations.

$$I(t) = \frac{U}{\sqrt{\frac{1}{LC} - \frac{R^2}{4 \cdot L^2}} \cdot L} e^{-\frac{R}{2L}t} \cdot \sin \sqrt{\frac{1}{LC} - \frac{R^2}{4 \cdot L^2}} t \tag{2}$$

The detailed design of the setup, including aspects of the housing, is relevant when considering the influences of all relevant components of the structure, i.e. the pulsed power generator and the consumer unit consisting of tool coil and workpiece, on the parameters of the oscillating circuit. The major functions of this housing are

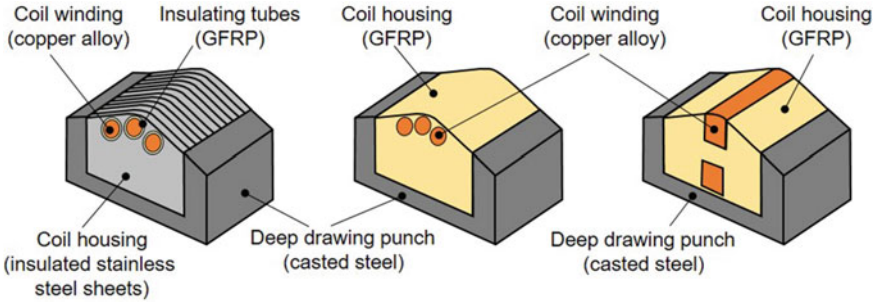

Fig. 3 Design concepts for the coil insert. (Color figure online)

the electrical insulation and mechanical stabilization of the conductor winding. In the investigated process combination, the housing must also be suitable for applying the load during the mechanical preforming operation. This study compares three different housing concepts (see Fig. 3).

The first one consists of a metallic coil body with integrated insulation tubes. The motivation for this approach was the desire to manufacture the tool insert for the integrated electromagnetic forming as far as possible from steel materials in order to guarantee high pressure and wear resistance. Furthermore, the goal comprised achieving good compatibility with the material of the surrounding deep-drawing tool, e.g. in terms of thermal expansion. However, it must be considered that this metallic body can influence the magnetic field distribution possibly, even to the extent that no more workpiece deformation is possible. To reduce this influence as far as possible, a non-ferromagnetic material can be applied and the formation of eddy currents in the coil body can be suppressed by building this body from individual layers, which are oriented perpendicular to the expected current direction and electrically insulated from each other by a suitable coating or foil. The total induced voltage is distributed among the individual layers so that the requirements on this insulation are relatively low with small layer thicknesses and a correspondingly high number of layers. In contrast, the requirements for the insulation of the coil winding itself are considerably higher so that additional continuous insulation tubes are necessary, e.g. tubes made of glass fiber-reinforced plastic (GFRP).

The second housing concept consists of an insulation coil body made of GFRP, which combines high insulation capability and acceptable mechanical strength for tensile and compression loads. Furthermore, this material does not influence the distribution of the magnetic field and the resulting pressure. The coil body completely encloses and insulates the individual turns so that no additional insulation tubes are required here. Thus, in comparison to the metallic coil body, the conductors can be arranged closer to each other and to the workpiece. This allows better focusing of the magnetic pressure on the very small calibration zone. However, when dimensioning the minimum insulation distance, the anisotropic insulation properties of GFRP must be taken into consideration.

In the third housing concept, the conductor is embedded in a similar GFRP coil body, but here the channels incorporating the conductor are open toward the workpiece. Here, an additional thin polyimide film provides the necessary insulation. This insulation material features excellent insulation capabilities, but due to its very limited strength and wear resistance, special design measurements such as a slight local recess must be taken to avoid mechanical loads. Nevertheless, this approach allows for much smaller insulation gaps between conductor and workpiece, which significantly improves the process efficiency [21].

In order to draw a substantiated comparison and to evaluate the different coil variants, it is much more meaningful to consider the estimated resulting pressure for the same capacitor charging energy and voltage, respectively, than the equal coil current postulated in Fig. 2. This means that different coil currents must be considered depending on the different electrical properties of the setup. However, neither the current course nor the electrical parameters of the oscillating circuit are known during the design phase. In the case of complex structures, in particular, the calculation is complicated by the circular dependency between these parameters. To solve this conflict [22], suggests a simple iterative approach. Still assuming a harmonic oscillation of the coil current, and consequently disregarding the damping effects caused by the resistance of the electrical circuit, the calculation strategy approximates the frequency and amplitude of the coil current as well as the frequency-dependent inductance of the electrical circuit.

Table 1 lists the parameters identified via this iterative approach for three investigated coil variants with five turns, three turns, and one single turn. These coil variants also served for testing the different design concepts for the coil inserts. Specifically, in the case of five-turn coil, the metallic coil housing (see Fig. 3 left) was chosen; for the three-turn coil the GFRP housing with closed conductor channels (see Fig. 3 middle) was selected; and for the single-turn coil, the GFRP housing with open conductor channels and additional polyimide film (see Fig. 3 right) was applied. Figure 4 shows the corresponding local pressure distributions acting at the moment of maximum current. The calculations were performed via the free special-purpose program of finite element simulation femm 4.2 by David Meeker [20]. As this program is limited to 2D harmonic field simulations, only the parallel sections

Table 1 Current course parameters and important characteristics of the oscillating circuit for different coil variants

Tool coil	Capacitor charging		Inductance of oscillating circuit (μH)	Discharging current	
	Voltage (kV)	Energy (kJ)		Amplitude (kA)	Frequency (kHz)
Five-turn coil	10	16.5	3.4	79	4.7
Three-turn coil	10	16.5	1.9	132	6.4
Single-turn coil	10	16.5	0.33	319	15.4

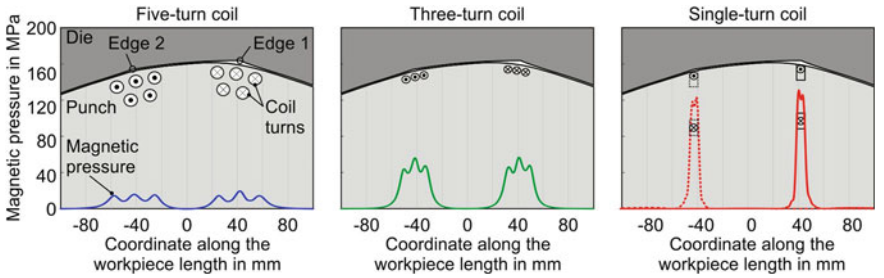

Fig. 4 Estimated pressure distribution for different coil variants assuming a capacitor charging voltage of 10 kV. (Color figure online)

of the coil can be modeled. In order to consider the additional inductance caused by the coil ends (variable depending on the specific coil design) and the pulsed power generator (determined as 85 nH by measurements without any load inductance), an additional inductance is added to the calculated value. This additional inductance is estimated as 1500 nH for the five-turn coil, 900 nH for the three-turn coil, and 100 nH for the single-turn coil. All calculations are based on a capacitor charging voltage of 10 kV. An efficiency of 65% was assumed for the transfer of capacitor charging energy to inductive energy of the tool coil according to the calculations of Risch [23].

As expected, a decreasing number of turns leads to a decrease of the inductance, therefore causing a higher and faster current pulse. The smaller insulation distances between the individual turns and between coil winding and workpiece, which were enabled via the different housing concepts, enhance this effect. At the same time, the geometric modification leads to better focusing of the magnetic pressure. This means that especially in the case of the single-turn coil, a very high-pressure pulse acts directly below edge 1.

Important differences between the investigated single-turn coil variant and the two multi-turn coil variants (i.e. the three-turn coil and the five-turn coil) comprise the non-rotationally symmetric cross-section and the arrangement of the return conductor. The change in the cross-section geometry results from the attempt to keep the distance between the tool coil and workpiece as small as possible. In order to reach this aim, the coil surface was adjusted to the shape of the preformed sheet. Realizing this cross-section requires changing the manufacturing strategy of the coil winding. In the case of the multi-turn coils for the round conductors, round copper rods served as input material so that only marginal subsequent processing was required here. The connection of the different linear conductors to one complete coil turn was realized via insulated clamps at the ends of the coil. On the contrary, the more complex cross-section shape of the single-turn coil was manufactured by milling. In order to facilitate the milling of the complete turn from a copper plate, the return conductor was arranged in one vertical plane with the forward conductor far away from the workpiece. Compared to a similar single-turn coil with the same cross-section but with the return conductor arranged close to the workpiece below the

second calibration edge, this layout increases the load inductance. However, since the absolute inductance of the single-turn coil is very low, this phenomenon was accepted here. In order to calibrate edge 2, a second coil winding was inserted in this area (without electrical connection to the first one). Figure 4 (dashed lines) indicates this second winding and the corresponding pressure. After calibrating edge 1, the second coil turn is connected to the pulsed power generator and edge 2 is calibrated in a second discharging process.

4 Experimental Results

First tests of the developed tools were carried out with steel workpieces (DC04; thickness 0.6 mm) and aluminum workpieces (EN AW-3103; thickness 0.6 mm). Figure 5 shows the experimental setup on the example of the five-turn coil and compares the measured coil current with the numerically predicted one. Although the simulation slightly overestimates the current, the accuracy of the simulation approach is good, considering all simplifications.

Figure 6 compares the preformed reference components and exemplary calibrated parts. In this example, a capacitor charging voltage of 12 kV was used, which corresponds to a capacitor charging energy of 23.8 kJ. After solely preforming the sheet metal workpiece by closing the tool halves, the parts show strong springback. Permanent deformation is hardly noticeable, especially in the case of aluminum workpieces. On the contrary, the calibrated part features much better geometric accuracy.

The tests have also proved to be qualitatively successful regarding the intended sharpening of the radii of edge 1 and edge 2. In order to quantify this effect, the obtained edge radius was determined in the cross-section. For this purpose, samples were taken from the components in the area of the formed edges, which were then embedded and measured with an optical microscope as shown in Fig. 7.

The figure also shows a comparative overview of the edge radii achievable with the regarded coil variants. It is obvious that in all cases increasing the capacitor

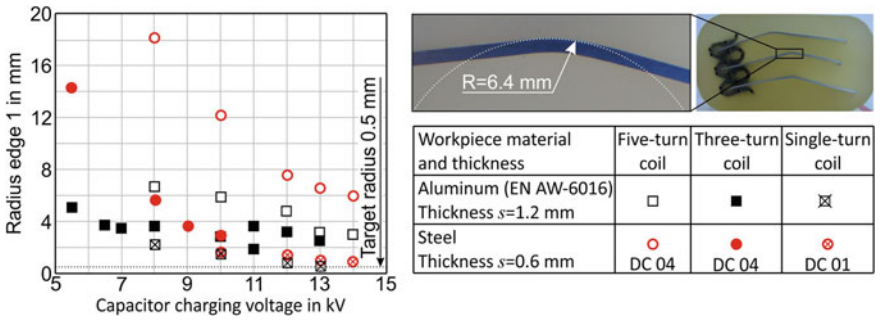

Fig. 7 Edge radii achievable by electromagnetic calibration. (Color figure online)

charging energy leads to a decreasing edge radius. This trend is strong at first and eases off later. This fundamental relationship is independent of the respective coil variant and the workpiece material (steel or aluminum). In addition, the investigations on all coil variants confirm that, with otherwise identical parameters, significantly sharper edges are achieved for aluminum semi-finished products than for steel sheets. These results were expected since the higher electrical conductivity and the lower strength and density aluminum in general are considered to be more suitable for being processed by EMF.

A comparison of the different inductor variants with each other shows that, compared to the five-turn coil, sharp edges result at significantly lower capacitor charging voltages if the three-turn coil is applied with otherwise identical process parameters. Similarly, the achievable edge radius is lower again if the single-turn coil is used. This trend correlates well with the magnetic pressures calculated for the coil variants (see Fig. 4) and confirms that the single-turn coil leads to the highest process

efficiency compared to the other investigated coil types. Using EMF to calibrate the part with this coil made it possible for the first time to achieve the target edge radius of 0.5 mm for semi-finished aluminum products.

5 Summary and Conclusions

Innovative forming technologies and process combinations are essential in order to increase freedom of design and enable manufacturing of technologically challenging sharp-edged details in body-in-white components even from difficult-to-form materials such as aluminum alloys. Deep drawing with integrated electromagnetic calibration is a suitable approach for extending forming limits, although up to now all examples of this process combination for corner filling or edge sharpening have focused on forming radii equal to or greater than five times the sheet thickness. In contrast, the goal of the project "Sharp Design Edge" was to use electromagnetic forming for calibrating sharp-edged design elements with an edge radius of 0.5 mm.

In order to demonstrate the feasibility of this forming task, a modular prototype tool was designed, implemented, and tested for the electromagnetic calibration of sharp two-dimensional edges. The influence of essential parameters on the resulting component edge radius was investigated in a combined numerical-experimental process analysis considering process-specific, component-specific, and tool-specific aspects. In this study, the best solution proved to be a coil variant consisting of two individual windings for shaping the edges 1 and 2 with the return conductor being arranged far away from the sheet metal. An insulation insert made of glass fiber reinforced epoxy provides the insulation between the conductors and the surrounding metallic deep-drawing punch, while polyimide foil (Kapton) serves as insulation between the conductor and the sheet metal workpiece. The achieved edge radii show the great potential of the process, especially for aluminum workpieces. Here, the target radius of 0.5 mm was achieved, which is significantly smaller than the investigated sheet thickness of 1.2 mm. Therefore, this process must be considered a process of "bulk sheet metal forming".

Augmentation of Plasma-Based Impulse Generation with Rapid Chemical Reactions

Brian Thurston, Yu Mao, Troy Lewis, Anupam Vivek, and Glenn Daehn

Abstract The use of a chemical explosive mixture to augment the vaporizing foil actuator (VFA) and laser impact welding (LIW) processes is introduced in this study. A liquid explosive known as Picatinny liquid explosive (PLX) was used to augment the capabilities of both the VFA and LIW processes. The 304 stainless steel flyers 3 mm thick driven by PLX augmented VFA and unaugmented VFA are compared. Similarly, 0.442 mm thick Al3003 flyers driven by laser impact and PLX augmented laser impact are compared. In all cases, a photon Doppler velocimetry (PDV) system was used to collect the velocity–time profiles of the flyers. All PLX augmented experiments showed increases in both flyer acceleration and peak velocity over the same time scales as the unaugmented experiments. This indicates that the PLX-provided impulse occurs at the same time as the VFA/laser impulse. The augmented VFA experiments showed a 28% velocity increase over the unaugmented experiments at 10 kJ input energy. The augmented laser impact process exhibited peak flyer velocities 236% higher than laser impact using only the laser. Here we demonstrate that chemical augmentation is capable of significantly increasing flyer velocities for both VFA and LIW at the same input energies and under similar conditions. This development should expand the repertoire of flyer materials and thicknesses that can be impact welded by VFA and LIW.

Keywords Impulse forming · Explosive forming · Laser impulse · Vaporizing foil method

1 Introduction

Impulse forming techniques have various uses, including embossing, shearing, and welding. Safely producing a sufficient impulse to accomplish a given task presents some challenges. Safety, reliability, equipment design, etc. are all concerns. Here we demonstrate a hybrid approach for driving metal sheets for use in impact processes,

chiefly for impact welding. For the purposes of impact welding, the impact velocity is of crucial importance. Several approaches, as discussed in the next section, have been developed to drive flyer sheets to high enough velocity at impact, known as the critical velocity. As discovered, impact welding occurs with impact velocities ranging from 150 to 1500 m/s [1]. However, in general, to obtain a successful impact weld, an impact velocity of higher than 300 m/s is required [2–5]. Several techniques for driving flyer sheets to such high speeds have been developed, a subset of which can be used in a laboratory setting. In this document, we first briefly discuss the existing impact welding tools used in the industry, and then we do the same for two alternative impact welding technologies: vaporizing foil actuator (VFA) welding and laser impact welding (LIW). We then present hybrid approaches for VFA welding and LIW where a chemical explosive is added to the process. Experiments were performed to assess the feasibility of this hybrid approach for both the VFA and LIW techniques. The experimental process and results for the hybrid VFA approach are presented, followed by the same for a hybrid LIW process. The ramifications of the success of these two approaches are then discussed.

2 Industrial Impact Welding Tools

Two common tools for driving metals to high speed and causing them to impact weld are chemical explosives [6] and electromagnetic actuators [7], both of which present certain hurdles to widespread industrial application. A schematic of these processes is shown in Fig. 1. Besides the obvious safety concerns related to handling, storage, and application, explosives have a critical volume or diameter [8] below which they are difficult to detonate reproducibly. Therefore, while they are ideal for impact welding of very large workpieces, they do not scale down well for welding small areas. Electromagnetic forming or welding utilizes the principles of electromagnetic induction and forces between current-carrying conductors to launch a workpiece away from a stationary electromagnetic solenoid actuator [9]. As the process needs the workpiece as well as the actuator to carry the current, a low conductivity workpiece material is difficult or impossible to push directly. Therefore, launching titanium or austenitic stainless steel will require a driver made from a conductive material like, for instance, copper [10]. An excellent review of electromagnetic forming is provided by Psyk et al. [9] and they estimate the electrical to mechanical energy conversion efficiency of electromagnetic forming to range from 1 to 20%. However, to get the best efficiency in the conditions of coupling, conductivity, and discharge current, the characteristics have to be ideal. Additionally, process inefficiencies are difficult to overcome in electromagnetic welding due to limitations in current and resulting pressures that the solenoid actuator itself can experience before catastrophic failure [11].

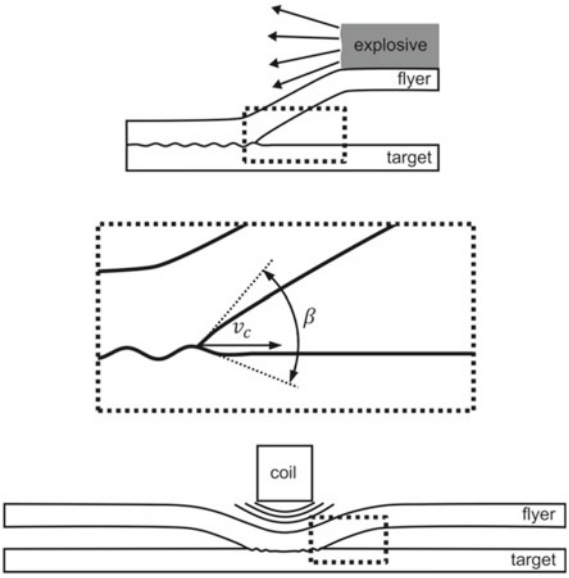

Fig. 1 Schematic of explosive welding (top) and magnetic pulse welding (bottom). From Groche et al. [2]

3 Alternate Indoor Impact Welding Tools

The VFA metalworking process is a novel technique developed at the Impulse Manufacturing Laboratory (iml.osu.edu) at the Ohio State University. Using the impulse generated by rapid electrically driven vaporization of an aluminum foil actuator, a metal sheet as a flyer can be accelerated to velocities of several hundreds of meters per second in a few microseconds, followed by a high-speed impact [12]. Various VFA applications have been developed, including welding, forming, shearing, embossing, etc. [13]. Depending on the flyer properties and processing parameters, the impact velocity can be as high as around 1000 m/s [13] and the pulse pressure magnitude is in the range of gigapascals [14]. Aluminum alloys as thick as 6.35 mm have been successfully joined to steel by VFA welding [15]. Compared to electromagnetic and explosively driven impulses, VFA can be safely performed in an indoor laboratory environment and can achieve higher energy efficiency [16]. However, the applications are limited to flyers with thickness in the magnitude of millimeters. Scaling to large sizes, thicker, or stronger flyers can be problematic because of a diminishing return for increasing input energy, and the maximum impact velocity tends to be capped by the capacity of the equipment [13]. The cost of upgrading a VFA system, including using capacitors with higher capacitance and a power supply with a higher maximum charging voltage, is high and marginally increasing.

It is possible to launch flyer sheets to velocities suitable for impact welding with a high-energy laser pulse. This technique, first proposed by Daehn and Lippold [17], has been given the name laser impact welding (LIW). The basic setup for this technique requires a high-energy pulsed laser system capable of providing several

joules of energy over a time period normally measured in the tens to hundreds of nanoseconds [18, 19]. This laser pulse can be used to propel flyers on its own, or more commonly the pulse can be directed to an absorbing or backing material applied to the flyer to convert the laser energy more efficiently to kinetic energy. Here, a backing material should be understood to be an optically transparent material used to confine the expanding plasma generated by a laser pulse. Black paint is a common absorbing material used along with water, glass, or polycarbonate as a backing material for inertial constraint [20]. This technique has been used to propel 25 μm thick 1100 aluminum flyers to speeds in excess of 900 m/s with a laser pulse energy of 3 J [20]. However, this technique is limited to flyers of relatively small thicknesses, measured in the low hundreds of micrometers or less. As the flyer thickness increases, the maximum achievable speed decreases for a laser pulse of a fixed power [18]. Increasing the power density of the laser beam, either by reducing the focal size and/or increasing the output power, can produce greater flyer speeds. However, there are limitations to the power density that can be delivered to a flyer sheet. Using an ND:YAG laser with a pulse length of 8 ns and pulse energy of 3 J, Wang et al. found that beam energy densities greater than 1.19×10^{14} W/m^2 can cause a breakdown of the air, resulting in a plasma spark that absorbs the pulse energy [20]. This puts a limit on the power density of a beam traveling through air. Backing materials also have their limits, Berthe et al. found that power densities beyond 10^{14} W/m^2 caused the formation of parasitic plasmas at the surface of water layers used as backing materials [21]. Similar limitations are also likely to exist for other backing materials.

4 Hybrid Concept

Here a hybrid concept is described where VFA and laser impulses can be augmented with an explosive chemical mixture applied at the site of the impulse. For the purposes of safety, an explosive mixture having relatively low sensitivity and fast detonation velocity is desired. Safe chemical byproducts are also desirable. For the purposes of VFA welding where larger energy deposition into a foil is impractical, either because of cost or available capacitor storage energy, additional energy may be provided by augmentation via a chemical explosive. This chemical explosive would be placed near the vaporizing foil in quantities that add useful energy to the foil explosion. In the case of LIW, where energy is greatly constrained by the cost of pulsed laser systems and the fundamental limitations of pulsed power density in air, any additional energy could be of great utility in driving foil sheets.

It has been found that an explosive mixture based on nitromethane (CH_3NO_2) is well suited for the purpose of augmenting the VFA and LIW processes. The nitromethane-based explosive used here is referred to as Picatinny liquid explosive (PLX). The mixture used here is based on a recipe described in a YouTube video on the Tech Ingredients channel, “DON’T TRY THIS AT HOME!”, [22], and US patent 3,713,915 [23]. The tested recipe consists of the following ingredients which can be

freely purchased: 30 ml of nitromethane 99+%, 1.5 ml of ethylenediamine 98+%, 2.1 cm^3 loose spherical 3.0–4.5 micron aluminum powder, and 1.18 g of PMMA (acrylic) chips. The purposes of the ingredients are as follows: nitromethane as an explosive material, ethylenediamine as a sensitizer, and fine aluminum powder as a sensitizer and fuel [22, 23]. The PMMA is added as a gelling agent to prevent the aluminum powder from falling out of suspension [22], although we have found stirring is still necessary prior to use. All of these components can be easily purchased. While the detonation velocity of this exact mixture has not been measured, the literature reports the detonation velocity for PLX (nitromethane 95% with ethylene diamine 5% only) to be around 6200 m/s [24], and the detonated nitromethane will decompose into CO_2, CO, NO_2, and NO [25]. The critical diameter for the propagation of a detonation in PLX at 20 °C is estimated to be 18 mm, when tested in a long glass tube [26]. In this work, we demonstrate that useful detonations of very small volumes of PLX can be created via the VFA method and by laser impulse.

Nitromethane is reported to be a high explosive material, although an insensitive one. Nitromethane has been found to be unaffected by drops of 1.95 m [26] and in ten out of ten shots to be unaffected by rifle fire [27]. U.S. Army Material Command reports an explosion temperature of 430 °C for nitromethane alone and for nitromethane sensitized with 5% ethylenediamine, both for confined samples [27]. Nitromethane is known to be a skin, eye, and lung irritant and is harmful if swallowed [28]. Once sensitized with ethylenediamine, nitromethane becomes more sensitive to shock; however, it is still relatively difficult to detonate. In tests by U.S. Army Material Command nitromethane sensitized with 5% ethylenediamine was unaffected in five out of five rifle bullet impacts [27]. With the addition of aluminum powder, the PLX will become relatively more sensitive to shock [22].

5 Enhancement of the VFA Technique via Chemical Augmentation

Here, a technique for chemically augmenting the VFA process is presented. A schematic of the setup is shown in Fig. 2a, b. A 3.175 mm thick 304 stainless steel sheet was used as a flyer. A 6.35 mm thick Al5052 block with a central hole of 30 mm diameter was used as the standoff. A capacitor bank system with a capacitance of 426 μF, a maximum charging voltage of 8.66 kV, a maximum charging energy of 16 kJ, and a current rise time of 12 μs was used. Two layers of 0.762 mm thick foils with 10.16 mm wide effective area were applied as the original actuator, the geometry of which is shown in Fig. 2c. For augmentation, 0.4 mL of the PLX mixture was soaked into eight layers of paper towel material. The eight layers of PLX-soaked paper towel were placed with three layers above and below the foils and with the remaining two layers placed between the foils. At discharge, the effective area of the actuator was vaporized to plasma, deforming the flyer into the standoff hole area. A photon Doppler velocimetry (PDV) probe was set above to measure the velocity

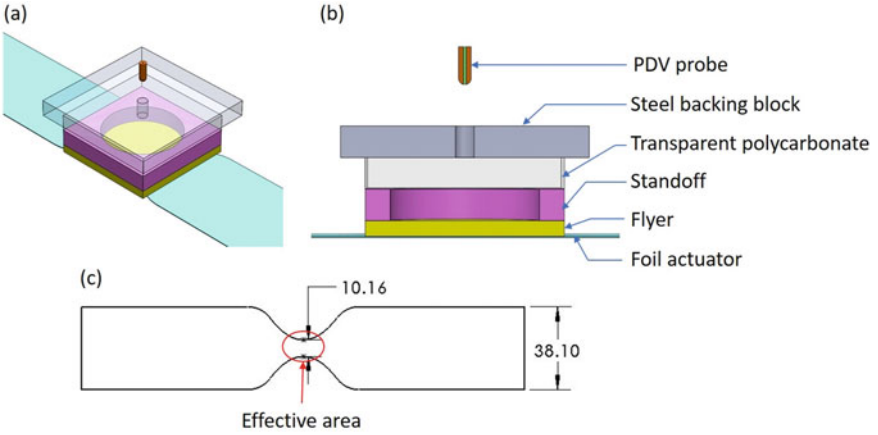

Fig. 2 Isometric (**a**) and front cross-section, (**b**) schematic of experiment setup, and foil actuator geometry (**c**). Units are in mm. (Color figure online)

Test #	Actuator	Input energy (kJ)
1	Original	10
2	Augmented	10
3	Original	16

of the center of the flyer. A transparent polycarbonate block was used to protect the probe. The whole stack-ups were fixed by a pair of S7 steel backing blocks which were bolted together. The top S7 block had a central hole for the PDV laser. For comparison, three different inputs were tested, and the processing parameters are shown in Table 1.

Flyers were deformed by VFA and impacted with the polycarbonate block for all three tests. The sound of the augmented test at 10 kJ was not easily distinguished from that of the unaugmented 10 kJ test. The shapes of the deformed steel sheets are similar for each test and a representative example is shown in Fig. 3. Velocity traces of the three tests are also shown in Fig. 3. The peak velocity is maximum with the augmented actuator at 10 kJ reaching 457 m/s, followed by 419 m/s with the unaugmented actuator at 16 kJ and 357 m/s with the unaugmented actuator at 10 kJ.

As shown by the velocity curves in Fig. 3, instead of extending the time of the acceleration period, the PLX increases the acceleration (slope of the curve) of the flyer, which reaches a higher peak velocity at a similar time or even earlier than the flyer driven by the unaugmented actuator at 10 kJ. This indicates that the reaction for chemical shock is fast enough compared to the plasma driving process to add useful work. As shown by the data, in terms of peak velocity of the flyer, the impulse generated by the augmented actuator is not only increased by 28% compared to that by the same amount of input energy (10 kJ) without augment but is also 9%

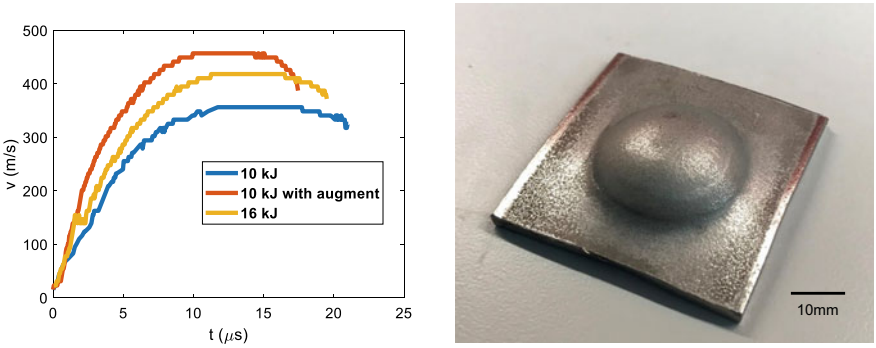

Fig. 3 Left—velocity versus time curves for the three test conditions. Right—a steel flyer after VFA test 1 (see Table 1). (Color figure online)

higher than the impulse generated by the unaugmented actuator at an input energy of 16 kJ, which itself had a 17% higher velocity than with an input energy of 10 kJ. The data also proves the mentioned diminishing return of increasing input energy, and that from input energy of 10–16 kJ without augmentation, the peak velocity only increased 17% with a 60% increase in the input energy. With augmentation, the energy efficiency is dramatically enhanced and the capability limit of the VFA system is therefore significantly boosted with a minimal increase in cost.

6 Augmentation of Laser-Driven Flyers

A technique for augmenting a laser pulse for propelling flyers is illustrated in Fig. 4. For comparison, a similar setup as in Fig. 4 was used where the PLX layer was replaced with water to show the difference in effectiveness with and without the addition of PLX. The flyer sheets were prepared from Al3003 shim stock. The shim stock came with yellow paint which was removed with a fiber laser engraver. The

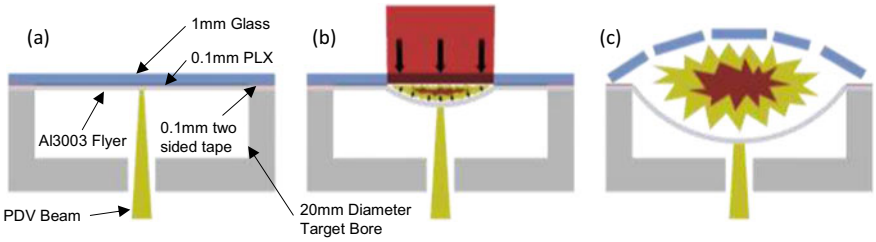

Fig. 4 Experimental setup and sequence of events. **a** Setup with PDV probe. **b** Laser pulse arrives and detonates PLX through glass. **c** Explosion drives the flyer and ejects the glass microscope slide. Images are to scale. (Color figure online)

thickness of the flyer sheets was then measured to be 0.442 mm. One side of each flyer was painted black with a black Sharpie marker to better absorb laser light. The flyers were then placed over a 20 mm diameter bore with the black painted side facing outward. The bore contained an access hole at the bottom for a PDV beam which was used to measure the flyer velocity. The surface of the flyer was covered with clear packing tape. This tape was used to prevent components of the PLX from interacting with the Sharpie ink. Double-sided tape of 0.1 mm thickness was used as a spacer to create a cavity in which a PLX film would sit. This tape was added to the flyer outside the cavity area of the bore (see Fig. 4a). A bead of PLX was placed onto the packing tape in the center of the flyer and pressed flat with a 1 mm thick glass microscope slide. The microscope slide was adhered to the flyer by means of the double-sided tape spacers. This resulted in a PLX film of 0.1 mm thickness which was semi-transparent and gray in color. The PLX was detonated by an 8.1 ns laser pulse with a total energy of 3.15 J focused to a diameter of 10 mm at the flyer surface. The laser system used has a flat-top beam profile [20]. This resulted in an average light intensity of 4.95×10^{12} W/m^2 being absorbed by the PLX film and the painted flyer surface. The total volume of PLX impinged upon by the laser beam amounted to 7.85 mm^3. Flyer velocities were captured using a PDV system, and the placement of the beam can be seen in Fig. 4.

In total, ten flyers were driven with the laser system. Five of the flyers were driven with the laser impulse and PLX. When detonated by the laser the PLX added to the sound of the laser impact, resulting in a pop similar in volume to a loud clap. The remaining five flyers were driven by laser energy only; in this case, the PLX was replaced with water. The velocity profiles of these flyers are shown in Fig. 5. The peak velocities of the flyers with PLX occur at approximately 7 μs. With water, only the peak velocity occurs at 5 μs. It is clear from this data that PLX augmentation provides a significant boost to the flyer velocity and that the impulse from the PLX occurs simultaneously with the impulse from the laser. The average velocity of the PLX flyers was 353 ± 25 m/s. The average velocity of the flyers with water only was

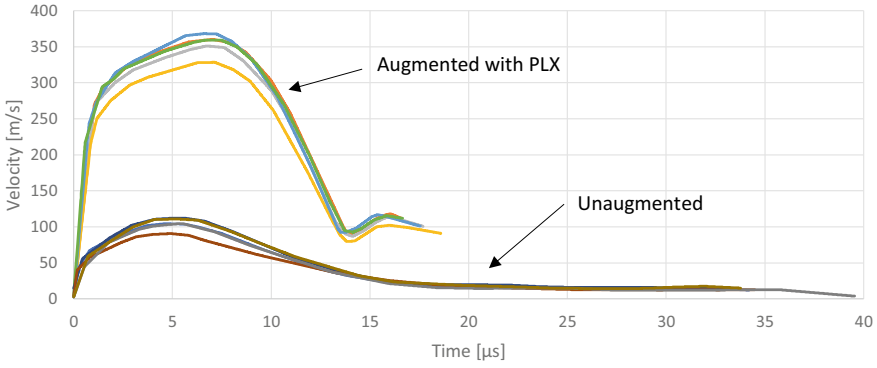

Fig. 5 The velocity profiles of augmented and unaugmented laser impulses to flyer sheets. (Color figure online)

105 ± 13 m/s. On average the flyers driven by the laser and PLX had peak velocities 236% higher than the flyers driven by the laser energy alone.

In Fig. 6a–c, a representative result of the shots without PLX can be seen. In Fig. 6b, a mark left by the laser beam can be seen in the center of the flyer. Figure 6c shows a side profile of a flyer backed with glass and water. The average displacement of such flyers was 1.2 mm. In Fig. 6d–f, a flyer deformed by the laser and PLX can be seen. From Fig. 6d, f, one can make out a conical profile. This cone shape is believed to result from the difference in area between the PLX detonated by the laser beam and the area of the bore into which the flyer was driven. Because of this conical shape, we believe that only the PLX illuminated by the laser light was detonated and that this detonation failed to propagate (the total area of the PLX was a 20 × 20 mm^2). Additionally, in several tests, remnants of PLX were found at the periphery of the flyer. The estimated volume of PLX detonated is 7.85 mm^3 below the 10 mm diameter laser spot. This diameter/volume is significantly smaller than the diameters/volumes for which detonation was possible in PLX without aluminum powder according to Makovky and Lenji [26]. The exact energy contributed by the PLX and the efficiency by which it propelled the flyer is unknown, but the effect is significant. In Fig. 6e the side of the flyer upon which the PLX and laser light acted is shown. From this image, it can be seen that the damage to the Sharpie mark is minimal and there is no aesthetic damage to the flyer base material from the PLX explosion.

The effect of chemical augmentation on the laser impact process is similar to the effect on the VFA process. Just as before, augmentation by PLX increases both the maximum flyer velocity and the rate of acceleration, all within the same time period over which these processes normally occur. The implications for LIW of this

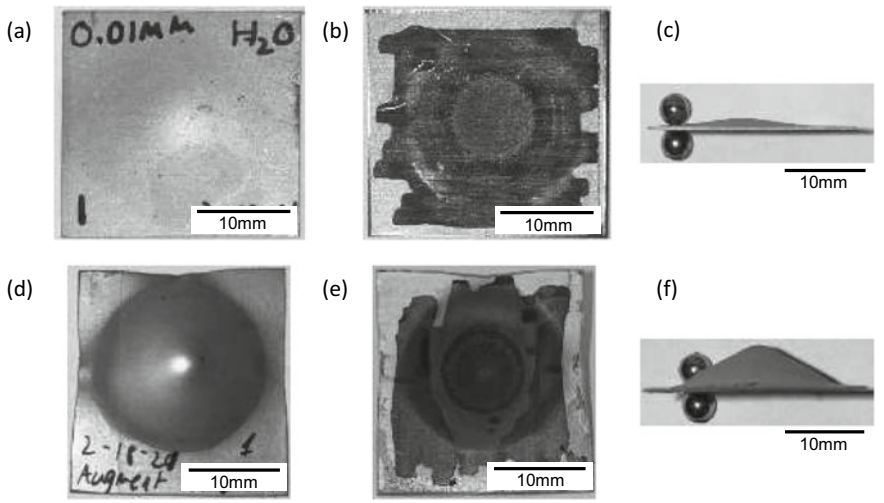

Fig. 6 Comparison between the flyer deformation induced by the laser with water (**a**, **b**, **c**) and the deformation produced with the use of PLX with the laser (**d**, **e**, **f**)

chemical augmentation process are significant. Here we have demonstrated that with a layer of only 0.1 mm of chemical explosive the 3 J laser pulse of an existing LIW welding system can be used to drive a flyer of 0.442 mm thickness to a velocity beyond 300 m/s, which is considered a safe minimum necessary for impact welding. Whereas by itself such a laser was only able to attain speeds of around 100 m/s under similar conditions. In addition, the surface finish of the flyer was relatively unaffected by the blast of the chemical explosive.

7 Conclusions and Open Questions

In this work, we have shown that it is possible to chemically augment both the VFA and LIW processes via a nitromethane-based chemical explosive. The detonation period of the explosive is sufficiently fast to add meaningful amounts of energy to the velocities of flyers driven by VFA and laser impact. For the VFA process, a 28% velocity increase in a 3 mm steel flyer was observed when using a PLX-augmented double-foil actuator through which 10 kJ of energy was discharged. When augmented, a double-foil driven with 10 kJ outperformed an unaugmented double-foil driven by 16 kJ of energy by 9%. For the purposes of laser impact welding, the use of chemical augmentation by PLX has been shown to be of great significance. A 0.1 mm thick, 10 mm diameter volume (7.85 mm^3) of PLX detonated by a 3.15 J laser pulse focused to a 10 mm diameter produced a 236% velocity increase compared to flyers driven by the laser impulse alone for 0.442 mm thick Al3003 flyers. Augmentation by PLX or other mixtures shows promise for improving the process efficiency of both VFA and LIW.

There is much work left to be done to optimize this technique. The minimum energy density for VFA foils necessary to detonate the PLX is unknown. Similarly, the energy density of a laser beam required for detonation has not been measured. The optimal PLX recipe for these processes still needs to be determined. The amount of aluminum powder in the PLX may have a significant impact on the size of impulse necessary for detonation and on the amount of energy that can be produced. The effect of flake versus spherical aluminum powder is unknown. Other chemical explosives may perform better than PLX for these processes. For laser impact purposes the backing material can play a significant role. It is hypothesized that the use of thicker glass backing materials could lead to higher flyer velocities. An ideal backing material for laser impact welding would survive the explosions and would also be massive enough to direct most of the energy of the chemical augment into the flyer. As it stands, a significant amount of the PLX energy is wasted in shattering and scattering the glass microscope slide used as a backing material for laser impact purposes. Additionally, it should be noted that the PLX recipe used here degrades within 24 h when exposed to air, and when sealed the mixture slowly degrades over a period of weeks. The recipe used in this work was one week old at the time of the experiments and had been stored in a sealed glass bottle after production. The degradation of the

sealed mixture is hypothesized to be due to chemical reactions between the aluminum powder and the other ingredients in the mixture.

Recent Developments of Vaporizing Foil Actuator Technique for Manufacturing Applications

K. Sajun Prasad, Jianxiong Li, Blake Barnett, Yu Mao, Glenn S. Daehn, and Anupam Vivek

Abstract Vaporizing foil actuator (VFA) is an impulse or high-speed manufacturing technology using electrically driven rapid vaporization of thin conductors to produce short-duration pressure pulses of high magnitude. This impulse technique has been implemented for various applications such as high strain rate forming, shearing, collision welding, and springback calibration. VFA technology for manufacturing processes potentially offers improved accuracy, reliability, and environmental safety and creates opportunities to design new products by joining similar and dissimilar material combinations. The paper includes the results of industrially relevant "work-in-progress" research with the VFA tool. The applications of the process, mainly regarding advanced manufacturing such as metal-matrix composite (MMC) welding, axisymmetric welding, and impact-mediated additive manufacturing processes, are presented and discussed. The applications of the method characterize adequate responses to support the manufacturing process.

Keywords Vaporizing foil actuator · Impulse manufacturing · Metal-matrix composite joining · Axisymmetric welding · Ballistic additive manufacturing

1 Introduction

Vaporizing foil actuator (VFA) is an innovative manufacturing technology that utilizes high-pressure impulse created by sudden vaporization of thin metallic foils and wires, activated by the passage of a high current for a minute fraction of time. For the past few decades, explosives [1], magnetic pulse (MP) [2], and hydraulic discharge [3] are a few tools that are prevalently applied for impulse metalworking processes. Each of these impulse manufacturing process variants has some advantages over the others. Explosives are challenging to automate in a production line due to the limitations to scale the process to thin sheets or small weld zones; moreover, increasingly stringent safety regulations inhibit their use. However, processes

https://doi.org/10.1007/978-3-030-75381-8_111

like magnetic pulse (MP), VFA, and laser-induced processes (LI) can be automated and integrated into the conventional production environment. Both MP and LI are environmentally friendly processes with limited to no emission of gas or smoke, radiation, heat, or shielding gas during the process [4]. MP operation is limited to specific energy and pressure levels due to coil longevity issues. VFA allows for the mitigation of these issues as the actuator employed is a consumable. The group at The Ohio State University (https://iml.osu.edu/) implemented the VFA tool successfully for low-cost collision welding at characteristic scales comparable to magnetic pulse welding (MPW) [5], and it is often referred to as vaporizing foil actuator welding (VFAW) . VFAW has been successfully utilized to produce strong joints for various similar and dissimilar combinations such as Al-Steel [6], Al-Cu [7], Al-Ti [8], Ti-SS [9], Ti-Cu [10], steel-steel [11], NiTi-SS [12], and many other exotic and hard to join material combinations. The technique also provides the ability to weld in several geometries, viz., sheet to sheet, sheet to castings, sheet to extruded parts, sheet to tube, and tube to tube under different geometries, i.e., patch, spot, butt, flange, and line configurations. The ability to weld a wide range of material pairs allows manufacturers to improve product designs and manufacturability substantially.

The group also used the concept VFA for various manufacturing processes, including shearing [13], tube compression [14], joining [14], forming, and embossing [15]. Recently, Prasad et al. [16] demonstrated an innovative facility using the VFA technique to utilize different high-speed impact processes such as powder compaction, spallation, and impact collision bonding of dissimilar material. Stress relief is another VFA application, which could find use when forming high-yield-strength material that exhibits significant springback. Vivek [17] described springback calibration technique, where the VFA would allow the part with retained elastic strains (causing severe springback) to be formed, then shocked with pressure from the vaporizing foil. This shock would relieve the elastic strains and stresses in the sheet and, in effect, lock the metal into its desired shape. Here we present VFA as a complementary driving mechanism to existing technologies in the specific cases of metal-matrix composites (MMCs) , axisymmetric welding, and impact-mediated additive manufacturing.

Metal-matrix composites can present challenges to deformation-mediated processing due to their high strengths and the abrasive nature of reinforcement phases. Solid-state processing of MMCs is currently accomplished via friction stir welding (FSW) and ultrasonic welding (USW) and has demonstrated success in several applications [18, 19]. In USW, MMC material candidates are confined to those with relatively soft metal phases, such as aluminum and copper, which are natively compatible with the welding process. USW also has the unique advantage of preserving the integrity of continuous fiber-reinforced composite phases due to the minor strains induced during welding [20]. In contrast, FSW introduces large shear strains into the weld zone, disrupting and even breaking reinforcement phases into smaller fragments [18]. This intimate contact between ceramic reinforcement phases and the FSW stir tool can lead to rapid tool wear, increasing FSW costs [21]. Recently, VFA has been demonstrated to successfully weld a variety of flyer plate materials to thick steel MMC targets with nugget pullout failures in mechanical

testing. This complements the strength, thickness, and tool wear challenges observed in the current state-of-the-art of MMC solid-state joining.

In axisymmetric joining, there are two significant modes of consolidation: tube expansion and tube contraction. Tube expansion, in particular, faces challenges across length scales due to accessibility to the internal diameters of the expanding donor tube and the durability of driving mechanisms and fixtures. Tube expansion axisymmetric joining is most often accomplished via MPW or explosive welding (EXW) [22]. MPW is most effective when the donor tube has high magnetic permeability and a moderate size range of tubes. Small donor tubes require MPW coils that can fit into the tube interior, and the combination of small wire gauge in the coil and the high impulse loads generated by reaction forces can create challenges for MPW coil longevity [23]. EXW has a long history of axisymmetric joining [24] and is insensitive to the electromagnetic properties of the donor tube. However, procurement, handling, and process control for EXW can present challenges in cost and repeatability. VFA and exploding conductor techniques have recently been demonstrated to achieve axisymmetric joining in their own right and can also provide an accessible testbed to rapidly optimize process parameters before committing to the infrastructure required by EXW trials.

Deformation-mediated processing techniques provide desirable advantages when applied to additive manufacturing, where traditional melt-based methods often require post-processing to rehabilitate microstructural porosity, phase segregation, and solidification texturing [25, 26]. While dimensional control in deformation-mediated additive manufacturing is not as refined as traditional methods, they can bring advantages in build rate, build envelope size, and as-built microstructures and material properties. Gas dynamic cold spray (CS) and additive friction stir (AFS) deposition are both deformation-based additive manufacturing techniques that have been successfully developed for applications across a wide range of materials [27, 28]. Ballistic additive manufacturing (BAM) has been demonstrated, wherein a succession of disks sheared from continuous feedstock sheets are deposited via impact for near-net-shape manufacturing and repairs [29]. While cold spray uses inert process gas such as nitrogen or helium to accelerate powdered feedstock, BAM uses VFA or laser shock ablation to shear its feedstock from sheet stock and reduce consumables costs. BAM also serves as a tool to explore the effects of varying the surface area to volume ratio of highly strained zones in deformation-based consolidation; AFS completely recrystallizes its deposited material [30], while cold spray deposits are characterized by a mosaic of recrystallized feedstock particle boundaries with largely retained particle core crystallography on the length scale of the particles themselves (typically 10s of microns) [31, 32]. BAM creates similar variation but on the order of millimeters and offers new opportunities to explore the effects of engineered microstructures on as-built additively manufactured component performance.

2 Recent Developments Using the VFA Technique

2.1 MMC Welding

SiC-reinforced 8009 aluminum (8009/SiC/11$_p$) of 10 mm thick plate was welded to Al7075-T6 sheet of 1 mm thick using VFA spot welding technique. MMC has superior high-temperature mechanical properties compared to conventional aluminum alloys [33]. In the present work, a maximum capacitor bank energy of 16 kJ and a current rise time of 12 μs was applied for successful MMC welding. A 0.0762 mm thick actuator with the foil dimension as per Fig. 1a was used. The VFA experimental setup sequence for the welding is shown in Fig. 1b. Before welding, a circular pocket of 12.7 mm diameter and 0.6 mm depth was machined on the MMC block using a CNC mill. Al7075 flyer driven by the plasma from the actuator vaporization accelerated through the pocket and impacted with MMC, resulting in impact welding as depicted in Fig. 1c.

Further, a peel test was performed on the welded sample, during which the MMC side was fixed and Al7075 was being pried, which resulted in a nugget failure (Fig. 1c). This indicates the stronger weld than the parent Al7075 material, which is desirable for a successful joint. The welded sample was sectioned across the red dash line (Fig. 1c), and the corresponding microstructure shows no evidence of melting, heat-affected zone, or cracking (Fig. 1d). Additionally, a clear wave profile signifying

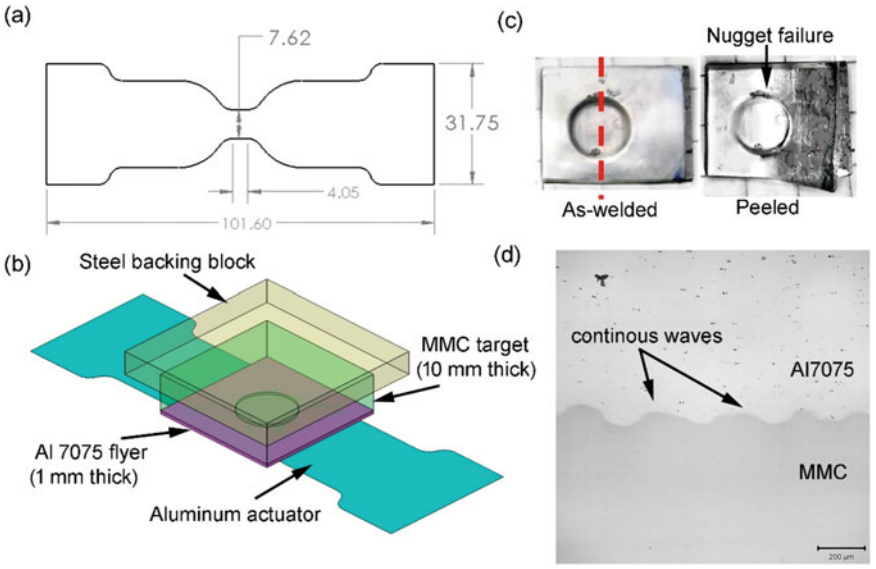

Fig.1 Schematic of **a** actuator geometry, **b** experiment setup, **c** sample as-welded and after peel test, and **d** cross-section of Al7075-MMC weld. (Color figure online)

solid-state metallic bonding was formed between the MMC and Al7075, indicating good weld strength.

2.2 *Axisymmetric Welding by Tube Expansion*

For the first time, axisymmetric welding of aluminum tubes has been achieved through vaporizing foil actuator (VFA). Figure 2 shows the schematic of the tube welding fixture and welded tube. Two plastic tubes were used as the standoffs to provide an acceleration distance for the flyer tube. The dimensions of the flyer tube, standoff tubes, and target tube are shown in Table 1. The central mandril used to withstand high-velocity impact was not purely metallic but insulated by two urethane rods. The tubular foil was composed of five parallel-connected 0.002″ spot-type foils

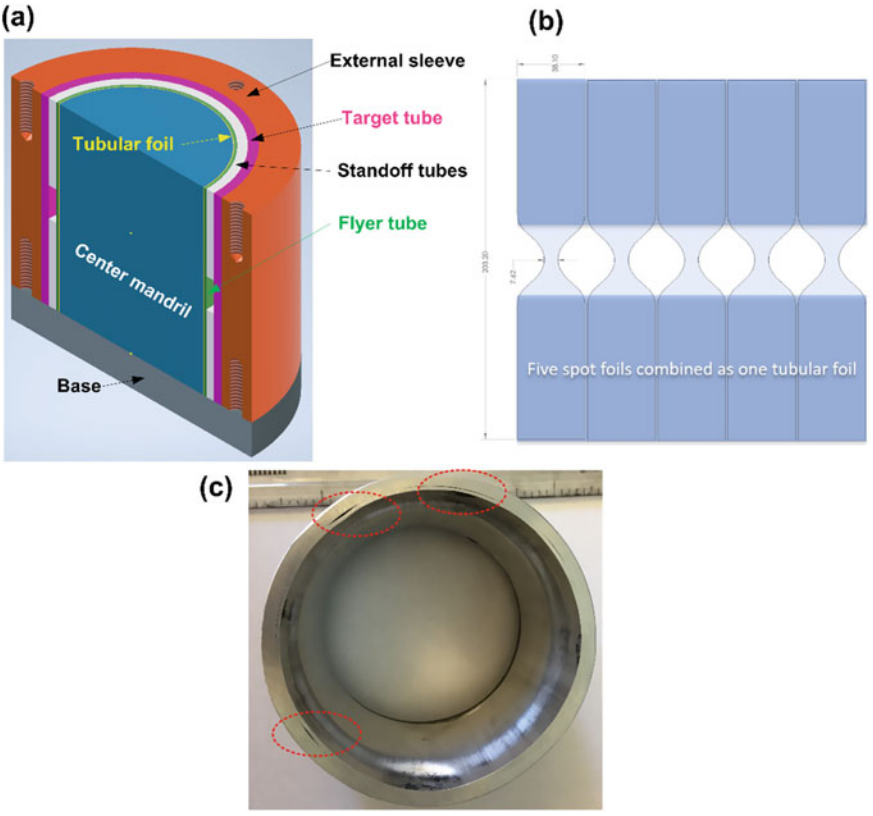

Fig. 2 **a** Schematic of axisymmetric welding of aluminum tubes using vaporizing foil actuators, **b** configuration of tubular foil composed of five spot-type foils, and **c** cross-section of welded aluminum tubes. (Color figure online)

Table 1 Dimensions of flyer tube, standoff tubes, and target tube used in tube welding trials

	Outer diameter (mm)	Inner diameter (mm)	Thickness (mm)
Flyer tube	63.5	61.7	0.89
Standoff tubes	69. 3	64	2.65
Target tube	76.2	69.85	3.175

(Fig. 2b). All the other conductors were insulated to avoid shunt electrical surges away from the tubular foils. The outer backing block was made of high-strength steel to prevent further deformation after the tube welds formed. The standoff separation distance is 24 mm and the standoff distance is 3.15 mm. The energy source was a capacitor bank entailing maximum energy of 16 kJ and a current rise time of 12 us. Input energy of 15.8 kJ was used to vaporize the tubular foil in several microseconds. After welding, the cross-section of the aluminum tube weld was prepared and observed in the optical microscope. The cross-section image of the tube weld in Fig. 2c shows a clean axisymmetric weld with some unwelded zones, which was caused by incomplete sublimation of foils due to insufficient input energy.

The key aspect in tube welding using VFAs are the confinement between the inner backing block, tubular VFAs, and flyer tube; the confinement between standoff tube, flyer tube, target tube, and outer backing block; and the complete vaporization of all foil actuators at the same time under proper input energy. VFA tube welding advantages over magnetic pulse welding are the irrelevancy of material conductivity and no tube size limitation if the input energy is enough. Theoretically, using tubular VFAs, tubes of any size can be welded under vaporization of corresponding numbers and shapes of VFAs. In the future, axisymmetric welding using VFAs can be applied to join dissimilar metal tubes since VFA welding of dissimilar metals has been proven effective [34, 35]. This strong adaptability provides high potential in automobiles and other engineering sectors that need different-sized tube welds.

2.3 Ballistic Additive Manufacturing

A novel additive manufacturing method based on vaporizing foil actuator has been demonstrated, referred to as ballistic additive manufacturing (BAM) . There are two ways to achieve BAM parts using VFA. One is to directly weld thin flyer sheets to a pre-machined part that generally exhibits a V-shape groove with an inclined angle around 10–25°. The second is to use a combined shearing and welding method to deposit multiple sheared parts through a die block to a pre-machined part. After deposition, the BAM part can be machined to the desired shape.

BAM can be applied to conduct a crack repair on parts. As shown in Fig. 3a–d, three 2 mm thick 1100 aluminum sheets were welded to a target sheet (6061 Al) with a pre-machined hole. After machining and cross-sectioning, the repaired part

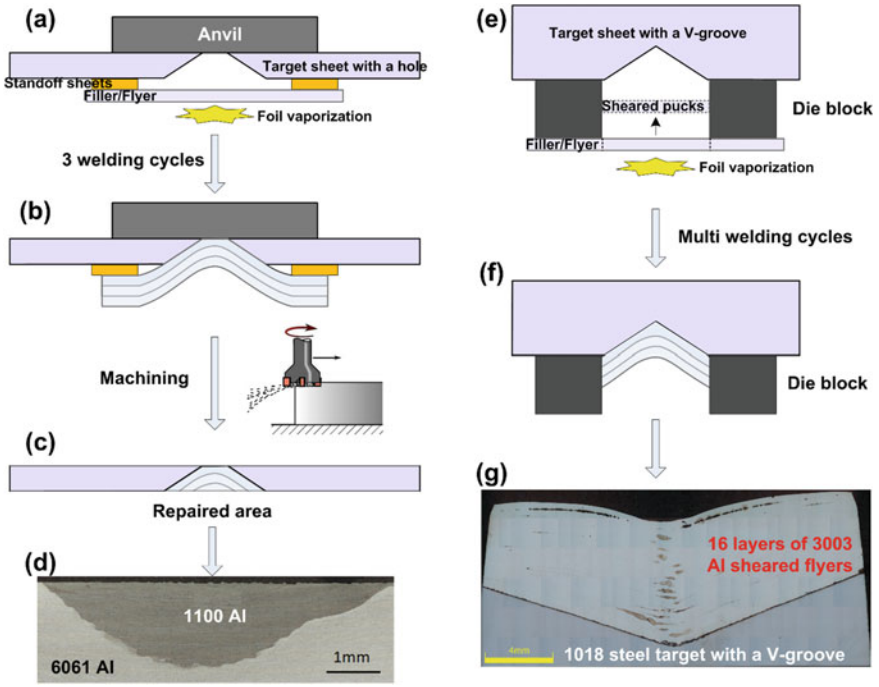

Fig. 3 **a**–**d** Ballistic additive manufacturing achieved by directly welding flyer sheets to a pre-machined part and **e**–**g** shearing metal pucks into the pre-machined part. (Color figure online)

exhibits defect-free microstructures. Wavy interfaces were exhibited between the matrix and the first additive layer, which is typical of impact welding. Figure 3e–g depicts the crack repair process using a combined shearing and welding method. Sixteen 0.5 mm thick 3003 Al flyer sheets were sheared into oval-shaped pucks. These sheared aluminum pucks travel through the die block and are welded to a 1018 steel target with a V-groove. The cross-section image shows that these aluminum sheared parts are connected well except for some jetting segregations in the middle and voids in the top layer interface. These two trials proved that BAM could be achieved reliably through VFA while more process optimization, design, and property examinations are needed.

Future interests lie in several aspects. First, the development of an automatic launch system including a separate shooting gun and a robot arm holding the target will play a vital role in the BAM process. The robot arm could change the impact angle and standoff distance of the flying metal pucks coming out from the gun. In this way, the impact angle and flyer velocity could be in situ controlled, and thus optimal parts could be potentially achieved. Second, a holistic comparison between BAM and traditional metal AM technologies should be carried out in terms of energy efficiency, deposition rate, resolution, and dimension limitations. BAM plus conventional subtractive manufacturing process will show great potential in

fabricating components with complex structures and repairing cracks in automotive and aerospace components.

3 Conclusions

In the present paper, recent trends and developments of vaporizing foil actuator for manufacturing applications are reviewed. Recent advances in component manufacturing processes such as high strain rate forming, shearing, collision welding, and springback calibration processes face increasing demands to achieve low cost, material versatility, high dimensional accuracy, high strength, and environmental safety. VFA-assisted applications are an increasingly helpful solution for meeting these requirements. The paper includes niche research applications such as joining metal-matrix composite, axisymmetric welding, and additive manufacturing processes using the VFA tool. The practical applications of the method resulted in good responses to support manufacturing process definition. The VFA process needs more development to compete with traditional mass-production methods because of its lower production rate.

Grain Size Effect on Formability in Electromagnetically Assisted Micro-Bulging of Pure Titanium Sheet

Chengxi Zhu, Jie Xu, Haiping Yu, Debin Shan, and Bin Guo

Abstract It has been revealed that the grain size effect has a great effect on the formability of metal foils during quasi-static forming processes. However, there is little research on how size effects influence the formability of metal foils during the high-speed forming process, e.g., electromagnetically-assisted forming. To characterize the grain size effect in electromagnetically assisted micro-bulging, a miniaturized Nakazima test was conducted using a specially designed device. Pure titanium foils of thickness 103 μm and different grain sizes were utilized in the experiment. In addition, SEM and TEM methods were used to clarify how grain size influences the fracture surface and microstructure in electromagnetic forming.

Keywords Size effect · Formability · Electromagnetic micro-bulging · Micro-forming · Pure titanium

1 Introduction

Due to the requirement of product miniaturization in many industry clusters, many technologies for micro-manufacturing received a wide study and were well developed recently. Among them, micro-forming is the most attractive approach to fabricate micro-parts because of its numerous advantages, such as low cost, high production efficiency, and the good mechanical properties of the micro-formed parts [1, 2]. However, there exists a key issue which is called size effect during micro-forming which affects the deformation behaviors, especially in sheet metal forming [3, 4]. The size effect is mainly caused by the significant reduction of grain number in deforming zone. It is necessary to study how the size effect affects the deformation behaviors of sheet metals. Fu et al. [5] conducted a tensile test with annealed pure copper foils with different thicknesses and grain sizes to study the size effects on fracture behavior. It is found that flow stress, fracture stress and strain, and the number of micro-voids on the fracture surface decrease with the decreasing ratio of specimen size to grain size.

https://doi.org/10.1007/978-3-030-75381-8_112

Meng et al. [6] performed forming limit experiments of SUS304 foils with different thicknesses and grain sizes and found that the micro-formability of metal foils was shifted down with a reduction in the ratio of specimen size to grain size, and the severe scatter in the forming limit curve (FLC) of 20 μm thick foil was observed.

Electromagnetic forming technology (EMF) was developed in the early 1960s. It is a high-energy, high-speed forming method that uses electromagnetic force to deform the sheet metal. It is suitable for forming complex shapes of workpieces because it needs no punch. Due to the precise control of the power supply, the controllability and accuracy of electromagnetic forming are very high [7]. Furthermore, the output displacement of the micro-forming system driven by electromagnetic force can reach the order of millimeters, which can fully meet the micro-forming displacement requirements. Because of the advantages of electromagnetic forming technology, it has received great attention from the industry and has been widely used in automotive, instrumentation, electronics, and military industries. Choi et al. [8] employed electromagnetic sharp edge forming in order to form a sharp edge with a corner radius of 10 mm which was not successful in conventional square cup drawing. In addition, the electromagnetic tool coil was designed with the aid of topology optimization to enhance the efficiency of the electromagnetic sharp edge forming process. Su et al. [9] proposed a new two-step electromagnetic forming that combines electromagnetic forming with electromagnetic calibration for local features of large-size sheet metal parts, such as an oblique hole-flanging. Simulation results showed that during EM calibration, the stress distribution of the workpiece was improved, the bending moment was reduced which is responsible for the shape and size errors, then the rebound was restricted. Consequently, the fitting ability and the forming accuracy were significantly enhanced.

Kamala et al. [10–12] from Ohio State University developed a driving device capable of generating uniform magnetic pressure. The device was used for the rapid manufacturing of micro-boxes and for the research on electromagnetic micro-forming of foils. The results show that the electromagnetic forming technology effectively suppresses wrinkling and the material surface has high accuracy and has greater flexibility than traditional sheet forming. Cheng and Lee [13] from Taiwan Cheng Kung University carried out research on electromagnetically assisted high-speed bulging of A5052 aluminum alloy to study the grain size and forming speed on the forming limit of the spherical cap. The results show that regardless of the microstructure of the sample, the formability of the electromagnetically formed aluminum plate is better than that of quasi-static forming. And when the t/d presenting the ratio of specimen thickness to average grain diameter increased from 6.99 to 27.17, the limit dome height (LDH) value showed an initial increasing trend, then decreased, and the maximum LDH value appeared in the case of t/d of 9.45. However, there is still little research on how the size effect affects the deformation behavior of titanium sheets in electromagnetic bulging.

2 Experiments

2.1 Sample Preparation

Commercially pure titanium foils of thickness 103 μm were used as the testing material in this research. To obtain different strain paths, specimens with three different shapes were designed in this study for the forming limit tests. The dimensions of the test samples of three strain paths are presented in Fig. 1a.

After cutting, the samples were ready for the bulging test, which is termed as the "as-received" in this paper. Meanwhile, some machined samples were heat-treated to explore the effect of material microstructure on deformation behavior. The annealing temperatures and dwelling times are 670 °C and 0.5 h, 700 °C and 1 h, and 720 °C and 5 h in the vacuum environment, respectively. To attain the microstructure of the specimens, the specimens were etched with a solution of 2 ml HF, 1 ml HNO_3, and 17 ml H_2O for 30 s. The metallographic observation was conducted on the microscope, and Fig. 2 shows the metallographic structure. The average grain size and the ratio of specimen thickness to average grain size (t/d) under different heat treatment conditions are shown in Table 1, respectively. It is observed that the grain size increases with the annealing temperature. To calculate the strain after bulging,

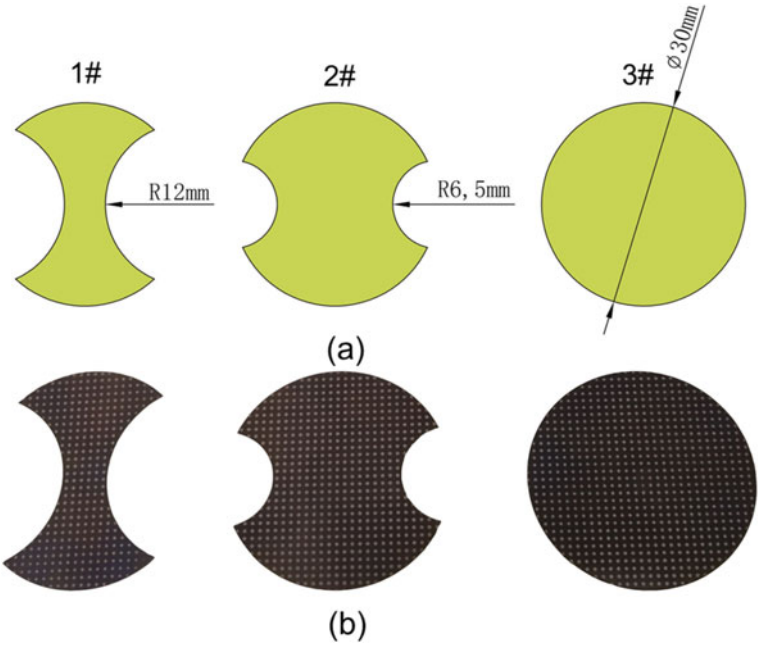

Fig. 1 The test samples of three strain paths. **a** Dimension of the samples; **b** the dotted samples. (Color figure online)

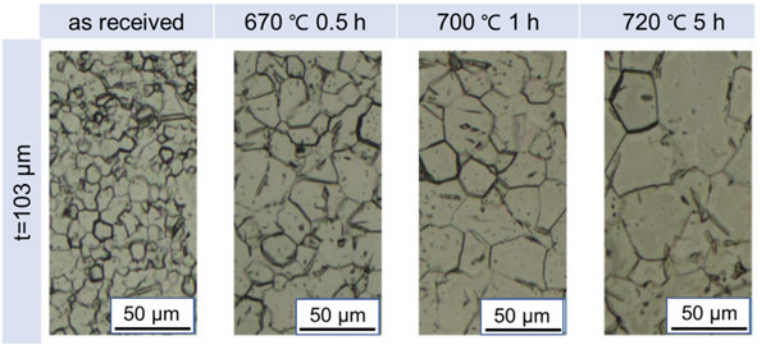

Fig. 2 Microstructure of specimens with different heat treatments. (Color figure online)

Table 1 Grain size and t/d value of different heat treatment condition

	As received		670 °C 0.5 h		700 °C 1 h		720 °C 5 h	
t = 103 μm	d/μm	t/d	d/μm	t/d	d/μm	t/d	d/μm	t/d
	7.5	13.7	15.5	6.6	27.4	3.8	38.2	2.7

all the samples were etched before bulging to produce white dots that are 0.5 mm in diameter and spaced 0.5 mm from each other. Figure 1b shows the dotted samples.

2.2 Electromagnetic Bulging Test

The equipment used in this experiment is a 25 kJ electromagnetic pulse system. To increase the punch speed during forming, we designed a set of electromagnetic bulging device, including the coil, driving plate, punch, blank holder, and the bottom die (Fig. 3). The diameter of the semi-spherical punch used in this experiment was 15 mm. To ensure that all the specimens would be bulged at the same speed, all the bulging tests were conducted at the voltage of 5 kV and the electric capacity of 100 μF. The strong electromagnetic force generated by the coil expelled the driving plate and punch to impact the specimen at high speed. After bulging, the strain distributions of the bulged specimens were measured by ARGUS system, which is a 3D strain measurement system of high accuracy. The strains near the fracture were selected as the forming limit of the different specimens.

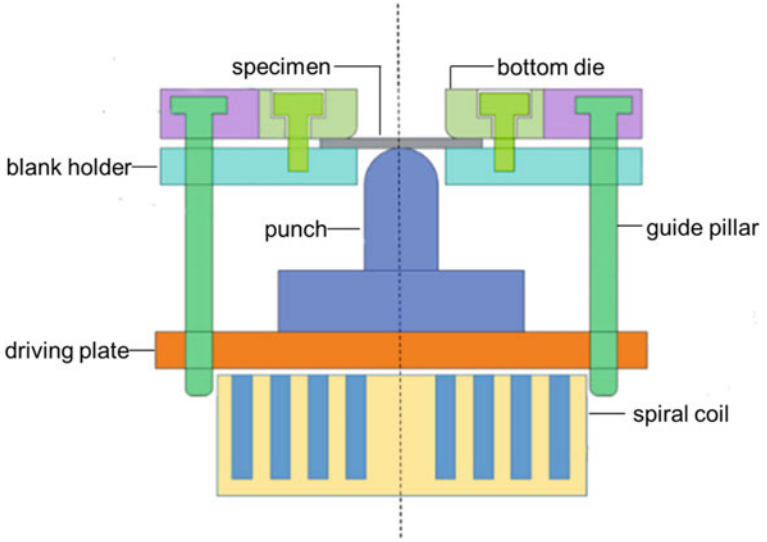

Fig. 3 Specially designed electromagnetic bulging device. (Color figure online)

3 Results and Discussion

3.1 Effect of Size Effect on Forming Limit

Figure 4 shows the strain distribution of the specimens with t/d = 13.7 after electromagnetic bulging. The strain of the dot beside the fracture zone is selected as the forming limit strain. Figure 5 illustrates the forming limit strain of different strain paths and different t/d. It is found that the forming limit shifts down with the decrease of t/d from 13.7 to 2.7, especially for the bi-stretching condition. On the one hand, the uniform strain will decrease with t/d resulting in a decreasing forming limit strain.

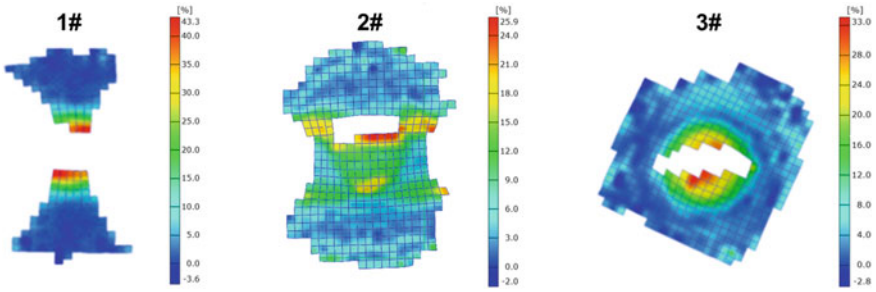

Fig. 4 Strain distribution of the specimens with t/d = 13.7 after electromagnetic bulging. (Color figure online)

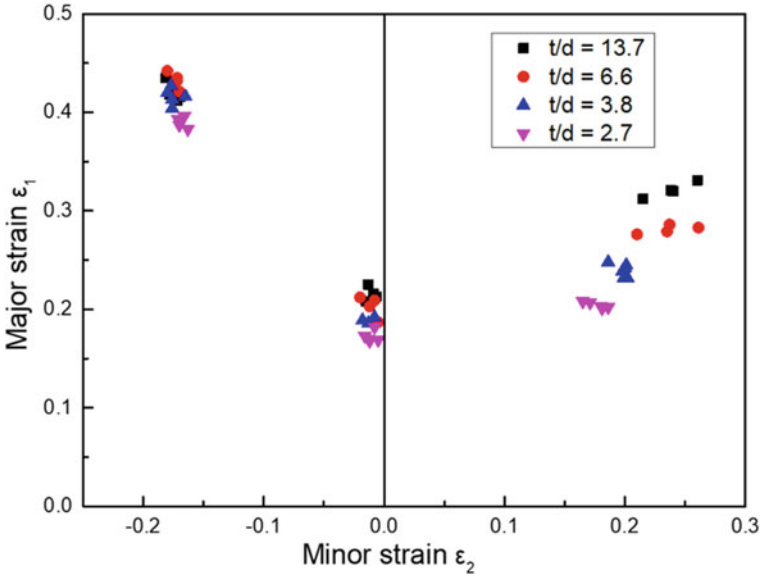

Fig. 5 Forming limit diagram of pure titanium sheet with different t/d. (Color figure online)

On the other hand, according to the surface layer model, the internal layer of the specimen can be treated as polycrystalline material and the thickness of it decreases with t/d. As a result of a decrease of t/d and the internal layer, it becomes easier for micro-voids and micro-cracks to coalesce and grow over the sheet thickness in such a way to form macroscopic fracture.

3.2 Effect of Size Effect on Fracture Surface

To study the size effect on the fracture surface of titanium sheet in electromagnetic bulging, the SEM method was adopted. Figure 6 shows the fracture surface of the 1# specimens with different t/d. As can be seen, there are many dimples on the fracture surface that are well distributed when t/d is 13.7, which indicates a ductile fracture of the specimen. However, the dimples on the fracture surface distribute more and more inhomogeneously with the decrease of t/d and there are dimples much bigger than others when t/d reaches 2.7. It can be considered that when t/d is high, the small dimples which take place during deformation endures many restrictions. But when t/d decreases, the restriction becomes smaller and smaller, leading to abnormal growth of the small dimples. This coordinates with the analysis about forming limit above.

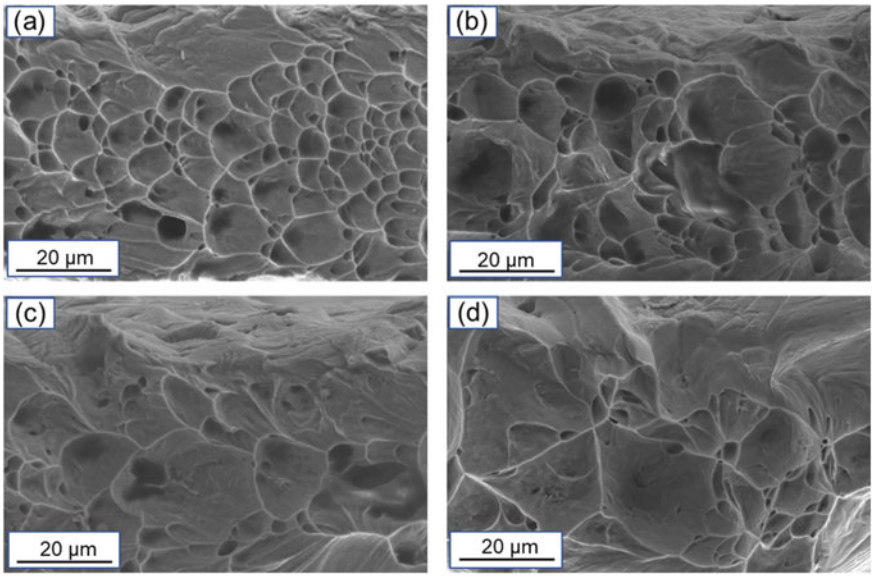

Fig. 6 SEM of fracture surfaces of specimens with different t/d. **a** t/d = 13.7; **b** t/d = 6.6; **c** t/d = 3.8; **d** t/d = 2.7. (Color figure online)

3.3 Effect of Size Effect on Microstructure

The microstructures of the 1# specimen near the fracture surface were characterized by TEM, and the results are displayed in Fig. 7. It shows that numerous dislocations were piled up at the grain boundaries twin boundaries or phase boundaries as marked

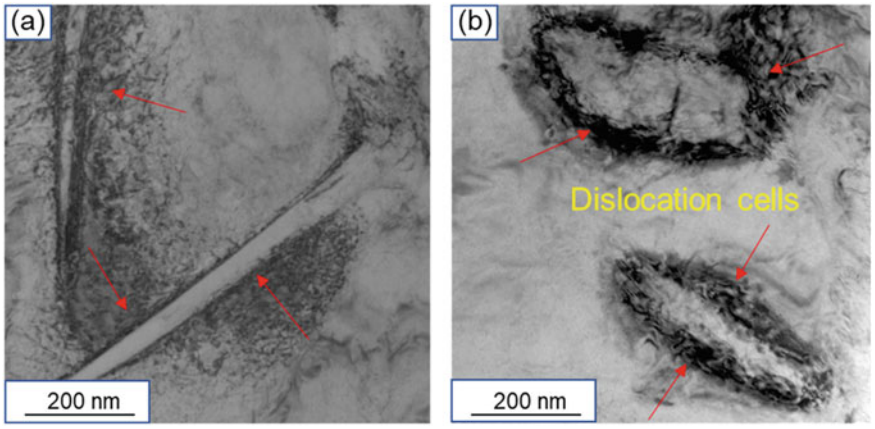

Fig. 7 TEM of specimens with different t/d. **a** t/d = 13.7; **b** t/d = 2.7. (Color figure online)

by red lines in Fig. 7a and there are few dislocation cells when t/d is 13.7. Meanwhile, when t/d is 2.7, some tangled dislocation configurations marked by the red lines can be observed in Fig. 7b. The grains are fine when t/d is 13.7, so there is no sufficient slipping distance for dislocations to tangle together and dislocations prefer to pile up at grain boundaries. Meanwhile, dislocations tend to tangle together and form dislocation cells when grains are coarse.

4 Conclusion

In this study, grain size effect on forming limit, fracture, and microstructure evolution of pure titanium foils in electromagnetic micro-bulging was explored using a specially designed device.

(1) The forming limit of titanium foils in electromagnetic forming shifts down with the decrease of t/d from 13.7 to 2.7 especially for the bi-stretching condition. This is mainly because of the decrease of an internal layer with a decrease of t/d according to the surface layer model.
(2) The dimples on the fracture surface distribute more and more inhomogeneously with the decrease of t/d. And there are dimples much bigger than others when t/d reaches 2.7. The root cause is that the small dimples which take place during deformation endure fewer restrictions with a decrease of t/d, leading to abnormal growth of the small dimples and earlier fracture of the specimen.
(3) Dislocations prefer to pile up at grain boundaries when grains are fine because of lack of slipping distance while dislocations tend to tangle together and form dislocation cells when grains are coarse.

Mathematical Model and Quantitative Analysis of Residual Stress Hole During Laser Shock Peening

Xiuquan Cheng, Junhao Zhang, Sizhu Cheng, Chang Yan, and Qinxiang Xia

Abstract Laser shock peening (LSP) can induce residual compressive stress on the component surface, thus improving the fatigue life of the component. Therefore, LSP has been extensively employed in aerospace, vehicle engineering, and other industrial fields. To research the influence factors of residual stress hole (RSH) which often occurred in LSP, a "volcano shape" mathematical model was conducted. Indexes for quantitatively describing RSH were proposed, such as relative crater depth, relative crater width, and stress loss ratio. Preliminary analysis based on the experimental study was carried out. The results showed that the relative crater depth is the main impact factor to RSH. Overlapping LSP is suggested to be adopted when the relative crater depth is more than 10%. In addition, the spacing of the adjacent spot centers should be equal to the "crater" radius of RSH so as to get the uniform residual stress under the premise of higher LSP efficiency.

1 Introduction

Shot peening has been widely used in aviation, vehicle, construction, and other fields. In recent years, laser shock peening (LSP), which can more effectively improve the strength and fatigue life of the treated components [1, 2], has gradually been applied.

Many reported researches of LSP focused on the residual stress distribution and the fatigue performance [2–5]. Some researchers found that the residual compressive stress at the laser projection center is smaller than the surrounding area [6–8]. This phenomenon is called residual stress hole (RSH) or loss of residual compressive stress [9]. According to the research of Wang et al. [10], sparse wave generates in the laser projection area and propagates. Then, part of the sparse wave reflects back when it propagates to the spot edge. The reflected sparse wave will encounter in the laser projection center and causes secondary plastic deformation. The secondary plastic deformation with severe shear plastic strain reduces the axial and radial strain generated in the shock wave loading stage. Then, an RSH occurred in the laser projection center.

The existence of RSH not only reduces the residual compressive stress value but also deteriorates the uniformity of stress distribution. Both of them reduce the strengthening effect of LSP.

2 Establishment of Mathematical Model of RSH

Figure 1 shows the typical distribution of surface residual stress after single-point

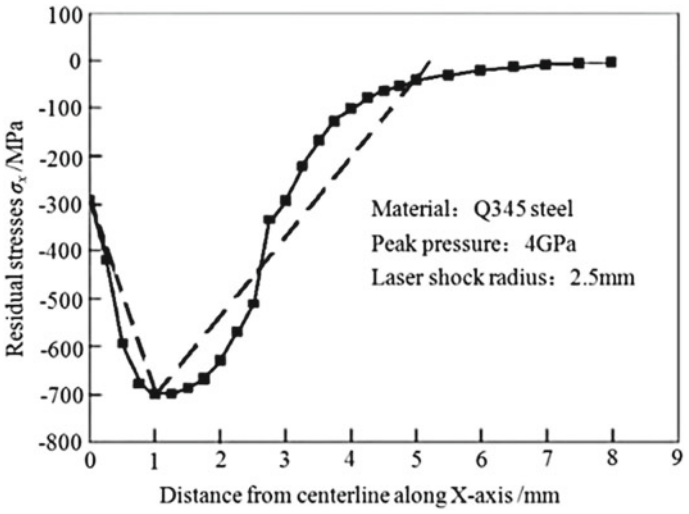

Fig. 1 The typical distribution of the residual stress after single point LSP

LSP [11]. The solid line corresponds to actual residual stress distribution, and the dotted line corresponds to simplified residual stress distribution. Circular spot laser is widely used in the LSP process, which can induce residual stress in the form of axisymmetric distribution. The research of this paper is based on the LSP with circular spot. The simplified residual stress dotted line in Fig. 1 is similar to a half-inverted volcano. By flipping the simplified residual stress dotted line, "volcano model" can be established and as shown in Fig. 2. In this "volcano model", the crater region (inverted cone region) represents the region of RSH, D_0 is the diameter of the residual compressive stress region induced by single point LSP, and D_c is the crater diameter of the RSH. σ_0 is the maximum residual compressive stress on the peened surface, and σ_c is the residual stress loss at the bottom of the crater, where it is located in the laser projection center.

According to the "volcano model" in Fig. 2, the larger the volume of the inverted cone, the more serious is the RSH. The volume of the inverted cone is determined by the crater diameter D_c and crater depth σ_0. Therefore, the stress loss ratio k was defined as the ratio of the volume of the inverted cone V_c to the total volume V_0, as shown in Eq. (1):

$$k = \frac{V_c}{V_0} = \frac{D_c^2 \sigma_c}{(D_0^2 + D_0 D_c + D_c^2)\sigma_0} \tag{1}$$

The larger the stress loss ratio, the more severe is the RSH. k_1 is defined as the relative crater depth and k_2 is defined as the relative crater width:

$$k_1 = \sigma_c / \sigma_0 \tag{2}$$

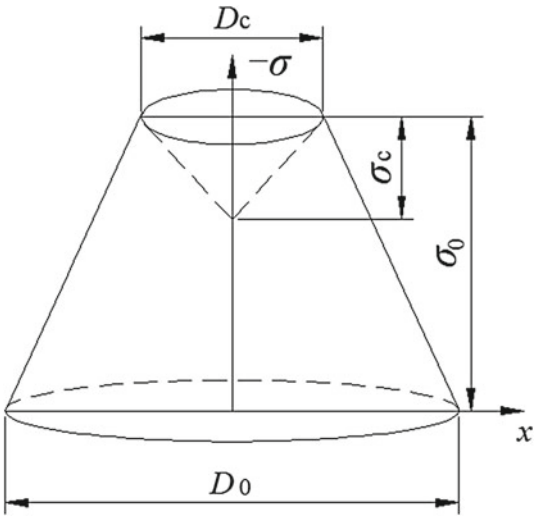

Fig. 2 The volcano model of surface RSH

$$k_2 = D_c/D_0 \tag{3}$$

Substituting Eqs. (2) and (3) into Eq. (1):

$$k = k_1 k_2^2/(1 + k_2 + k_2^2) \tag{4}$$

3 Effect of Main LSP Parameters on RSH

According to Eqs. (2)–(4) and residual stress data of LSP test, the effect of the main LSP parameters on RSH was quantitatively analyzed. The target material is 7075-T6 aluminum alloy covered with a transparent flexible energy confinement layer and an energy-absorbing layer. The confinement layer was cured by bisphenol A-epichlorohydrin epoxy resin and cycloaliphatic amine curing agent [12]. The energy-absorbing layer is obtained by laminating black electrical tape and black double-sided tape. The equipment used in the LSP test is Nimma-Extra type solid-state laser. The residual stress was measured by an X-ray diffractometer. The parameters adopt in the LSP test were presented in Table 1. The number of test specimens in each group was 5, and the average value of five specimens was regarded as the final result.

3.1 Effect of Laser Shock Energy E *on RSH*

Figure 3 shows the residual stress loss ratio k, relative crater depth k_1, and relative crater width k_2 of the specimens after LSP with different laser energy value. It can be seen that with the increase of laser energy, the stress loss ratio k, relative crater depth k_1, and relative crater width k_2 show a large increase. This shows that the intensity of the secondary plastic deformation in the laser projection center is positively related to the laser energy. The influence of laser energy on the relative crater depth k_1 is

Table 1 The parameters of laser shock

Spot condition	Parameters	Parameter value	Constant parameters
Single-point LSP	Laser energy E/J	1.0, 1.5, 2.0, 2.5, 3.0	$T = 1, D = 2$
	Repeated shock times T	1, 2, 3, 4, 5	$E = 2, D = 2$
	Diameter of spot D/mm	1.0, 1.5, 2.0, 2.5, 3.0	$E = 2, T = 1$
Overlapping LSP	Overlap ratio η/%	30, 40, 50, 60, 70	$E = 2, T = 1, D = 2$

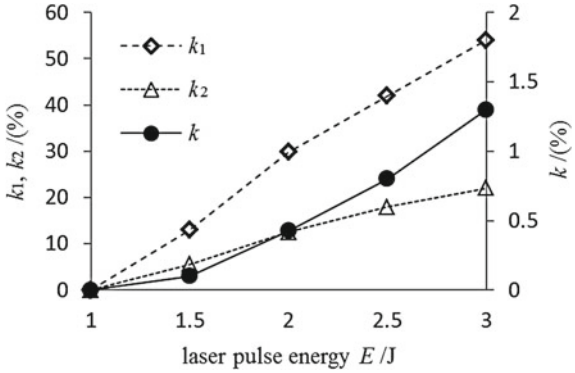

Fig. 3 Influence of laser pulse energy E

significantly greater than that on the relative crater width k_2. In addition, the value of stress loss ratio k is always less than 2% among the energy range of Fig. 3. But it cannot be considered that the residual stress on the surface is uniform because when the laser energy is 3 J, the relative crater depth k_1 has exceeded 50%.

3.2 Effect of Laser Spot Diameter D *on RSH*

Figure 4 shows the residual stress loss ratio k, relative crater depth k_1, and relative crater width k_2 of the specimens after LSP with different spot diameter. It can be seen that with the increase of the spot diameter, the stress loss ratio k and the relative crater depth k_1 are obviously decreased, while the relative crater width k_2 is relatively stable, which shows that the hole size changes synchronously with the spot size. In addition, when the spot diameter increase from 1 to 3 mm, the relative crater depth k_1 decreases from 68% to about 13%, which indicates that the loss of residual compressive stress is significantly reduced.

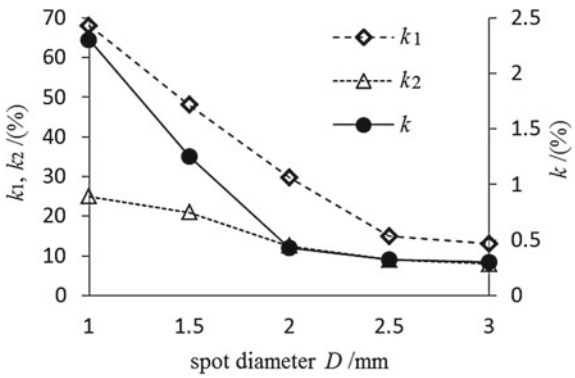

Fig. 4 Influence of spot diameter D

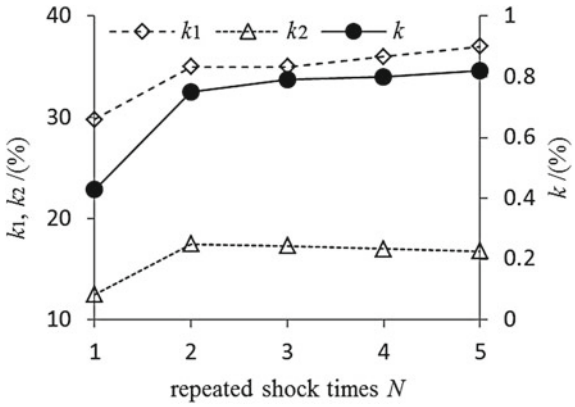

Fig. 5 Influence of shock times *N*

3.3 Effect of Repeated Shock Times N *on RSH*

Figure 5 shows the residual stress loss ratio k, relative crater depth k_1, and relative crater width k_2 of the specimens after LSP with different repeated shock times. It can be seen that with the increase of repeated shock times, the stress loss ratio k and relative crater depth k_1 increased. And the most obvious increase occurs in the second shock. After the second shock, k_1 and k_2 tend to be stable. The impact mechanism of increasing repeated shock times on RSH is similar to that of increasing laser energy. The material undergoes work hardening during the first shocking, which makes it more difficult for secondary plastic deformation during subsequent shocking. Therefore, starting from the second shocking, the stress loss ratio k and the relative crater depth k_1 tend to stabilize. The stress loss ratio k increases from 0.4 to 0.8% when the number of repeated shock times increases from 1 to 5. It shows that increasing the number of repeated shock times can improve the level of residual compressive stress, but the loss of residual stresses is still serious.

3.4 Effect of Overlap Ratio H *on RSH*

The overlap ratio η refers to the overlapping ratio of adjacent light spots in the direction of the centerline, which can be calculated according to Fig. 6, that is:

$$\eta = L/D \times 100\% \tag{5}$$

Figure 7 shows the residual stress loss ratio k, relative crater depth k_1, and relative crater width k_2 of the specimens after LSP with different overlap ratio values. It can be seen that with the increase of overlap ratio, the stress loss ratio k, relative crater depth k_1, and relative crater width k_2 all decrease significantly. When the overlap ratio increases from 30 to 70%, the relative crater depth k_1 decreases from 14 to

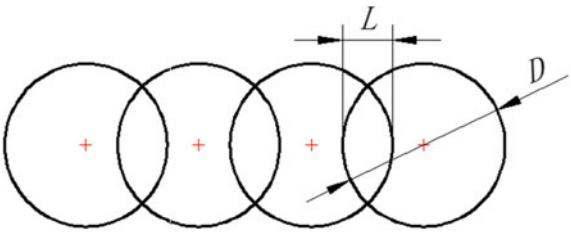

Fig. 6 The calculation of overlap ratio. (Color figure online)

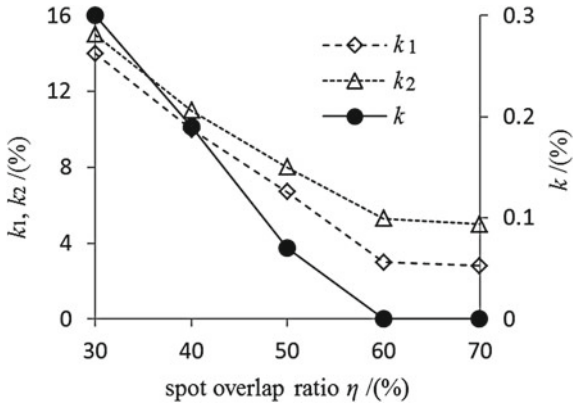

Fig. 7 Influence of overlap ratio η

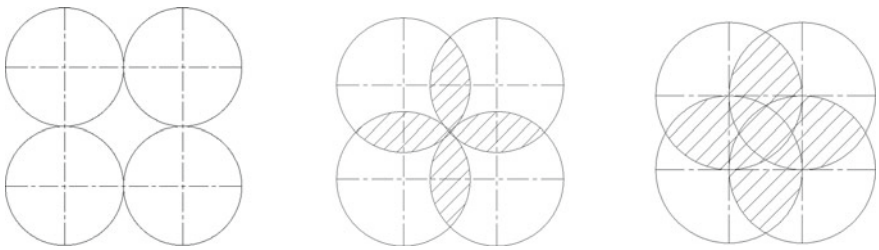
2.8%, and the stress loss ratio k decreases from 0.3 to 0%. This is because when the overlap ratio increased, the light spots overlap with each other, and the position where the surface residual stress generated by a spot may superpose with an adjacent spot. Thereby, a complementary effect formed, and the uniformity of the residual stress on the surface is improved.

In addition, the residual stress loss does not decrease linearly with the increase of the overlap ratio, and it does not change much when the overlap ratio is larger than 60%. The spot diameter used in this group of tests is 2 mm, and the RSH radius of single point and one-time LSP is about 0.6 mm. If the distance between the adjacent spot centers is set to 0.6 mm, the spot overlap rate $\eta = 60\%$. According to the experimental data, when the center distance between the adjacent spots is equal to the radius of the RSH, the uniformity of residual stress was improved obviously. However, if the overlap ratio of the spot is further increased, the uniformity of the residual stress will not be significantly improved, and the work efficiency will be reduced.



4 Results Analysis and Discussion

According to Sect. 3, the stress loss ratio k caused by the RSH is not large and, basically, less than 2.5%. The influence of LSP parameters on relative crater width k_2 is relatively small and, basically, less than 25%. The relative crater depth k_1 is very sensitive to changes of LSP parameters, and the variation range of k_1 is 0–68%. Therefore, the main impact factor on the stress loss ratio k is relative crater depth k_1, which will seriously affect the uniformity of residual stress distribution on the surface.

It can be obtained from Sect. 3 that when the laser energy E increase from 1 to 5 J, or the repeated shock times N increase from 1 to 2 times, the stress loss ratio k increase significantly. When the spot diameter D increase from 1 to 2.5 mm, or the overlap ratio η increase from 30 to 60%, the stress loss ratio k is reduced greatly.

The surface residual compressive stress level can be increased by increasing the repeated shock times or the overlap ratio. In terms of improving the uniformity of the residual stress, a large overlap ratio has obvious effects. The overlap ratio is easy to implement in practice and is an effective way to improve the uniformity of residual stress.

The overlap ratio in engineering is generally selected based on the overlapping features of the spot geometry, such as the typical overlap ratio of 0, 29.3, and 50%, as shown in Fig. 8. However, the existence of RSH was not taken into consideration when trying to improve the uniformity of the residual stress on the surface. Therefore, the uneven distribution of surface residual stress cannot be effectively suppressed. If the center distance between the adjacent spot is equal to the radius of RSH, the loss of the residual stress can be compensated to the greatest extent so as to obtain a better distribution uniformity of the surface residual stress with higher efficiency of LSP.

(a) η=0% (b) η=29.3% (c)η=50%

Fig. 8 The common overlap ratio

5 Conclusions

(1) Quantitative analysis indexes for residual stress hole were proposed, such as relative crater depth k_1, relative crater width k_2, and residual stress loss ratio k. It is found that k is not large (<2.5%), but it will seriously affect the uniformity of the residual stress on the surface of the component, and the degree of unevenness may even reach 68%. Relative crater depth k_1 is the main factor that causes uneven distribution of residual stress.
(2) As the laser shock energy or shock times increases, the degree of residual stress loss becomes more severe. Conversely, as the spot diameter or spot overlap ratio increases, the degree of residual stress loss decrease.
(3) In the case of constant laser shock energy, in order to increase the residual compressive stress on the surface and improve the uniformity of its distribution, it is recommended to use the spot overlap LSP instead of increasing the shock times at the same location.
(4) The spot overlap ratio should be selected to ensure that the distance between adjacent spot centers is equal to the crater radius of RSH.

Simulation and Experimental Analysis of Electromagnetic Pulse Spot Welding of Sheet Metal with a Field Shaper

Hang Zhang, Ning Liu, Qingjian Wang, and Hongfa Ding

Abstract The magnetic pulse spot welding studied in this paper can achieve the connection of sheet metal with the aid of a field shaper. The magnetic field shaper which is placed between the metal components and an electromagnetic coil has the function of concentrating the magnetic field, enhancing the electromagnetic force around the weld zone; meanwhile, it can protect the electromagnetic coil. This paper carried out a numerical simulation of the principle of the field shaper for magnetic pulse welding of sheet metal by means of the FEA software COMSOL. The electromagnetic and structural parameters of the high-strength coil and field shaper have been designed, and an electromagnetic welding platform is built, the welding experiments of 304 stainless steel sheet and 1060 aluminum sheet both with a thickness of 1 mm are carried out, respectively. The experimental results show that the method can achieve the connection of sheet metal very well.

Keywords Magnetic pulse spot welding · Field shaper · Electromagnetic force · Welding platform · COMSOL

1 Introduction

Resistance welding is a commonly used spot welding method, which started in the 1850s and is widely used in the field of industrial manufacturing [1]. Spot welding is a resistance welding method, which is to assemble the weldment into a lap joint and press it between the two columnar electrodes to melt the base metal with resistance heat to form the welding spot. When welding, there is no need for filler metal, high productivity, small deformation of weldment, and easy to realize automation. However, resistance welding needs to meet the condition that the melting point of the metal to be welded is close, which makes resistance welding limited on some occasions. Aluminum and its alloy are widely used on many occasions because of their good mechanical properties and low density. However, when an aluminum

alloy is connected with stainless steel, it is difficult to realize it by traditional resistance welding because of its large melting point difference. Magnetic pulse welding (MPSW) is a solid-state welding technology, which can well weld the same and different metals, and there is no requirement for the melting point of metals [2].

At present, the commonly used electromagnetic pulse welding methods are mainly divided into plate welding and pipe welding [3]. Pipe welding usually uses the combination of the solenoid coil and field shaper [4], which is placed inside or outside the pipe, and the high-speed movement of pipe driven by electromagnetic force collides to complete the welding process. Because of the unique ring shape of pipe fitting, which is conducive to the formation of eddy current and ensures the quality of welding, and the research of electromagnetic pulse welding technology in pipe fitting is also relatively sufficient, so it has been widely used in industry [5].

However, the research on the magnetic pulse welding of plates is relatively less. Among them, Aizawa et al. first designed a method for electromagnetic pulse welding of plates [6]. In this way, the coil made of a single wire drives the plates to accelerate, and the plates move relative to each other and collide with each other at high speed to complete the welding process. However, this method has high requirements for welding equipment. Weddeling et al. designed a new electromagnetic welding method for plates [7], which uses a uniform pressure coil to drive the plate movement, and completed the welding and analysis of aluminum joints. For the first time, Deng used a flat structure field shaper in the magnetic welding of plates, and successfully realized the welding of aluminum and stainless steel [8].

Through the simulation analysis and summarizing of the rules, this paper design a set of welding equipment. The welding equipment is designed to realize the connection between aluminum plate and stainless steel plate. In the following chapters, the basic principles, finite element simulation, and experimental research are introduced, respectively.

2 Basic Principle and Design

2.1 Basic Principle

The MPSW system mainly comprises a charging system, capacitor bank, discharge switch, drive coil, field shaper and plates, as shown in the schematic diagram of Fig. 1. A strong magnetic field is generated by the discharge of the capacitor to the coil, and the field shaper placed between the coil and the plate converges to the magnetic field so that the powerful Lorentz force in the welding area drives the flyer plate to impact the parent plate with high-speed movement to realize the welding. As shown in Fig. 2a, the traditional flat field shaper is a circular platform structure with a straight hole in the center, and there is a slit along the radial direction so that the induced current on the upper surface can flow to the lower surface, and the current density through the lower surface is greater due to the area difference between the

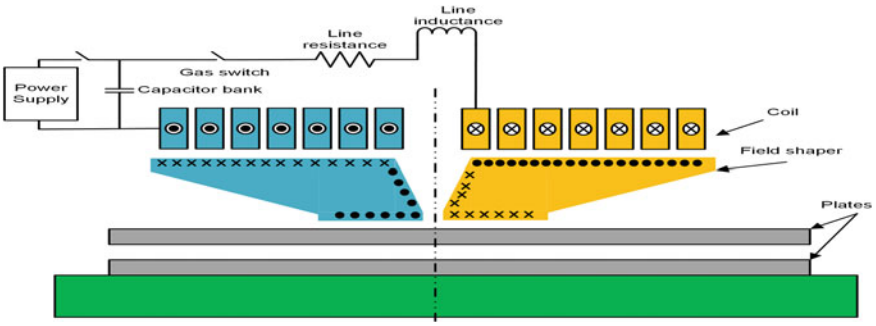

Fig. 1 Schematic diagram of the welding system. (Color figure online)

Fig. 2 **a** Traditional field shaper, **b** optimized field shaper. (Color figure online)

upper and lower surfaces. The instantaneous current in the field shaper induces eddy current in the plate, and the magnetic field generated by the eddy current and the coil current overlaps linearly, resulting in a local strengthened magnetic field, so a huge Lorentz force is generated under the action of the induced current in the plate.

The Lorentz force generated by the field shaper is pulse-shaped. The area with a large Lorentz force deforms and moves first, thereby driving the deformation of other areas. The pulsed electromagnetic force will have the problem that the deformation of some areas is not enough to achieve the welding. In order to overcome this problem, this paper optimizes the structure of the field shaper as shown in Fig. 2b, thus increasing the area of the welding area.

The equivalent circuit model of the MPSW device based on field shaper is shown in Fig. 3. It can be seen that the coil, field shaper and plate are all equivalent to a series connection of resistance and inductance. The field shaper is coupled by the electromagnetic field with the coil and the plate, respectively. The equivalent circuit of magnetic pulse welding satisfies the following equations:

$$i_c = -C\frac{du_c}{dt} \tag{1}$$

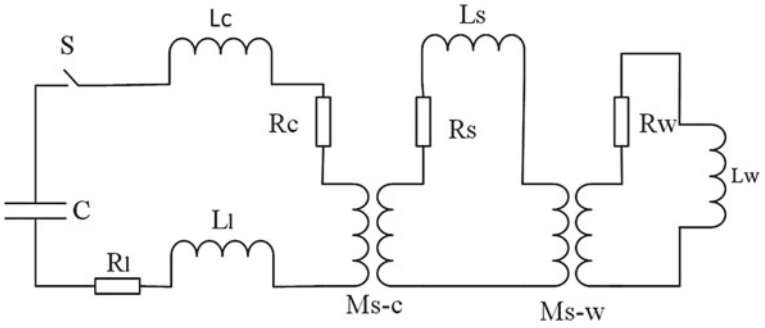

Fig. 3 Equivalent circuit model of EMPW device

$$i_c R_l + L_l \frac{di_c}{dt} + u_{coil} = u_c \tag{2}$$

$$i_c R_c + L_c \frac{di_c}{dt} + M_{s-c} \frac{di_s}{dt} = u_{coil} \tag{3}$$

$$i_s R_s + L_s \frac{di_s}{dt} + M_{s-c} \frac{di_c}{dt} + M_{s-w} \frac{di_w}{dt} = 0 \tag{4}$$

$$i_w R_w + L_w \frac{di_w}{dt} + M_{s-w} \frac{di_s}{dt} = 0 \tag{5}$$

where R_l, R_c, R_s, and R_w represent the equivalent resistance of circuits, coils, collectors, and workpiece, respectively. L_l, L_c, L_s, and L_w represent the equivalent inductance of circuits, coils, collectors, and workpiece, respectively. M_{s-c} and M_{s-w} represent the equivalent mutual inductance.

The essence of the electromagnetic effect of MPSW can be well understood by the equivalent circuit treatment of the system. The equivalent circuit model considers the electromagnetic coupling between components, which can improve the calculation accuracy. The calculation of the equivalent circuit model is less, which can reduce the calculation time and improve the processing efficiency.

2.2 Numerical Model

There is a strong coupling relation between the electromagnetic and structure fields in the electromagnetic pulse welding process. Finite element modeling is a reliable simulation tool to solve the problem of complete coupling in MPSW calculation. Compared with the advantages and disadvantages of many finite element software, COMSOL is used to simulate the process of electromagnetic welding in this paper. The software can couple the circuit, electromagnetic field, and structure field in order,

and get more accurate results. In order to facilitate the simulation analysis, this paper decided to adopt the 2-D model, but the existence of the gap in the field shaper led to the non-axisymmetric structure of the device. In order to simplify the device into the 2-D axisymmetric model, the area of field shaper is set as a single turn coil, and the cross-section current is set as zero in COMSOL.

A 2-D axial symmetry finite element model is developed using COMSOL for the welding system in Fig. 4. The simulation includes three physical models: "Circuit analysis model" to calculate Eqs. (1)–(5) for the discharge current, "Magnetic analysis model" to calculate flux density and electromagnetic, and "Solid mechanics" to simulate the plate deformation behavior caused by the electromagnetic force. The system parameters used in the simulation analysis are listed in Tables 1 and 2. For a discharging voltage of 10 kV, the current waveform obtained through simulation and experimental measurements, respectively, are in good agreement with each other as shown in Fig. 5. Since the first pulse of current is the main function of welding, only the first pulse waveform is taken. The distribution of electromagnetic force and deformation behavior are numerically analyzed, and the nephogram of the electromagnetic force and the deformation behavior of the plates are shown in Fig. 6.

2.3 Welding Device Design

The schematic of the designed welding device is shown in Fig. 7. Two epoxy plates are fixed under the support of the bolt to resist the huge reaction force produced in the welding process. The upper oxygen plate is also used as the coil framework, as shown in Fig. 8a, and the copper conductor with a section of 3×5 mm^2 is wound on

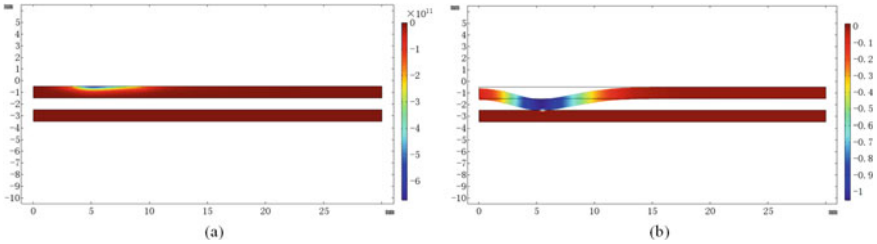

Fig. 6 **a** Nephogram of the electromagnetic force, **b** Nephogram of the deformation behavior. (Color figure online)

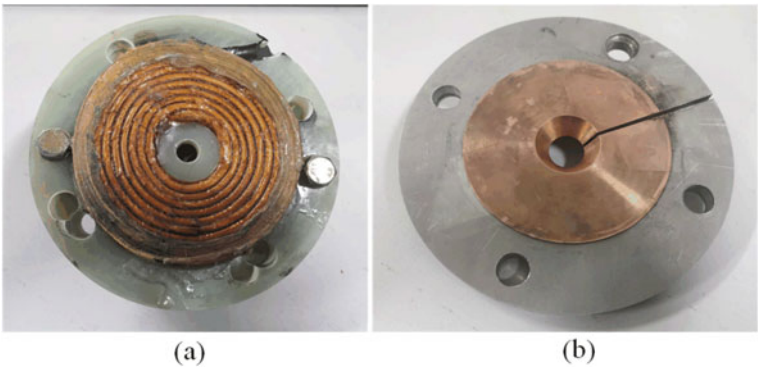

Fig. 8 **a** Coil, **b** stainless steel tray. (Color figure online)

the framework by the winding machine. In order to avoid the local gap of the coil in the winding process, special glue is needed to be used for filling during the winding process. The outermost layer is reinforced by Zylon fibers to prevent the wire from being damaged due to the huge stress and deformation during the discharge process. As the core part of the device, the field shaper will be repelled by both coils and plates during the welding process, so it is urgent to ensure its reliability. By comparing the

properties of various materials, Cu-Cr-Zr can meet the needs. In order to fix and protect the field shaper, it is embedded in a stainless steel tray with a thickness of 10 mm as shown in Fig. 8b. Opening a gap on the stainless steel bracket in the same direction with the gap of the field shaper can cut off the conductive circuit, avoid the short circuit at the gap of the field shaper, and also reduce the eddy current in the stainless steel bracket. All parts are fixed by bolts, and the plate is placed between the epoxy plate and the stainless steel bracket during the welding process.

3 Experiment and Discussion

The equipment used in the experiment is presented in Fig. 9, including a power supply of 200 kJ, a capacitor bank of 100 μF with a peak voltage of 15 kV, the welding device, and the plates.

The welding experiments are carried out under different voltage and different pre-welding gap. Considering the insulation strength of the coil, the maximum discharge voltage is set as 12 kV, and the welding experiments are carried out under the voltage of 7–12 kV by an increase of 0.5 kV and the pre-welding gap of 1–2.5 mm by an increase of 0.25 mm. The welding window was obtained according to welding results, which show the effects of the discharge voltage and pre-welding gap on the welding performance as shown in Fig. 10. It can be seen that effective coordination between the welding voltage and gap is needed for obtaining a good welding performance in the MPSW process. From the results, it can be concluded that the welding of the two sheet metals can be realized when the voltage was over 8 kV.

The following sections analyze the welding samples, which were welded by the optimized field shaper with the discharge voltage of 10 kV and the pre-welding gap of 1.5 mm. The appearance of the welding sample is shown in Fig. 11a. It can be seen that the deformation area of the plate exactly coincides with the lower contour of the field shaper. The bulge area corresponds to the central hole of the field shaper.

Fig. 9 **a** Power supply, **b** capacitor bank, **c** welding device. (Color figure online)

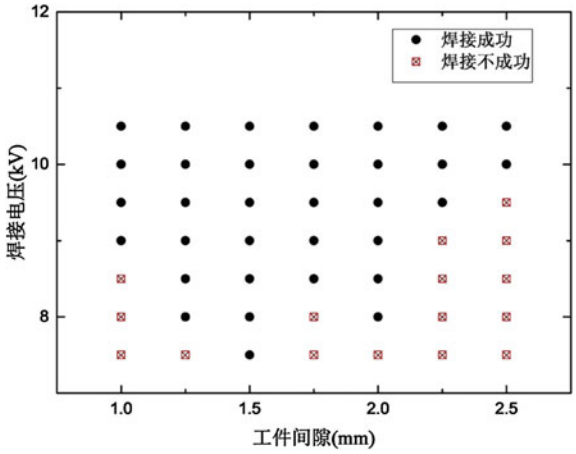

Fig. 10 Schematic of the designed welding device. (Color figure online)

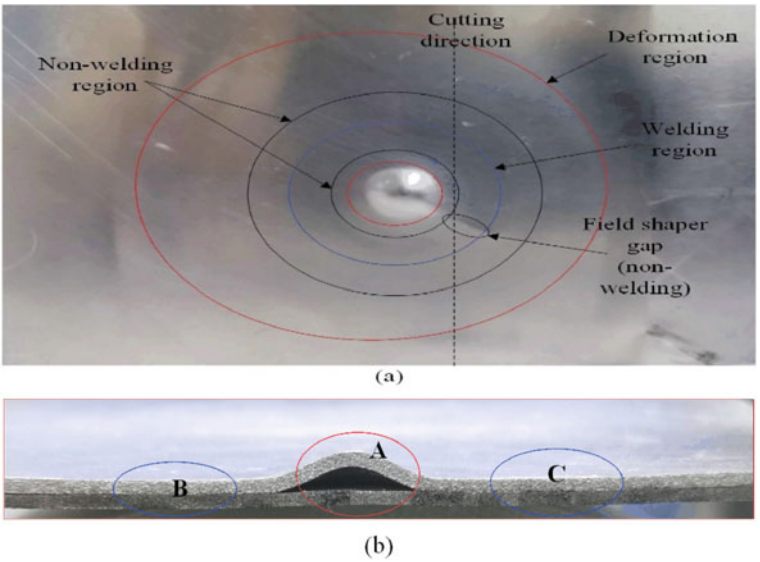

Fig. 11 **a** Appearance of the welding sample, **b** section of the welding sample. (Color figure online)

The welding area is located at the periphery of the bulge area. The non-welding area is mainly divided into two parts, one part is between the bulge area and the welding area and the outermost area, the other part corresponds to the gap of the field shaper. The welding device completes the local welding of the plates.

In order to study the detailed characteristics of welding, the section analysis of the welding sample is carried out in this paper. The cutting direction of the interface

is shown in Fig. 11a. In Fig. 11b, we can clearly see the bulge part in the center of the deformation area in region A, and both regions B and C are well welded.

4 Conclusion

In this paper, the welding device for the plate welding is designed, which is verified by simulation and experiment. A 1060 aluminum alloy sheet of thickness 1 mm can be effectively actuated by the use of the high-strength coil system with a field shaper and welded to a 304 stainless steel sheet with the same thickness at a capacitor discharge voltage of 7.5 kV. Also, an effective coordination between the welding voltage and gap is needed for obtaining a good welding performance in the MPSW process.

Mechanical Properties of Aluminium/Stainless Steel Bimetal Composite Fabricated by Extrusion Process

Kai Soon Fong, Danno Atsushi, Dharmesh Kumar, Wee Kiat Ong, and Suwat Jirathearanat

Abstract In this work, an indirect extrusion process was designed to manufacture a stainless steel reinforced aluminium composite. The design utilized a feeding mandrel to prevent the deformation of the stainless steel wire and to facilitate the embedding of the wire within the aluminium alloy during extrusion. By using this method, a 12 mm diameter 6061 aluminium alloy embedded with a 2 mm diameter 304 stainless steel wire was successfully fabricated. Energy-dispersive X-ray spectroscopy revealed that aluminium and iron elements had diffused into the interfacial layer between the aluminium/stainless steel to induce some degree of metallurgical bonding. The yield strength, tensile strength, and elongation to failure of the extruded composite after solution and ageing heat treatment were 343.8 ± 5.5 MPa, 405.3 ± 5.1 MPa, and 18.0 ± 1.3%, respectively. As compared to extruded aluminium, yield strength, ultimate tensile strength, and elongation to failure were improved by 41.8%, 31.6%, and 6.3%, respectively. This result suggests that the composite material has better strength and toughness as compared to aluminium alone.

Keywords Metallic composite · Backward extrusion · Indirect extrusion · Aluminium fastener · Aluminium alloy · Stainless steel

1 Introduction

A metallic composite structure consisting of two or more metals was developed to achieve unique and better mechanical performances by combining the advantages of the different metals [1–5]. Kleiner et al. [5] demonstrated a method to produce aluminium and steel composite by the extrusion process. In this process, a modified extrusion tooling with supply channels was designed to continuously or selectively feed steel wires or steel wire ropes into the aluminium to improve its strength. The aim was to make the extrusion process more economical for manufacturing high-strength metallic composite structures by overcoming the current disadvantages seen in metal

matrix composites (MMC) extrusion. MMC extrusion, such as particle or short fibre reinforced aluminium profiles, is manufactured by extrusion of a reinforced billet prepared from powder metallurgy. This method leads to a significantly higher extrusion force, increases tool wear, and imposes a limitation on the minimum wall thickness that can be extruded. However, by feeding the reinforcement wires during the extrusion process, the extrusion force can be significantly reduced which reduces tool wear. Also, the manufacturing cost will be lower since a normal aluminium billet can be used. Based on this work, other studies were conducted to expand the process capabilities such as open die hot forging process for post-shaping the aluminium composite [6], a method for achieving functionally graded properties along with the extruded profiles [7], method of embedding of non-metallic material [7], die design optimization for embedding lower strength materials [8], and fabrication of a "nervous" structure by the embedding of shape memory alloy [9].

In this study, a simplified indirect extrusion tooling was designed for the manufacturing stainless steel wire reinforced aluminium composite, suitable for low-volume manufacturing of small composite components. To reduce the cost and productivity, a general-purpose 100 ton vertical hydraulic forming press was used instead of a horizontal extrusion press typically used for continuous extrusion for aluminium profiles. To examine the quality of the composite extrusion, the joining interface was investigated by scanning electron microscope (SEM) and energy-dispersive X-ray spectroscopy (EDX), the mechanical properties were examined by tensile tests, and the fracture morphology was examined by SEM.

2 Experimental Procedure

2.1 Materials and Experimental Setup

The materials used in the extrusion tests were 6061 aluminium and 304 stainless steel (spring temper). Figure 1a shows a schematic of the indirect extrusion process to illustrate the configuration of the workpieces before the start of extrusion. In this study, the aluminium preform has a height of 50 mm, an outer diameter of 38 mm in diameter, a centre hole diameter of 2.2 mm, and a machined profile at the base of the preform for inserting over the mandrel. The diameter of the stainless steel wire was 2 mm with a total length of 280 mm. The outer surface of the wire was prepared with silicon carbide grinding paper and cleaned with isopropyl alcohol. The inner surface of the centre hole diameter in the aluminium preform was prepared by wire brushing and rinsed with isopropyl alcohol. The extrusion tests were performed using a 100 ton hydraulic press and the extrusion speed was 5 mm/s. The container die was preheated to 420/450 °C and allowed to dwell for 15 min before the start of the extrusion tests.

The aluminium preform was first dropped into the container die. After which, the wire was manually inserted into the centre hole of the aluminium preform from

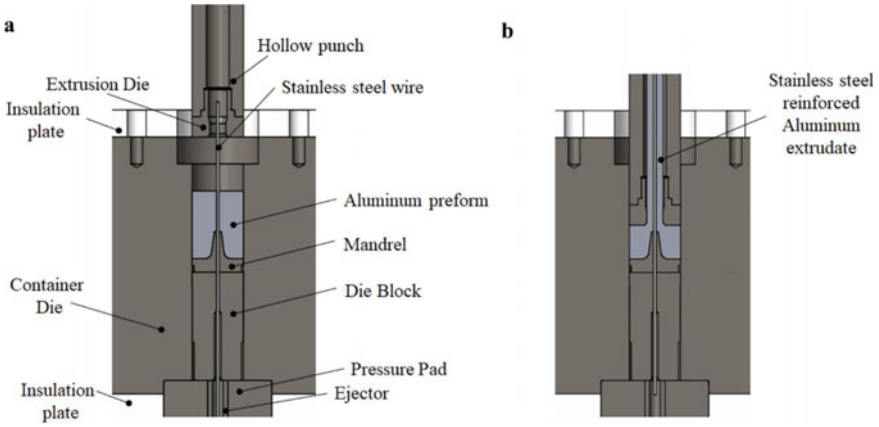

Fig. 1 **a** Schematic diagram of the indirect extrusion tooling and forming process before extrusion, **b** after extrusion. (Color figure online)

the top, and into the centre holes of the mandrel and die block. Both the aluminium preform and stainless steel wire were heated within the container for 15 min before extrusion.

Figure 1b shows a schematic of the aluminium and stainless steel composite after extrusion. By using the mandrel, the wire can be continuously embedded and drawn into the aluminium alloy without fracture or significant deformation. The extrusion die hole diameter, bearing length, and extrusion ratio was 12 mm, 10 mm, and 10, respectively. The aluminium/stainless steel composite was ejected from the container die after extrusion and allowed to cool in air.

Figure 2a, b show the images of the tooling and the extruded aluminium/stainless steel composite, respectively. For benchmarking purpose, an aluminium alloy without

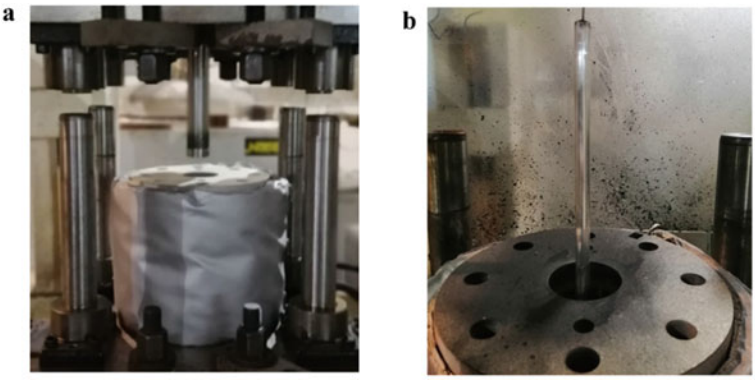

Fig. 2 **a** Experimental tooling, **b** image of the extruded aluminium/stainless steel composite. (Color figure online)

wire was also extruded. For the tensile tests, all the extruded samples were subjected to T6 heat treatment which consists of a solution treatment at 545 °C for 60 min and artificial ageing at 177 °C for 8 h.

The aluminium/stainless steel interface was examined using a scanning electron microscope (SEM) and energy-dispersive X-ray spectroscopy (EDX). Tensile tests were performed on Instron 5982 testing machine at room temperature with a nominal strain rate of 10^{-3} s^{-1}. Cylindrical tensile samples with a gauge length of 24 mm and a diameter of 6 mm were machined from the extrusion. A minimum of three tensile specimens was tested to ensure repeatable stress–strain curves and for obtaining an average yield strength, tensile strength, and total elongation. Computed tomography (CT) of the extruded samples were performed using GE Phoenix v|tome|x m 3D CT metrology system (GE sensing and Inspection Technologies GMBH) equipped with a 180 kV Nanofocus X-ray tube. The CT scanning parameters were 160 kV tube voltage, 200 μA tube current, 15 μm voxel size, 14 μm focal spot size, and 100 μm detector pixel size.

2.2 Simulation Procedures

The extrusion of 6061 aluminium and 304 stainless steel wire was simulated using the commercial FE software DEFORM 3D. A 1/4 section model was carried out to reduce computation time. Rigid-visco-plastic deformation and thermal effects were incorporated in this simulation. The friction between the die and the specimen interface was expressed by using the friction model defined as follows:

$$\tau = mk = m\frac{\tilde{\sigma}}{\sqrt{3}} \tag{1}$$

where τ is the shear stress, m is the friction factor, k is the shear strength, and $\tilde{\sigma}$ is the flow stress of the specimen material. The exact friction coefficient between the materials depends on the temperature and pressure and is not fully understood or can be mathematically expressed. For the current study, high friction between the aluminium and stainless steel materials were utilized which appropriately represent the extruded samples observed in the experiments. The friction factor of 0.8 was assumed at the billet-container and die interface and 0.4 was assumed at the die bearing interface [10]. The friction between stainless steel interface heat transfer coefficients is generally a complex function determined by the interface pressure, amount of sliding, and interface temperature. In the current study, the interface friction was assumed to be 1.0 to represent bonding of the two materials. The details of the simulation parameters are shown in Table 1.

Table 1 FE simulation parameters

Parameters	Description/values
Billet material	6061 aluminium
Wire material	AISI 304
Die material	H13
Friction factor between aluminium and tool	0.8
Friction factor at die bearing	0.4
Friction factor at aluminium/stainless steel	1.0
Heat transfer coefficient between tooling and air (N s^{-1} mm^{-1} $°C^{-1}$)	0.02
Heat transfer coefficient between tooling and aluminium material (N s^{-1} mm^{-1} $°C^{-1}$)	20
Heat transfer coefficient between aluminium and stainless steel material (N s^{-1} mm^{-1} $°C^{-1}$)	11
6061 thermal conductivity (N s^{-1} $°C^{-1}$)	180.175
6061 heat capacity (N mm^{-2} $°C^{-1}$)	2.43
304 thermal conductivity (N s^{-1} $°C^{-1}$)	20.0
304 heat capacity (N mm^{-2} $°C^{-1}$)	3.7

3 Results and Discussion

3.1 Optimization of the Mandrel to Extrusion Die Distance by Simulation

The simulation results of the indirect extrusion process without and with mandrels are shown in Fig. 3a–c. As shown in Fig. 3a, when mandrel was not used, the wire was subjected to deformation together with the aluminium which led to deformation and subsequent fracture near the start of the extrusion process. This was because of the excessive pressure built up at the bottom of the wire-aluminium interface which tightly constraint the wire from sliding and prevent it from moving together with the aluminium material. Figure 3b–c shows the initial distance, d, between the extrusion die and mandrel that has to be optimized to prevent wire deformation. From this simulation study, d had to be not more than 20 mm for the wire to be successfully drawn into the aluminium extrudate without failure. It was demonstrated that the mandrel is effective in reducing the pressure and friction at the aluminium/wire interface and thus help to facilitate the drawn-in of the wire into the aluminium extrudate during the extrusion process. The use of a feeding mandrel inevitably limits how much material can be extruded without the mandrel colliding or being too close to extrusion die. However, depending on the extrusion ratio, a small amount of billet height reduction can result in a sufficiently long extrusion. In this case, an extrusion die exit diameter of 12 mm and an initial billet diameter of 38 mm can

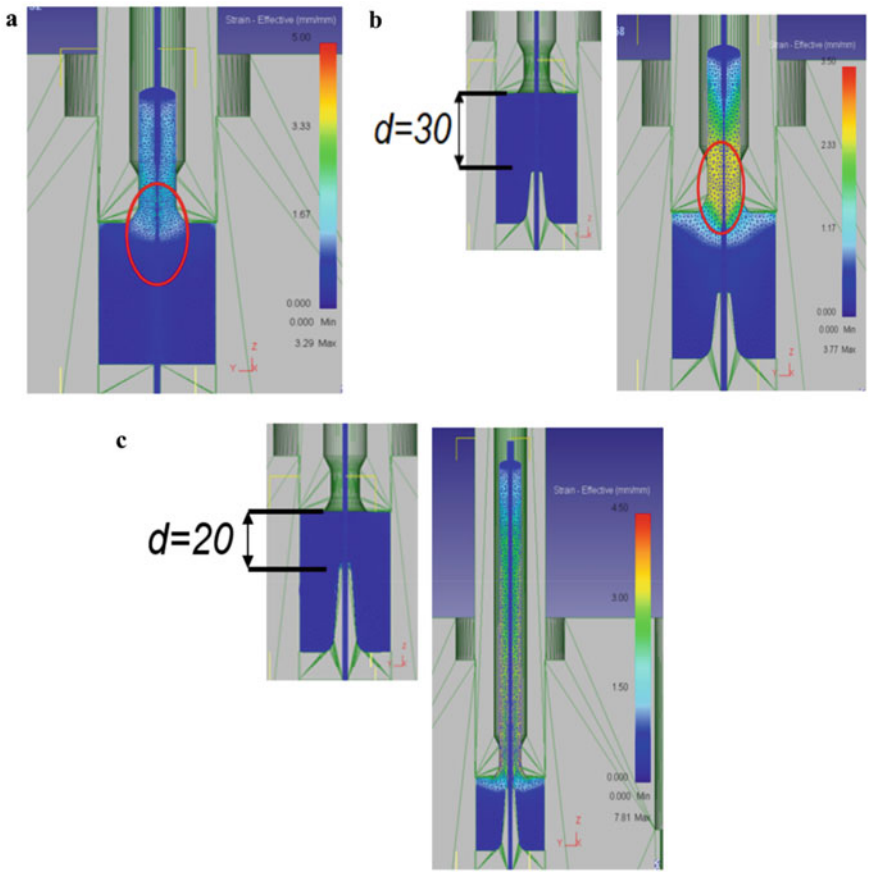

Fig. 3 **a** Wire fractured without mandrel, **b** wire fractured with mandrel d = 30 mm, **c** wire intact with mandrel d = 20 mm. (Color figure online)

result in around 200 mm extruded length with just 20 mm reduction in the billet height.

3.2 Observation of Extruded Composite

Figure 4a shows a sample of the composite extruded with feeding mandrel of d = 30 mm. In this case, the wire was fractured within the extrudate and this was determined simply by measuring the total length of the wire before and after extrusion. When there is a fracture, the wire length will be much longer than the initial length and a significant portion of the wire can be observed to remain below the billet (on the left in the picture) and not drawn into the extrusion. Figure 4b shows the samples

Fig. 4 **a** Extruded sample (wire fractured) without mandrel, **b** extrude samples (wire intact) with mandrel, d = 20 mm. (Color figure online)

extruded using the feeding mandrel with d = 20 mm. The wires were not broken based on the length measurements and the wires were observed to have drawn into the aluminium extrusion with little length remaining below the billet.

CT scanning measurements were also performed on the samples extruded with mandrel d = 20 and 30 mm, as shown in Fig. 5a–d. As shown in the 2D overview scanned results, the wire was not fractured during extrusion when mandrel d = 20 mm was used. These measurements show good agreement with the simulation results. As shown in the detailed cross-sectional CT scan results in Fig. 5c–d, the process is well capable of embedding the stainless steel wire in the middle of the extrudate without any observable delamination or defects.

3.3 SEM Examination of the Aluminium and Steel Interface

Figure 6a, b displayed the SEM image of the aluminium/stainless steel composite and the interfacial morphology between the aluminium and stainless steel after extrusion, respectively. As shown in Fig. 6b, a slightly wavy aluminium/stainless steel interface was created after extrusion without any gap. Furthermore, a thin interface was observed between the two materials. The interface was further analyzed by EDX and the elemental mapping is shown in Fig. 6b. It was revealed that this was a diffusion interface layer of ~500 nm in thickness, and a gradient of Al and Fe atom content distribution was formed at this interface. This suggests that the extrusion process was able to induce a certain extent of metallurgical bonding between the aluminium/stainless steel composite. The extrusion pressure and high extrusion temperature may have promoted the diffusion of Al and Fe atoms from the aluminium and stainless steel material, respectively, to create a diffusion layer. This distribution

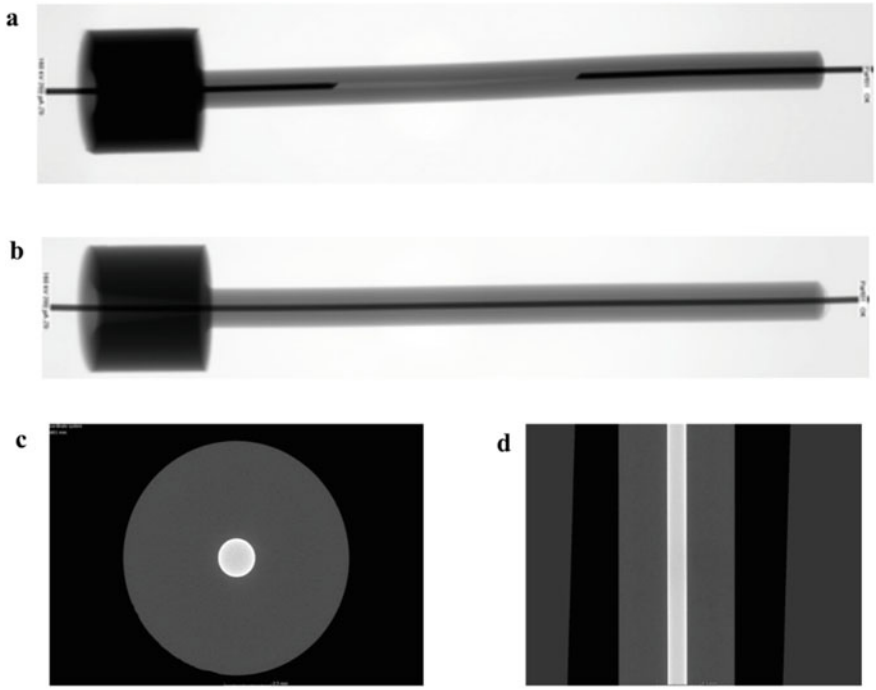

Fig. 5 **a** 2D overview CT scan results of the composite extruded with mandrel d = 30 (**a**), **b** composite extruded with mandrel d = 20, **c** cross-sectional CT analysis of the composite extruded (mandrel d = 20) at the plane perpendicular to the extrusion direction, **d** cross-sectional CT analysis of the composite extruded (mandrel d = 20) at the plane parallel to the extrusion direction. (Color figure online)

of elements was similar to what was observed in the interface layer between 6061 aluminium alloy and 304 stainless steel prepared by laser-metal inert-gas welding [11].

3.4 Mechanical Properties

Figure 7a shows the engineering stress–strain curves of the different extruded samples. A comparison of the values of the yield strength, ultimate tensile strength, and elongation to failure of the different samples are shown in Fig. 7b. From Fig. 7a–b, it can be clearly seen that aluminium/stainless steel composite resulted in a significant improvement in mechanical strength without scarifying ductility. The results of the composites extruded at 420 and 450 °C were quite similar with the latter having slightly better properties. The yield strength, ultimate tensile strength, and elongation to failure of aluminium alloy after extrusion were 242.5 ± 2.5 MPa, 308 ± 7.1 MPa,

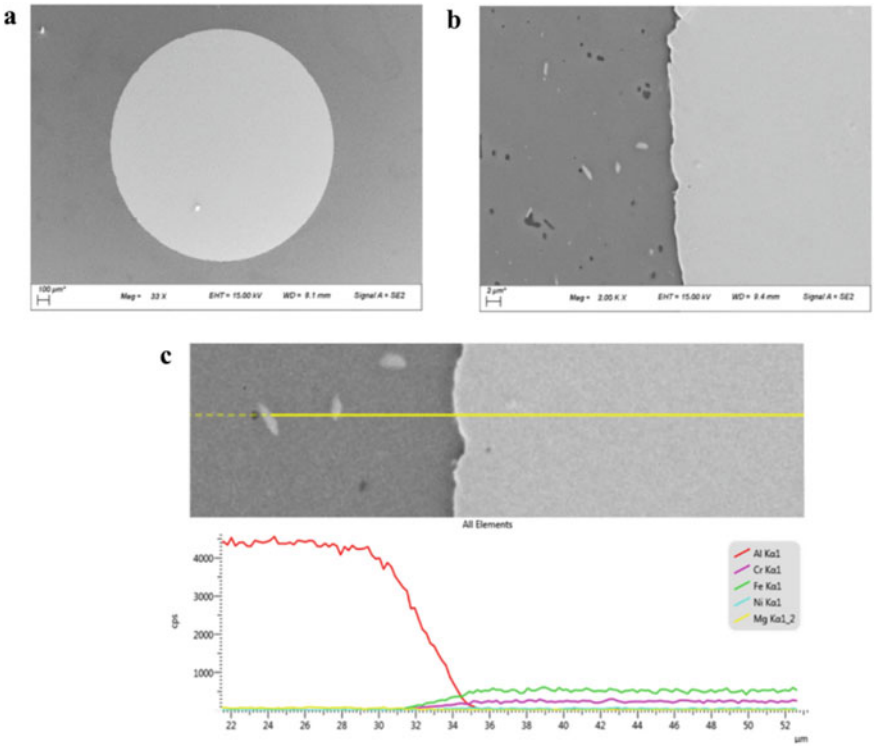

Fig. 6 **a** SEM image of aluminium/stainless steel composite, **b** SEM image of the aluminium/stainless steel interface, **c** EDX analysis of the chemical composition in the aluminium/stainless steel interface. (Color figure online)

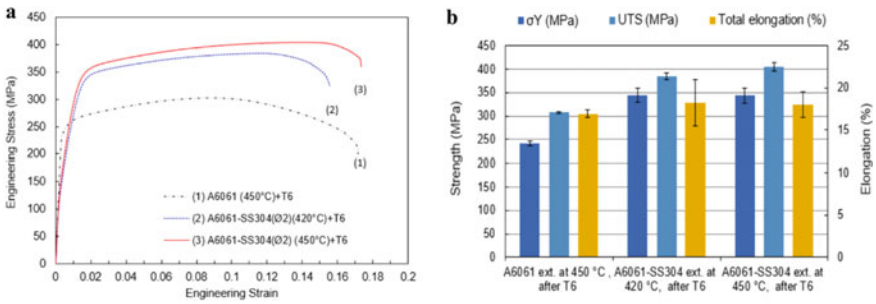

Fig. 7 **a** Engineering stress–strain curves of the aluminium/stainless steel composite, **b** yield strength, ultimate tensile strength, and elongation to failure of the aluminium/stainless steel composite. (Color figure online)

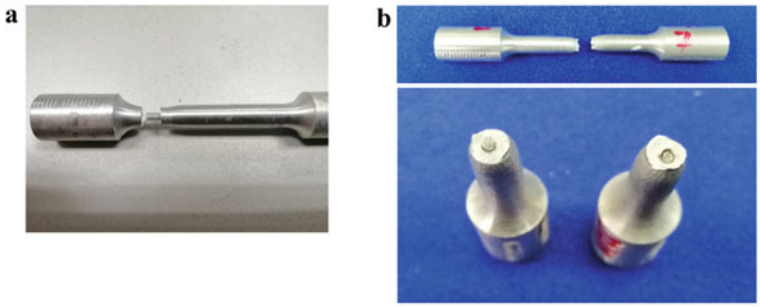

Fig. 8 **a** Failure of the tensile specimen in non-metallurgical bonded condition, **b** failure of the tensile specimen in the metallurgically bonded condition. (Color figure online)

and 16.95 ± 1.2%, respectively. The yield strength, ultimate tensile strength, and elongation to failure of aluminium/stainless steel composite extruded at 450 °C were 343.8 ± 5.5 MPa, 405.3 ± 5.1 MPa, and 18.0 ± 1.3%, respectively. This translated into an overall improvement of yield strength, ultimate tensile strength, and elongation to failure by 41.8%, 31.6%, and 6.3%, respectively. This result suggests that the composite material has better strength and toughness as compared to aluminium alone.

Figure 8 shows the images of the failures of the aluminium/steel composite tensile specimens. The tensile failure in the case of insufficient metallurgical bonding at the aluminium/stainless steel interface is shown in Fig. 8a. In this case, delamination of the wire/aluminium interface occurred early in the tensile test and resulted in the wire slipping from the aluminium alloy. Insufficient bonding can happen when surface contamination and oxide layers were not properly removed during the surface preparation and cleaning steps. If sufficient metallurgical bonding had occurred, the failure will appear like what was observed in Fig. 8b. Here, it can be seen that both materials fractured together. This was only possible because the interface bonding strength was high enough to prevent the wire from slipping.

3.5 Fracture Morphology

The fracture morphology was examined under SEM and the results are shown in Fig. 9a–b. The fracture surfaces of the stainless steel wire are shown in Fig. 9b location 1 and 2. The fracture surface at the middle (location 1) of the wire contained dimples of varied size and depth. The outer area (location 2) of the wire displayed more cleavage facets which was an indication of shear fracture mode. From Fig. 9a, it can be seen that necking of the wire occurred before fracture. These observations suggest that the wire failed by ductile–brittle fracture mode.

The fracture surfaces of aluminium are shown in locations 3 and 4 that contained a high fraction of dimples and were more uniform as compared to that of the wire

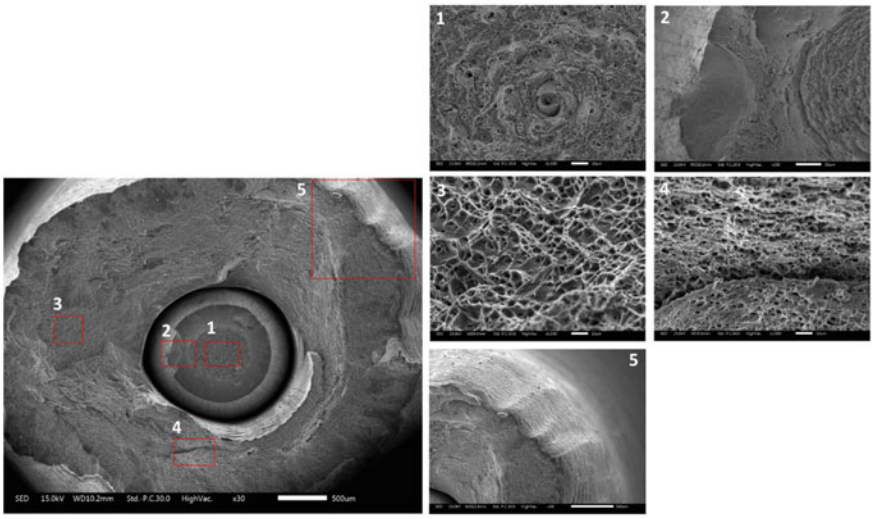

Fig. 9 **a** Fracture morphology of the aluminium/stainless steel tensile specimen, **b** enlarge images of the fracture surface at different areas of the tensile specimen. (Color figure online)

fracture surface. These fibrous appearances and the cup-and-cone fracture appearance of the tensile specimens (in Fig. 8b) were indicative of a ductile fracture mode. Location 4 shows one of the typical appearances of a discontinuity of the fracture surface that were observed in the aluminium material. This occurred due to the sudden dislodged of the material caused by the constraint imposed by the secondary wire material. Location 5 shows the image of the outer edge of the aluminium material which appeared wrinkled and supposedly caused by the constraint imposed by the wire. This observation suggests that the wire was metallurgically bonded to the aluminium material which agrees well with EDX analysis shown in Fig. 6.

4 Conclusions

A bimetal 6061 aluminium alloy and 304 stainless steel cylindrical extrusion rod of 12 mm diameter and 200 mm length were successfully manufactured by indirect extrusion process. From this study, the following conclusions can be made:

(1) FEM simulation and experiment confirmed that an initial distance of not more than 20 mm between the feeding mandrel and extrusion die was necessary to ensure that wire deformation can be avoided and for it to be drawn into the aluminium extradite.

(2) A diffusion interface layer, containing both Al and Fe atoms, of 500 nm in thickness was observed between the aluminium and stainless steel materials. This suggests that the extrusion pressure and temperature were high enough

to promote the diffusion of Al and Fe atoms from the aluminium and stainless steel material to create a metallurgical bonding.

(3) After solution and ageing heat treatment, the yield strength, ultimate tensile strength, and elongation to failure of the bimetal composite were 343.8 ± 5.5 MPa, 405.3 ± 5.1 MPa, and 18.0 ± 1.3%, respectively. When compared to the extruded aluminium alloy without wire, the yield strength, ultimate tensile strength, and elongation to failure were improved by 41.8%, 31.6%, and 6.3%, respectively. This result suggests that the composite material has better strength and toughness as compared to aluminium alone.

(4) The fracture surface of stainless steel wire contained dimples and cleavage facets which are indicative of a ductile–brittle fracture mode. The aluminium fracture surface appeared more fibrous with a high fraction of dimples. Furthermore, the presence of discontinuity of fracture surface and wrinkled appearances in the aluminium was indicative of good bonding between the aluminium and stainless steel material.

From Bridge to Bumper: Utilization of Pre-stressing During Manufacturing of Hybrid Sheet Metal Structures

Henning Husmann and Peter Groche

Abstract Pre-stressing is often used in civil engineering to increase the load-bearing capacity of bridges and buildings. In order to exploit this potential in sheet metal structures as well, efficient processes for joining and pre-stressing of tendons are required. Therefore, an approach to join and pre-stress fiber-reinforced plastic (FRP) straps and sheet metals during a forming process is proposed. The FRP strap is placed around two collars drawn into the sheet. A punch plastically expands the collar, while the FRP strap is elastically elongated, resulting in beneficial pre-stresses after unloading due to the different spring-back. In this paper, the predominant mechanism is verified and parameters influencing the pre-stress are identified by experimental and numerical investigations. The hypothesis is investigated that a customized pre-stress and thus a higher strength during the structure's usage can be controlled by varying the collar's expansion. Possible applications include bumpers and side-impact beams.

Keywords Pre-stress · Joining · Forming

1 Introduction

The principle of pre-stressing has been used for hundreds of years to increase the load-bearing capacity and performance of products and structures. Barrels, for example, receive their tightness by a purposeful compression of the individual wooden staves by means of tensioned hoops [1]. But also modern structures are pre-stressed in order to fulfill their function [2]. This is due to the fact that pre-stressing allows versatile possibilities of influencing the properties of functional structures. In addition to increased stiffness and strength [3, 4], the vibration behavior [5], as well as the fatigue strength [6], can be influenced. Applications can be found in a variety of industries. In most cases, compressive stresses are applied to structures at failure-critical locations in order to compensate for tensile stresses that occur during use. Cold forging dies, for example, which are usually made of brittle, high-strength materials,

https://doi.org/10.1007/978-3-030-75381-8_116

are pre-stressed by containers so that their inner wall is set under compressive stresses counteracting the tangential tensile stresses occurring during forming. Thus, higher strength materials can be processed and the number of endurable load cycles can be increased [7]. Further examples are pre-stressing of piezo crystals to bear tensile forces [8], tempering of safety glass in order to increase the bending strength [9], as well as autofrettage of tubes and vessels to bear higher pressures and more load cycles [10].

In structures like bridges, which are mainly submitted to bending loads, a compressive pre-stress at the bottom of the girder can be used to compensate for the tensile stresses arising from external bending loads and thus significantly increase the load-bearing capacity while decreasing the total deflection. This makes it possible to considerably reduce dead loads and to achieve leaner structures. The compressive pre-stress is created by high-strength tendons, which are set under tension and subsequently connected to the structure. After the external tensile load is removed from the tendon, the girder is compressed until the system is in equilibrium. The positive effects of pre-stressing are used in both concrete and steel structures. For concrete constructions, a distinction is made between pre-tensioned and post-tensioned structures. In pre-tensioned structures, the tendons are pre-stressed before the concrete is casted and then molded in the pre-stressed state. In steel construction and in post-tensioned concrete structures, on the other hand, the tendons are attached to a girder after its shape is given [11].

High-strength steels and, more recently, fiber-reinforced plastics (FRP) are used as the material for the tendons. Due to corrosion and in some cases fatigue failure of steel tendons, FRP are increasingly gaining in interest and significance in construction [12]. Here, FRPs are mainly used in the form of strips and laminates made of carbon fiber-reinforced plastics [13]. Numerous research projects dealt with the influence of such pre-stressing systems on the load-bearing behavior of structures. Deuring [3] describes the beneficial effects of pre-stressed carbon fiber-reinforced plastics adhered to the bottom side of concrete beams. By means of four-point bending tests, it was shown that the load carried by the FRP as well as the stiffness and strength of the girder were significantly increased with increasing pre-stress of the tendon [3]. Ghafoori and Motavalli investigated the influence of pre-stressed carbon fiber-reinforced plastic plates attached to steel beams on the flexural behavior. Their investigations showed that the geometric and mechanical properties of the FRP can increase the stiffness and the yield load capacity of the beam, whereas the pre-stress does not affect the stiffness of the beam until cracks occur. Nevertheless, it is possible to both increase the yield and the ultimate load capacity by applying a pre-stress to the FRP [14].

The attachment of the FRP has a considerable influence on the failure behavior of such reinforced structures since very high shear stresses can lead to a premature failure of the FRP or the structure to be reinforced [15]. For this reason, manifold investigations are focused on the development of suitable anchorage systems for FRP tendons in the form of rods, lamellae, straps, and strands. The most common systems are based on bonding or a frictional connection. An extensive overview of the proposed systems can be found in the reviews of Erki and Rizkalla [16], Schlaich

et al. [17] as well as Schmidt et al. [18]. According to Zwingmann [19], bonded and friction-locked connections are usually less suitable for lightweight construction solutions, as they require complex massive metallic anchor bodies to be attached to. Here, pin-loaded straps can be an alternative, since the connection geometry is created out of the lightweight FRP strap itself. For this reason, pin-loaded straps are also used in applications with a high demand for lightweight designs like sailing rigs [19].

Even though the principle of pre-stressing is already used on a large scale in the construction industry and also occasionally in many other areas of technology, it is far from being established in all load-bearing structures. If, for example, sheet metal structures used in cars, trucks, airplanes, and trains are considered, it can be seen that high efforts are being made to increase the performance of the structures at low weight. The approaches range from new materials, complex component geometries, energy-intensive heat treatment processes to hybrid designs employing different materials to decrease the mass of the structures. However, the principle of pre-stressing is not represented. This can be explained by the necessity for complex systems for tensioning and anchoring the tendons. While the effort required for pre-stressing and the weight of the anchor systems have a negligible influence on a structure like a bridge with significant dead loads, mass-produced sheet metal structures, such as those found in cars, are subject to fundamentally different requirements. In addition to an enormous cost pressure prohibiting complex assembly and pre-stressing processes, there are hardly any anchoring systems available that are suitable from a lightweight point of view, as the anchors can easily exceed the weight of the tendon itself.

At the same time, established forming processes for sheet metals offer suitable possibilities to solve these issues, as they allow creating attachment points in an integral form. In addition, spring-back differences after a conjoint forming can be utilized to generate a frictional connection. Marré et al. [20] illustrated this mechanism in the context of joining by hydroforming. As shown in Fig. 1, tube A is placed inside of the joining partner B leaving an initial gap between them. By applying an increasing pressure p on the inside of tube A, the tube is expanded until the gap is closed and the

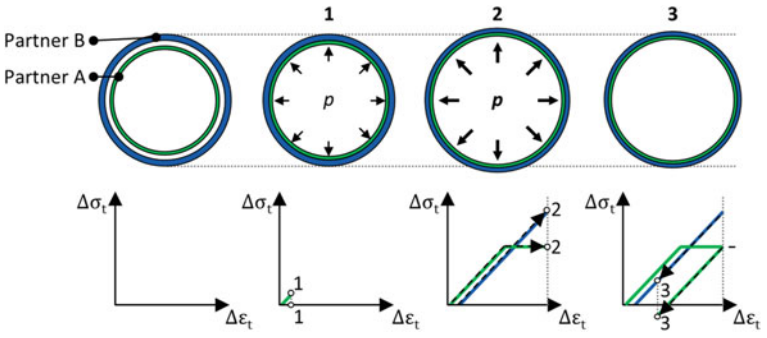

Fig. 1 Mechanism for joining by hydroforming according to Marré et al. [20]. (Color figure online)

two parts are in contact (state 1). A further increase of the pressure leads to a conjoint expansion of both parts. Here the inner part is deformed elastically and plastically, while the outer part only experiences elastic deformations (state 2). After the pressure p has been relieved, the elastic spring-back of the outer part is stopped by the plastically deformed inner part leaving residual stress, which results in a frictional connection. Afterward, the inner part is loaded by compressive tangential stresses σ_t resulting from the outer part which is submitted to tensile stresses (state 3) [20].

2 Joining and Pre-stressing by Widening of an FRP-Wrapped Metal Collar

A novel joining and pre-stressing technique is proposed, which enables the reinforcement of sheet metal structures using continuous fiber-reinforced thermoplastic tapes. The proposed process is shown in Fig. 2. Here, an FRP strap is loosely wound around two collars previously drawn into the sheet metal. Subsequently, one of the collars is widened elastic-plastically using a conical-shaped punch, while the FRP strap is elongated purely elastically. After the punch is retracted, both components spring-back. Here, the FRP strap is prevented from returning to its initial shape by the plastically widened collar. The resulting stresses are used to join the components and to counteract external bending loads submitted to the hybrid structure during its usage.

While the bending stiffness of the resulting structure is to be influenced to a large extent by the geometric shape of the sheet metal and the FRP strap arranged orthogonally to it, the generated pretension shall, in particular, increase the yield and failure strength of the metallic component under bending loads. By varying the expansion ratio of the collar, the pre-stress is to be varied in a targeted manner in order to enable an application-optimized adjustment of the strength against bending. Internal sheet metal components in cars, buses, trains, and airplanes that are subjected to one-sided loads are seen as a promising field of application for the structural components that can be produced with this technology since the structural properties can be influenced, both in terms of design and process technology. This is of particular

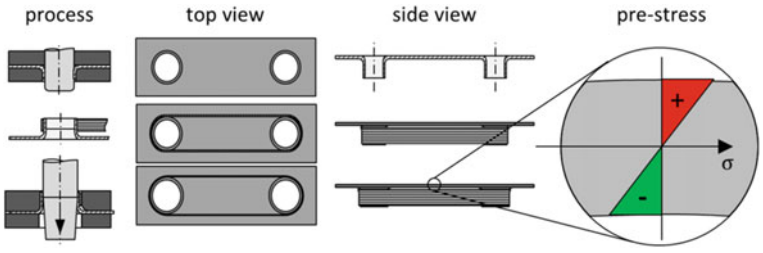

Fig. 2 Proposed joining and pre-stressing process. (Color figure online)

interest for crash structures, as these are subject to strict requirements regarding stiffness, strength, and energy absorption capacity. The possibility of setting different pre-stress values could be used to influence the load-deformation behavior without significantly changing the geometry of the structures.

The assumed structural behavior described shall be investigated and confirmed in the paper at hand. Here, the following hypotheses are to be investigated:

- By means of a plastic expansion of at least one of the two wrapped collars, an FRP strap can be joined to a sheet metal structure and to create a beneficial bending pre-stress
- The generated pre-stress can be significantly influenced, both in terms of design and process technology, thus enabling a targeted influence on the mechanical behavior of the hybrid structure
- A targeted pre-stress counteracting the stresses resulting from an external bending load can increase the maximum failure load of a hybrid structure.

Numerical and experimental investigations are carried out to test these hypotheses. The mechanism for joining and pre-stressing of the hybrid structures as well as the resulting pre-stresses for different process and design parameters are analyzed by means of a finite element simulation. An experimental setup serves for the qualitative validation of the model. Finally, bending tests are performed, to prove the stiffening and reinforcing effect against bending loads.

3 Materials and Methods

3.1 Specimen Geometry and Preparation

The specimens geometry used for the experimental investigations is shown in Fig. 3. The sheet metal structure to be reinforced is represented by a rectangular, laser-cut sheet metal blank made of 1 mm thick steel (DC04, 1.0338) with a width of 50 mm, and a length of 150 mm. Two drilled holes with a diameter of 8 mm are placed in the sheet's center axis with a distance of 100 mm center to center. In a combined

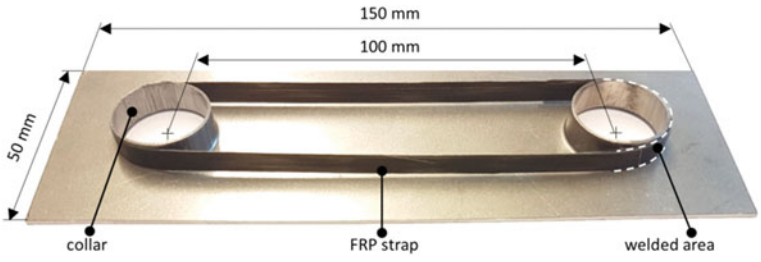

Fig. 3 Specimen geometry. (Color figure online)

collar drawing and wall-ironing process using a die with a diameter of 21.24 mm and a tractrix-shaped punch with a diameter of 20 mm, two collars are produced. Afterward, they are ground to a collar height of 7.5 mm measured from the blank top surface. The collars produced in this way have an inner diameter of 20.00 mm and an outer diameter of approx. 21.27 mm. Finally, an FRP strap with unidirectional fiber orientation and a thickness of 0.25 mm is manually wound around the two collars. In the bending tests performed, the width of the strap is set to 5.5 mm, while a width of 6.5 mm is used for comparison with the numerical results. The glass-fiber-reinforced polyamide tape (*BASF Ultratape B3WG12 UD01*, glass content: 60 wt.%) is locally melted by hot air and welded to itself within the area of the right side collar by applying a slight tension at the tape's free end. For the bending tests, also sheet metal blanks with two collars but without an FRP strap are used as a reference structure.

3.2 Setup for Joining and Pre-stressing of the Hybrid Structures

The experimental setup for widening the collar of the hybrid structures is based on the tool shown in Fig. 4. It consists of a cylindrical punch with a conical tip, a blank holder, a die, and two 3D printed support structures. The diameter of the punch increases from 19.5 mm at the smallest point to 21.5 mm at its maximum. The tapered section has an axial length of 25 mm. It is followed by a cylindrical shaft. The blank holder has a larger inner diameter of 25.5 mm to avoid contact with the collar and two grooves to take in the strap. Thus, it is only contacting the blank on its top planar surface. The die serves to support the sheet during the widening process. It has a hole with a diameter of 21.7 mm so that there is only a small gap between the punch and the die during the widening process, thus preventing the sheet from bending downwards. Two additional sheet supports are arranged next to the blank holder and the die to prevent curvature of the sheet metal due to the increasing pre-stresses. As they are only subjected to minor loads, they are 3D printed using PLA (polylactide), whereas all other tool components are made of steel (1.2379). The upper sheet support has a groove for the strap, while the lower sheet support is flat.

The single-acting tool is used on a 2,500 kN servo press. Figure 5 depicts the

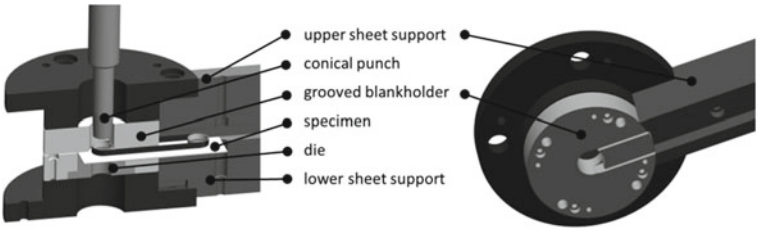

Fig. 4 Sectional view of the tool system (left) and blank holder components (right)

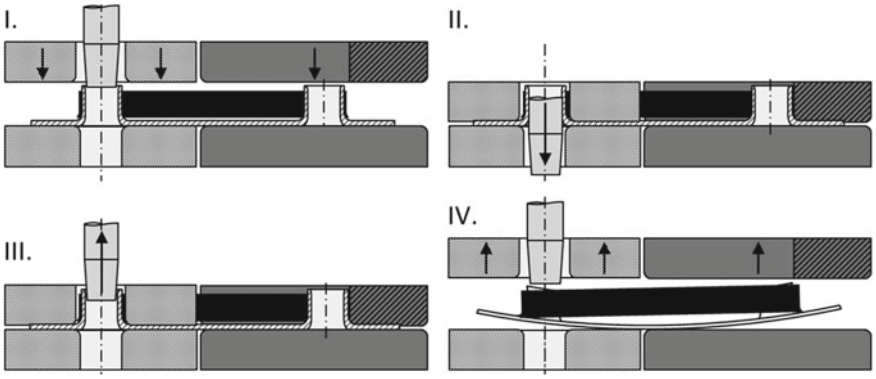

Fig. 5 Experimental process procedure

process steps of the experimental investigations, in which only the collar opposing the welded zone of the FRP strap is expanded. As a lubricant, a non-water-miscible, highly alloyed drawing, and punching oil (*Multidraw CF 4 by Zeller + Gmelin GmbH & Co. KG*) is applied with a cloth to the punch and inner collar surface. Then, the specimen is placed on the die, and the lower sheet support with the collar concentrically aligned to the punch. Afterward, the blank holder loaded by eight compression springs with a spring rate of 66.03 N/mm is moved down until it is in contact with the blank (phase I.). The collar is then widened by moving the punch downwards until the cylindrical area is fully inserted into the collar. During the downward movement of the punch, the springs are compressed providing an increased blank holder force. The total force increases from approx. 2.64 kN at the beginning of the widening process to a maximum of approximately 15.85 kN at its end (phase II). After fully retracting the punch (phase III), the blank holder is moved upwards so that the hybrid structure can completely spring-back (phase IV).

3.3 Setup for the Numerical Investigations

The numerical investigations are used to carry out the majority of the parameter studies. For the FEM analyses, the software *Dassault Systèmes Abaqus 6.14* is used. Since the model is primarily designed to identify influencing parameters and qualitative phenomena, the model complexity is reduced in comparison with the experimental setup. The blank holder, the die, as well as the sheet supports are considered in the form of two fixed analytical rigid planes arranged parallel to each other at a distance of 1 mm while contacting solely the sheet metal blank's planar surfaces. The punch is also designed as an analytical rigid with the already described geometry. Furthermore, the strap consists of one to three layers, each modeled as a seamless loop with a constant thickness. The sheet metal and the FRP strap are meshed with

deformable continuum hexahedral elements with reduced integration and hourglass control (C3D8I) with at least three elements over the component's thickness. The element edge lengths in the area of the collars are set to a maximum of 0.5 mm and increase to a maximum of 2 mm in the middle of the specimen. All contacts are modeled using the option "hard contact" in the normal direction and a penalty algorithm with a constant coefficient of friction in the tangential direction. By means of a numerically performed parameter variation during the widening of a non-wrapped collar and comparison with experimental results, a frictional coefficient between the planar sheet metal areas and the blank holder planes as well as between the inner collar wall and the punch of 0.1 was determined. Between the outer collar wall and the FRP strap, on the other hand, it is varied between 0.1 and 0.5 within the conducted parameter study, representing a span of coefficients stated in the literature and manufacturer's data for the contact between PA6 and steel [21, 22] as well as FRP tapes and steel [23, 24]. For the contact between the individual layers of the FRP strap, finally, the frictional coefficient is set to 0.4, which corresponds to a mean value the manufacturer's data suggests for a contact of PA6 with itself and glass-fiber-reinforced PA6 with itself [22] since micrographs show a fiber agglomeration in the tape's core and only a few fibers near the tape's surface. For the metallic component, an isotropic elastic–plastic material model is used, allowing for plastic deformation of the structure. The necessary flow curves are determined by tensile tests and extrapolated using the "Ludwik" equation [25]. It should be noted that the pre-hardening of the material in the collar area by the previously performed collar drawing process is not considered in the model. Due to the low plasticity of FRPs in the fiber direction, the CFRTP strap is modeled as fully elastic. Its anisotropy is taken into account by a material model based on engineering constants, calculated from manufacturer's specifications and data from literature. A material orientation tangent to the edge of the strap accounts for the fiber direction. Table 1 lists the most relevant material properties.

The whole pre-stressing process is divided into three steps, each lasting one second. The model is shown in Fig. 6. In the first step, the punch is moved downwards until the cylindrical part of the punch is completely inserted in the collar. Subsequently, the punch is moved back to its initial position. In the last step, the contacts to the two blank holder planes are released so that the sheet can spring back completely. During the spring-back phase, the sheet's edge near the expanded collar is fixed. While the first two steps use an explicit solver with a mass scaling of 10,000,

Table 1 Material properties of sheet metal and FRP tape

Material	Young's modulus (N/mm^2)	Density (g/cm^3)	Strain at break (%)	Yield strength (N/mm^2)	Tensile strength (N/mm^2)
DC04 (1.0338)	210,000	7.85	27.5	195	330
FRP tape 0° (PA6-GF)	33,000	1.72	3.4	–	770

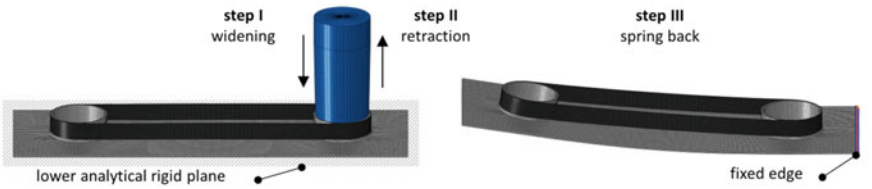

Fig. 6 Model and procedure of the numerical investigations (upper analytical rigid plane not depicted). (Color figure online)

Table 2 Parameter variations for the numerical investigations (reference configuration highlighted in bold)

Parameter for variation	Variant 1	Variant 2	Variant 3
Number of layers (-)	**1**	2	3
FRP layer thickness (mm)	**0.25**	0.30	0.35
FRP strap width (mm)	5.5	6.0	**6.5**
Frictional coefficient FRP-collar (-)	**0.5**	0.3	0.1
Maximum punch diameter (mm)	20.5	**21.0**	21.5
Distance between the collars (mm)	**100**	150	200

the last step is solved using a static implicit solver to avoid extensive oscillations due to the release of the energy elastically stored in the deformed specimen.

Six parameters are investigated in the numerical studies. To determine the dependence of the pre-stress on the stiffness of the tendon, straps with 1–3 layers are modeled. In addition, the thickness, as well as the width of the straps, is varied to three different values. Different coefficients of friction between metal and FRP, maximum punch diameters, and collar distances are also part of the variation. Based on the reference configuration highlighted in bold in Table 2, the individual parameters are changed according to the listed values.

3.4 Setup for the Bending Test

For the evaluation of the reinforcing and stiffening influence, three-point bending tests are performed. The test setup shown in Fig. 7 is used for this purpose. It consists of two supports with a 90° edge on which the specimen is placed with the collar facing downwards and a cylindrical punch with a horizontally oriented axis and a diameter of 10 mm. The support edges are spaced 127 mm apart so that the wrapped collars have enough distance to the supports so that they do not collide with them during bending. The influence of the non-reinforced sheet sections is minimized by keeping the gap as small as possible. The position-controlled tests are carried out using a tensile/compression testing machine (*Zwick Allround-Line 100 kN*) with a punch

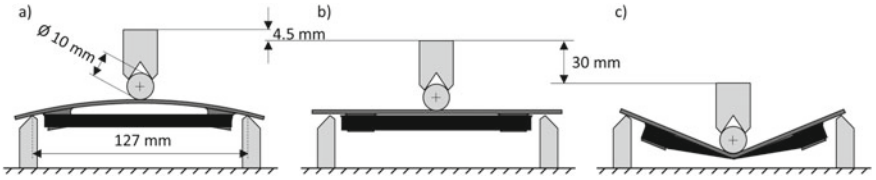

Fig. 7 Test setup for three-point bending

speed of 0.10 mm/s. At the start of the test (Fig. 7a), the punch is located 5.5 mm above the supports (4.5 mm above a flat sheet's top surface) so that the specimens curved by the pre-stressing can be inserted free of force. Afterward, the punch is moved down by 34.5 mm. In addition to the pre-stressed specimens, two types of comparison geometries are investigated. One type consists of a sheet metal blank with two collars and an almost tension-free wound strap. The other sample geometry consists of a sheet with two collars and without a strap. In order to take the stiffening effect of a collar with a larger diameter into account, one of the collars is widened in these samples as well. Since these specimens are almost flat at the beginning of the test, the punch comes into contact with the sheet after a distance of about 4.5 mm has been covered (Fig. 7b). Three samples are examined for each variant.

4 Results

4.1 Validation and Evaluation of the Results After the Collar Widening Process

Figure 8 shows a first overview of the results of the experimental and numerical investigations after the widening and spring-back of the specimen with the geometry described in Sect. 3.1 of this paper and a 6.5 mm wide FRP strap. It can be seen from both results that the sample has a distinct curvature due to the pre-stressing force generated by the collar's expansion. Although the collars' axes are, due to this curvature, no longer parallel to each other, the strap is securely held in its position and

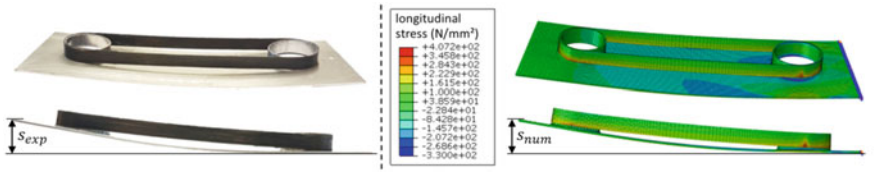

Fig. 8 Experimentally pre-stressed specimen (left) and numerical result (right). (Color figure online)

does not slip off the structure. To estimate the quantitative agreement of the numerical and experimental results, the extent of the curvature is examined. For this purpose, the specimens end with the widened collar is clamped flat on a surface, while the vertical deflection s_{exp} (cf. Fig. 8) of the other end of the upper edge is measured using a dial gauge. Three samples are measured. For the experimentally produced structures, the average displacement of the edge is 11.78 mm. The deviations are −0.71 mm to the minimum and 0.80 mm to the maximum. In the numerical representation of the process, the edge shifts by a distance of $s_{num} = 11.46$ mm in the vertical direction. Although the experimentally pre-stressed specimens are subject to comparatively high fluctuations, both investigations show comparable results so that both can be regarded as valid.

In order to evaluate if a frictional connection between collar and strap was created, the contact normal stresses between the components after completion of the collar widening process but before spring-back are analyzed. Here, the numerical results show that contact stresses of between 5 and 15 N/mm^2 occur at over 95% of the wrapped area. The numerical model is also used to examine the amount of pre-stressing more closely. For this purpose, the stresses in the longitudinal direction of the specimen are evaluated along a path that lies centrally in the transverse direction of the sheet on the concave surface (cf. left side of Fig. 9). After complete spring-back, pronounced compressive stresses appear on this collar-side surface. These amount to 142.85 N/mm^2 on an arithmetic average. While the compressive stresses increase to up to 148.21 N/mm^2 at a distance of about 6 mm to the edges, the center of the sheet has lower stress of about 137.00 N/mm^2. The non-uniform distribution of the stresses is due to the onset of plastic deformation of the base sheet around the collar. The inhomogeneous plastic compression of the sheet in the longitudinal direction leads to an inhomogeneous planar stress state after spring-back, in which the highly compressed areas in the middle of the sheet are set under tensile stresses by the less plastically compressed areas at the sheet edges. This non-uniform deformation is also evident in a local increase of the sheets width in the area of the collars to about 50.75 mm. While the pre-stress in the sheet metal is manifested as a bending load, the strap is loaded by tension.

The diagram on the right side of Fig. 9 shows the development of the tensile force F_s transmitted by the strap during the pre-stressing process. When the punch

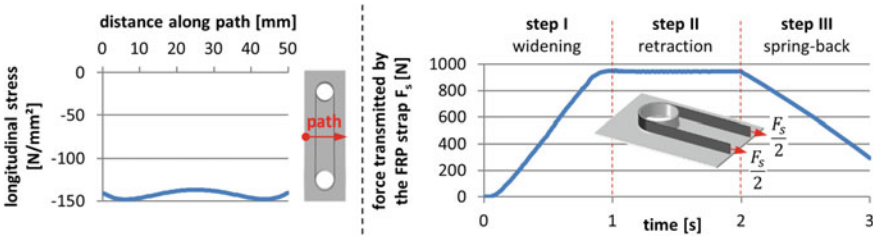

Fig. 9 Longitudinal stresses at the sheets collar-side surface (left) and force transmitted by the FRP strap during the pre-stressing process (right). (Color figure online)

is inserted into the collar, the strap force increases nonlinearly until the collar wall is completely in contact with the conical punch. Afterward, the force increases in an almost linear manner until the cylindrical section of the punch gets in contact with the collar. After one second, the punch has reached its bottom dead center with the maximum strap force of approx. 953.94 N. This force decreases when the punch is pulled out, leaving a strap force of approx. 943.20 N at the end of step two. Particularly noteworthy is the low level of collar spring-back. In the third and final simulation step, the sample can spring back completely, whereby the force decreases considerably to a value of about 293.37 N due to the bending of the sheet metal blank. However, this strong reduction of the strap's tension due to the spring-back is highly dependent on the bending stiffness of the sheet metal structure. An equally strong decrease is not to be expected for stiffer structures.

In summary, both the experimental and numerical results confirm the hypothesis presented at the beginning, that a hybrid FRP sheet structure can be joined and simultaneously pre-stressed by widening one of two FRP-wrapped collars.

4.2 Determination of Parameters Influencing the Pre-stress

In the following, the influence of various parameters on the pre-stress will be examined. The previously presented strap force F_s will serve as a comparative value. Figure 10 shows the numerically determined strap forces depending on the varied parameters. Since the curve described in Fig. 9 (right) is qualitatively identical for all variations, only the forces at the end of the respective steps are shown.

Overall it can be stated that almost all parameters have a significant influence on the pre-stressing strap force that can be generated. It is also shown that even if there is a greater effect on the pre-load after the first step, only minor changes occur after the punch is withdrawn, i.e., at the end of step 2. In the following, the individual variation results will be briefly presented and discussed.

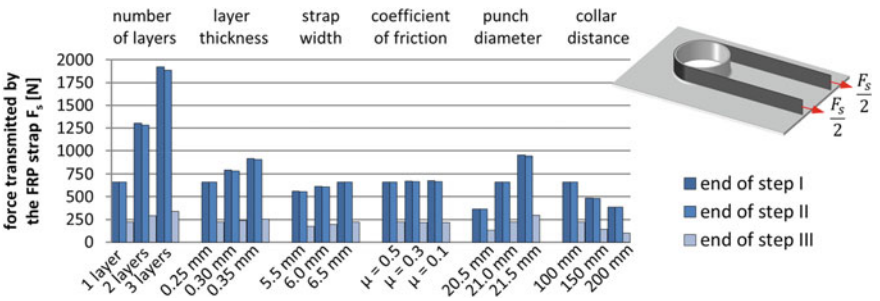

Fig. 10 Results of the numerical parameter study—forces transmitted by the FRP strap. (Color figure online)

If the **number of the straps layers** is increased, the total transmitted force increases almost proportionally with the increased total cross-section area of the strap. This can be explained by the fact that the absolute elongation is imposed geometrically by the ideally stiffly modeled punch. As the cross-section of the strap increases, its stiffness increases by the same factor. Correspondingly, the tensile force, which is linearly dependent on the stiffness, is increased equally. The same behavior can be observed when increasing the **layer thickness** or the **strap width**. As the cross-section and thus the stiffness of the tendon is increased here as well, a greater tension force is created. At first sight unexpected is the almost completely negligible influence of the **frictional coefficient** between the collar and FRP-strap. In order to explain this, the development mechanism of the strap's tension force must be examined more closely. It results from the change in length of the strap as a reaction to the widening of the collar. Since this change in length mainly depends on the expansion ratio, the absolute strains do not change by varying the frictional coefficient. The strain distributions and therefore the stresses occurring in the strap, however, are significantly influenced by the apparent friction. As described above, the elongation of the strap is mainly caused by the expansion of the collar. If the **punch diameter** is increased, the force transmitted by the strap increases accordingly. A larger **collar distance** finally leads to a reduction of the strap force. This is due to the fact that a constant expansion ratio leads to a constant absolute elongation of the strap. If the initial strap length is increased, its stiffness is reduced so that lower forces occur.

4.3 Mechanical Properties of the Pre-stressed Hybrid Structures Under Bending Loads

The results of the bending tests are shown in Fig. 11. The diagram on the left side shows the force–displacement curves of one representative specimen per tested variant. The deviating values of the other samples of the same type are shown as

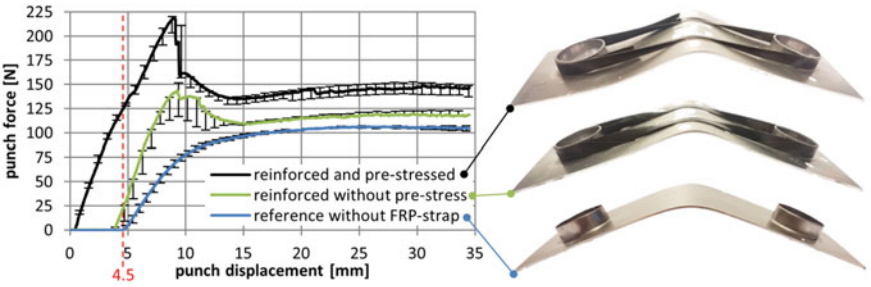

Fig. 11 Results of the bending tests: force–displacement-curves (left) and specimens after the bending tests (right). (Color figure online)

error bars in the diagram. Since the sudden drop in force does not occur at the same punch displacement for all samples, the deviations increase around this area. The specimens after bending are shown on the right side of Fig. 11. Their order from top to bottom corresponds to that of the graphs in the diagram.

First, the **reference sample without a reinforcing strap** shall be examined. As described in Sect. 3.4 of this paper, the punch in the test setup starts 4.5 mm above the sheet surface. As soon as this distance has been covered and the punch comes into contact with the plate, the forces increase linearly with stiffness of about 18.0 N/mm. Above approx. 55 N, the sample starts to yield, and the slope decreases. The maximum force of 106.4 N is reached after a punch stroke of about 27.1 mm. In comparison, the **specimen provided with a non-pre-stressed strap** shows a distinctly different curve. As the wrapped strap already applies a very small preload to the sheet, the sheet is slightly curved so that the punch comes into contact with the sample shortly before reaching a distance of 4.5 mm. The force then increases almost linearly with stiffness of approximately 35.6 N/mm. The maximum force of 143.6 N is reached at a punch displacement of about 9.3 mm. Here the force drops spontaneously due to the tilting of one side of the FRP strap. Afterward, the force rises again until the other side of the strap tilts as well and another drop occurs. Subsequently, the curve approaches a path running parallel to that of the reference curve. The **reinforced and pre-stressed specimen**, finally, comes into contact shortly after the start of the test due to the initial curvature resulting from the pre-stress. While a qualitatively similar behavior like that of the loosely reinforced specimen can be seen, the forces are considerably higher for the pre-stressed sample. The maximum force is about 220.96 N. The stiffness in the elastic area, however, is very similar and amounts to approx. 37.0 N/mm.

In summary, the test results show that joining a sheet metal structure with an FRP strap can significantly increase the stiffness and strength compared to a metallic reference structure. In addition, it can be concluded, that the introduction of a targeted pre-stress can significantly increase the failure loads under bending stresses, even if the individual components are not changed in their cross-section. The pre-stress, however, has no significant influence on the stiffness of the respective structure.

5 Conclusion and Outlook

In the paper at hand, a novel joining method was presented, which allows for strengthening and purposefully pre-stressing of sheet metal structures by widening of an FRP-wrapped collar. Based on the results of experimental and numerical investigations regarding the joining and pre-stressing process as well as characterizing bending tests on the structures produced this way, the following conclusions can be made:

- By means of a plastic expansion of at least one of two wrapped collars, an FRP-strap can be joined to a sheet metal structure and a beneficial bending pre-stress in the metallic component can be generated.

- The generated pre-stress can be significantly influenced both in terms of design and process technology, thus enabling a targeted influence on the mechanical behavior of the hybrid structure. Here, an increase of the FRP strap's stiffness or the expansion ratio of the collar leads to an increase of the generated pre-stress, whereas it is decreased by a larger distance of the collars.
- A targeted pre-stress counteracting the stresses resulting from an external bending load can increase the maximum load before failure of a hybrid structure by more than 50% without changing the cross-sectional geometry of its components.

Due to the manifold influencing parameters and their impact on the generated pre-stress, it is expected that fluctuations in process parameters and properties of semi-finished products can have significant effects causing deviations from a targeted mechanical behavior. In further investigations, the process control is to be improved by enabling an in-situ measurement of the pre-stresses. It is also planned to transfer the new process technology to more complex sheet metal structures such as bumpers and side-impact beams, in which the influence of a defined pre-stress on the mechanical properties can be used to create structures with a desirable failure behavior.

Computer-Aided Modeling of the Hot Forming Staking Process Based on Experimental Data

Sebastian Härtel, Eric Brückner, Birgit Awiszus, and Michael Gehde

Abstract As a non-detachable and point-acting joint, thermoplastic staking is primarily used for the production of electronic and sensor elements as well as for the joining of components in the automotive interior and exterior. Commonly, the advantages of staking processes are its cost-efficient and seemingly simple process control. Regarding the industrial application, staking is principally a well-established forming process. However, despite the high number of applications, the joint design and the process settings are mainly based on extensive empirical tests. At present, the FE simulation of these thermoplastic staking processes is not state-of-the-art. Due to these facts, within the frame of the paper, these gaps are to be closed by the computer-aided modeling of the hot forming staking to map the heating and forming behavior of this process close to reality. This procedure demands the associated experimental validation of the simulation. In summary, the numerical model shows high conformity to the experimental data and allows a simulative mapping of the morphological characteristics of the riveted joint as well as indicative statements to the process parameters, which means in particular the minimal heating time for forming and the optimized post-heating time for a morphological homogenization.

1 Introduction

Conventionally, the staking processes are differentiated according to their type of heat input. Referring to this, it has to be distinguished in heat conduction (hot forming staking), convection (hot air staking), intermolecular friction (ultrasonic staking), and radiation (infrared and laser staking). However, the fundamental forming procedure of all staking processes is basically equivalent. Figure 1 schematically shows the associated processes sequence. In this regard, the rivet pin is formed by a forming tool (punch), starting at its end face and continuing to the end position, until the punch touches down on the upper part. The characteristic design of the rivet head is introduced into the forming punch in its negative style.

As a significant advantage, the staking processes ensure the joining of different material types. While one of the joining partners, which means the lower part with the mostly constructively integrated rivet pin, has to be a thermoplastic one, there are nearly no limitations for the material selection of the upper part. This fact predestines the staking processes for their application in the field of mixed-material compounds.

Due to the high diversity of applications and materials, the plastic staking process is subjected to complex requirements that must be compensated by a sufficient understanding of the process and targeted quality assurance in order to ensure safe process application. In this context, the knowledge of the interactions between process setting, material properties, and joint quality is an essential prerequisite. However, these issues have not yet been adequately covered by the scientific community. In fact, the dimensioning of the rivet design as well as the process optimization is mainly based on empirical tests and special expert knowledge.

While plastic staking has been increasingly investigated in depth in recent years using experimental studies to increase process understanding [2, 3, 5, 6], the numerical analysis and simulative representation of the staking processes are not the common state-of-the-art. Regarding simulation, the basic challenge is the change of the plastic material from solid to a molten state and back during staking. Furthermore, the thermal condition has a very high influence on the material's structure and must be considered very precisely.

For manufacturing processes, in which solids interact with fluids, various calculation approaches currently exist. By using a coupled-fluid structure calculation, the

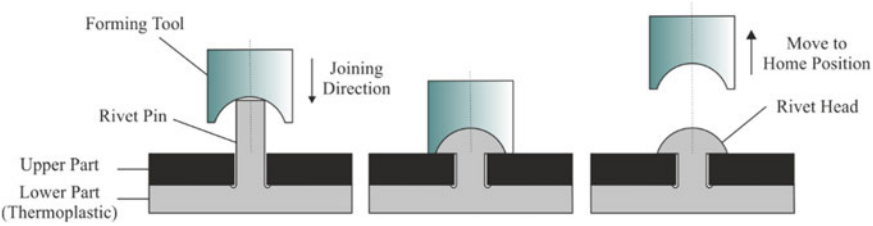

Fig. 1 Principle of a staking process, **a** before staking, **b** rivet joint after staking [1]. (Color figure online)

polymer injection forming (PIF) was simulated in [4]. However, this kind of simulation could not be applied because of the continuously changing of the material state during the staking process. Additionally, calculations in [7, 8] were already done, which use pure structure code and the rate-power-law. Nevertheless, by using even this type of process simulation, the definition of the melt range was carried out in advance and not continuously during forming. The literature also provides some numerical simulation results of the infrared staking process. However, in [9, 10] the viscous flow behavior of the plastic melt was neglected and the elastic–plastic material behavior was only considered in the temperature range of 15–100 °C.

The first and so far only scientific analysis and numerical mapping of a real staking process, by considering material and process conditions close to reality, was carried out by [1]. Härtel et al. has successfully simulated the double-stage process of hot air staking. In this regard, the Hensel-Spittel approach was used to describe the material behavior for the elastic–plastic state. Additionally, the Lagrange approach was applied to describe the flow behavior of the molten thermoplastic material. In detail, it was done with the Ostwald-de Waele power-law model. In contrast to [9, 10], the numerical model also considers the viscous material behavior of the melt during the staking process. Finally, the model shows high qualitative conformity to the experimental data, allows the evaluation of the minimum heating time, and provides information about the material's structure based on the hot air staking process.

However, the simulation of [1] still has the limitation that the melt formation and forming are carried out in separate process steps and thus represent the double-stage process of hot air staking. In contrast, for single-stage staking processes the melt formation and forming alternate continuously. This kind of staking process has not yet been numerically modeled.

2 Research Objectives

In comparison between simulation and experiment, the single-stage process hot forming staking should be numerically modeled for the first time. In this context, the influence of the process parameters, in particular the joining force and heating time, was the focus of the present experimental and numerical investigations.

In this regard, the heating and forming behavior during staking was analyzed in depth. It was the aim to create a simulation model close to reality, to predict the melt formation, the forming behavior, as well as the morphology of the riveted joint. The simulation should give some information about the minimal heating time of the rivet pin to form the rivet head and should predict potentially the weak points of the joint. Additionally, the numerical simulation should increase the process transparency in regard to the influence of the rivet design as well as the influence of the thermoplastic material. Based on these information, in the future, it should be possible to predict the joint properties by numerical simulation close to reality.

3 Experimental Process Analysis—Reference Test

The following experimental investigations were carried out using a hot staking machine (type B2000-H) of the company bdtronic GmbH (Weikersheim, Germany). The advantages of the machine concept are a precise temperature control to a maximum of 400 °C, a pneumatic joining force application up to a maximum of 120 N, and the existing configuration of the cooling system. Figure 2 shows a schematic illustration of the hot forming staking procedure. It can be described as a single-stage process, which means the heating and forming of the rivet pin take place simultaneously.

In the first process step, the forming punch is heated in its home position to the operating temperature without coming into contact with the rivet pin. Once this temperature is reached, the forming punch is moved toward the rivet pin with a constant joining force. As a result of the applied temperature and force, the rivet pin is continuously shaped by the forming punch. In this regard, the heat transfer is based on thermal conduction. After reaching the end position of the punch, which means a perfect joint, the punch is actively cooled by having a cool airflow to the top of the punch (step 3). After the end of the cooling period, the punch moves back to its home position (step 4). The joined components can then be removed.

The following results in the present paper are based on the material polypropylene (PP), type Moplen HP501 H (manufacturer LyondellBasell, Rotterdam, the Netherlands). Polypropylene is a semi-crystalline thermoplastic material that tends to crystallize strongly, exhibits ductile material behavior, and has excellent properties for structural analysis by microscopy to investigate the heating and forming behavior. The rivet pin has a diameter of 3.0 mm and a length of 10.8 mm. By using an upper mating part of steel X5CrNi18-10 (1.4301) its properties are not changed by the staking process. The thickness of the mating part is 3.0 mm, which leads to a constant protruding length of the rivet pin of 7.8 mm. The rivet head had the common industrial design of a hemisphere with a diameter of 6.0 mm and was adapted to the protruding volume of the rivet pin. Regarding the experimental investigation of the heating and forming behavior, transmitted-light microscopy was used. Therefore,

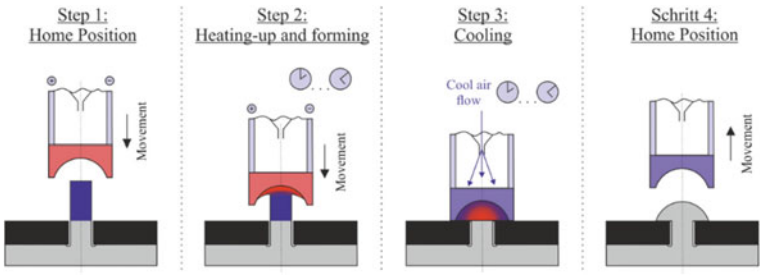

Fig. 2 Schematic illustration of the hot forming staking consisting of four process steps. (Color figure online)

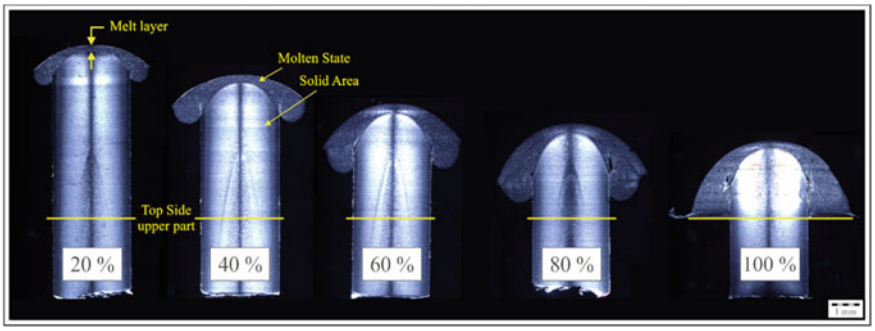

Fig. 3 Melt formation and forming behavior shown by thin sections of the rivet pin/rivet head for different steps of forming (transmitted-light microscopy). Process parameters: material polypropylene (PP), joining force 30 N, and punch temperature 300 °C. (Color figure online)

the rivet pin and rivet joint were prepared as an extracted thin cut (thickness 10 μm) in the center plane of the rivet pin. By using a polarization microscope (Olympus BX51, Olympus Corporation, Shinjuku City, Tokyo, Japan), the melted and recrystallized area was measured (software Imagej, National Institutes of Health, Bethesda, Rockville, MD, USA) characterized by the melt formation during staking.

Based on the experimental tests, Fig. 3 shows the time-dependent melt formation and forming behavior by means of a stepwise sequence during hot forming staking. Resulting from the thermal energy input of the punch, a thin melt layer could be detected on the upper side of the rivet pin during the entire staking procedure. As a consequence of the joining pressure, the punch displaces the melt into its side areas and thus continuously shapes the rivet pin. As forming progresses, the free volume of the punch fills up increasingly and the displaced plastic melt goes into contact with the non-plasticized rivet pin. However, when the punch has reached its end position, a geometrically complete rivet head is shaped.

However, a closer examination of the rivet joint (see Fig. 4) shows that the rivet head is not intrinsically tied to the rivet pin. Consequently, the theoretical "maximum load-bearing head height" must be divided into the two components of the "reduced load-bearing head height" and the "weld line height". It can be noted that this kind of weld line seems to be very similar to a cold weld line in injection molding. Due to the unequal thermal levels of the generated plastic melt (high temperature) and the not plasticized rivet pin (low temperature), the melt cannot tie to the rivet pin during the encounter.

4 Numerical Process Simulation

In regard to the numerical process simulation, the software simufact.forming (Simufact Engineering GmbH, Hamburg, Germany) was used to build a numerical model

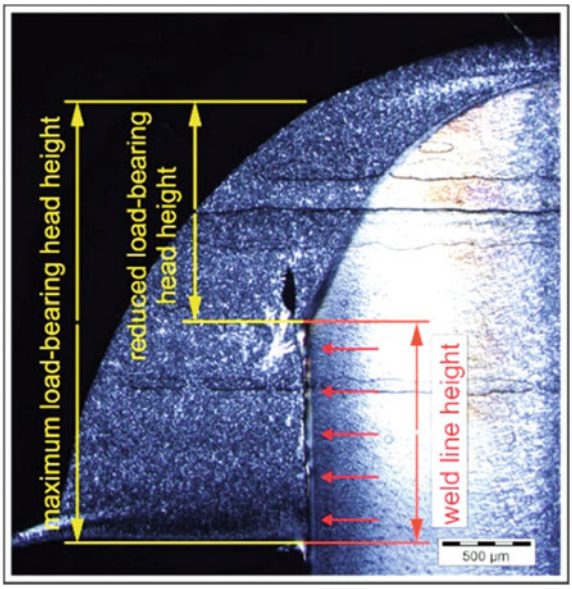

Fig. 4 Resultant materials morphology in the rivet joint based on Fig. 3 shown by a thin section (transmitted-light microscopy). An incomplete joint of the rivet head and the rivet pin by having a characteristic weld line. Derivation of the important design parameters of the joint material polypropylene (PP). (Color figure online)

of the hot forming staking process. The process simulation was carried out with a 2D rotationally symmetrical model by using the real tool geometry. However, the punch is constantly force-controlled in accordance with the experimental investigations. Additionally, the punch has a temperature of 300 °C and the upper part (joining partner) has a temperature of 20 °C. The heat transfer coefficient of the tools to the workpiece is set to 10.000 W/m^{2}K. To be able to reproduce the material flow close to reality, the rivet pin was meshed very finely with an element edge length of 0.1 mm (quad elements). Figure 5a shows the basic simulation setup of the hot forming staking process.

Regarding numerical simulation, one of the biggest challenges is the definition of material behavior. The material is partially melted by contact with the hot punch and is consequently displaced in the molten state. Thus, during the entire staking process, the PP material is present in both the solid and the molten material state. In order to be able to reproduce this within a contact body, a suitable subroutine must be used. This subroutine has been already developed by Härtel et al. for hot air staking and is presented in [1]. Furthermore, Härtel et al. describe in detail how the necessary material data are determined and mathematically considered by the subroutine in the simulation [1].

However, as presented in Fig. 5b, the core elements of the material determination and description are summarized for both the solid and the molten state. The simulation setup allows the simulation of the hot forming staking process for the first time and thus a deeper process analysis than it is possible through purely experimental work. To ensure that the simulation gives realistic results, a comparison with the experimental results was necessary. Afterward, the verified simulation can be used for deeper

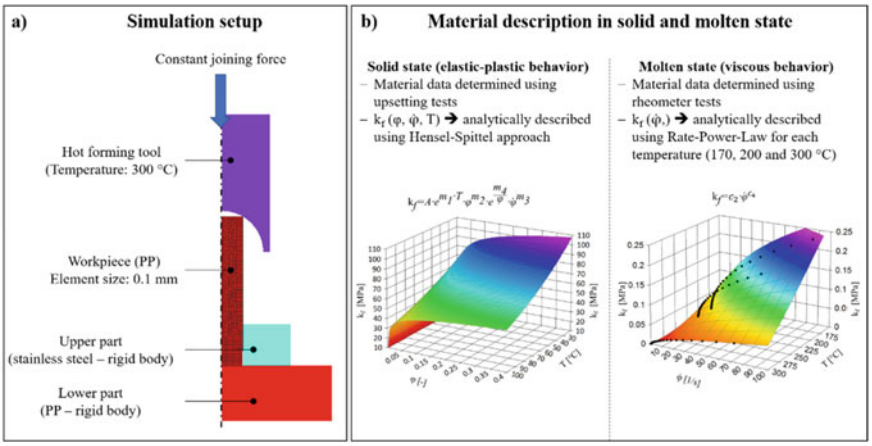

Fig. 5 **a** Simulation setup for the hot forming staking process; **b** material properties for the solid and molten state concerning [1]. (Color figure online)

process analysis. The following process parameters were used for the verification of the numerical simulation:

- Temperature of the punch: 300 °C
- Joining force: 30 N/120 N
- Variation of the post-heating time: $t_A = 0$ s/5 s/10 s/20 s.

At the beginning of the numerical analysis, the calculated process duration was compared with the experimentally determined heating time which is necessary to shape the rivet pin completely and form out the rivet head. Table 1 shows that the calculated process duration correlates very well with the experimentally measured duration. The deviation is less than 10%.

Additionally, based on the experimental data in Fig. 3, Fig. 6 shows the results of the simulated melt formation and melt flow in comparison to the experiment for different steps of forming (stroke of 40 and 80%) by having a joining force of 30 N. In this context, a high-level agreement could be detected between the calculated and the real conditions. In both cases, the material is successively melted and displaced.

Furthermore, in Fig. 6 the numerically calculated temperature distribution is displayed. From this, the melt layer thickness formed can be derived indirectly, insofar as the temperature is above the melting temperature of approx. 160 °C. The experimentally determined melt layer thickness of 0.26 mm, by having a stroke of 80%, is very close to the calculated melt layer thickness of 0.22 mm.

Table 1 Comparison of the experimentally measured and numerically calculated process duration

Process duration—experiment	Process duration—simulation	Deviation
5.0 s	5.35 s	7%

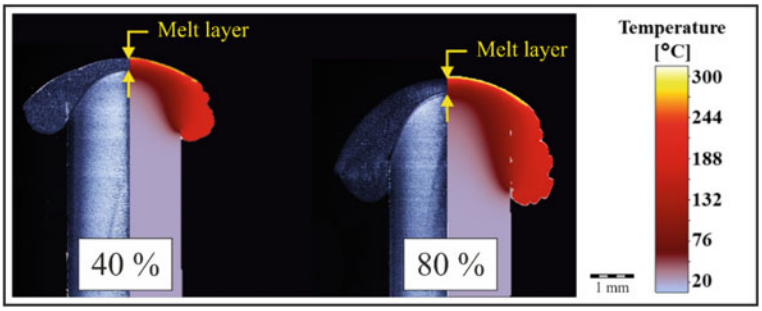

Fig. 6 Comparison of the experimental data according to Fig. 3 (thin sections) and the calculated melt formation (simulation) during forming for different steps of forming (exemplary stroke of 40 and 80%). Process parameters: material polypropylene (PP), joining force 30 N, and punch temperature 300 °C. (Color figure online)

Due to the high agreement between the numerical and the experimental data, the created model can subsequently be used for this kind of process simulation. Consequently, in the next step, the influence of the joining force was analyzed. For this purpose, a further simulation was carried out with a constant joining force of 120 N. Additionally, the rivet joint was analyzed focusing on the formation of weld lines. Concerning this matter, self-contacting areas at the end of the process were evaluated in the simulation, analogous to the approach in [1]. As shown in Fig. 7, a higher joining force of 120 N leads to an increasing in the weld line height. By using a joining force of 30 N, the weld line height is only 1.20 mm, which means a percentage of 65% compared to the weld line by using a joining force of 120 N. Consequently, based on the numerical results and the assumption that a weld line weakens the

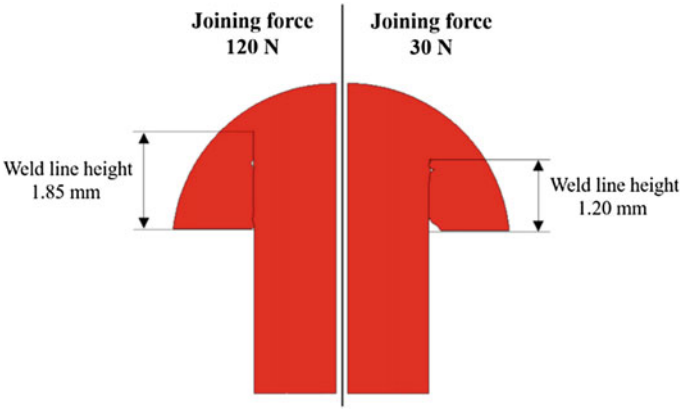

Fig. 7 Emerging weld lines for a joining force of 120 N in comparison to a joining force of 30 N. (Color figure online)

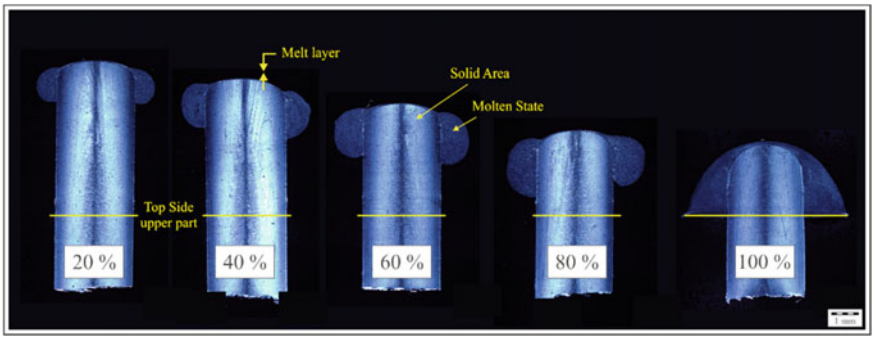

Fig. 8 Melt formation and forming behavior shown by thin sections of the rivet pin/rivet joint for different steps of forming (transmitted-light microscopy). Process parameters: material polypropylene (PP), joining force 120 N, and punch temperature 300 °C. (Color figure online)

Table 2 Comparison of the experimentally measured and numerically calculated weld line height for different joining forces of 30 and 120 N

Joining force (N)	Calculated weld line height (mm)	Experimental weld line height (mm)
30	1.20	1.20
120	1.85	1.90

seam properties, a low joining force should be preferred to have maximized joint properties.

In order to prove the influence of the joining force experimentally, the melt formation and forming behavior was also carried out by using a joining force of 120 N. The time-dependent melt formation and forming steps are shown in Fig. 8. It could be demonstrated that the melt formation, and in particular the weld line height, could be influenced by the joining force of the punch significantly. In contrast to Fig. 3, an increased joining force of 120 N leads to a smaller melt layer between punch and rivet pin. At the end of the forming process also, increased weld line height could be detected. The real measured weld line height was very close to the calculated values as shown in Table 2. Regarding the strength of the joint, by using a high joining force lower mechanical properties are expected, which was already shown in [2] for several thermoplastic materials.

5 Experimental and Numerical Analysis of the Post-heating

The experimental investigations revealed that the joint quality can be significantly improved by additional energy input. In this case, additional heating follows directly after the forming process. Here, thermal energy is introduced into the rivet head without any further punch movement. This procedure leads to an increasingly melt formation of the rivet head and is so-called “post-heating”. However, the post-heating

is mainly described by the post-heating time t_A. The numerical simulation was now used to determine the minimum reheating time in order to minimize the weld line height. In this regard, Fig. 9 shows the results of simulation and experiment in comparison. It can be seen that the distribution of molten areas (red-colored) and still solid areas (blue-colored) significantly depends on the post-heating time. However, the weld line height only decreases disproportionately with an increasing post-heating time. A complete bond between the rivet pin and the rivet head, which means no weld line would appear, does not seem to be possible. The simulation model clearly shows that the reason for this effect is the heat dissipation of the joining partner because of the high thermal conductivity of stainless steel. It can thus be stated that a post-heating time of 10 s leads to a significant reduction of the weld line height. A further increase in the post-heating procedure must be rated as inefficient.

These findings can be confirmed by tests regarding the mechanical properties of the rivet joint (tensile load). Nevertheless, in order to detect this effect precisely, the material-specific as well as design-specific properties of the joint must be taken into account. As shown in Fig. 10, no determinable increase of the breaking force could be detected for the material PP. This fact could be explained by the failure behavior of the joint and the pronounced ductile material behavior in combination with the present rivet design. In this case, the combination of the boundary conditions resulted in the failure occurring predominantly in the rivet pin. Consequently, the principally improved joint quality is not reflected in the breaking forces of the joint.

In contrast, the material PA66-GF30, reinforced with 30% of short glass fibers, reveals a significant increase of the breaking force by having a rising post-heating time in the range of 5–20 s (see Fig. 10) and thus confirms the results of the numerical model clearly. Consequently, the post-heating process enables the systematical optimization of the joint properties regarding specific requirements in terms of mechanical properties.

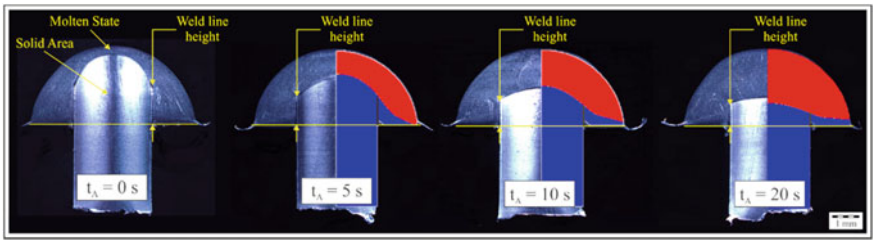

Fig. 9 Comparison of the experimental data (transmitted-light microscopy) and numerically calculated melt formation by using a post-heating time t_A. Distribution of molten (red-colored) and solid (blue-colored) areas in order to analyze the resulting weld line height (black-colored line). Process parameters: material polypropylene (PP), joining force 30 N, punch temperature 300 °C, and variation of the additional heating time t_A. (Color figure online)

6 Conclusion

The present paper demonstrates the computer-aided modeling of the hot forming staking process based on experimental data. Hereby, the numerical model shows high qualitative conformity to the experimental data, which means that the simulation represents the material behavior very realistically with a high degree of accuracy. As shown by the experimental data, the melt formation and the forming alternate continuously during the staking process, which leads to a constant shaping of the rivet pin. As a consequence of these boundary conditions, the rivet joint has some process-related weak points in form of weld lines between the rivet pin and the side areas of the rivet head. This fact can significantly decrease the joint quality. By adapting the process procedure, by using a so-called post-heating, the joint quality can be improved. Nevertheless, the required cycle time increased as well. However, the presented numerical model of the hot forming staking process is able to build up the joint formation close to reality. As a consequence, it is possible to simulate the staking process by using different process parameters and consequently analyze the final properties of the joint. Additionally, the numerical model allows the simulation of the additional heat input (post-heating). It showed that the weld line height can be predicted with high accuracy. Regarding an industrial application of the hot forming staking process, a low joining force leads to an improved joint quality without a post-heating. A post-heating leads to improved joint quality as well. Finally, it should be positively noted that the experimental investigations of Brückner [2] completely support the presented numerical results and findings.

However, an outstanding topic is to validate the numerical model by using different material types and to link the heating and forming properties with the mechanical properties of the joint (strength and failure behavior).

Acknowledgments This study is promoted from budgetary fund of the German Research Foundation (DFG - Project number 413515815). The authors would like to record our appreciation for this support. Furthermore, they would also like to thank the company bdtronic GmbH for their technical and advisory support.

Fatigue Characteristics and Failure Mechanism of Self-piercing Riveted Joints of DP590 and AA6061 Plates

Zhichao Huang, Yinglian Jia, and Jiamei Lai

Abstract Duplex steel, aluminum alloy, carbon fiber-reinforced composites, and other materials have become the preferred lightweight materials for automobiles. The self-piercing riveted joints of dual-phase steel DP590 and aluminum alloy AA6061 were selected for fatigue tests, and the fatigue properties of the joints were analyzed. The typical fatigue failure fractures were observed by scanning electron microscopy (SEM), and the microfailure mechanism of the joints was analyzed. The results show that the fatigue properties of self-piercing riveted joints are different with different upper substrates. The failure modes of the AA35 joints are all fractures of the lower substrates. When the upper substrate is DP590 plate under high fatigue load, the cracks are easy to initiate in the rivet area. The cracks of the other self-piercing riveted joints originate on the side of the lower plate and extend along the riveted area to the width of the substrate.

1 Introduction

In response to the increasingly stringent requirements of the country for automobile exhaust emissions, major automobile manufacturers have increased the research and development of automobile lightweight design technology. From the point of view of reducing the weight of the whole vehicle, the designers can reduce fuel consumption during the use of the vehicle and achieve the purpose of reducing CO_2 emissions. Under the premise of ensuring the strength and safety performance of the vehicle, the vehicle lightweight must take comprehensive measures from the material of

parts, the connection mode, and the structural design of the whole vehicle. The test shows that the application of new materials (such as carbon fiber composite board) and light materials (such as aluminum alloy) is an effective way to realize the lightweight of the automobile body and improve the driving economy. At this time, the connection between parts of different materials becomes an urgent problem. Because the melting point temperature of different materials, such as dual-phase steel, aluminum alloy, and carbon fiber composite, is quite different, resistance spot welding is not suitable for the connection of these heterogeneous materials. In recent years, the self-piercing riveting technology has become a research hot spot of different material connection modes, which is through the plastic deformation of rivets and plates to form a mechanical internal lock to complete the connection of parts. The technology has the advantages of no heat generated in the process of connecting parts, no need for pre-drilling, no damage to the anti-corrosion ability to connect parts, simple operation, and easy to realize automation. It is very suitable for connecting parts of different materials [1–3].

Some scholars have analyzed the mechanical properties of the self-piercing riveted joints structure of parts with different materials, such as Rao, Hirsch, and Ding Wenyou [4–6], and pointed out that the interaction between the specimen shape and the fatigue properties of the self-piercing riveted aluminum carbon fiber composite. Abe et al. [7] obtained that the flow stress of high-strength steel plates and the combination of plates have an effect on the connection performance of plates by using conventional rivets and dies for self-piercing riveting of high-strength steel and aluminum alloy plates. Jin Wenhao et al. [8] studied the corrosion mechanism of steel aluminum dissimilar metal self-piercing riveting joint, which is of great significance to improve the corrosion resistance of metal material self-piercing riveting joint. Mori et al. [1] studied the process optimization of aluminum alloy high-strength steel dissimilar metal self-piercing riveting and proposed that the length of rivet is the most important factor affecting the undercut and bottom thickness. Chung et al. [9] used aluminum alloy 5052 with a thickness of 1.5 mm and high-strength steel SPCC as a base plate for the self-piercing riveting test. The results showed that the static strength of U.S-L.A joint was higher than that of U.A-L.S joint, but the fatigue strength of the two joints was higher than that of the former.

At present, the research on self-piercing riveting of parts with different materials mainly focuses on the connection between composite materials, high-strength steel, and aluminum alloy, while the research on dual-phase steel and high-strength aluminum is rare. In this study, DP590 and AA6061 plates were tested by self-piercing riveting. The influence of the upper substrate on the fatigue life of the riveted joints was analyzed by a fatigue test. The typical fatigue failure fracture was observed by SEM. The microfailure mechanism of DP590 and AA6061 joints was explored.

2 Experimental Procedure

2.1 Self-piercing Riveting Test

2.1.1 Rivet and Die

The self-piercing riveting test was carried out on RV300023 self-piercing riveting machine of Henrob Company in the UK. Figure 1a shows the dimensions of the semi-hollow rivets. The rivet is made of 36MnB4 high-strength steel and is coated with zinc-tin alloy. The rivet head is Φ 7.7 mm, the rivet leg is Φ 5.3 mm, and the length of the leg is different. The mechanical behavior of the rivets is listed in Table 1 [10]. The concave die is shown in Fig. 1b.

2.1.2 Materials and Experimental Setup

The self-piercing riveting test connecting materials of base plates are, respectively, DP590 and AA6061. The mechanical properties of these materials are listed in Table 2. In this study, the dissimilar SPR joint was made of 1.2 mm thick DP590 plate and 2.0 mm thick AA6061 plate. In addition, 1.5 mm thick AA6061 plate and 2.0 mm thick AA6061 plate were made up of similar SPR joint. The thicker plates in each

Table 2 Mechanical properties of DP590 and AA6061 plate

Materials	Ultimate tensile strength (MPa)	Yield strength (MPa)	Young's modulus (GPa)	Elongation (%)
DP590	520	275	200	25
AA6061	315	205	68.6	12

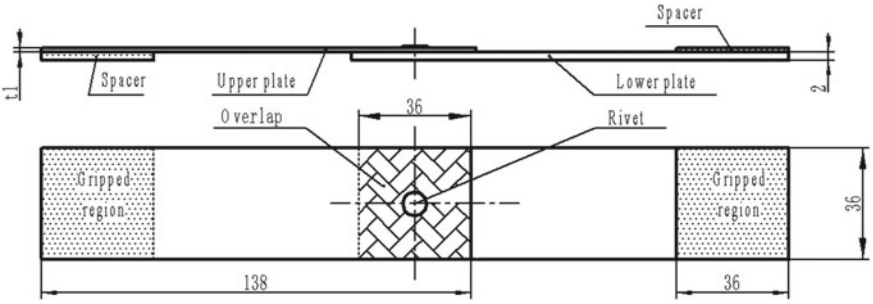

Fig. 2 Dimensions of plates and connection mode

Table 3 Rivet length of each group of joints and joint ID

Joint ID	Upper thickness (mm)		Lower thickness (mm)		Joint stack (mm)	Rivet length (mm)
DA32	DP590	1.2	AA6061	2.0	3.2	6
AA35	Al6061	1.5	AA6061	2.0	3.5	6

group were in the lower layer. The materials were sheared into 138 mm × 36 mm samples. All are connected by a lap joint. Also, details of plate assemblies and joining parameters were shown in Fig. 2.

The hardness of rivets in this test is the H4 series. Table 3 listed the rivet length of each group of SPR joints.

2.2 Mechanical Property Test

According to the test method shown in Fig. 2 and Table 3, the riveting pressure is about 190 MPa. The 14 test samples are prepared for each group, five of which are used for the tensile test and others for the fatigue strength test.

2.2.1 Tensile Test

The strength of all self-piercing riveting joints was evaluated by the tensile test. RGM-4030 microcomputer-controlled electronic universal material testing machine is used for the tensile test. Figure 2 showed an overlap area of 36 mm × 36 mm. In order to avoid the deviation between the load axis and the centerline of the test samples loaded, a spacer shall be placed at each gripping end of the test sample. The size of the spacer was 36 mm × 36 mm. For each group of joints prepared, five test samples are randomly selected for the tensile test. And the tensile test was set at a constant speed of 2 mm/min on the universal material testing machine.

Table 4 Statistics of the mean values of the maximum static loads of two groups of joints

Joint ID	Statistical parameters			
	Mean value of maximum static load F_{MAX}/kN		Coefficient of variation	Confidence interval
DA32	F_{1MAX}	9.18	0.01692	8.9842–9.3698
AA35	F_{2MAX}	6.87	0.03521	6.5737–7.1749

The maximum static loads of DA32 and AA35 joints are obtained by the tensile test, and the validity of the data is verified by Origin software. At the level of 5%, the two groups of tensile test data are significantly from the normal distribution population. According to the statistical theory, random samples are extracted from the normal population, and the validity of data can be tested by t-distribution when the sample size n value is small (generally $2 \leq n \leq 30$). Interval estimation was carried out by using the pivot variable method, and the mean values of the maximum static loads of the joints in each group were tested within the 95% confidence interval. The mean values of maximum static loads of DA32 and AA35 joints were 9.18 kN and 6.87 kN, respectively, as shown in Table 4.

2.2.2 Fatigue Test

The fatigue test equipment is a QBG-50 microcomputer-controlled high-frequency fatigue test machine produced by Changchun Qian bang Test Equipment Co., Ltd. The samples DA32 and AA35 used for the fatigue test are the same batches as those used for the tensile test. The mean values of the maximum static loads of the two groups of samples in the tensile test are taken as the limit values of the maximum static loads and dynamic loads set in the fatigue test. The clamping method of samples is the same as that of the tensile test, and the spacer should be added at the clamping end. It is required that the same sample test cannot be stopped from the beginning to the end of the test during the fatigue test. If the test must be stopped in the middle of the test due to the failure of the testing machine or other reasons, the number of cycles and downtime shall be recorded. And the data of the test sample can only be used as reference data.

The fatigue test was conducted in the pull–pull mode. The excitation applied to the fatigue test was the cyclic load of a sine wave with the frequency f of 80 Hz, and the stress ratio was set as $R = 0.1$. First, 1–2 specimens were extracted, respectively, for the pre-fatigue test at selected load levels to estimate the fatigue life of samples at each stress load level. Subsequently, three stress levels of the maximum static load mean value of the joints in each group were selected as corresponding fatigue load levels in the fatigue test, and three specimens were tested at each load level. In the process of the fatigue test, the failure judgment of the samples is based on when the fatigue cycle of the specimen exceeds 2 million times or obvious cracks appear in the specimen. Statistical data such as the mean life of each specimen of the two

Table 5 Fatigue life statistics of two groups of SPR joints

Joints ID	DA32			AA35		
Load level	70%	50%	30%	70%	50%	40%
Life mean	17,600	50,500	427,667	43,167	151,567	400,500
AD	0.586	0.294	0.402	0.477	0.468	0.323
Shape parameter	12.22	7.661	8.694	10.93	12.17	2.386
Scale parameter	18,466	53,978	455,099	45,115	157,764	454,814

groups of joints obtained in the fatigue test are shown in Table 5. The AD in Table 5 is Anderson darling statistics, indicating the degree to which the measured data obey a specific distribution. The smaller the statistic is, the better the distribution fits the data. The shape parameters describe the distribution of data and determine the shape of the distribution function. The scale parameter defines the position of the Weibull curve relative to the threshold.

3 Results and Discussion

3.1 Analysis of the Fatigue Test Results

Weibull distribution is the most commonly used distribution for reliability data modeling, so this test data is processed by Weibull distribution. The principle of Weibull distribution data processing is to model the life distribution of multiple identical and independent processes that lead to failure based on the weakest link model, in which the failure time is determined by the first process that reaches the critical stage. Since the Weibull distribution is theoretically derived from the minimum extreme distribution, an effective model can be provided for the application of the weakest link, such as the failure of material strength. In this test, two-parameter Weibull distribution was used to analyze and test the fatigue life of all joints [11], and the distribution density function was

$$f(x) = \frac{\alpha}{\beta}\left(\frac{x}{\beta}\right)^{\alpha-1} \exp\left(-\left(\frac{x}{\beta}\right)^{\alpha}\right)$$

where α and β are the shape parameters and scale parameters of the Weibull distribution.

Since the fatigue test data has the characteristics of small samples and large dispersion, it is difficult to directly solve the Weibull parameters. Therefore, Minitab can be used to process the fatigue test data. It can be seen from Table 5 that the scale parameter β calculated at a 95% confidence interval is greater than the life mean value, which can verify that the data obtained from the fatigue test is effective.

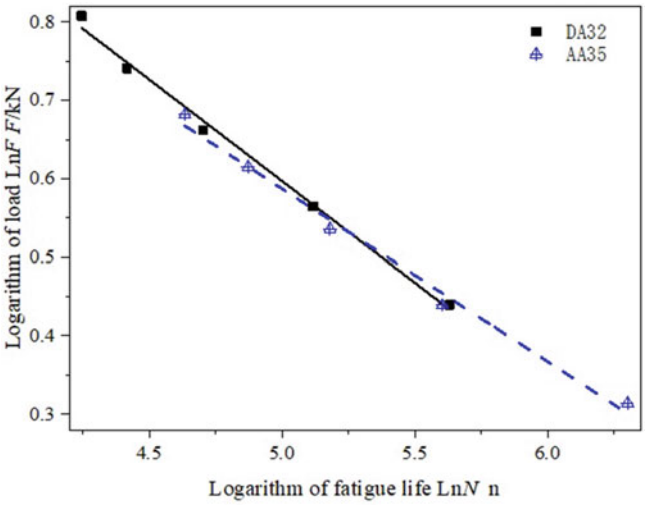

Fig. 3 *F–N* curves of two sets of joints. (Color figure online)

According to the test data obtained from the fatigue test, the least square method was used to fit the fatigue test data of each group of joints, and the two-parameter logarithmic *F–N* curve was obtained [3, 12]. The fatigue load–life (*F–N*) curves of DA32 and AA35 joints were obtained by calculation, as shown in Fig. 3. The fitting equations are $\ln N = 0.26\ln F + 1.89$ and $\ln N = 0.22 \ln F + 1.69$. The fitting goodness $R2$ of the two groups of fitting curves is 0.9943 and 0.9911, respectively. It can be seen that the fatigue load life curve fitted by the test data is effective.

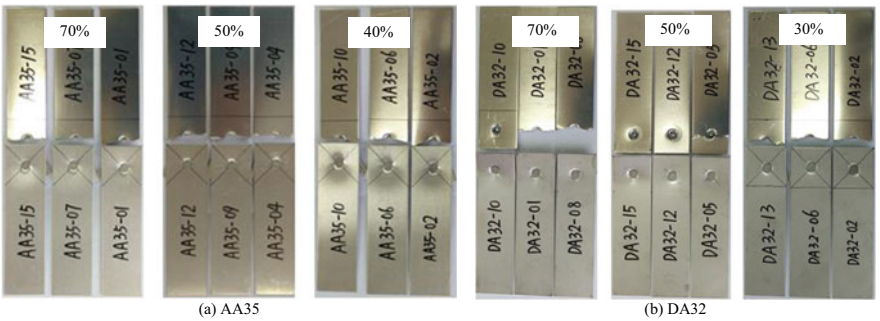

Figure 3 shows that the two fatigue load–life curves of $\ln N = 0.26 \ln F + 1.89$ and $\ln N = 0.22 \ln F + 1.69$ fitted from the fatigue test data intersect at the point (5.26, 0.53). And the fatigue life at this junction is 181,970 cycles, which is between 30 and 50% of DA32 joints load level or between 40 and 50% of AA35 joints load level, respectively. It can be seen that at a higher load level, the fatigue life of DA32 joints is longer than that of AA35 joints under the same load. However, at a lower load level, the fatigue life of AA35 joints is longer than that of DA32 joints under the same load. It means that the upper plate of different materials will affect the fatigue life of the self-piercing riveted joints.

3.2 The Influence of the Upper Plate on Fatigue Failure Mode

In DA32 and AA35 self-piercing riveted joints, only the upper plate is different. The upper plate of DA32 joints is duplex steel with a thickness of 1.2 mm DP590, and the upper plate of AA35 joints is AA6061 aluminum alloy with a thickness of

1.5 mm. It can be seen from Fig. 4a that the fatigue failure mode of AA35 joints is all lower plate fracture. The fracture position of the lower plate is extending along the riveting area of the lower plate to the width of the plate and running through the middle of the riveting area. Since the upper and lower plates of AA35 are all made of aluminum alloy AA6061, the fretting wear of the self-locking structure formed by the rivet leg and the lower plate in the locking area becomes the stress-sensitive area during the fatigue test. So the fatigue failure of AA35 joints is due to the fatigue wear and fracture of the lower plate.

It can be seen from Fig. 4b that the fatigue failure modes of self-piercing riveted joints DA32 are different under different load levels. When the load level is 30%, the fatigue failure is lower plate failure. With the increase of the applied load, when the load level reaches 50%, the fatigue failure mode is transferred from the fracture failure of the lower plate to the rivet fracture failure of all the rivets. However, one specimen is a mixture of a rivet and a lower plate fracture. When the load level continues to increase to 70%, the main fatigue failure mode of DA32 joints is lower plate failure and one sample is rivet fracture failure. In addition, the fracture failure of the lower plate gradually expands from the middle part of the rivet to the direction of plate width and plate thickness in the form of fatigue failure of DA32 joints, and finally, the joint connection fails. At the lower load level, the rivet leg and the lower plate of DA32 joints produce fretting wear under the action of a small variable load. In the self-locking area, the fatigue resistance of the lower plate aluminum alloy AA6061 is the weakest. And the weak part of the DA32 joints is the lower plate aluminum alloy AA6061, so the fatigue failure mode under this load level is the lower plate fracture failure. The alternating force of rivets in DA32 joints increases gradually with the increase of load level, and the fretting wear between the rivet leg and the base plate is not the main contradiction of connection failure. The impact resistance of the rivets connecting the upper and lower plates is the key to the failure of the connection. Therefore, the main fatigue failure mode of the DA32 joint under the medium load level is rivet fracture. When the fatigue load increases to a certain value, the fatigue life of DA32 joints is obviously reduced under the action of a large variable load. At this time, the rivet and upper plate in the riveting lock area have

(a) AA35 (b) DA32

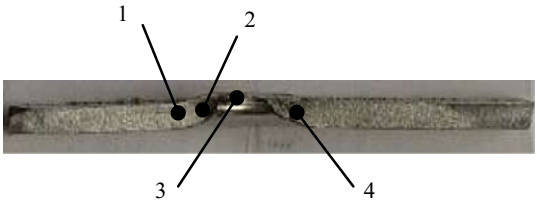

Fig. 4 Two sets of fatigue failure samples for SPR joints. (Color figure online)

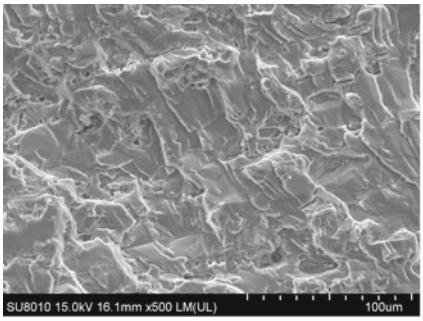
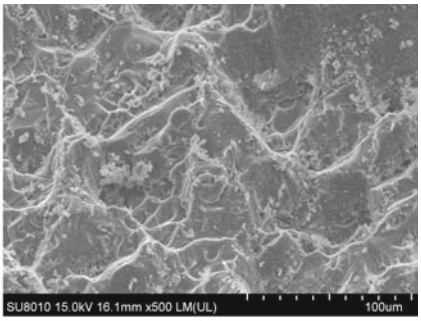
good tensile strength. And the lower plate becomes the weakest position in the lock, so the main fatigue failure form becomes the fracture failure of the lower plate.



3.3 Failure Mechanism of Joints

3.3.1 Failure Mechanism of AA35 Joints



The fracture morphology of the lower plate of the No. 4 sample AA35 joint is shown in Fig. 5. In Fig. 5c, e, micropores, a large number of particles, tearing edges, and secondary cracks can be observed, which is the remarkable feature of the fatigue

(b) 1 # Regional microstructure

(c) 2 # Regional microstructure

(d) 3 #Regional microstructure

(e) 4 # Regional microstructure

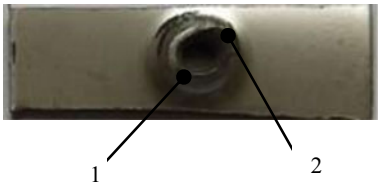

Fig. 5 Fracture surface of the lower plate for group AA35 No. 4. (Color figure online)

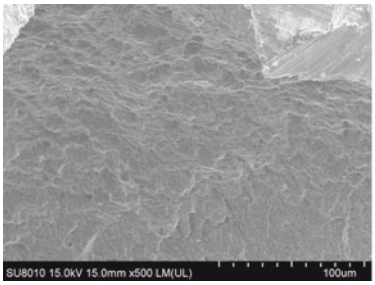
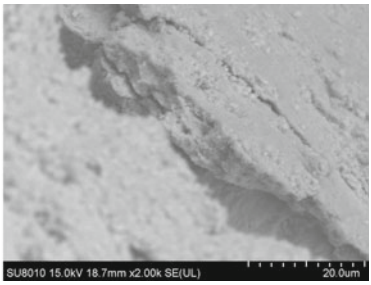
source area. According to the macroscopic morphology of the 2# and 4# regions in Fig. 5a, there are a large number of black abrasive particles in this part, indicating that the microcrack growth of this part is slow and there is no obvious fatigue striation. Under the action of alternating stress, the crack will open and close repeatedly on the surface of the crack when it is expanding, which will cause the fracture surface to experience many times severe "rubbing" and "abrasion" process so that a large number of black oxide particles appear on the fracture surface.



There are obvious fatigue striations, microcracks, and "beach marks" in Fig. 5d. With the passage of time, under the action of alternating tensile stress, the cracks sometimes expand and sometimes stop, and the separated parts of the cracks sometimes close and sometimes open, so the fracture produces the so-called "beach mark". Corresponding to each stress cycle, there will be a striation pattern on the fatigue fracture surface, which is a significant feature of the fatigue fracture surface. In Fig. 5b, there are dense fatigue fringes and small hole-like secondary crack sources. Here is the stable crack growth area. Under the stress cycle, the crack propagates to the direction of plate thickness and width, and finally, the lower plate fracture connection fails.

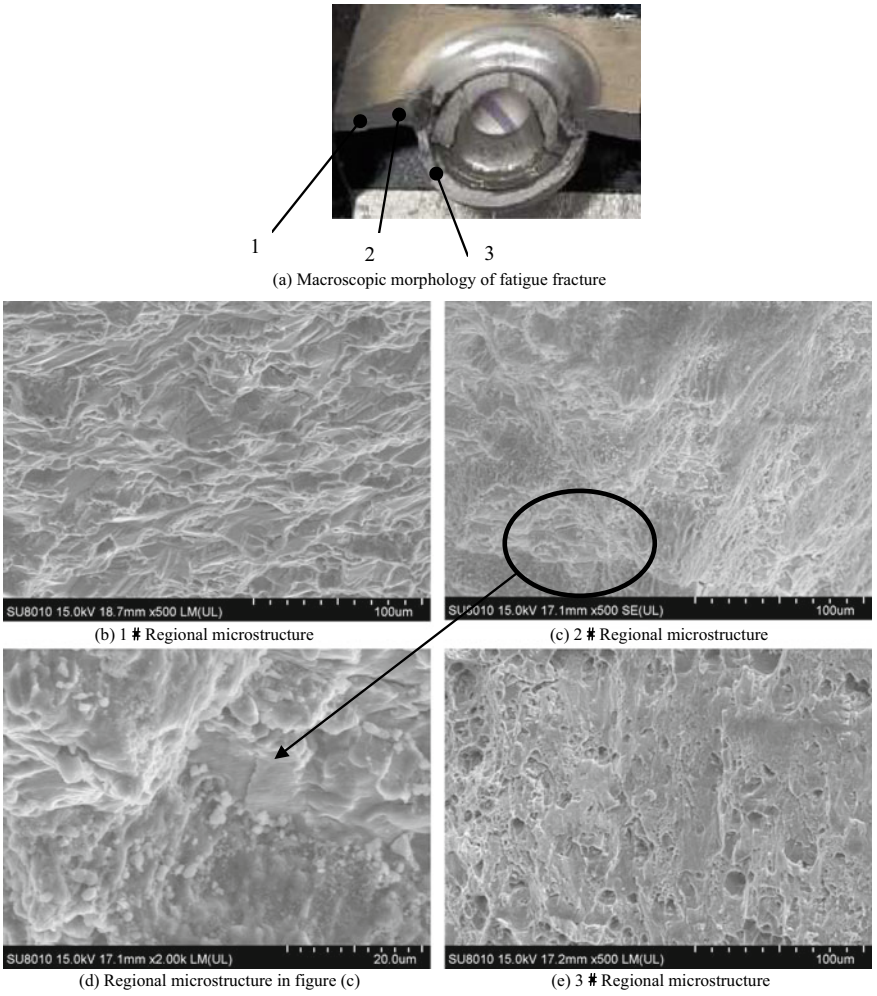
3.3.2 Failure Mechanism of DA32 Joints



The results of SEM of the rivet fracture of DA32 group 5 are shown in Fig. 6. Select an area of rivet fracture as shown in Fig. 6a, and the observation results are shown in Fig. 6b. It can be found that the morphology of this region shows the characteristics

(a) Macroscopic morphology of fatigue fracture

(b) 1 # Regional microstructure



(c) 2 # Regional microstructure

Fig. 6 Fracture surface of rivet for group DA32 No. 5. (Color figure online)

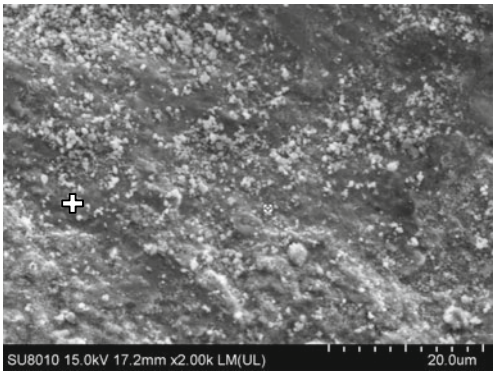
of fatigue stripe and river pattern, which belongs to the fatigue quasi-brittle fracture feature. In Fig. 6c, a large number of microfatigue cracks and particles are observed on the rivet leg, and it can be seen that the rivet also has plastic deformation in the fatigue test of the DA32 sample.

The lower plate fracture of DA32 Group No. 5 sample was observed by SEM, as shown in Fig. 7. From Fig. 7a of the actual failure sample, it can be seen that there are a large number of black particles in 2#. It can be seen from the microstructure of Fig. 7c, d that there are micropores and a large number of particles in this part. These particles are the wear debris formed by strong microvibration at the contact between rivet foot and lower plate under the action of alternating load. In the local position

(a) Macroscopic morphology of fatigue fracture

(b) 1 # Regional microstructure

(c) 2 # Regional microstructure



(d) Regional microstructure in figure (c)

(e) 3 # Regional microstructure

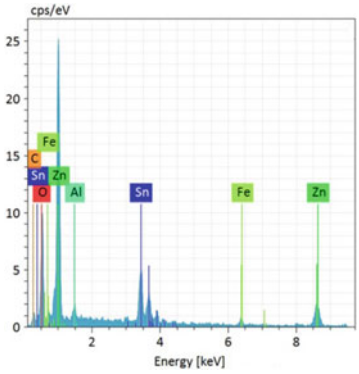


Fig. 7 Fracture surface of the lower plate for group DA32 No. 5. (Color figure online)

of the contact surface, the wear debris gathers here to produce stress concentration, which leads to the damage of the interface of the base metal and the formation of tiny cavities. Under the action of alternating load, these micro-holes connect and expand gradually, the stress at the crack tip will increase continuously, and new microholes will be generated at the same time. And finally, the joint connection fails, so this part is the fatigue source area. In Fig. 7b, obvious fatigue strip tearing edge, a large number of microcracks, and wider cracks are seen, which are obvious microscopic characteristics of the fatigue growth zone. In Fig. 7e, a large number of torn dimples and microcracks can be seen, which is the transition area from the fatigue growth zone to the transient fracture zone. In the process of forming local microcracks, the joint between dimples is stretched or broken, which makes the fracture crack expand. With the increase of the number of cycles, the crack propagates to the thickness and width of the plate, which eventually leads to the instantaneous fracture of the joint. The high hardness of rivets in DA32 group joints leads to a quasi-brittle fracture of rivets under moderate fatigue load. At the same time, the rivet leg and the lower plate, and the upper plate and the lower plate produce severe vibration wear in this process, which makes the lower plate break and leads to connection failure.

According to the energy spectrum analysis of the black particles in the contact between the rivet foot and the lower plate in Fig. 7, the main components are Zn, O, Sn, C, Fe, and Al, and the atomic mass percentages are, respectively, 38.75%, 26.42%, 23.05%, 7.61%, 2.92%, and 1.48% in Fig. 8. Among them, Zn and Sn elements are the coating elements on the rivet surface, respectively. C and Fe elements are from the worn rivets or the upper plate, and the Al element is from the substrate. It can be speculated that the rivets in the fatigue test of DA32 joints have severe microvibration wear, which leads to the steel rivets falling off. The friction heat produced in the process of vibration intensifies the speed of forming black oxide particles by chemical changes with oxygen elements in the air, which is the source of the initiation and propagation of fatigue cracks. It is also confirmed that under the action of alternation, contact wear will occur and eventually lead to the failure of the connection.

(a) Microstructure of the lower plate surface

(b) Energy spectrum of fatigue wear debris

Fig. 8 Fracture surface of the lower plate for group DA32 No. 5. (Color figure online)

4 Conclusions

(1) At a higher load level, the fatigue life of DA32 joints is higher than that of AA35 joints under the same load. At a lower load level, the fatigue life of the AA35 joints is higher than that of the DA32 joints under the same load.
(2) The failure mode will change obviously if the upper substrates are different. When the upper plate of the joint is replaced by DP590, the fatigue failure is changed from one form to many forms. When the DA32 joint is at a medium load level, the joint is rivet fracture failure. At high load level and low load level, the failure mode of the joint tends to be the fracture failure of the lower plate. The fracture zone is located in the rivet fastening area and extends to the width and thickness of the plate. AA35 joints all have lower plate fracture failure, and the fracture zone is under the rivet region, which transfers from the middle part of the rivet to the direction of plate thickness and plate width.
(3) Rivet fracture is characterized by fatigue stripe and river pattern, which belongs to fatigue quasi-brittle fracture. There are a lot of particles, micropores, and tearing edges in the source area of fatigue crack of the lower plate fracture, and a lot of fatigue stripes and beach marks in the crack propagation area.
(4) The energy spectrum analysis of the black particles in the contact area between the rivet foot and lower plate indicates that the rivet suffers from severe fretting wear in the joint fatigue test, which results in the peeling of the surface coating on the rivet foot and aggravates the failure rate. Therefore, the fatigue life of the joint can be effectively increased by slowing down the friction and wear of the joint.

Fretting Damage and Fatigue Property Analysis of Self-piercing Riveted Joints of AA5052 Aluminium Alloy

Zhichao Huang, Yongchao Zhang, and Jiamei Lai

Abstract The fatigue tests of self-piercing riveted joints of AA5052 aluminium alloy were carried out by axial tension-tension loading mode. The microfracture characteristics of the specimen were analyzed by a scanning electron microscope. The fatigue property as well as the fretting damage failure mechanism of SPR joints with different parameters (distance, stress ratio, load level and riveting direction) were studied. The results show that the fatigue cracks occur in the fretting damage area where stress concentration exists. The form and the distribution of the fretting debris are important factors that affect the fatigue property of the joint. Within the value range, fatigue life increases with the increase of stress ratio, however, decreases with the increase of loading level adopted. The fatigue property of joints differs between different riveting directions. Better strength property could be obtained when the riveting direction reverses.

1 Introduction

With the promotion of energy-saving and emission reduction as well as the popularization of environmental protection awareness, the increasing application of the lightweight concept in the design and manufacturing phase of a vehicle has become an inevitable trend. The light metal materials such as aluminium alloy, magnesium alloy, and titanium alloy are widely used. The emergence of all-aluminium car bodies could achieve effective weight reduction on the basis of ensuring the basic functions. However, questions such as oxidation and deformation arise when

the lightweight materials are connected by the traditional resistance spot welding process. As a cold forming technology, self-piercing riveting (SPR) technology has advantages of simple process, low energy consumption, low pollution, stable and controllable forming quality, all of which could effectively connect homogeneous and heterogeneous light material and is widely used in manufacturing industry [1–4].

The fatigue fracture destruction in mechanical structure accounts for about 50–90% of the total mechanical failure, so it is of great importance to study the fatigue property and failure mechanism of the SPR joints. Xing et al. conducted static and fatigue tests of SPR joints with different numbers and distribution patterns of rivets. The results show that the mechanical properties are influenced by not only the rivet number but also the rivet distribution pattern [5]. Han et al. studied the effect of specimen configuration on the mechanical behaviour of multi-layer SPR joints. The effect of configuration on the strength and the failure mechanism is significant. Secondary bending plays an important role in the static shear failure of the specimen [6]. Liu et al. generalized the process parameters which influence the fatigue property of the SPR joint and summarized the methods to improve the fatigue performance of SPR joint [7]. Li et al. conducted the fatigue characteristic study of 6111T4 aluminium alloy and HSLA340 steel SPR joints. It is found that rivet shank fracture is prone to occur under high-load level and frictional wear generates on the interface between substrates, as well as substrate and rivet [8]. Han et al. investigated the fretting behaviour of aluminium alloy SPR joints with different interfacial conditions. The results show that the use of wax-based solid surface lubricant and PTFE tape could prolong fatigue life [9]. Huang et al. found that the fatigue strength of SPR joints increases with the increase of stress ratio, and the fatigue strength decreases with the increase of the maximum load through the TA1 titanium alloy SPR joint fatigue test and fracture wear analysis. In addition, the influence of riveting position on the fatigue strength of shear specimens was studied [10, 11]. Zhao et al. systematically studied the influence factors of the fatigue life and failure modes of SPR joints. The results show that the increase of the substrate thickness and strength can effectively improve the fatigue life of SPR joints [12]. Moraes et al. discovered that interface contact force exists in the initial area of fretting wear from a high-accuracy finite element analysis of SPR forming process. They also found that the fatigue cycle failure prediction model based on linear elastic fracture mechanics indicates that initial wear fatigue occurs in the high interface contact force area [13].

At present, the research of the influence factors on fatigue property and failure mechanism of light metal material SPR joint is not thorough enough. On the basis of the single-factor experiment method, the influence of riveting position, load level, stress ratio, and riveting direction on the fatigue property and failure mode of the AA5052 aluminium alloy SPR joints were analyzed. The scanning electron microscope was adopted to analyze the microstructure of fatigue fracture, and the joint fatigue failure mechanism was generalized. Through the fatigue test and mechanism analysis of the AA5052 aluminium alloy SPR joints, the fatigue behaviour characteristics were discussed, which can provide a certain reference for the extended application of SPR technology of aluminium alloy and other light metal materials in automobile manufacturing and other industries.

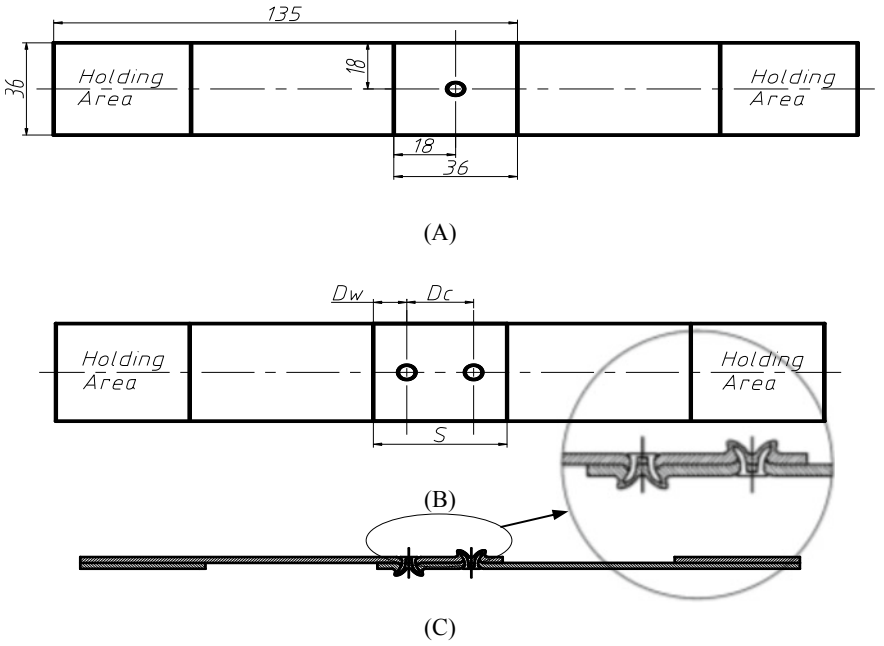

Fig. 1 Schematic diagram of lap specimen

2 Experiment Preparation

2.1 Specimen Preparation

In this experiment, the AA5052 aluminium alloy substrate was used to prepare the specimen for the static tensile test and the fatigue test. The geometry dimension of aluminium alloy was 135.0 * 36.0 * 2.0 mm, and the geometric size of the lap specimen was shown in Fig. 1. Figure 1a, b is schematic diagrams of a specimen with one and two rivets, respectively. Dw represents the distance between the centre of the nail hole and the short edge, while Dc represents the distance between the centres of the two nail holes longitudinally, and S represents the lap length. The rivet adopted is the semi-tubular rivet produced by Henrob company, and the size of which is ϕ 5.3 * 6.0 mm.

2.2 Experiment Scheme

Firstly, the static tensile tests of a single-rivet specimen and a two-rivet specimen with different Dc and riveting directions were conducted. Their failure maximum loads

Table 1 Maximum load in static tensile test

Specimen	Single-rivet	Two-rivet					
		Same direction			Opposite direction		
		15.0	25.0	35.0	15.0	25.0	35.0
Load/KN	4.76	9.53	9.75	9.67	9.25	9.90	9.26

Table 2 Fatigue test scheme

Rivet number	*Dc*/mm	Stress ratio (*R*)	Load level (*L*)	Riveting direction
Single	–	0.1	50%	–
Two	15.0	0.1	30%	Same direction (*T*) Opposite direction (*F*)
	25.0	0.2	50%	
	35.0	0.3	70%	

were obtained. A different percentage of the load was taken as the maximum load in the tension-tension fatigue test. The RGM4030 universal tensile testing machine was adopted and the displacement control speed was 2.0 mm/min. Five specimens were tested in a static tensile test for each parameter, and 3 specimens with similar results were selected for analysis. The *Dc* adopted in the test was 15.0 mm, 25.0 mm, and 35.0 mm, respectively. The failure maximum load obtained was listed in Table 1.

The fatigue tests of SPR specimens were carried out on the basis of the data in Table 1. The experiment scheme was shown in Table 2. The symbol *R* represents stress ratio; *L* represents load level; *T* represents same direction and *F* represents opposite direction.

The QBG-50 high frequency fatigue testing machine was adopted in the fatigue test. The sinusoidal wave was selected for tension-tension loading with a loading frequency of about 85 Hz. The fatigue test was carried out 5 times for each parameter, and 3 specimens with similar results were selected for analysis, so as to avoid inaccurate results caused by data dispersion.

3 Fatigue Test and Analysis

3.1 Fatigue Test of Single-Rivet Specimen

The fatigue test of a single semi-tubular rivet SPR joint was conducted. The lap length was 36.0 mm, and the stress ratio *R* was 0.1. 70% of the maximum load (4.76 KN) obtained in the tensile test was taken as the maximum load in the fatigue test. The static load was 1.83 KN and the dynamic load was 1.49 KN from the formula. The mean number of load cycles of the specimen is about 180.3 * 103 times. If the

maximum load adopted was 9.75 KN obtained in the two-rivet SPR joint static tensile test, then the fatigue life was shorter and the failure of the joint occurred sooner.

3.2 *Influence of Dc on Fatigue Property*

The influence of parameter *Dc* on the fatigue property of specimen was analyzed, and the *Dc* was 15.0 mm, 25.0 mm, 35.0 mm, respectively. 50% of the maximum load value (9.75KN) obtained in the tensile test of the specimen with better static strength was taken as the maximum fatigue cyclic load, and the stress ratio *R* was 0.1. The fatigue life of the specimen with different *Dc* was shown in Fig. 2.

It can be seen from Fig. 2 that the fatigue life of the specimen increases with the increase of *Dc*. While the base material is connected by self-piercing riveting technology, the riveting point is the location of main material failure and flow moulding, and stress concentration easily generates under the action of cyclic load, which inevitably promotes the damage and destruction of SPR joints. The smaller the distance between the centres of the rivet holes, the less material that can bear the impact of the cyclic load. And the two moulded riveting points are more likely to interact with each other, resulting in the accelerated failure of the specimen.

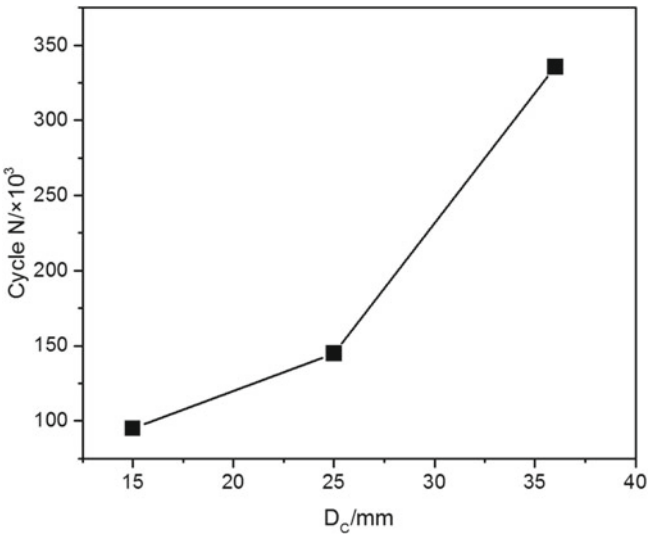

Fig. 2 Fatigue life with different *Dc*

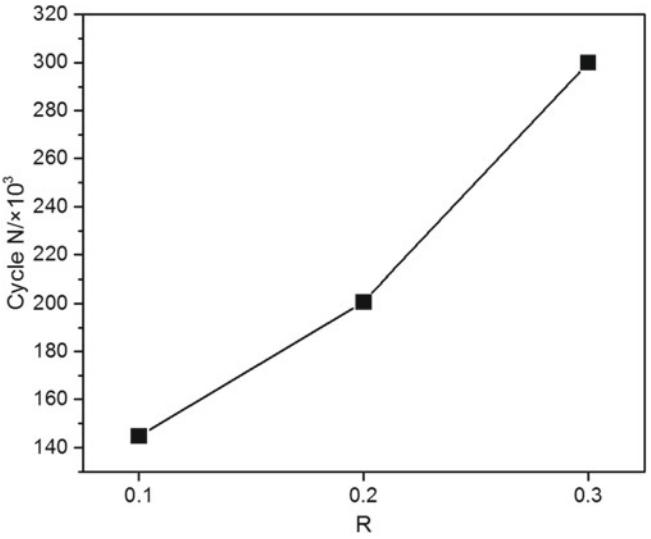

Fig. 3 Fatigue life with different *R*

3.3 Influence of Stress Ratio on Fatigue Property

The stress ratio adopted was 0.1, 0.2, 0.3, respectively. 50% of the maximum load value (9.75 KN) obtained in the static tensile test was taken in the fatigue test and the *Dc* was 25.0 mm. In the fatigue test the static load was 2.68 KN and the dynamic load was 2.19 KN. The influence of stress ratio on fatigue property of the specimen was analyzed and the relationship of cycle fatigue life and stress ratio was shown in Fig. 3.

As can be seen from Fig. 3, the higher the stress ratio, the higher the cycle fatigue life. The stress ratio is the ratio of the minimum load to the maximum load under cyclic loading. The stress amplitudes corresponding to the three stress ratios were 2.19 KN, 1.95 KN, and 1.70 KN, respectively. It can be seen that as the stress ratio increases, the stress amplitude decreases gradually, then the driving force of dislocation motion under cyclic load decreases likewise. The destruction rate of the material flow moulding decreases and the fatigue life increases accordingly. The result indicates that the value of stress amplitude adopted in the fatigue test has a great influence on the fatigue life of the SPR joints.

3.4 Influence of Load Level on Fatigue Property

30%, 50%, and 70% of the maximum load value (9.75 KN) obtained in the static tensile test were taken, respectively, as fatigue load for fatigue property analysis.

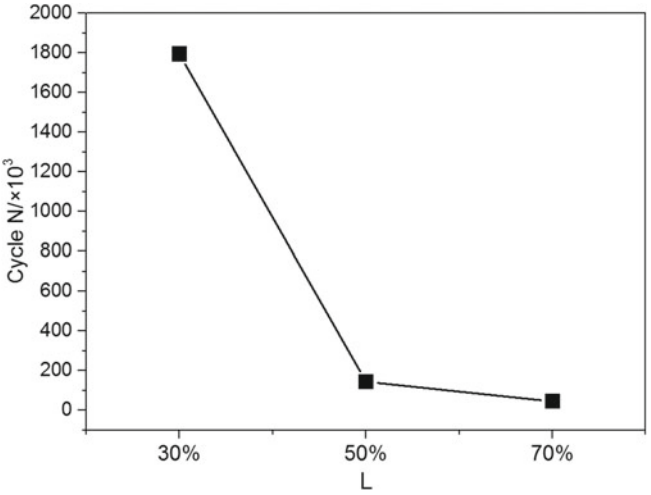

Fig. 4 Fatigue life with different load

The stress ratio adopted was 0.1. The relationship of cycle times and load level was obtained, as shown in Fig. 4.

When the static load was 3.75 KN and the dynamic load was 3.07 KN, the number of load cycles is 45.1 * 103. When the static load was 1.61 KN and the dynamic load was 1.32 KN, the number of load cycles is 1796.2 * 103. As seen in Fig. 4, the fatigue life of the specimen decreases significantly with the increase of the load level. When the riveting point is subjected to cyclic loading, the joint damage gradually accumulates and the substrate gets broken at the last stage of fatigue test. While the load value decreases, the static load and dynamic load decrease accordingly. The linear change rate of rigidity of the SPR joint gradually tends to be gentle, then the surface wear, crack initiation and propagation slow down, and the fatigue life of the joint increases.

3.5 Influence of Riveting Direction on Fatigue Property

The fatigue property of a two-rivet SPR joint with two kinds of riveting directions was analyzed. The opposite riveting direction was shown in Fig. 1c, and the comparison of the specimen can be seen from Fig. 5.

Compared with the specimen connected from the same riveting direction, the fatigue life could be increased by about 14.8% by changing the riveting direction. Self-locking structures are moulded on both the upper and the lower surface of the substrates by opposite direction riveting. Under cyclic loading, the relative micro-amplitude motion of the substrates could be better suppressed. In addition, the premature occurrence of buckling could be prevented and the lateral force of substrates on

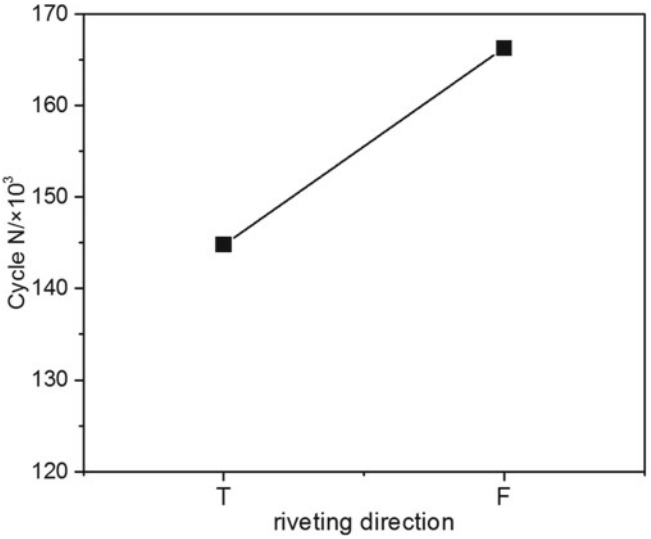

Fig. 5 Fatigue life with different riveting direction

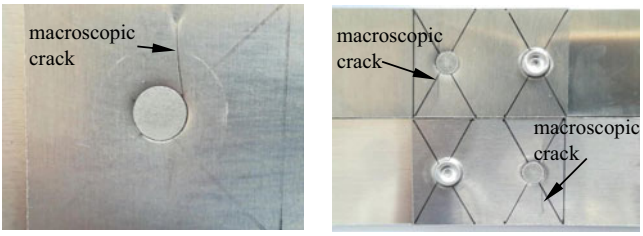


the rivet could also be reduced, thus damage of self-piercing riveting structure can be delayed to some extent.

4 Failure Mode and Fracture Analysis

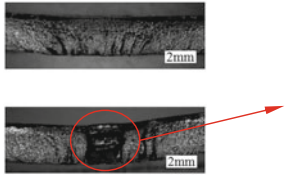
4.1 Macroscopic Failure

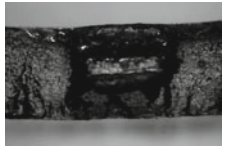
The fatigue failure mode of specimens with different parameters is the substrate material fracture, while the rivets are not broken. The failure mode of a single-rivet SPR joint is the fatigue fracture of substrate at the moulding structure. The crack direction is about 90°from the loading direction, showing a symmetrical distribution along the direction of the substrate width. The failure mode of the two-rivet SPR joint with the same riveting direction is the fatigue fracture of the substrate at the moulding structure close to the piercing end near the upper fixture while no macroscopic crack occurs at the other riveting point. Macroscopic fatigue cracks occur both at the riveting holes when riveting direction reverses and are distributed at the end of the piercing substrate. Once the crack emerges around the riveting hole, it would expand rapidly along the substrate width to both ends under cyclic loading. The overall crack length is about 20.0 mm, accounting for half the width of the substrate. The failure modes of various riveting specimens were shown in Fig. 6.

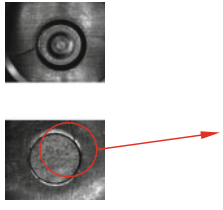
The Dino microscope was adopted for preliminary analysis of the upper substrate section, as shown in Table 3. It can be seen that there are obvious material groove

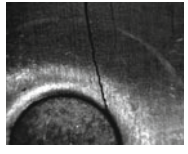
(A) Single-rivet joint (B) Two-rivet joint

Fig. 6 Macroscopic crack and fracture. (Color figure online)

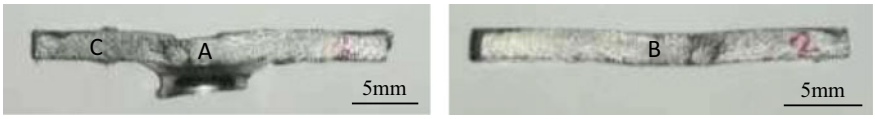








faults around the riveting hole along the direction of substrate thickness. This kind of morphology radiates upward from the contact surface between the substrates, and the length is about two-thirds of the substrate thickness, which does not extend to the upper surface of the upper substrate. The substrate profile around the hole is relatively rough and that away from the hole is smoother.



4.2 Microscopic Morphology Analysis of Substrate Fracture

The fatigue fracture specimens were naturally pulled off on the tensile testing machine, and then the scanning electron microscope samples of the section were prepared for observation. The macroscopic fracture section was shown in Fig. 7.

SEM microstructures of the fatigue failure fracture were shown in Fig. 8. Obvious macroscopic cracks can be observed in Fig. 8a and the cracks extend along the direction of substrate thickness. Figure 8b is the microscopic morphology of area A in Fig. 7a with a magnification of 1000 times, and under cyclic loading the micro-cracks initiate in this area. Obvious micro-cracks could be observed. Figure 8c is obtained by magnifying 5000 times of the same area. It can be found that micro-cracks exist along the direction of substrate thickness, and fatigue striation characteristics are dispersed on the micro-morphology. Figure 8d shows the microscopic morphology of area B in Fig. 7b with a magnification of 10,000 times. From the graph evident fatigue striation characteristics can also be discovered. Figure 8e is obtained by magnifying 2000 times of area near the surface of the upper substrate. Figure 8f shows the microscopic morphology of area C in Fig. 7a with a magnification of 500 times. Both figures present evident brittle fracture characteristics and it is consistent with the phenomenon of rapid fracture in the later stage of fatigue test. In addition, evident accumulation of powdery substance can be observed on the contact surface between the substrates, and the area is highly coincident with the crack initiation area. Therefore, during the fatigue fracture failure process of the AA5052 aluminium alloy SPR joint, material fretting wear occurs violently on the contact surface between upper and lower substrates. The generation and nucleation of fretting debris which is torn off from the substrates promote the initiation of fatigue micro-cracks, and the

(D) (E) (F)

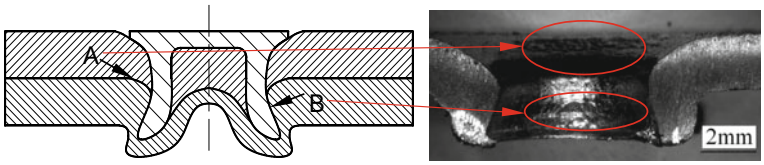

Fig. 8 Microscopic morphology of different fracture region

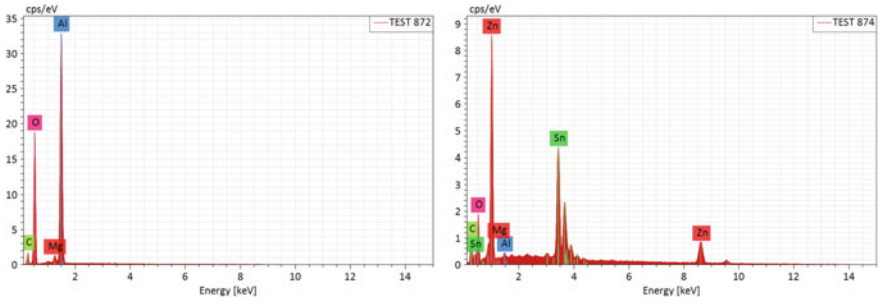
cracks extend to a certain depth below the surface of the substrate. Simultaneously the cracks extend along the direction of substrate width till the macroscopic fatigue fracture failure finally.

4.3 Wear Analysis

The SPR specimens with macroscopic fatigue cracks after the fatigue test were pulled off on the tensile testing machine to prepare for the wear analysis test sample. Observation shows that there are black wear areas on the surface between the substrates as well as rivet shank and the lower substrate, as shown in Fig. 9 (A area: contact surface between substrates; B area: contact surface between rivet shank and lower substrate).



By the combination of scanning electron microscope observation and energy spectrum analysis, it can be seen that there exist more aluminium and oxygen elements in

(A) (B)

Fig. 9 Wear area diagram of SPR joint. (Color figure online)

the fretting debris on the contact surface between substrates. It can be inferred that the composition of the black fretting debris is mainly Al_2O_3, that is the *Al* element torn off from the substrate is oxidized into fretting debris. In the fretting debris on the surface between the rivet and the lower substrate, there exist more *Zn*, *Sn*, *Mg*, and other elements. This is because the rivet surface has anti-oxidation coating containing Zn, Sn, and other elements. The result indicates that small relative motion and contact force exist in the area under cyclic loading. Therefore, it can be seen that the fretting wear of the SPR joints under cyclic loading mainly exists on the contact surface between substrates and rivet shank. Exfoliation, oxidation as well as nucleation occur during the fatigue test till final failure. The formation of fretting debris in the wear area is related to material property and the environment. At the initial stage of wear, the substrate material falls off under the action of shear force and then becomes fretting debris, which moves on the surface of the material and produces cold welding points under the action of extrusion. With the increase of cold welding points, the mutual adhesion and tear increase. The oxidation would be enhanced and the wear rate would be accelerated, resulting in the increase of abrasive particles that promote the initiation and propagation of micro-cracks. Under continuous cyclic loading, the micro-cracks unite into macro-crack and lead to the fatigue failure of the riveting structure (Fig. 10).

(A) Contact surface between substrates (B) Contact surface between rivet and substrate

Fig. 10 Energy spectrum analysis of fretting debris. (Color figure online)

5 Conclusions

(1) Within the distance value range of two riveting centres, the fatigue life of the SPR joint increases with the increase of the distance. Compared with the two-rivet SPR specimen with the same riveting direction, the fatigue life could be increased by about 14.8% when the riveting direction is opposite.
(2) With the increase of stress ratio or the decrease of load level, the relative fretting and damage of the riveting structure decrease, consequently the fatigue fracture failure would be delayed and the fatigue life of the SPR joint can be significantly improved.
(3) The fatigue failure of the specimen is the fracture of the upper substrate, and it can be known that the fatigue micro-cracks initiate on the contact surface between the substrates through SEM analysis. The micro-cracks unite into the macroscopic crack and extend along the direction of substrate thickness and width. The area far away from the rivet hole represents brittle fracture and has typical fatigue failure characteristics.
(4) On the contact surface between substrates as well as the rivet and the lower substrate, there exist obvious fretting wear areas. Fretting debris and accumulation exist in these areas, and the black debris is mainly Al_2O_3 mixed with Mg, C, Zn, Sn, and other elements. The debris accelerates the initiation and propagation of fatigue crack and finally results in the fatigue fracture failure of the SPR joints.

Elastoplastic Finite-Element Analysis of Multi-Body Processes for Joining Mechanical Parts

SukHwan Chung, Jaedong Yoo, and ManSoo Joun

Abstract Fabricating lightweight assembly of auto parts is of great importance and joining technology using plastic deformation is very attractive because of high strength and structural reliability. In developing such assembling processes, prediction technology with high accuracy is essential to optimize the structural system and minimize the manufacturing cost. However, the related technologies are still insufficiently developed for the sake of application because of complexity of the problem. In this paper, an improved methodology of conducting elastoplastic finite-element analysis of multi-body metal forming processes is given with emphasis on the contact condition treatment. The presented approach is applied to simulate a rotary forging process of assembling a third-generation hub bearing unit. The inner races of the duplex pair taper roller bearings are considered elastic materials. Prestresses imposed on them are predicted.

Keywords Elastoplastic finite-element method · Multi-body metal forming · Rotary forging · Penalty method

1 Introduction

Finite-element predictions have become prevailing in the related industries because they can contribute to constructing an acceptable scientific platform for process design and technical management. The simulation technology has played key roles in innovating especially the forging industry [1, 2]. Our experiences [3–5] make us say that most predictions are reliable and that the costly trial-and-errors can be excluded from the process development procedure of common forgings including bearing parts, gear parts, fasteners, etc.

To the contrary, there are still some topics in metal forming simulation which should be improved, theoretically and practically, which include finite-element predictions of forging processes for hard-to-form materials such as magnesium and titanium and predictions of multi-body forming processes. These topics belong to major interests of metal forming researchers owing to strong request to save global environments. The trend of global automobile market can be characterized by steadily increasing use of light materials and/or high strength materials with high structural reliability. To cope with this trend, researchers are focusing their efforts on expanding the applications of lightweight material and integrating several parts into a single part and thus joining technology relying on plastic deformation has increasingly become one of the core technologies.

Even though metal forming simulation technique already became indispensable in the field of metal forming, engineers, or researchers are not still supported by appropriate CAE technologies for solving some practical problems and related mechanics occurring in various joining processes because of their mechanical and geometric complexity. Recently, several predictions of multi-body metal forming or joining processes [6] were introduced, which are based on some improved numerical schemes including contact condition treatment scheme of the singular nodal points which meet over two objects or planes of symmetry.

In this study, theoretical backgrounds of joining process simulation or multi-body metal forming simulation based on the elastoplastic finite-element analysis are given and its application to a rotary forging process of assembling a third-generation hub bearing unit are presented, which is one of extreme applications of multi-body problems in metal forming, showing the versatility of the approach.

2 Elastoplastic Finite-Element Formulation

Because elastoplastic deformation is path-dependent, total process should be analyzed by a series of solution steps with sufficiently small step sizes. In dealing with large deformation, large rotation as well as large strain should be considered. For this purpose, deformation gradient tensor **F** for each solution step is calculated, which is polar decomposed into the rotation tensor **R** and the right stretch tensor **U** as follows:

$$\mathbf{F} = \mathbf{RU} \tag{1}$$

From the right stretch tensor defined in the above equation, the strain increment $\Delta\boldsymbol{\varepsilon}_{ij}$ is defined by

$$\Delta\boldsymbol{\varepsilon}_{ij} = \ln(\mathrm{U}_{ij}) \tag{2}$$

Stress increment from solution step n to solution step $n + 1$, denoted as $\Delta\boldsymbol{\sigma} = [\Delta\sigma_{xx}, \Delta\sigma_{yy}, \Delta\sigma_{zz}, \Delta\sigma_{xy}, \Delta\sigma_{yz}, \Delta\sigma_{zx}]^T$, is calculated by the radial return method

using strain increment $\Delta\boldsymbol{\varepsilon} = [\Delta\varepsilon_{xx}, \Delta\varepsilon_{yy}, \Delta\varepsilon_{zz}, \Delta\varepsilon_{xy}, \Delta\varepsilon_{yz}, \Delta\varepsilon_{zx}]^T$ as follows:

$$\boldsymbol{\sigma}^*_{n+1} = \boldsymbol{\sigma}_n + \Delta\boldsymbol{\sigma} = \boldsymbol{\sigma}_n + \mathbf{C}\left(\Delta\boldsymbol{\varepsilon} - \Delta\boldsymbol{\varepsilon}^p\right) = \boldsymbol{\sigma}_n + \mathbf{C}^{ep}\Delta\boldsymbol{\varepsilon} \tag{3}$$

where $\boldsymbol{\sigma}^*_{n+1}$ is stress calculated without considering the rotation from the solution step n to solution step $n+1$. $\boldsymbol{\sigma}_n$ expresses the stress at the solution step n which was already calculated in the previous solution step. $\mathbf{C}$ is elastic stiffness matrix and $\Delta\boldsymbol{\varepsilon}^P$ is the plastic strain increment. During iteration to obtain converged solution of Eq. (3), the elastoplastic consistent tangent stiffness $\mathbf{C}^{ep}$ is applied for better convergence. The process of calculating the elastoplastic consistent tangent stiffness and stress increment. $\Delta\boldsymbol{\sigma}$ depends on yield criterion and the way of calculating $\Delta\boldsymbol{\varepsilon}^P$. In this study, von Mises yield criterion is applied.

Stress at the solution step $n+1$, denoted as $\boldsymbol{\sigma}_{n+1}$, is calculated by transforming the stress $\boldsymbol{\sigma}^*_{n+1}$ calculated from Eq. (3) using the rotation tensor R as follows:

$$\boldsymbol{\sigma}_{n+1} = \mathbf{R}\boldsymbol{\sigma}^*_{n+1}\mathbf{R}^T \tag{4}$$

It has been well known that hexahedral elements are better of tetrahedral elements in terms of numerical stability and solution accuracy. However, it is very difficult to generate automatically hexahedral finite-element mesh system for metal forming simulation. To the contrary, tetrahedral finite-element mesh system can be generated in any situation for such purpose. However, they are exposed to numerical locking phenomena due to excessively constrained incompressibility, which can be solved by adding a degree-of-freedom of hydrostatic pressure onto a node.

In general, metal forming simulation problem is conceptually defined by a deformable body V with displacement (or velocity) prescribed boundary S_u and traction prescribed boundary S_t to find out the unknowns of displacement (or velocity) $\mathbf{u}$ and hydrostatic pressure p. The above boundary value problem can be formulated by the following weak form:

$$\int_V \delta\boldsymbol{\varepsilon}^T\boldsymbol{\sigma}dV - \int_V \delta\boldsymbol{\omega}^T\mathbf{b}dV - \int_{S_t} \delta\boldsymbol{\omega}^T\mathbf{t}dS = 0 \tag{5}$$

$$\int_V \delta q\left(\varepsilon_v + pK^{-1}\right)dV = 0 \tag{6}$$

where $\delta\boldsymbol{\omega}$ is arbitrary except that $\delta\boldsymbol{\omega} = 0$ on S_u and δq is arbitrary. In the above equations, $\boldsymbol{\sigma}$ and $\boldsymbol{\varepsilon}$ are stress tensor and strain tensor, respectively, and $\mathbf{b}$ and $\mathbf{t}$ are body force and traction, respectively. In addition, $\boldsymbol{\varepsilon}_v$ means volumetric strain and K is the bulk modulus of elasticity. The volumetric strain can be expressed as

$$\boldsymbol{\varepsilon}_v = \mathbf{m}^T\boldsymbol{\varepsilon} \tag{7}$$

where $\mathbf{m}^T = [1\ 1\ 1\ 0\ 0\ 0]$.

If the solution at the solution step n was calculated, the solution at the solution step $n+1$ can be calculated by substituting Eqs. (3) and (7) into Eqs. (5) and (6) as follows:

$$\int_V \mathbf{B}^T\left(\boldsymbol{\sigma}_n' + \mathbf{D}_d\mathbf{B}\Delta\mathbf{U}\right)dV - \int_V \mathbf{B}^T\mathbf{m}\mathbf{N}_p\, p dV - \int_V \mathbf{N}_u^T\mathbf{b}dV - \int_{S_t} \mathbf{N}_u^T\mathbf{t}dS = 0 \tag{8}$$

$$-\int_V \mathbf{N}_p^T\mathbf{m}^T\varepsilon_v dV - \int_V \mathbf{N}_p^T\mathbf{m}^T\mathbf{B}\Delta\mathbf{U}dV - \int_V \mathbf{N}_p^T K^{-1}\mathbf{N}_p p dV = 0 \tag{9}$$

where $\boldsymbol{\sigma}'$ is the deviatoric stress, $\mathbf{D}_d$ the deviatoric stress–strain relationship and $\mathbf{B}$ the strain–displacement matrix.

When the interpolation function of displacement, denoted as $\mathbf{N}_u$ and that of hydrostatic pressure, denoted as $\mathbf{N}_p$ are of the same order in the tetrahedral finite-element mesh system, numerical vibration of hydrostatic pressure occurs. To cope with this problem, tetrahedral MINI-element is applied [7]. In this scheme, the bubble interpolation function $\mathbf{N}_b$ with bubble displacement $\Delta\mathbf{U}_b$ is additionally employed to increase the order of displacement and to solve the numerical problem.

Applying Newton–Raphson method to Eqs. (8) and (9), the following finite-element equations can be derived.

$$\begin{bmatrix} \mathbf{K}_0 & \mathbf{H}_{ub} & \mathbf{H}_{up} \\ \mathbf{H}_{ub}^T & \mathbf{H}_{bb} & \mathbf{H}_{bp} \\ \mathbf{H}_{up}^T & \mathbf{H}_{bp}^T & \mathbf{V} \end{bmatrix} \begin{bmatrix} \Delta\mathbf{U} \\ \Delta\mathbf{U}_b \\ \Delta\mathbf{P} \end{bmatrix} = \begin{bmatrix} \mathbf{f}_{ext} \\ 0 \\ 0 \end{bmatrix} - \begin{bmatrix} \mathbf{f}_{int} \\ 0 \\ \mathbf{f}_p{}^p \end{bmatrix} \tag{10}$$

where $\mathbf{f}_{ext}$, $\mathbf{f}_{int,}$ and $\mathbf{f}_p$ are external force vector, internal force vector and internal force vector concerned with hydrostatic pressure, respectively. The subscript 0 represents the term concerned with standard interpolation function, the subscript b expresses the term concerned with bubble interpolation function, and the subscript p represents the term concerned with hydrostatic pressure. The submatrices of total stiffness matrix are defined as

$$\begin{aligned} &\mathbf{K}_0 = \int_V \mathbf{B}_0^T\mathbf{D}_d\mathbf{B}_0 dV,\ \mathbf{H}_{ub} = \int_V \mathbf{B}_0^T\mathbf{D}_d\mathbf{B}_b dV,\ \mathbf{H}_{bb} = \int_V \mathbf{B}_b^T\mathbf{D}_d\mathbf{B}_b dV \\ &\mathbf{H}_{up} = -\int_V \mathbf{B}_0^T\mathbf{m}\mathbf{N}_p dV,\ \mathbf{H}_{bp} = -\int_V \mathbf{B}_b^T\mathbf{m}\mathbf{N}_p dV,\ \mathbf{V} = -\int_V \mathbf{N}_\mathrm{u}^\mathrm{T} K^{-1}\mathbf{N}_u dV \end{aligned} \tag{11}$$

$\mathbf{f}_{ext} = \int_V \mathbf{N}_u^T\mathbf{B}_0 dV + \int_{S_t} \mathbf{N}_u^T\mathbf{t}dS$, $\mathbf{f}_{int} = \int_V \mathbf{B}_0^T\left(\boldsymbol{\sigma}_n' + \mathbf{m}\mathbf{N}_p\mathbf{P}\right)dV$, $\mathbf{f}_p = -\int_V \mathbf{N}_p^T\left(\mathbf{m}^T\varepsilon_v + K^{-1}\mathbf{N}_p\mathbf{P}\right)dV$

Deleting the bubble displacement $\mathbf{U}_b$ from Eq. (10), the following finite-element equations can be derived:

$$\begin{bmatrix} \mathbf{K}_0 - \mathbf{H}_{ub}\mathbf{H}_{bb}^{-1}\mathbf{H}_{ub}^T & \mathbf{H}_{up} - \mathbf{H}_{ub}\mathbf{H}_{bb}^{-1}\mathbf{H}_{bp} \\ \mathbf{H}_{up}^T - \mathbf{H}_{bp}^T\mathbf{H}_{bb}^{-1}\mathbf{H}_{ub}^T & \mathbf{V} - \mathbf{H}_{bp}^T\mathbf{H}_{bb}^{-1}\mathbf{H}_{bp} \end{bmatrix} \begin{bmatrix} \Delta\mathbf{U} \\ \Delta\mathbf{P} \end{bmatrix} = \begin{bmatrix} \mathbf{f}_{ext} \\ 0 \end{bmatrix} - \begin{bmatrix} \mathbf{f}_{int} \\ \mathbf{f}_p \end{bmatrix} \tag{12}$$

3 Treatment of Multi-Body Boundary Conditions

Considering that two materials are contacting each other during joining process as shown in Fig. 1, it should be satisfied that the normal velocity component of material 2 at *j*-th node should be the same with that at the same position of material 1. The normal velocity of material 1 at the same position of *j*-th node of material 2 can be calculated from Eq. 13, where the normal velocity at the contacting node of material 2, denoted by $\mathbf{n}_i^1$, is defined by the surface normal direction of material 1 and r is the relevant ratio of position of *j*-th node of material 2 at the corresponding segment of material 1.

$$\mathbf{v}_j^{1n} = \mathbf{v}_j^{2n} \rightarrow \left((1-r)\mathbf{v}_{i-1}^1 + r\mathbf{v}_i^1\right) \bullet \mathbf{n}_i^1 = \mathbf{v}_j^2 \bullet \mathbf{n}_i^1 \tag{13}$$

The constraint can be numerically treated by using penalty method, where the term shown in Eq. (14) is added to the weak form for the elastoplastic finite-element equations shown in Eq. (5), where ξ is the penalty constant.

$$\xi\left(\left((1-r)\mathbf{v}_{i-1}^1 + r\mathbf{v}_i^1\right) \bullet \mathbf{n}_i^1 - \mathbf{v}_j^1 \bullet \mathbf{n}_i^1\right)\left(\left((1-r)\delta\mathbf{v}_{i-1}^1 + r\delta\mathbf{v}_i^1\right) \bullet \mathbf{n}_i^1 - \delta\mathbf{v}_j^1 \bullet \mathbf{n}_i^1\right) \tag{14}$$

If two materials are perfectly bonded, the additional constraint that the tangential velocity at the contacting points should be satisfied likely to the normal directional velocity constraint as shown in Eq. (15), where $\mathbf{t}_i^1$ is the tangential direction defined by the contacting surface of material 1. Otherwise, the frictional force acts on the contacting area as shown in Eq. (16), where $\boldsymbol{F}_n$ is the normal directional nodal force

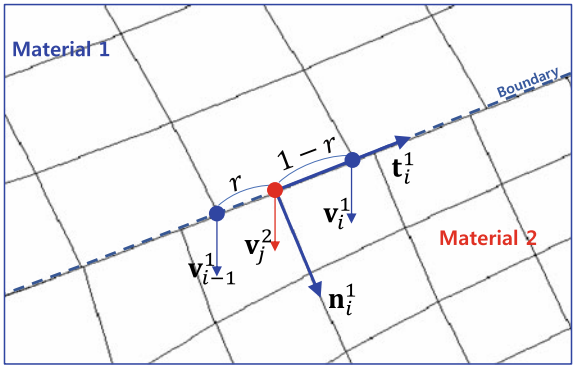

Fig. 1 Schematic description of the relation between the velocities at the contacting surface of multi-body. (Color figure online)

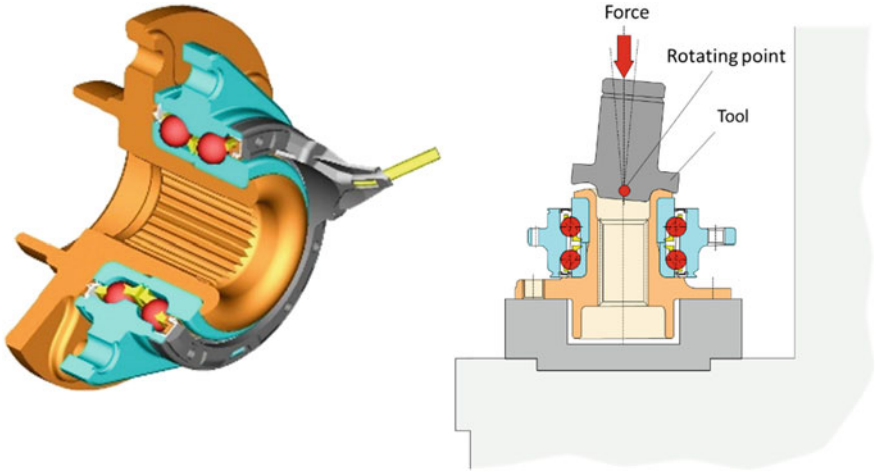

of given node.

$$\xi\left(\left((1-r)\mathbf{v}_{i-1}^{1}+r\mathbf{v}_{i}^{1}\right)\bullet\mathbf{t}_{i}^{1}-\mathbf{v}_{j}^{1}\bullet\mathbf{t}_{i}^{1}\right)\left(\left((1-r)\delta\mathbf{v}_{i-1}^{1}+r\delta\mathbf{v}_{i}^{1}\right)\bullet\mathbf{t}_{i}^{1}-\delta\mathbf{v}_{j}^{1}\bullet\mathbf{t}_{i}^{1}\right) \tag{15}$$

$$\boldsymbol{F}_{t}=\mu\boldsymbol{F}_{n}\mathrm{g}(\Delta\mathbf{v}_{t}),\ \mathrm{g}(\Delta\mathbf{v}_{\mathrm{t}})=\frac{\pi}{2}tan^{-1}\left(\frac{|\Delta\mathbf{v}_{t}|}{\mathrm{a}}\right) \tag{16}$$

4 Simulation of a Rotary Forging Process of Assembling a Third-Generation Hub Bearing Unit

With the development of automobile fabrication technology, a third-generation hub bearing assembled with ABS sensor becomes generalized through the consistent integration with surrounding parts as shown in Fig. 2a. It is usual that an orbital forming or rotary forging process [8–10] has been applied to assemble hub with bearing units as shown in Fig. 2b. In designing the orbital forming process, proper residual stress after assembly is one of the major concerns not only because excessive stress during orbital forming can cause damage in bearing unit [11] but also because insufficient stress can cause the clamping force to be much reduced. Nonstandard prestresses can thus cause premature fracture of bearing parts. However, most studies on these topics [12–15] have focused on revealing plastic deformation of material

(a) Third-generation hub bearing unit (b) Rotary forging process

Fig. 2 Third-generation hub bearing unit and its rotary forging process to assemble hub and bearing units. (Color figure online)

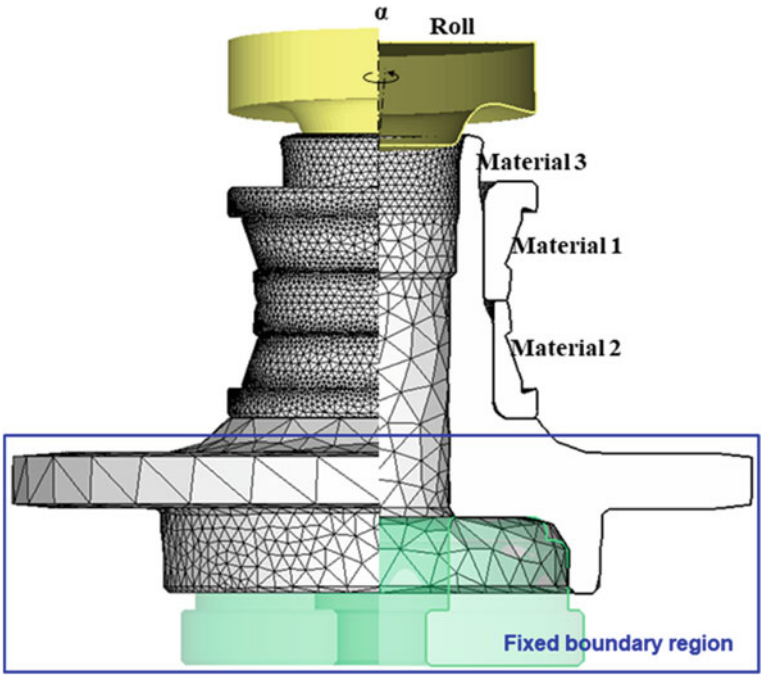

Fig. 3 Finite-element analysis model. (Color figure online)

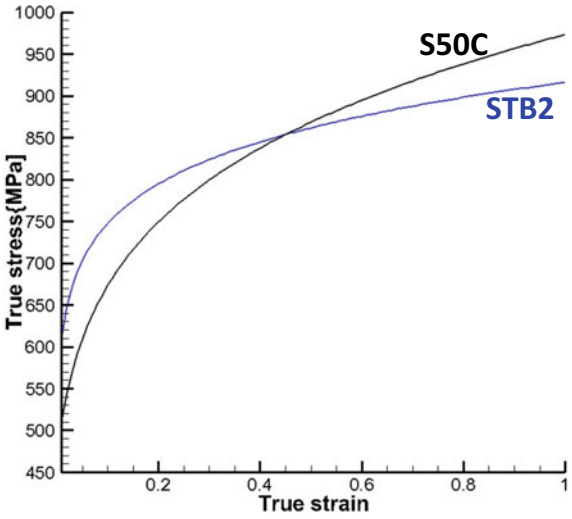
during assembling the unit. As far as we know, there is no research work published with keywords of both hub bearing and residual stress. Most research works have thus seemed to stay outside of main issues of this subject.

Figure 3 shows an elastoplastic finite-element analysis model of the multi-body flow analysis problem, composed of three materials including hub (S50C) and two inner races (STB2) of a duplex pair taper roller bearing, an upper die, that is, a forming tool in the upper side and a clamping tool to assign essential boundary conditions. The forming tool was assumed rigid while all the materials were assumed to behave elastoplastically. The clamping tool at the lower side is employed to impose zero-velocity boundary conditions onto all the nodes which are inside the clamping tool. Young's moduli of all the materials are assumed 210 GPa and flow stresses are shown in Fig. 4 [4]. The frictional stresses between the rotating tool and the hub material were formulated by hybrid law of Coulomb friction and constant shear friction and coefficient of Coulomb friction and friction factor were assumed 0.1 and 0.2 [5, 16], respectively. The interfaces between materials were assumed frictionless because sliding motions between them are negligible. It was assumed that the hub material is fixed and that the forming tool evolves while moving downwards and it rotates with respect to its own idling axis. Note that the above tool motion in the analysis model is mechanically the same with its original motion, that is, the forming tool moves down only while idling with respect to its central axis, implying that the relative



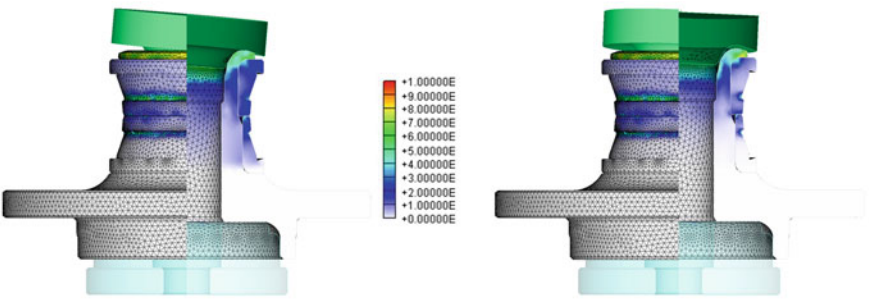


Fig. 4 Flow stresses of the materials. (Color figure online)

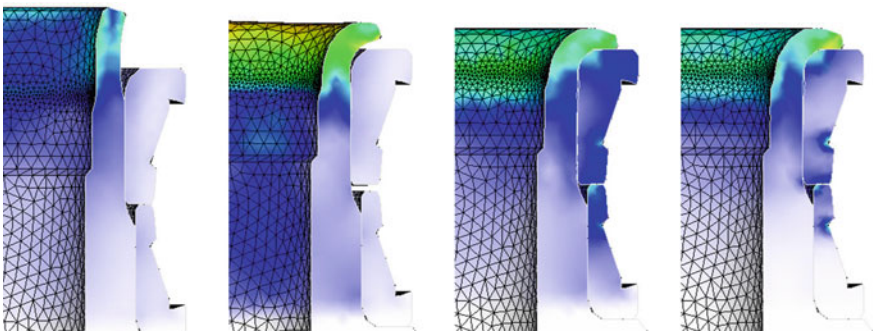

velocity is the same with each other. The evolving velocity was assumed 200 rpm and the moving-down velocity 1.6 mm/s. The forming tool moves down for 8.2 s, stays for 0.8 s, and returns for 1.5 s to its original position. Total number of tetrahedral elements amounts to 33,000 and that of solution steps 8400. The penalty constant ξ was assumed 10,000,000.

Figure 5a shows the effective stress at the instant when the forming tool touches its lowest position and Fig. 5b shows the residual after the forming tool returns. It should be noted that the difference between the effective stress at the final contact of the forming tool with the material (see Fig. 5a) and the final residual stress is not remarkable because the forming tool always contacts very partially with the material to be formed. Of course, the stress distribution of the material during being formed varies quite much with the location of the forming tool. Figure 6 shows the

(a) At the end of forming (b) After unloading

Fig. 5 Effective stresses at the end of forming and after unloading. (Color figure online)

(a) t = 1.459s (b) t = 6.667s (c) t = 9.018s (d) t = 9.073s

Fig. 6 Variation of effective stress (**a**–**c**) and residual stress (**d**). (Color figure online)

variation of effective stress at a cross-section with the elapsed time. Because we exerted purposely a little greater forming load on the forming tool (180 kN) than its limit (120 kN), so much greater stress can be observed at the round corners of the inner races. Of course, we can simulate the process with limit forming load assigned to avoid the excessive prestresses at the fatal corners.

5 Concluding Remarks

In this paper, multi-body metal forming simulation technology was presented, which is based on elastoplastic finite-element method with tetrahedral finite-elements and contact treatment scheme based on penalty method. To check the rigidity of the approach and some numerical schemes employed, an extremely complicated multi-body forming process of a rotary forging process of assembling a third-generation hub bearing unit was simulated. It was verified from this application that the approach with various numerical schemes is stable and general.

The finite-element predictions were discussed with emphasis on the residual stresses, which are greatly important in conducting the assembling process design. From the application, it was shown that the proposed multi-body metal forming simulation technology can provide process engineers with meaningful information about prestresses and interfacial stresses for optimizing an assembly process of mechanical parts as well as their joining process and that it will contribute to advances in plastic deformation based assembling technology in terms of increased strength with reduced weight.

A New Non-destructive Testing Method Applied to Clinching

Rémi Lafarge, Alexander Wolf, Christina Guilleaume, and Alexander Brosius

Abstract To pursue better quality, there is a strong need for efficient and robust non-destructive testing methods for joining processes. A new approach has been proposed to detect loose bolted joints using acoustic waves. This method measures the dissipation of energy by recording the propagated waves on the surfaces of the joining partners next to the joint. The authors show a link between the torque moments applied to the bolt and the ability of the joint to transfer acoustic energy using both simulations and experiments. In this article, the method's ability to detect variations of certain process parameters of the clinching process was investigated numerically. To this extent, results of FEM calculations of the joining process are used to simulate the non-destructive testing method. By varying parameters of the clinching model, their influence on the transmission of energy within the joint is studied.

1 Introduction

Clinching is a joining by forming process without the application of additional components. Using specific tools, an interlock between two or more sheets is formed. This joining process has numerous advantages from an industrial perspective including the ability to join different materials and a great cost-effectiveness. However, the main testing solutions employed to assess the quality of a joint are currently destructive: mechanical testing like the peel test or measuring geometric properties like the undercut, neck thickness, or the final bottom thickness in cross-sections.

For a given tool geometry and corresponding parameter set, the general quality of the clinching process can be validated before the beginning of mass production using conventional destructive testing methods. Non-destructive testing (NDT) is mainly aimed at a fast quality assessment during production to detect defective joints resulting from process disturbances like tool wear, punch displacement or material variations like sheet thickness, surface roughness, or yield strength.

The article numerically investigates the sensitivity of a new NDT method to changes in different input parameters that could be evolving during the process: friction forces, punch displacement and die punch relative positioning.

2 State of the Art

The aim for a lightweight design concept, especially in the area of transportation demands a flexible usage of different materials to best utilise their respective properties. Therefore, various joining techniques exist for applying form-locking as well as material or frictional bonds between two or more materials [1].

The focus of this paper is the clinching process, where two overlapping sheets of metal are formed plastically to create an interlock without an additional functional element like a rivet or bolt. The load capacity of the form-locking and frictional bond is primarily defined by the undercut and the neck thickness, see Fig. 1. In the process, the two sheets are fixed in position on the die and the punch presses the material into the die, thereby creating the undercut and form-lock. The geometry of the resulting joint regarding undercut, neck thickness and bottom thickness can be varied by using different die and punch geometry combinations, adjusting the process to different materials and sheet thicknesses. Neugebauer et al. [2] improved the process for the joining of magnesium alloys and presented a die-less clinching process. Due to this easy and variable setup and high flexibility of joinable materials, clinching is one of the most applied processes in the automotive industry [3].

A number of or non-destructive evaluation techniques exist for different kinds of joints. The selection of the particular method in each case depends on, e.g. the

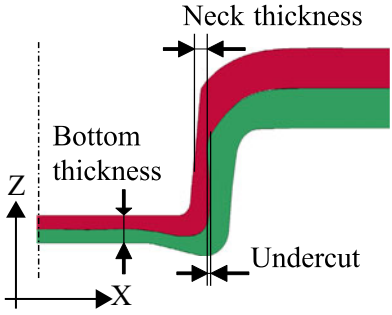

Fig. 1 Geometrical properties of a joint. (Color figure online)

material combination, the safety requirements and regulations, or the accessibility of the connection. A well-known procedure is the pulsed thermography testing that analyses the heat propagation in and around the joint [4]. It is suitable for all kinds of materials and can also be used on large structures like wind turbines for condition monitoring [5]. Another option is the ultrasonic sound testing which is mainly used for welded joints [6]. Other lesser known testing solutions for joints next to the expensive CT-scan or radiography testing are measurements of the electrical profile [7] or Terahertz imaging [8]. All the mentioned options are limited in their applicability to clinched joints. Sometimes the dimensions of the connection are too large or too small, sometimes the material properties are incompatible with the process parameters. Most importantly, the costs often exceed the usefulness of the procedure when having hundreds of joints on large structures consisting of 10000–30000 parts in a car up to several million part in an aircraft [9].

Different NDT are available for the clinching process. Optical tests using crack detection lack safety and are not suited for industrial application [10]. Measuring bottom thickness is possible but lacks reliability [11]. Finally, the condition monitoring of process parameters by pre-defined hull curves is currently the best and most reliable method to ensure a safe connection and is also used with regard to quality management norms [12]. However, this method does not verify the geometrical forming of a proper cross section of the joint.

Wolf et al. [13] proposed a new NDT for evaluating joint quality. A elastic stress wave is generated and travels through the joint. Part of the energy is transmitted through the link while another part is reflected, so three waves are present: one emitted, one reflected and one transmitted. By measuring the transmitted and reflected stress waves, it is possible to evaluate the bolted connection, in this case determining whether the bolt is loose or tightened. This proposed method has the advantages of being non-destructive, very fast, and theoretically applicable to many different materials including composites. In Wolf et al. [14] the ability of this method to detect loose joint was studied numerically and experimentally. In this paper, the possibility of extending this method to clinched joint will be studied.

3 Modelling

The sensitivity of the testing method will be investigated numerically. For this purpose, a complete model of the evaluation process must be implemented. The sequence of the analysis starts with the forming process of the clinching point. Then, as the tools are removed, springback occurs and will be simulated. Finally, the measurement process itself will be simulated. Post-processing is then done using a user routine implemented in Python. LS-DYNA (R11) is used to compute the model, using Massively Parallel Processing (MPP) and double precision. Between every simulation of the analysis sequence, a dynain file is created, containing the current deformed mesh

coordinates and stress information for every element. These values are then used to initialise the next simulation step. Every simulation is performed in three dimensions using a single symmetry plane.

3.1 Forming Simulation

The forming process is simulated first. The geometry of the tools used is represented Fig. 1. The simulation is run using implicit mode of LS-DYNA, with dynamic analysis activated and adaptive timesteps. Implicit integration scheme is here used due to the quite slow process, compared to the critical timestep (following Courant's stability criteria) associated with the mesh. Using explicit scheme would therefore lead to a very high number of timestep and therefore a very high computation time. The mesh is created using Hypermesh, using a variably sized hexahedral mesh for the sheet and shell elements for the tools. The deformable parts contain around 691000 elements. A fully integrated element formulation is used to prevent hourglassing issues. The material model is implemented as an elastic–plastic model with von Mises criteria and associated flow rule and isotropic strain hardening parametrised with a power law. No strain rate effect is taken into account. The material parameters correspond to a DC04 (1.0338) steel. The contact is simulated using a penalty function. The friction model implemented is a simple Coulomb law. Default friction coefficient is 0.1 and the punch displacement is set to 5.1 mm. The simulation time is about 7 h using 16 cores on Intel Xeon CPU E5-2680 v3 @ 2.50GHz.

3.2 Springback Simulation

Simulation of springback is also performed using an implicit scheme. The simulation is initialised using the dynain file written at the end of the preceding forming simulation. The same material and contact models are used as in the forming simulation. All additional degrees of freedom are removed by fixing an adequate number of nodes. A dynain file is generated as output at the end of the simulation. Running time is about 1 h using 8 cores.

3.3 Stress Wave Simulation

The measurement process consists of an analysis of a stress wave propagation through the joint. It is, therefore, done using the explicit mode of the solver, as the explicit integration scheme is much more adapted to short time simulation and stress wave propagation studies. The simulation is initialised using the dynain file output of the previous springback simulation. The same contact model is employed, but a purely

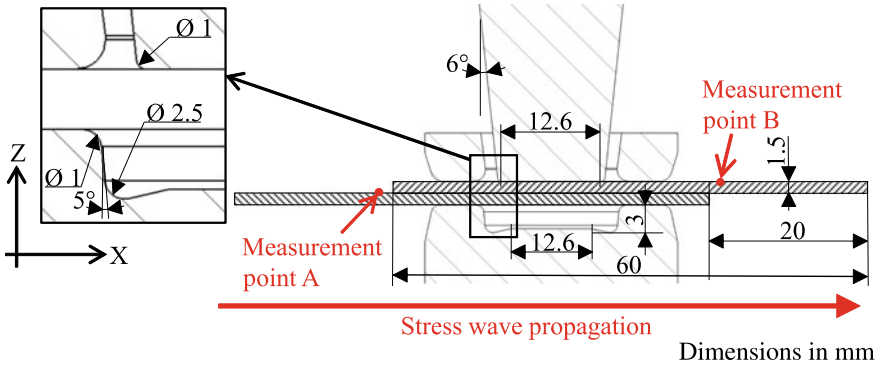

Fig. 2 Tool's geometry and measurement points. (Color figure online)

elastic material model is used. The load consists in nodal force in x-direction (see Fig. 2) applied on the surface of the lower sheet. The amplitude and length are chosen such that the resulting stress wave peak at given stress value of 25 MPa and with length of 20 ms. For post-processing, a user routing implemented in Python is employed, which enables calculations on node and element values. Two measurement points are created by selecting elements on the blank and averaging their stress level for the component colinear to wave propagation (σ_{xx}), see Fig. 2.

4 Results and Conclusions

The parameters of the numerical analysis are presented in Table 1. For each simulation, only one parameter is changed. The goal is to validate the idea that the parameters can influence stress wave propagation through the joint. If there is a detectable difference between resulting stress waves, this method can theoretically be used to test clinched joints.

Table 1 Parameter change for every simulations

Simulation	Parameter change
#1	All parameters are nominal
#2	Friction is increased to 0.3
#3	Punch displacement is decreased to 4.1 mm
#4	Punch is displaced 0.2 mm in the X direction
#5	Die is rotated 1° around Y axis

Table 2 Properties of simulated clinched joint

Simulation	Neck thickness in µm				Undercut in µm				Bottom thickness in mm			
	Left		Right		Left		Right		Left		Right	
#1	490		490		106		106		1.04		1.04	
#2	493	0.6%	493	0.6%	119	12%	119	12%	1.05	1%	1.05	1.0%

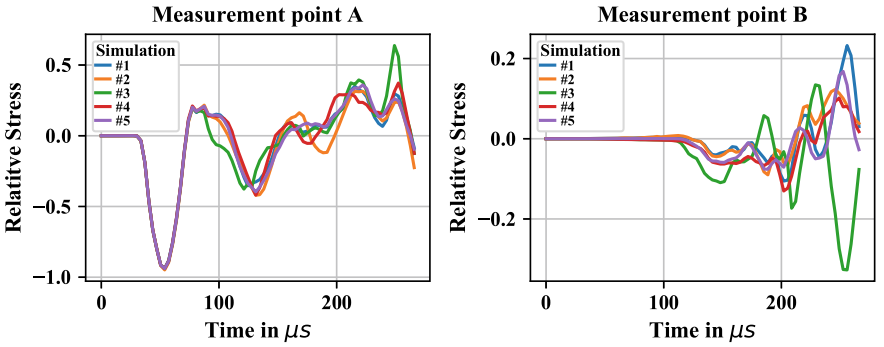

Fig. 3 Stress values at point A and B. (Color figure online)

Table 2 presents the results of the forming and spring back simulation. Neck thickness, bottom thickness, and undercut have been measured using mesh information. The percentages represent the relative deviation to the first simulation.

Figure 3 presents the measurement at the two measuring points for all simulations. The relative stress is the average stress value divided by the peak of the stress wave. From the results of the five simulations, it can be derived that both reflected and transmitted waves are affected by changes to the different input parameters analysed here. Table 3 present characteristic values of the first transmitted wave and the first reflected wave. The percentages represent the relative deviation to the first simulation. By comparing this information with the results of the forming simulation presented in Fig. 2, it appears that changes to the friction coefficient have very little influence on the geometric properties of the joint and consequently on the transmitted and reflected first wave. Unlike the bolted connection investigated in [14], where friction forces transmitted most of the energy, it seems that in clinching point, the energy transmission is more dependent on the geometrical parameters of the joint.

The results of the simulation show that the transmission of the energy is affected by the process parameter variation. Therefore, this method is generally suitable to detect deviations in clinched joints. At this point, the method does not yet link a specific property change to a certain characteristic of the transmitted and reflected

Table 3 Properties of transmitted and reflected waves

Simulation	Reflected wave				Transmitted wave			
	Length in μs		Peak		Length in μs		Peak	
#1	37.5		0.2		103		−0.105

#5	36.9	2%	0.208	4%	100	3%	−0.07	33%

stress waves, but a general sensitivity is demonstrated. This issue might be circumvented with a frequency domain analysis, where the exiting signal is sinusoidal. Some variation might be linked to specific frequencies, which then would be visible on a spectral diagram.

Investigation on the Strain Induced Oxide Layer Fracture and Bonding During Cold Rolling of Aluminum Alloys

Mahsa Navidirad, Wojciech J. Stepniowski, Elijah Cartier, Tyler Christ, Masashi Watanabe, and Wojciech Z. Misiolek

Abstract Physical bond rolling experiments of aluminum sheets have been investigated in this study. In addition to native oxides on surface of aluminum, a thick oxide layer was deliberately added to AA3xxx aluminum sheets by anodization. For better monitoring of evolution of the oxide layer during roll bonding, the anodized layer was colored with Indigo Carmine in the anodization process. A progressive reduction per pass ranging from 2 to 70% has been performed in consecutive experiments at a constant rolling speed to develop different degrees of oxide surface expansion leading to its fracture and leaving disparate oxide fragments. The evolution of the oxide fragmentation and bonding of aluminum sheets were systematically characterized as a function of deformation by electron microscopy. It was revealed that the crack width between fragmented oxides increases exponentially while the oxide fragment size decreases exponentially as a function of the reduction ratio.

Keywords Roll bonding · Direct recycling · Aluminum recycling · Coated strips · Metal expansion · Coating fracture

1 Introduction

Aluminum recycling process, which mainly involves re-melting of aluminum scraps and casting, is far less expensive and energy intensive than creating prime aluminum through the electrolysis of aluminum oxide mined as bauxite [1]. However, material loss during re-melting cannot be avoided due to contamination with oxides, oil, and plastic coatings of the scraps [2]. To overcome this problem associated with the re-melting, an alternative solid-state recycling, which is a process of converting metal chips to final or semifinal product through hot deformation techniques, has been proposed [3]. Until now, several attempts have been made regarding solid-state recycling of aluminum alloys by using machining chips of different shape and chemical compositions in combination with various severe plastic deformation methods

including hot extrusion [4–6]. One of the main challenges of this process is yielding a product with optimum mechanical properties by fulfilling the best condition for solid-state welding of aluminum chips. In fact, the natural oxide layer on the surface of the chips acts as a barrier in bonding a virgin metal to metal [7].

In this regard, studies of the cold-welding process a.k.a. solid-state welding would provide fundamental mechanism of chips welding [8]. Bay correlated the weld strength to the contact surface area and normal pressure and found that the bonding between chips is not achieved until a certain critical surface expansion has occurred [7]. According to Guley et al. [8] the sound welding of chips would be ensured when two criteria are fulfilled: (1) the oxide layer has to break down by imposing shear stress greater than a criterial shear stress level to cause the breaking of the oxide layer, and (2) the cumulative value of the ratio of the mean stress to the flow stress must be greater than a defined constant value for a given alloy and specific extrusion process conditions. Cooper et al. [9] also indicated that an aluminum interface must be stretched by a threshold strain to cause welding. The required strain would be decreased by increasing the normal contact stress, temperature, or shear stress. Moreover, increases in the strain rate have little influence on the bond strength at low temperatures, but significantly decreases the bond strength at temperatures above 423 K. In contrast, solid-state welding of aluminum strips at different temperatures and over different process paths revealed that diffusion is an important mechanism in bonding aluminum at high temperatures [10]. Le et al. [11] studied the crack propagation behavior in the oxide layer of a single aluminum sheet and showed that the spacing between cracks increases as the oxide film thickness increases. The oxide layer was fragmented into far smaller pieces when the oxide film was below a critical thickness. They concluded that metal will not penetrate through the broken oxide layer until a critical reduction of about 13% is reached.

All the mentioned theories above are in agreement that the main phenomena yielding a sound bonding are fracture of the surface oxide layer and exposure of fresh metal surface. It seems obvious that the fracture process of the oxide layer and the extrusion of metal through the oxide cracks is a topic requiring much more attention. In this work, the fragmentation of the surface oxide layer and metal deformation behavior of the aluminum sandwiches are systematically studied as a function of the reduction ratio during cold rolling. To obtain a comprehensive assessment on the fragmentation of oxide layer, aluminum strips were deliberately covered with anodically grown colored oxide film. The oxide fragmentation behaviors were carefully characterized by electron microscopy.

2 Experimental Procedures

Commercial purity Aluminum alloy (AA3003) strips with initial dimensions of 80 $\times$ 20 $\times$ 2 mm^3 were used as starting material. Samples were chemically polished by immersing them in 20% HNO_3 for 3 min followed by rinsing in 10% NaOH for 30 s. In order to anodize only one surface of the strips, backs, and edges of the samples

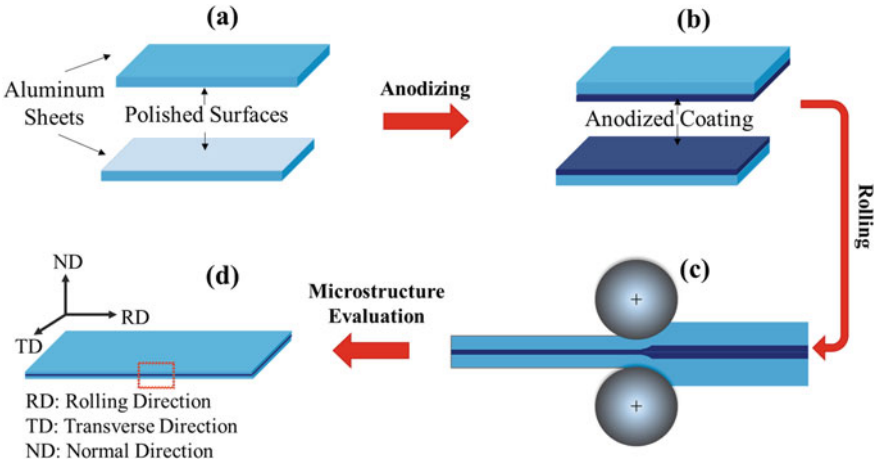

Fig. 1 Summary of roll bonding process of anodized aluminum sheets: **a** chemical polishing and painting, **b** anodizing, **c** roll bonding and **d** definitions of sample geometry for observation. (Color figure online)

were coated with acid-resistant paint. The strips were finally anodized in electrolyte of 20% H_2SO_4 at 1 °C under applied voltage of 23 V for 4 h to fabricate the oxide film with a thickness of ~40 μm. For better observation of evolution of the oxide layer, the electrolyte was dyed with Indigo Carmine, the organic dye-containing nitrogen and sulfur and providing a strong color. Several sandwich samples were made by clamping the coated surfaces of two sheets as internal sides of the bonded sandwich.

Roll bonding of the sandwiches was carried out using a laboratory 4-high rolling mill with a 40 mm working roll and rolling speed of 26 rpm. Each sandwich was rolled at specific reduction ratio between 2 and 70%. Finally, the Scanning Electron Microscope (SEM) with an X-ray energy dispersive spectrometer (XEDS) (Hitachi 4300SE/N) was used to observe evolution of oxide layer fragmentation, crack formation, and extrusion of metal through broken oxide layer as function of the reduction ratio. The schematic procedures of roll bonding process of anodized aluminum sheets are summarized in Fig. 1.

3 Results

A cross-sectional SEM image of a single coated Aluminum strip as well as XEDS spectra from the metal and coating layer are shown in Fig. 2. A uniform, smooth, and almost defect-free coating with a thickness of ~40 μm can be observed (Fig. 2a). The coating layer also seems to have a good adhesion to the substrate. By comparing XEDS spectra between the substrate and coating layer, Nitrogen and Sulfur, which

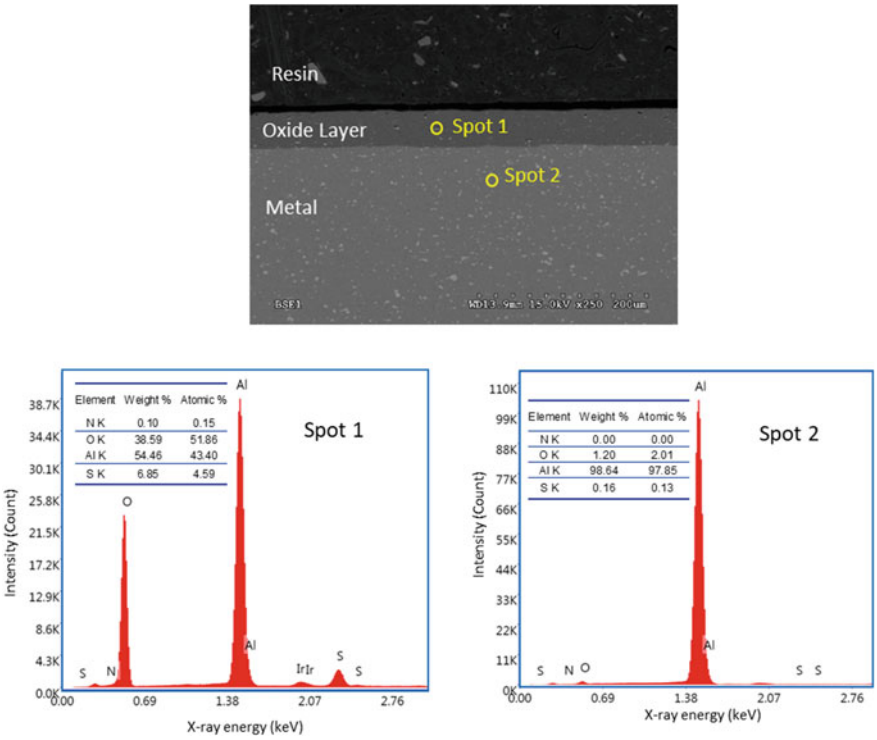

Fig. 2 A cross-sectional SEM micrograph of coated aluminum strip before rolling and XEDS spectra taken from regions indicated as spots 1 and 2 in the SEM image. (Color figure online)

are the main constituents of Indigo Carmine, are found in the coating layer as well as Oxygen.

None of these sandwich sheets were bonded by rolling below 70% reduction. There is even no sign of initial bonding at all at lower strains. In contrast, tight bonding between the strips was achieved in the sandwich rolled at 70% and the strips were hardly pulled away using hand force.

The oxide layers of unsuccessful bonded sandwich samples were observed by the SEM. Figure 3a–f shows a series of SEM images of oxide layer from the samples rolled at reduction ratios between 2 and 70%. Cracks are seen in the oxide layer of all the samples even at lowest reduction (2%) and the formed cracks in all the samples are running perpendicular to the rolling direction. At 10% reduction or higher reduction, oxides are clearly fragmented and almost uniformly stretched from one side of the sample toward the other side (Fig. 3c, d) and it seems that as the reduction ratio increases the density of cracks increases 3. This phenomenon is much more pronounced in the sample rolled at reduction ratios of 35 and 45% (Fig. 3e, f) in which some cracks even started to grow parallel to the rolling direction and leave small equal-sized fragments behind. Moreover, by increasing the reduction per pass,

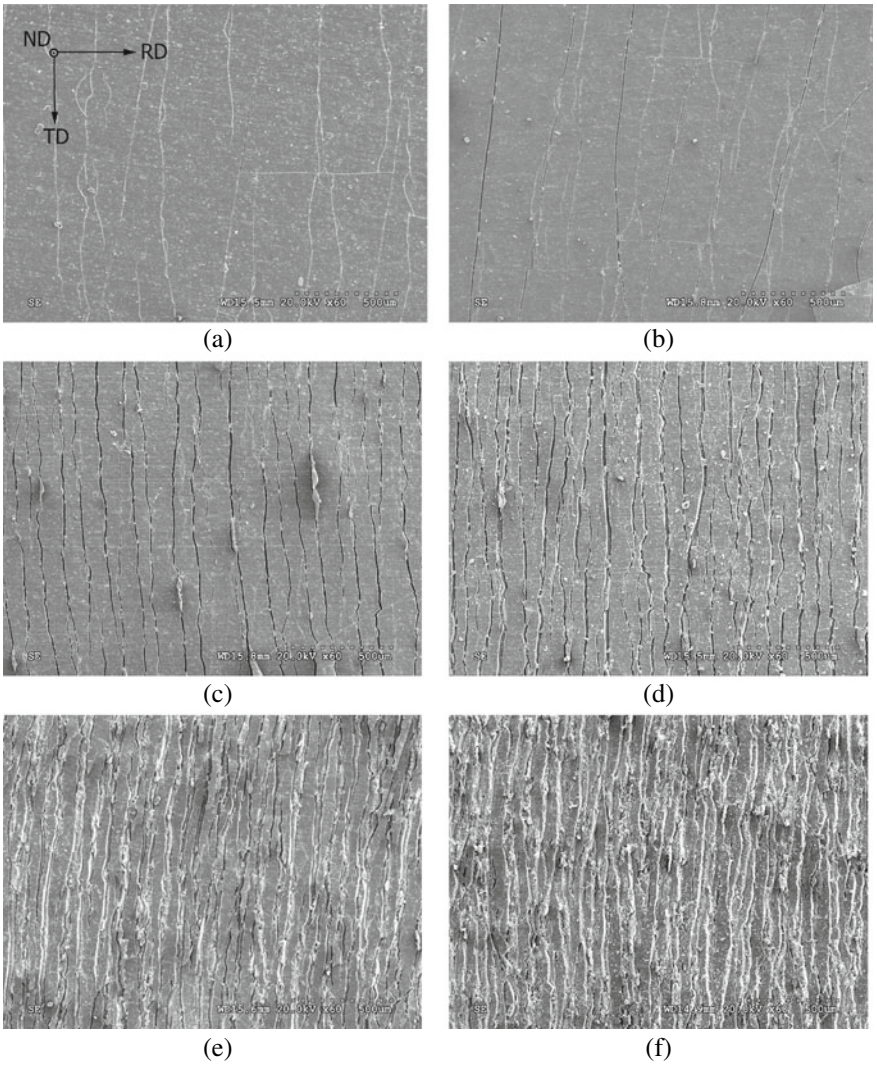

Fig. 3 A series of SEM images of the strip surface rolled at different reduction ratios: **a** 2%, **b** 5%, **c** 10%, **d** 18%, **e** 35%, and **f** 45%. RD, TD and ND represent rolling direction, transverse direction, and normal direction, respectively

the oxide layer is no longer flat, which indicates that some oxide fragments are raised and others are lowered during rolling. For better evaluation of oxide fragmentation as well as degree of oxide topography, cross section of the samples in the rolling direction was observed by the SEM (Fig. 4).

Figure 4 shows a series of cross-sectional images of the rolled sandwiches parallel to rolling direction at the different reduction ratios. It is seen that for samples rolled at

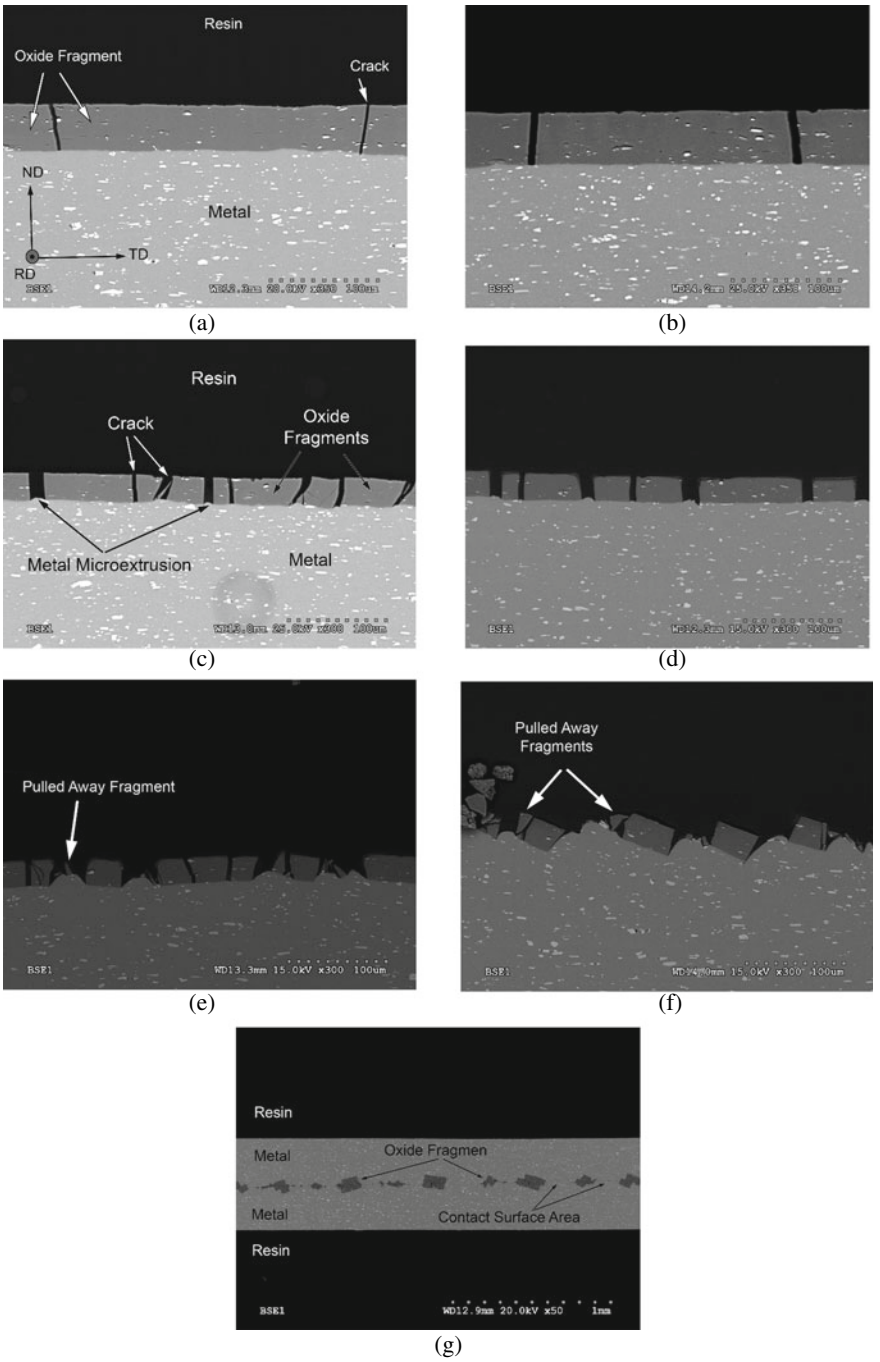

Fig. 4 A series of cross-sectional SEM images of strip rolled at the different reduction ratios: **a** 2%, **b** 5%, **c** 10%, **d** 18%, **e** 35%, **f** 45%, and **g** 70%

all reduction ratios cracks propagated through the entire oxide layer and the width of cracks increases by increasing the reduction ratio. At small reductions of 2 and 5% no metal micro extrusion was observed to happen through the cracks indicating that the applied strain at these ratios was not high enough for metal flow to happen through the crack channels. At 10% and 18% metal has only extruded partially through the cracks (Fig. 4a, b). However, it is seen that the chance of metal extrusion for 18% reduction is somehow higher than for 10% which could be due to the presence of wider cracks and higher amount of applied strain.

By increasing the reduction ratio, metal extrusion becomes more significant in the analyzed samples. For instance, in the cases of 35 and 45% reduction metal flow is high enough to extrude between fragmented oxides (Fig. 4e, f). It is seen that such high strains not only lead to higher degrees of metal micro extrusion through the cracks but also result in larger metal deformations. It means that deformation of metal substrate is in a way that rearranges the fragments and pulls some small fragments toward the contact surface area. This phenomenon seems to be a justifying reason for the observed topography in Fig. 3e, f. The metal extrusion between the fragmented oxides becomes more significant in the sample rolled at 70% reduction, which means that metal penetrated through the oxide layer and reached metal of another strip. This is why two strips were strongly bonded even with existence of enhanced oxide layers. In fact, equal or even higher fraction of metal area is connected than the presence of oxide fragments at the interface of both strips.

To find out the relationships between the crack spacing including the local extrusion of metal through fragmented oxides and the reduction ratio, the oxide fragment width and crack width are plotted as a function of reduction ratio in Fig. 5a, b.

The size of oxide fragments decreases with increasing the reduction ratio, which indicates more cracks are formed at higher reduction ratios. The decrease of the oxide fragmentation size is not linear, but rather exponential, i.e., the fragmentation size is abruptly reduced especially between the 2 and 10% reduction per pass conditions. On the other hand, increasing of the reduction ratio results in wider cracks as shown in Fig. 5b.

4 Summary

Cold rolling of aluminum sandwiches comprising of two anodized strips was carried out at different amount of reductions ranging from 2 to 70%. Expect the sample rolled at 70%, no bonding between the strips of the sandwiches rolled at different reduction ratios has occurred. Microstructure imaging of the surface and cross sections of the rolled strips revealed that by increasing the reduction ratio, the cracks tended to widen and the size of the oxide fragments had a decreasing trend which both behaviors were exponential. Decreasing pattern of fragment size could be explained as a result of increasing density of cracks as a function of the increasing reduction ratio. Increasing trend of crack width could also be due to the higher expansion of base metal under higher strains.

Ultrasonic Forming—Alternative to Orbital Riveting for Small Bimetallic Components

Wojciech Presz

Abstract The development of electrical equipment has resulted in an increase in the demand for electrical switches whose key element is contact. The orbital riveting technology has been successfully applied in assembling silver contacts. With the increase in production, attention has been paid to the possibility of obtaining significant savings by replacing part of the rivet with copper. As a result, bimetallic contacts have been created. It has also been proved that the direct transfer of orbital riveting technology from monometallic to bimetallic contacts narrows the technological window that the cost-effectiveness of the whole process is debatable. One of the factors behind the use of orbital forming is the decisive reduction in friction. A similar effect is given by ultrasonic assistance in microforming processes. Within this work, based on the laboratory experiment results, it was suggested to replace the orbital riveting with ultrasonic riveting in relation to the miniature bimetallic contacts.

Keywords Ultrasonic riveting · Orbital riveting · Bimetallic contacts

1 Introduction

In recent years, there has been a clear shift toward replacing heat engines with electric motors and, in general, replacing equipment using different types of energy with electrical equipment. The vast majority of electrical devices have a different type of construction that is simpler than other devices. This feature in particular predisposes them to miniaturisation, which is ubiquitous in the twenty-first century. Micro-electromechanical, micro-electro-electromechanical systems, micro-sensors, micro-machines, and micro-robots are no longer futuristic, but a reality. These advanced systems require parts and a large extent, metal parts. Parts that must meet high requirements for dimensional accuracy and surface quality. These requirements can

be met by parts made using metal forming technology [1, 2], specifically microforming technology [3]. Microforming mainly due to so-called "scale effects" [4] has been isolated from the metal forming area and is now a separate field. In this technology, special emphasis is placed on precise control of the structure of the material [5] and the structure of the surface layer [6]. This has a large impact on processes and the broadly understood quality of products [7]. Namely, surface layer and contact phenomena, affecting friction [8], lubrication [9], and galling [10], increasing the role of methods for preparing surfaces [11]. They also refer to the internal structure [12], which affects the surface quality and cracking mechanisms [13]. The scale effect even applies to machine construction [14], instrumentation [15, 16], tools [17] and to the design of the technological process plan [18]. Materials and friction tests using micro-samples are also done as their results differ from those obtained in macro tests [19]. Reducing the size of manufactured parts on one hand is a major challenge for traditional technologies, but on the other hand, mainly by removing the energy barrier the possibility of using other unconventional techniques like electrical assistance, magnetic waves [20], laser processing [21], and mechanical vibrations at different frequencies [22]. In the last few of these methods, ultrasonic vibrations are particularly of interest [23–25]. Ultrasonic vibrations can reduce ECAP forces [26] and micro-extrusion when friction is almost eliminated [27]. The use of ultrasonic vibrations may also cause phase changes [28], grains rotation [29], and specific macroscopic consequences in terms of cracking [30]. Under certain conditions of upsetting supported with ultrasonic vibrations, a specific shape of the side surface of the sample is formed to a phenomenon leading to antibarreling [31]. The name to a phenomenon called "barreling". This relates to the formation of the convex side surface of an upset cylinder. It is formed as a result of friction forces occurring on contact surfaces with the help of tools. Anti-barreling is the creation of a concave lateral surface. This effect is not observed in any upsetting processes involving ultrasonic vibrations [32]. The causes and consequences of this phenomenon are not fully explained and are currently being investigated. One of the hypotheses is that the punch "nose" temporarily detaches from the same surface [33]. The construction of micro-mechanisms requires appropriate joining technologies. Attention was paid to technologies that do not affect the precisely controlled material structure of micro-products—mechanical joining technologies. In the area of these technologies, a similar tendency is observed as in the case of metal forming. That is the tendency to separate mechanical micro-joining technologies [34] out of macro-solutions. In structural optimization, solid structures have long been replaced by structures made of materials with different properties. This concept is observed on a larger scale in the field of metal forming [35], and interest in methods of forming objects composed of various materials is growing. Such objects pose a particular technological challenge in the field of microforming [36]. Another area of metal forming technology that is undergoing rapid development is incremental forming [37]. It is an interesting alternative to material forming of the whole volume of the material. It consists of plasticizing only part of the volume of the element and successively moving the deformation zone to finally deform the entire object [38]. The main positive features of such methods are the most common reduction in maximum process force, and

local reduction in pressure and frictional forces. The presented subject of the analysis, is the technology of making bimetallic electric microcontact under ultrasonic assisted forging. It is in line with the latest trends in technology development and refers to relatively unknown issues.

2 Problem Statement and Method of Solution

2.1 Development of Orbital Riveting

Jeremiash Grant Kingsbury, an engineer employed as a top engineer by Thomas Edison, invented and patented a rotary tool for spin-forming heads on rivets and pins. Introducing his "Noiseless Rivet-spinning Machine". However, the description of the patent included a significant wording of "Improving on existing processes", which would indicate the existence of previous solutions. The company has developed a patented technology. An example of a table machine for the orbital riveting from the year 1950 of the last century is shown in Fig. 1b [39]. The real revolution was the patent of Z. Marciniak from the year 1970 [40], which introduced a method resulting from the construction of a machine—independent drive of two eccentricities. The motion of the matrix is composed of two movements in a circle with possible parameters to change. This means that all movements with the trajectory described by the X- and Y-coordinates resulting from the Eq. (1) are possible.

$$\begin{pmatrix} x \\ y \end{pmatrix} = r \cdot \cos\left(\frac{P}{Q} \cdot \alpha\right) \begin{pmatrix} \cos\alpha \\ \sin\alpha \end{pmatrix} \tag{1}$$

where: R is the radius (range) of the motion, and P and Q are the parameters from which the ratio depends on the type of circular curve.

A similar solution but in the riveting area was patented in 1973 years (c). C. Mink [41] presented the head used in riveting processes capable of executing complex punch movements. Currently, there are many planetary and radial riveting machines in the market (d) [42]. In the work it is suggested to use ultrasonic support (e) to form forming miniature rivets (e).

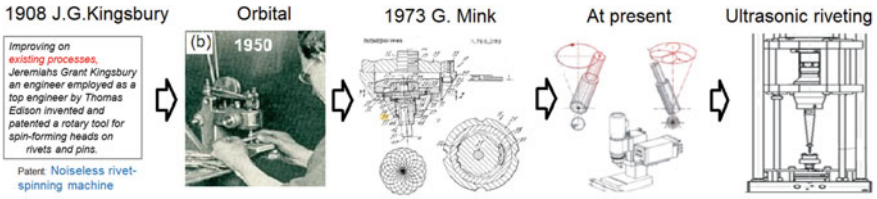

Fig. 1 Development of small/miniature component riveting—description in text. (Color figure online)

Fig. 2 Replacing the monolithic "rivet" in the production of double-sided contacts with a bimetallic rivet (b) causes delamination of the upper layer in some products. (Color figure online)

2.2 Orbital Riveting of Electric Contacts

The standard technological process for the production of small electrical contacts provides for the use of semi-finished products that are on the market in a wide range of dimensions in the form of silver rivets, Fig. 2. These rivets are connected to the frames most often by means of the planetary riveting process. This technology is well controlled and widely used. Riveting machines are also available in a wide range of size. Recently, in order to reduce material costs, a significant part of silver is replaced with copper and bimetallic rivets consisting of a copper shaft and silver contact part, Fig. 1b. In the analysed case, Fig. 2, the direct replacement of solid rivet with bimetallic rivet in the production process carried out by planetary riveting has encountered serious difficulties. In some parts of the products, delamination of the silver part from the copper part was observed. This phenomenon occurred at various stages of production and operation.

One of the factors in favour of using orbital forging is to significantly reduce friction. A similar effect has the use of ultrasonic assisted forming. Strengthening effect is achieved by the conditions of the so-called "dynamic effect" which is relatively easy to achieve in miniature products [43]. The paper suggests replacing orbital micro-riveting with ultrasonic micro-heading in relation to the assembly of miniature bimetallic contacts. Figure 3 shows successive modifications of the upsetting process to reduce frictional forces.

2.3 Delamination Process

The delamination observed in some products can occur in two stages: during operation and during the riveting process. As established on the basis of previous analyses [44], the distribution of materials in the contact head affects the tendency to delaminate during operation. The distribution shown in Fig. 4a is considered favourable because the lines of possible deformation converge when the contact surface is loaded. The most desirable form is that the outer material is "recessed" into the core material which forms a small coating at the edge of the contact head.

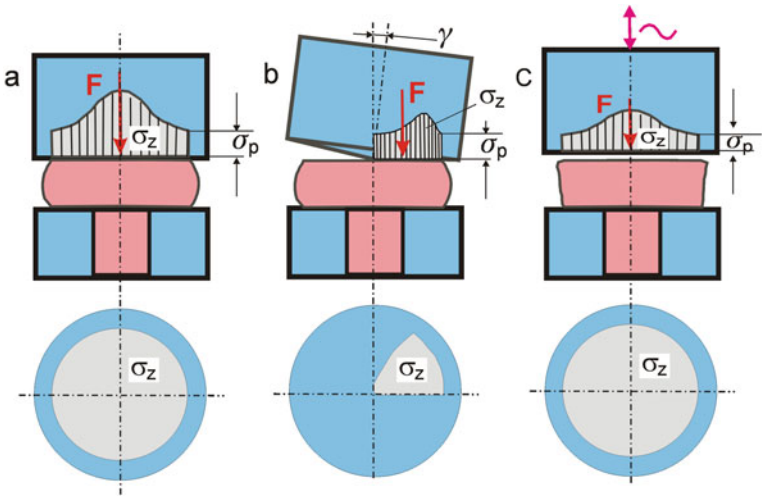

Fig. 3 Heading/riveting methods: **a** conventional heading—high process force, strong friction dependence, **b** orbital/planetary riveting—low process force, low friction, **c** vibration assisted heading/riveting—under development—expected: low friction uniform material flow. (Color figure online)

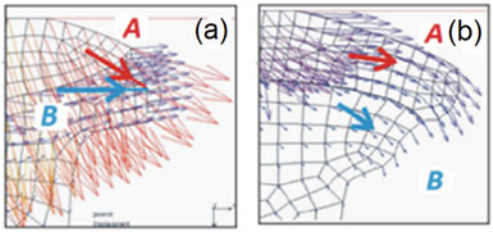

Fig. 4 Material flow in loaded head of contact: **a** concave and **b** convex border surface of materials distribution [44]. (Color figure online)

In general, the distribution of materials in the processes of metal forming of bimetallic billets depends, in addition to, geometrical factors such as the shape of tools, on their mutual interaction in the plastic state. A plastic interaction between two materials described with two-parameter stress–strain curves (2) is determined with the help of the Coefficient of Mutual Interactions of Plastic deformations—H_{MIP}, which is the ratio of their plastic resistance (3). It is decomposed into the product of two H_{C} and H_{n} coefficients according to (4) and (5). The first of the coefficients, H_{C} is a constant value.

$$\sigma_{\mathrm{pA,B}}(\varepsilon) = C_{\mathrm{A,B}} \cdot \varepsilon^{\mathrm{n_{A,B}}} \tag{2}$$

$$H_{\mathrm{MIP}}(\varepsilon) = \frac{\sigma_{\mathrm{pA}}(\varepsilon)}{\sigma_{\mathrm{pB}}(\varepsilon)} = \frac{C_{\mathrm{A}} \cdot \varepsilon^{\mathrm{n_A}}}{C_{\mathrm{B}} \cdot \varepsilon^{\mathrm{n_B}}} = \frac{C_{\mathrm{A}}}{C_{\mathrm{B}}} \cdot \varepsilon^{\mathrm{n_A} - n_{\mathrm{B}}} = H_{\mathrm{C}} \cdot H_{\mathrm{n}}(\varepsilon) \tag{3}$$

$$H_{\mathrm{C}} = \frac{C_{\mathrm{A}}}{C_{\mathrm{B}}} = const \tag{4}$$

$$H_{\mathrm{n}}(\varepsilon) = \varepsilon^{n_{\mathrm{A}} - n_{\mathrm{B}}} \tag{5}$$

where: $\sigma_{\mathrm{pA,B}}$—yield stress of material A and B, ε—equivalent strain, $C_{\mathrm{A,B}}$ (MPa), $n_{\mathrm{A,B}}$ [1]—material constant.

The second one changes according to deformation. Within this work, the role of this coefficient was neglected, limited only to the H_{c} coefficient.

2.4 FEM 3D Modelling

The commercial Simufact.Forming 14.0 package was used in isothermal static conditions with an elasto–plastic material model with deformation hardening. The 3D model shown in Fig. 5 consists of 2 deformable bodies: material A-1 and material B-2, and rigid bodies: matrix-3, base-4, and punch-5. Punch movement is an planetary motion around point P_0 while the end of the axis—P_1 moves along the rosette, Fig. 5c described by Eq. (6). The die has also a constant angular velocity. During the process, the base and frame moves at a velocity directed along the axis. Tilt angle $\gamma = 4°$.

$$\begin{pmatrix} x \\ y \end{pmatrix} = 0.7 \cdot \cos\left(\frac{11}{7} \cdot \alpha\right) \cdot \begin{pmatrix} \cos(\alpha + \varphi \\ \sin\alpha \end{pmatrix} \tag{6}$$

In addition, the other process was carried out in which the planetary movement was turned off and the process was transformed into a 3D upsetting process. Four variants of H_{c} factor (8) were tested. Assuming equal value of the hardening factors

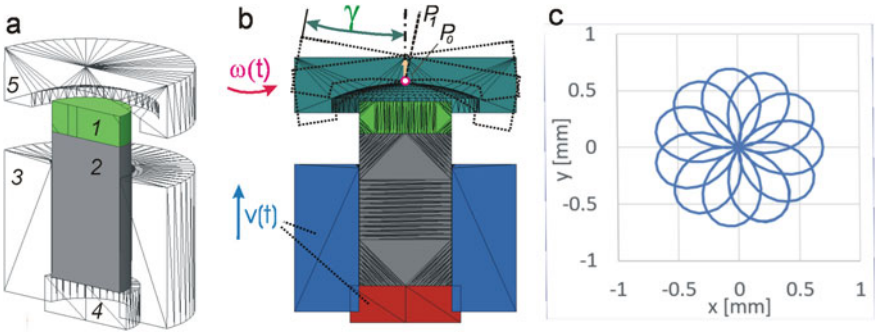

Fig. 5 **a** FEM model—description in text. **b** path of planetary motion, **c** linear velocity of edjector and rotational velocity of die. (Color figure online)

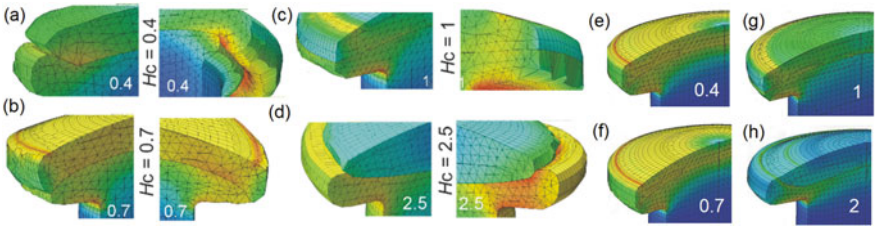

Fig. 6 Equivalent strain distribution after orbital (**a**, **b**, **c**, **d**) and standard (**e**, **f**, **g**, **h**) upsetting of bimetallic contacts consisting of materials of different H_c coefficient. (Color figure online)

for both materials (7).

$$n_A = n_B = 0.2 \tag{7}$$

$$H_C = 0.4, 0.7, 1, 2.5 \tag{8}$$

where H_c complies with (4).

The simulation results are shown in Fig. 6. In all cases, FEM simulations of orbital pressing in which $H_c \neq 1$ was observed to delaminate with a difference in deformation at the contact surface of both materials. Note that $H = 1$ in this case means the "plastic" identity of both materials, which is virtually impossible to achieve. Especially when we also take into account the hardening factors n that are different for different materials. The reason for the weakening of the bond of both materials is the cyclical change in the direction of the material flow, which occurs with each rotation of the swing die. Materials with different plastic properties generate shear stresses at the connection boundary when the direction of stress and strain changes. In classic upsetting this tendency was observed only in the case of (h). In this case, the outer material is much harder and is "pressed" into a much softer material making the process similar to extrusion. Thus, it can be concluded that the classical upsetting process does not entail any risk of delamination of the materials. However, the problem of obstructed flow of material in spherical tool upsetting conditions, which is related to friction, still remains unsolved. The solution to this problem is the main topic of this article and is presented in the next chapter.

2.5 Proposed Method of Solution

Classic upsetting has been replaced with orbital pressing due to riveting processes leads to the drastic reduction in the effect of friction in the process. This reduction increases the tool life and improves the surface quality of the product. As shown for bimetallic contacts, this method is associated with a high risk of delamination. The proposed solution is the use of ultrasonic upsetting. This process maintains a

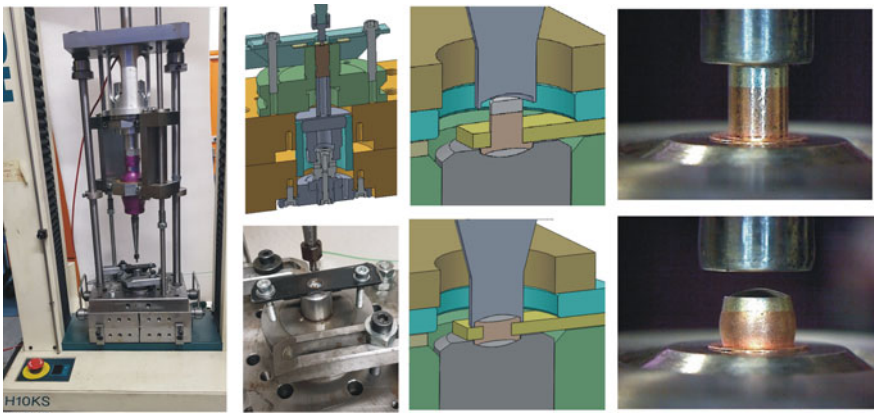

Fig. 7 Experimental setup—description in text. (Color figure online)

constant flow direction of materials as in classic upsetting but at the same time lowers the friction coefficient analogously to orbital forging.

3 Materials and Methods

3.1 Experimental Setup

The experimental stand, Fig. 7, consists of a testing machine and a set of dies placed on it. An ultrasonic system is mounted on the ram of the testing machine. The ultrasonic head consists of a piezoelectric transducer, a booster, and a sonotrode with a punch. An alternating current, oscillating with an ultrasonic frequency, is fed through a power supply to a piezoelectric transducer. The amplifier and sonotrode act as half-wavelength resonators, generating a standing waves at resonant frequency. The frequency used is 20 kHz. It is possible to adjust the amplitude indirectly, that is, by changing the supplied power. Prior to testing, the system characteristics were determined by measuring displacement on the punch face using the Keyence LK-H008 sensor. The results are shown in Fig. 8.

3.2 Specimens and Experimental Procedure

The research concerns bimetallic contacts with dimensions shown in Fig. 9. The hardness measurement showed similar hardness of both materials and thus a probable factor of H_c 1.

The experimental procedure includes several steps as outlined below.

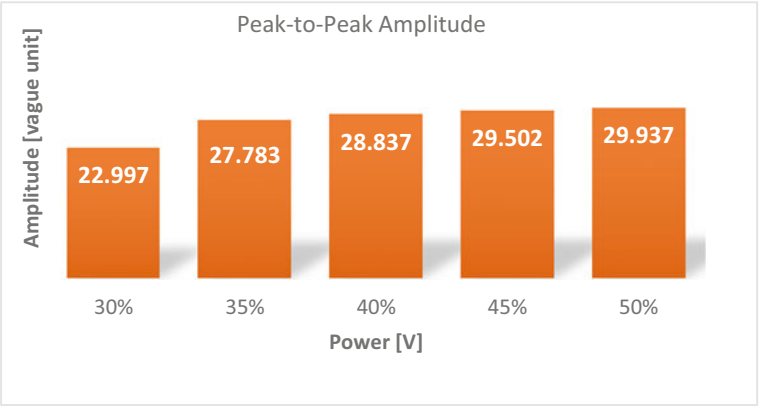

Fig. 8 Results of vibration amplitude testing of the upsetting tool. (Color figure online)

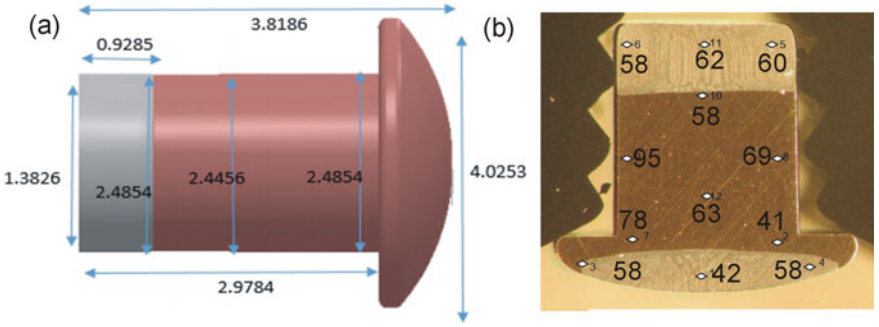

Fig. 9 Bimetallic contact tested: **a** dimensions, **b** structure with HV hardness measurement points marked. (Color figure online)

- Initial rivet height measurement.
- Lubricate the punch and matrix with MoS_2 content.
- Placing the rivet in the frame on the lower die.
- Tightening the frame with the clamp using screws.
- Approaching the punch system to the sample at the initial distance.
- Turning on the ultrasonic assistance system.
- Activation of the data acquisition system from the lower force sensor.
- Activating machine feed.
- Riveting to the assumed machine position at the set speed.
- Unloading at the set speed.
- Turning off the data acquisition system from the bottom sensor.
- Withdrawal of the stamp system.
- Removing the clamp.
- Removal of the frame with the contact highlighted.

- Measurement of final contact height.

  Warning! In the case of free upsetting, no frame or clamp was used.

4 Results

The riveting was performed with and without ultrasonic vibrations. Moreover, free upsetting processes were carried out. Examples are shown in Fig. 10. The contacts were riveted to different heights h_1. The examples selected for the analysis are summarised in Table 1.

Process forces were recorded in two ways.

1. Using the standard equipment of a testing machine. The strain gauge force sensor located on the ram and the built-in displacement sensor allows the registration of the vertical component of the process force as a function of the ram path.
2. By means of an additional piezoelectric sensor placed on the machine table under the lower die. This sensor, in combination with an acquisition system with adjustable sampling rate, enables the registration rapidly changing axial forces as a function of time. The records of the forces of selected riveting processes are shown in Figs. 11 and 12

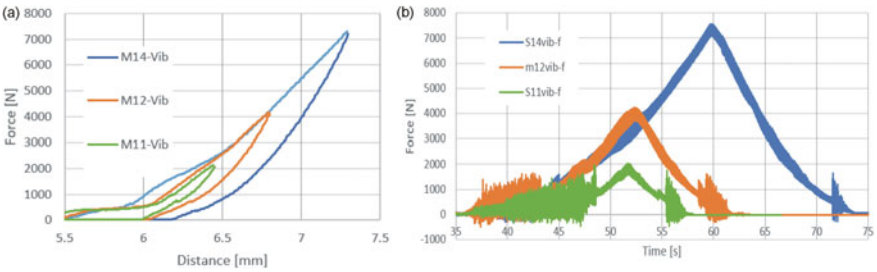

Fig. 12 US vibration assisted riveting: **a** testing machine, **b** additional force transducer. (Color figure online)

Processes with partial ultrasound support were also carried out. A record of the force during the process is shown in Fig. 13. The process begins without the use of vibrations, and after reaching a certain position of the piston, vibrations are periodically activated. They are also switched on periodically during the unloading phase.

5 Analysis of Results

5.1 Process Force

During upsetting with vibrations, the recording of the process force, Fig. 14a indicates the occurrence of the so-called "dynamic effect". It involves the surface of the punch breaking away from the surface of the workpiece. Each of the processes can be divided into four phases.

Phase 1 is the occurrence of a dynamic effect during the increase of force. This phase ends after reaching a force of about 550 N.

Phase 2 is ultrasonic upsetting with a punch in contact and the increasing process force.

Phase 3 is ultrasonic upsetting during unloading.

Phase 4 begins during unloading when the process load drops to a value (approx. 550 N) that allows the occurrence of a dynamic effect. This phase ends with complete relief.

During upsetting with vibrations, the recording of the process force, Fig. 14a indicates the occurrence of the so-called "dynamic effect". It involves the surface of the punch breaking away from the surface of the deformed object. The use of vibration support provides additional energy which is used to increase the deformation achieved. Figure 14b shows experimental rivet deformation courses as a function of process force. For example, with a given process force of 4000 N, vibration support increases the achieved deformation by approx. 0.1—segment *a* on the graph. As the force increases, this effect gradually decreases—sections *b* and *c*. This effect can also be presented as the occurrence of a decrease in the process strength as shown in Fig. 15. The process force as a function of the height of upset contact is presented there. For example, to reach a contact height of 2.95 mm, a traditional upset force of approx. 4000 N is needed. Vibration assistance reduces this force by a distance of *a*, which means a 40% decrease. For smaller contact heights—the dashed lines in Fig. 14, vibration support reduces the necessary strength successively by 36 and 23%. As the assumed height of the rivet decreases, the vibration efficiency decreases.

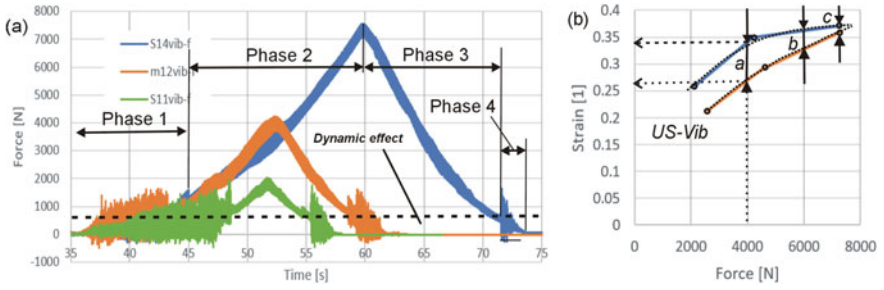

Fig. 14 **a** Analysis of US heading process forces recorded by piezo-transducer. **b** Obtained strain versus process force. (Color figure online)

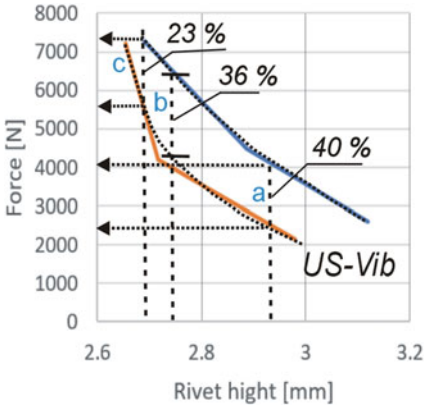

Fig. 15 Process force versus contact height. (Color figure online)

The highest support effectiveness is when there is a dynamic effect throughout the process or as much of it as possible.

5.2 Structure of Bimetallic Micro-contact

In all the processes carried out, there was no tendency of delamination of the silver layer from the copper matrix. A more even flow of material was observed compared to the classic upsetting process. In the example of Fig. 15c, the material flowed unevenly as opposed to example in Fig. 15d. The result of the dynamic effect is the intense deformation of material layers from those in direct contact with the punch and die to the lower layers.

Figure 16b shows the structure of upset contact. It is typical for ultrasonic dynamic upsetting, where so-called antibarrelling effect is present—outline *b*. The outermost layers underwent intensive deformation, while the central part remained practically undeformed. Traditionally upset contact has developed completely differently. Here, Fig. 16a, the outline *a* is convex and the middle part has been most deformed.

6 Conclusions

- The use of orbital forging to rivet the tested contacts may cause delamination.
- The use of the traditional upsetting process, as demonstrated by the FEM model study, does not indicate the risk of delamination; however, it causes an increase in frictional force, which due to the small size of the object, can cause asymmetrical deformations.

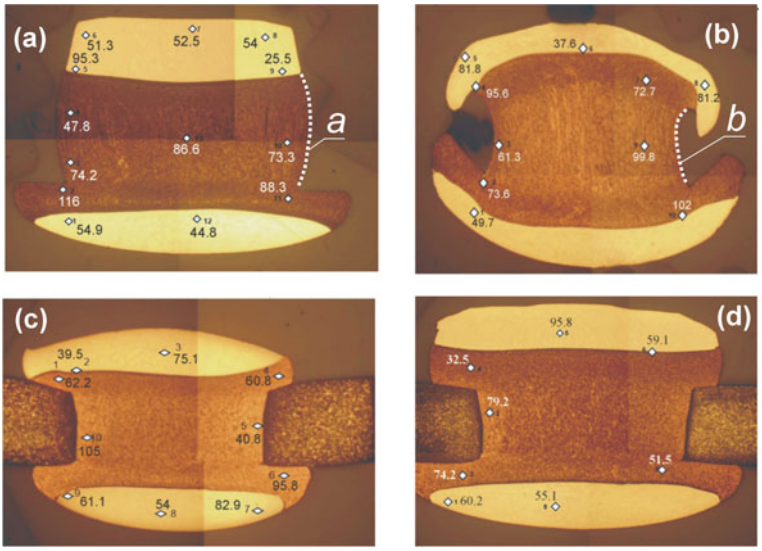

Fig. 16 Cross sections of deformed bimetallic micro-contacts: **a**, **b** free upsetting, **c**, **d** heading, **a**, **c** no vibration, **b**, **d** vibration assisted. (Color figure online)

- The application of the Ultrasonic forming process promotes uniform deformation and reduces the process force in the range of 23–40% compared to the conventional upsetting process.
- In the first and the last phase of all processes dynamic effects were observed, i.e. the surface of the punch was temporarily detaching from the component surface.
- In free upsetting tests, dynamic effect was dominating strongly effecting the shape into "antibarreling" one—concave side surface.
- To take full advantage of the possibilities of ultrasonic vibration support, it is recommended to select the system and shaped system in such a way that during the greatest possible part of the process occurs *dynamic effect*.

Self-Piercing Riveting Using Rivets Made of Stainless Steel with High Strain Hardening

Benedikt Uhe, Clara-Maria Kuball, Marion Merklein, and Gerson Meschut

Abstract Self-piercing riveting is an established technique for joining multi-material structures in car body manufacturing. Rivets for self-piercing riveting differ in their geometry, the material used, the condition of the material and their surface condition. To shorten the manufacturing process by omitting the heat treatment and the coating process, the authors have elaborated a concept for the use of stainless steel with high strain hardening as a rivet material. The focus of the present investigation is on the evaluation of the influences of the rivet's geometry and material on its deformation behaviour. Conventional rivets of types P and HD2, a rivet with an improved geometry made of treatable steel 38B2, and rivets made of the stainless steels 1.3815 and 1.4541 are examined. The analysis is conducted by means of multi-step joining tests for two material combinations comprising high-strength steel HCT780X and aluminium EN AW-5083. The joints are cut to provide a cross section and the deformation behaviour of the different rivets is analysed on the basis of the measured changes in geometry and hardness. In parallel, an examination of the force–stroke curves provides further insights. It can be demonstrated that, besides the geometry, the material strength, in particular, has a significant influence on the deformation behaviour of the rivet. The strength of steel 1.4541 is seen to be too low for the joining task, while the strength of steel 1.3815 is sufficient, and hence the investigation confirms the capability of rivets made of 1.3815 for joining even challenging material combinations.

1 Introduction

The lightweight design of car bodies offers an opportunity for further reducing fuel consumption and CO_2 emissions in traffic. As consequence of lightweight design, increasing use is being made of high-strength steel and aluminium [1]. Self-piercing riveting (SPR) is a common technique for the joining of these materials [2]. The four stages of the SPR process are demonstrated in Fig. 1. Two or more sheets are clamped between a blank holder and a die. A punch presses a semi-tubular rivet into the sheets. The rivet pierces the sheet on the punch side before flaring in the sheet on the die side. This then creates an interlock [3]. A typical force–stroke curve from the start of the joining process until the end of the return stroke of the punch is shown in Fig. 2. An analysis of the measured process curve permits the joining process to

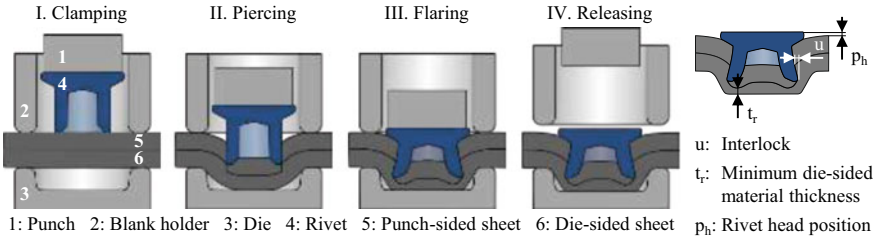

Fig. 1 SPR process stages and characteristic joint parameters in the cross section of a joint according to [4]. (Color figure online)

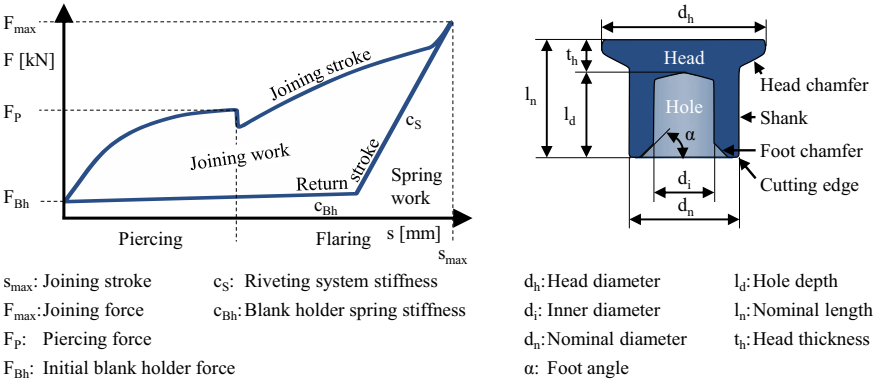

Fig. 2 Typical force–stroke curve and geometry parameters in the cross section of a rivet according to [4]. (Color figure online)

be examined by evaluating parameters like the joining force and the piercing force and is often used for non-destructive process monitoring.

The central components of SPR are the rivet and the die. The die is characterised by its depth and any shape elements like mandrels, while the rivet is characterised by its geometry, the material used, the condition of the material and the surface condition. The geometry parameters in the cross section of a rivet as per [5] are shown in Fig. 2. The rivet and the die are selected individually for each material combination as a function of the sheets to be joined [6].

The riveted joint has to meet certain quality criteria. The required values for the characteristic joint parameters must be reliably achieved. These are an indicator of the joint strength that can be expected. It is primarily the interlock and the minimum die-sided material thickness (see Fig. 1) that are of interest. Freedom from cracks in the joint must also be ensured in general. With brittle materials such as cast aluminium on the die side, cracks on the surface of the closing head are typical [7]. They are acceptable if they run in a radial direction. However, cracks in the tangential direction are never allowed. Cracks and other process faults are known from [8, 9]. These typically occur in the case of unsuitable process configurations or too large variation in the properties of the sheets to be joined. By changing the rivet or the die, it is possible to avoid the faults in the riveted joint. The commonly seen process faults are illustrated schematically in Fig. 3. In general, a distinction must be made between rivet faults and sheet faults.

Rivet overloading and hence a rivet fault occurs when the rivet is not adequately adapted to the strength and the thickness of the sheets to be joined. Not only the rivet geometry, which defines the stiffness of the rivet and the stress and strain conditions within the rivet, but also the rivet material, which determines the deformation resistance and the deformability, are crucial in this respect. Stress peaks, which normally occur in the rivet at the transition from the shank to the head, can cause cracks or fracture of the rivet. The emergence of cracks and fractures is facilitated by the use of brittle rivet materials with a high strength and low deformability. Depending on the individual situation regarding the properties of the sheets to be joined, the rivet can also be bent or compressed. Another type of process fault is the fracture of the

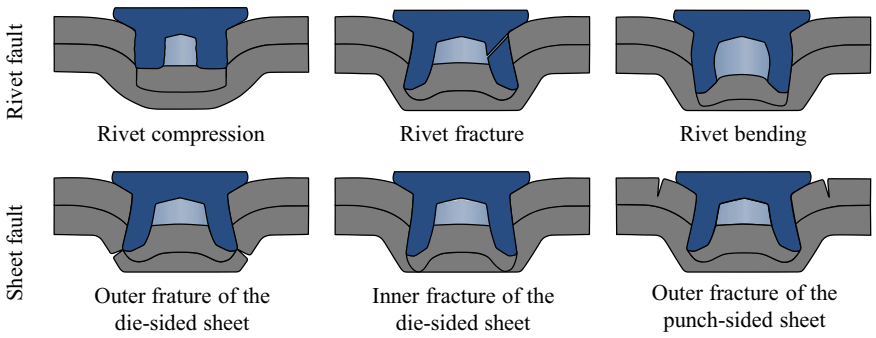

Fig. 3 Typical types of process faults of self-piercing riveted joints. (Color figure online)

sheets to be joined. This is especially the case with brittle die-sided sheet materials with low deformability, such as high-strength steel and cast aluminium. Outer fracture occurs in the case of excessive deformation, such as with deep dies. Inner fracture can occur when the rivet hole is filled with material and inner pressure is evolving or when a rivet is pressed too far. Fracturing of the punch-sided sheet is also possible, especially with thin sheets made of brittle materials. In the past, rivets with different features have been developed as a function of the requirements of the material combinations for car bodies. One promising approach is the use of stainless steel with high strain hardening as a rivet material. As already mentioned in [10], this has certain advantages. Due to the corrosion resistance of stainless steel, it is not necessary to coat the rivets. With stainless steel that has an adequate strength, it is also possible to omit the heat treatment. This shortens the manufacturing process for the rivets. Because the strength of the stainless steel is achieved through cold forming, systematic adjustment of the local strength is also possible. Attempts to use stainless steel as rivet material are known from [11, 12]. However, the strength attained in the rivet materials used for that attempts is not sufficient to meet the requirements for modern sheet materials. The focus of the present investigation is on an analysis of the deformation behaviour of rivets in high nitrogen steel 1.3815 and stainless steel 1.4541 and the evaluation of the joining result by comparison to conventional rivets. A common material used for conventional rivets is the treatable steel 38B2. An overview of the chemical composition of the rivet materials under investigation is given in Table 1. 38B2 contains the typical elements of treatable steel and 1.4541 represents a typical stainless steel. The high nitrogen steel 1.3815 has a special composition, however, with a high proportion of manganese, chromium and nitrogen. As nitrogen is normally undesirable in steels, it has a highly positive effect on the mechanical properties when interacting with the other elements of 1.3815 and is the reason for the high strain hardening [13]. The flow curves of the rivet materials under investigation are shown in Fig. 4. It can be seen that the attainable strength of 1.3815 is comparable to the strength of quenched and tempered 38B2, while the strength of 1.4541 is even lower.

Table 1 Chemical composition of the rivet materials

Material	Mass fraction of the chemical components [m%]						
	C	Mn	Cr	Ni	Ti	B	N
38B2	0.38	0.73	0.22	<0.05	<0.05	0.004	<0.05
1.3815	0.08	18.86	17.07	0.58	<0.05	<0.05	0.76
1.4541	0.02	1.55	17.14	9.19	0.27	<0.05	<0.05

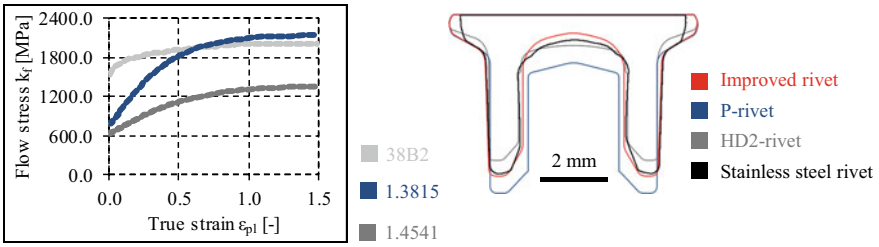

Fig. 4 Comparison of the rivet materials and the rivet geometries according to [10]. (Color figure online)

2 Concept for Rivets Made of Stainless Steel with High Strain Hardening

The investigation is conducted for the same material combinations as in [4]. Material combination 1 consists of high-strength steel HCT780X on both sides. Material combination 2 consists of aluminium EN AW-5083 on the punch side and HCT780X on the die side. All the sheets have a thickness of 1.5 mm. Experimental tests show the yield strength of steel HCT780X to be 565 MPa, with a tensile strength of 861 MPa at an elongation of 12.4%. The yield strength of aluminium EN AW-5083 is 157 MPa and its tensile strength is 292 MPa at an elongation of 18%. The steel sheets are galvanised, while the aluminium sheets are uncoated. These material combinations have different requirements regarding the rivet and the die. They are thus representative for the designing and testing of an innovative rivet. To join material combination 1, the rivet has to have an adequate strength and stiffness to pierce the high-strength steel on the punch side. The probability of cracks in the rivet is higher than for material combination 2. At the same time, the rivet must be able to pierce the punch-sided aluminium and take up the aluminium in the rivet hole in material combination 2. Additionally, the rivet must be able to flare without any fracture of the high-strength steel on the die side. Experimental sampling of both material combinations is carried out in [4]. For joining material combination 1, a rivet of type P and a flat die with a diameter of 8.4 mm and a depth of 2.0 mm are selected, while, for material combination 2, a rivet of type HD2 and a mandrel die with a diameter of 8.5 mm and a depth of 2.0 mm are used. Both the selected rivets, the P-rivet and the HD2-rivet, are coated with Almac®. They are made of steel 38B2, quenched and tempered to a hardness of 480 ± 30 HV10. Working on the basis of the properties of the selected rivets as well as on the simulation-based analysis of the material flow and the stress and strain conditions in the rivet during the joining process, an improved rivet geometry (see Fig. 4) is elaborated. This permits the reliable joining of both material combinations with just a single rivet geometry. The aim pursued by rivet design in [4] is the guaranteed attainment of the required values for the characteristic joint parameters, freedom from cracks in the joint and

Table 2 Rivets under investigation and their properties according to [10]

Rivet	Geometry	Properties
P	5.2 × 5.5 SK	Material: 38B2 Hardness level: 480 ± 30 HV10 Coating: Almac®
HD2	5.3 × 4.5 SK	
Improved	5.3 × 5.0 SK	
Stainless steel	5.3 × 5.0 SK (not fully formed)	Material: 1.3815 and 1.4541 Hardness level: Locally varying Coating: –

the avoidance of any bending and compression of the rivet. In addition, the manufacturability of the rivet by cold forming and the feedability of the rivet to the riveting system using common equipment are ensured. The rivet geometry of [4] is used as the target for the elaboration of a manufacturing concept for rivets in high nitrogen steel 1.3815 and stainless steel 1.4541 in [14].

A two-step concept is used for the cold forming process. The high strain hardening of the high nitrogen steel causes very high tool loads. The foot chamfer is thus increased from 60° to 70° compared to the target in [4] in order to reduce the stress prevailing in the tools. Due to the fact that the stress in the tools cannot be sufficiently reduced and that the tool materials used are already the most capable ones, it proved necessary to reduce the forming stroke. That leads to deviations in the manufactured rivets made of 1.3815 and 1.4541 from the target for the cold forming process, especially in the area of the rivet head. The head diameter is much lower than intended, and the hole depth and the rivet length deviate as well. On top of the systematic deviations, there are also deviations between the single rivets caused by process fluctuations. A comparison of the rivet geometries under investigation is given in Fig. 4. An overview of the properties of the different rivets is given in Table 2. In [15] an investigation concerning the deformation behaviour of rivets in accordance to the rivet's surface condition is conducted. It is seen that a zinc-nickel coating with a friction-reducing topcoat promotes rivet flaring, resulting in larger interlocks. The deformation behaviour of rivets coated with Almac® and uncoated rivets is similar, however. Thus, it can be stated that the joining process can also be performed without a rivet coating. The rivets in 1.3815 and 1.4541 are hence not coated. As the material strength is achieved by strain hardening during the forming process, they are not heat treated, too.

3 Analysis of Experimental Joining Tests

The aim of the investigation is the evaluation of the deformation behaviour of rivets made of stainless steel with high strain hardening by comparison to conventional rivets. For this, experimental joining tests are conducted and the joining results are

analysed. As in [4], riveting tongs of type TOX TE-X 80.250.351 (TOX® PRESSOTECHNIK GmbH & Co. KG, Germany), which can be mounted on industrial robots, are used for joining. The joining velocity is kept at 80 mm/s. Only the joining stroke is adapted depending on the different rivet types. Representative force-stroke curves for each combination of boundary conditions are shown in Fig. 5. With material combination 1, the characteristic force drop, which marks the piercing of the punch-sided high-strength steel sheet, can be seen with all rivets except the rivets made of 1.4541. As explained in detail below, this rivet is not able to pierce the punch-sided sheet and is compressed instead. The joining force with the improved rivet is higher than with the P-rivet. This is despite the fact that the joining stroke of 7.0 mm for the improved rivet is lower than the value of 7.3 mm for the P-rivet. The joining stroke is the distance between the stroke of the punch at first contact between the rivet and the punch-sided sheet and the maximum stroke. But as the length of the improved rivet geometry is reduced by 0.5 mm compared to the P-rivet, the improved rivet is pressed 0.2 mm further into the sheets. Moreover, the higher joining force results from the bevelled shank geometry of the improved rivet. The joining force is lower with rivets made of 1.3815 due to the lower head diameter, which results in a smaller contact area between the rivet head and the punch-sided sheet at the end of the process. With material combination 2, the punch-sided aluminium sheet is pierced continuously and no force drop is evident. On account of the same head diameter, the joining force of the HD2-rivet and the improved rivet are nearly equal. Due to the lower head diameter of the rivet made of 1.3815, the joining force is on a lower level.

For a detailed evaluation of the deformation behaviour, the joining process is interrupted four times, so that five steps, including the final joint, can be examined and the material flow, the mechanisms of material separation, and the interlock creation during the different process stages become visible. The strokes for the different steps are marked in Fig. 5. At each step, the joint is cut to provide a cross section and the Vickers hardness of the rivet is mapped in accordance with [16] using the measuring device KB 30 S (KB Prüftechnik GmbH, Germany). This allows the strain hardening during joining to be evaluated. The deformation of the different rivets when joining

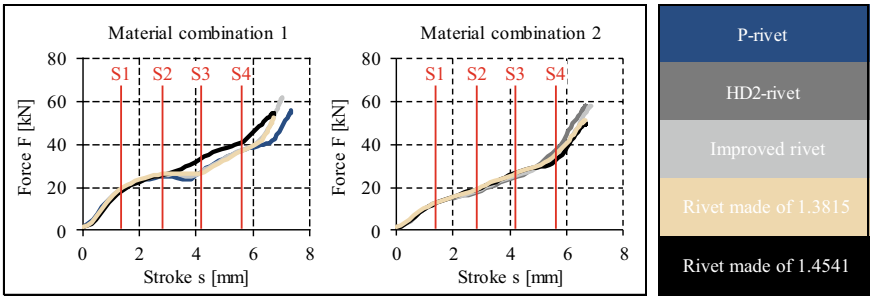

Fig. 5 Measured force–stroke curves with different material combinations and rivets. (Color figure online)

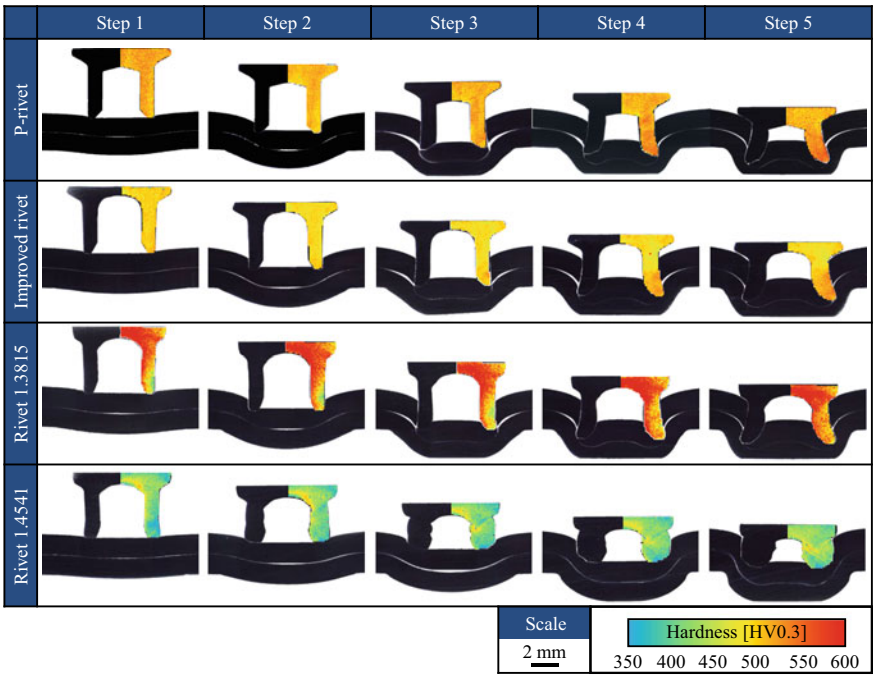

Fig. 6 Deformation of different rivets with material combination 1. (Color figure online)

material combination 1, together with the respective measured hardness, is shown in Fig. 6. In the first stage, the rivets are almost in the initial state. The first differences are evident and the special characteristics of the rivet hardness can be compared. The P-rivet and the improved rivet have a relatively homogenous hardness, which is slightly lower for the improved rivet due to batch variations. For both rivets, the hardness is in the targeted range of 480 ± 30 HV10. The hardness of the rivet made of high nitrogen steel 1.3815 displays local variations and is a function of the plastic strain attained during the forming process. Due to the higher plastic strain in the rivet head, the hardness and strength is higher there than for the conventional rivets, whereas the hardness in the outer rivet foot is lower. Since the forming process is the same, the hardness distribution is very similar in the rivets made of stainless steel 1.4541, but the hardness level is even lower due to the properties of the material. During the joining process, the hardness within the rivets increases as a function of the deformation. The affected areas are mainly the rivet shank and the rivet foot. The hardness within the P-rivet and the improved rivet is approximately 15% higher in the rivet foot at the end of the joining process. The increase in the hardness is limited by the material properties. In the rivets made of high nitrogen steel, the hardness also increases within the foot. At the end of the process, the hardness is no lower than the hardness within the rivets made of treatable steel. The hardness of the rivets in stainless steel 1.4541 does not increase significantly, because the

rivet has already attained its maximum hardness during the forming process. Due to its low hardness, the rivet is not able to pierce the punch-sided sheet. Instead, the rivet is highly compressed, starting at Step 2 already. The deformation of the other rivets, by contrast, starts after the piercing of the punch-sided sheet and is restricted almost exclusively to the flaring, which is needed to create the interlock. Only with the P-rivet can a slight compression and occasional cracks at the transition from the shank to the head be observed. As already mentioned in [4], this is be prevented for the improved rivet through the bevelling of the shank.

The joining results with material combination 2 are shown in Fig. 7. The material flow of the sheets is different from material combination 1, where a slug is created due to the low ductility of the high-strength steel on the punch side. In material combination 2, the punch-sided sheet is continuously pierced and the aluminium is formed into the hole in the rivet. Because of the missing slug, a die with a mandrel is needed to support the rivet flaring. Due to the mandrel, the die-sided sheet thins out a great deal during the joining process. This effect carries the danger of a fracture in the die-sided sheet, especially when using high-strength steel HCT780X as the die-sided sheet material. Because of that, the hole depth of the improved rivet is adjusted to this situation in [4]. The foot chamfer, which also has an impact on the deformation behaviour, is additionally adjusted to the piercing of the aluminium and the rivet flaring during the design of the improved rivet geometry in [4]. In the first

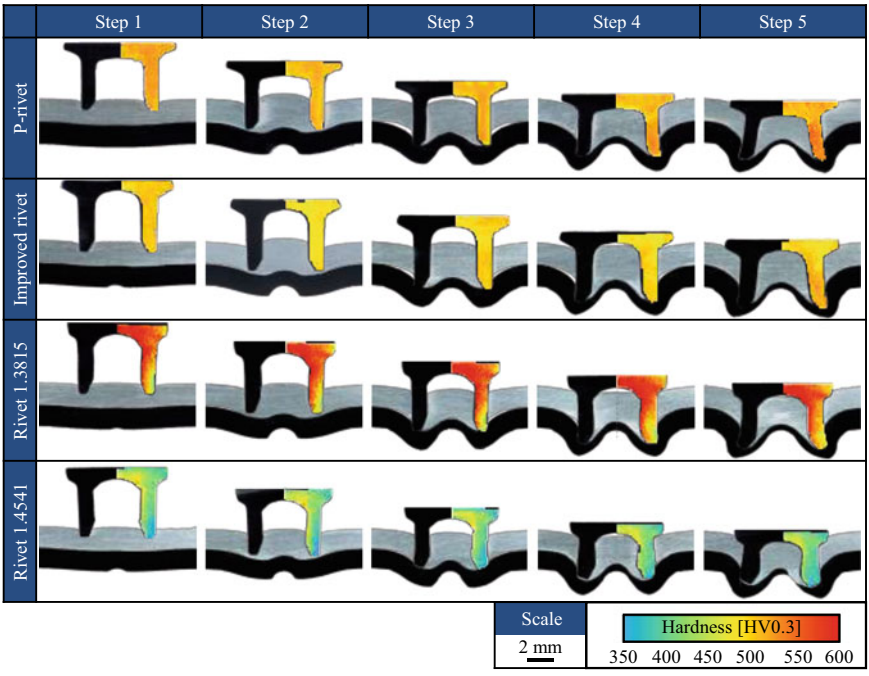

Fig. 7 Deformation of different rivets with material combination 2. (Color figure online)

stage, the same rivet hardness effects as have already been mentioned can be seen. After joining, the hardness within the foot of the HD2-rivet is higher than in the improved rivet due to the greater deformation. For this same reason, the hardness within the rivet made of 1.3815 is lower than the hardness achieved with material combination 1. Despite the deviations in the geometry of the rivet in 1.3815 and the varying hardness distribution, the deformation behaviour is similar to the behaviour of the improved rivet in overall terms, and it can be stated that rivets made of high nitrogen steel 1.3815 are able to join the two challenging material combinations under investigation. As for the HD2-rivet and the improved rivet, no cracks occur within the joint when using the high nitrogen steel rivets. A joint cannot be created for either of the two material combinations using rivets made of stainless steel 1.4541. The strength of the material is too low for its use as rivet material. With material combination 2, the rivet in 1.4541 is able to pierce the low-strength aluminium. However, after piercing, the rivet is unable to flare in the die-sided high-strength steel sheet. The rivet is compressed instead. The compression of the rivet causes a decreasing hole volume and, as a consequence, the fracture of the die-sided sheet.

The characteristic joint parameters with the rivets made of 1.3815 are measured over the cross section of the joints. The values are compared to the values from [4] in Fig. 8. It can be seen that the different lengths of the rivets have a significant influence on the minimum die side material thickness t_r. With material combination 1, in particular, the lower lengths of the improved rivet and the rivet made of 1.3815 cause a higher value for this parameter, while the value for material combination 2 is also slightly higher, despite the higher length of the improved rivet and the high nitrogen steel rivet compared to the HD2-rivet. This effect results from the bigger hole depth in the rivet, which makes for a lower inner pressure by providing more space for the aluminium that is formed into the rivet hole. When it comes to the interlock, the values achieved by the improved rivet are slightly lower than the values achieved with the P- and HD2-rivets. For all the values, a higher scattering is observed with the high nitrogen steel rivets due to deviations in the manufactured rivet geometry. However, the values required for a quality-assured joint are achieved in all cases.

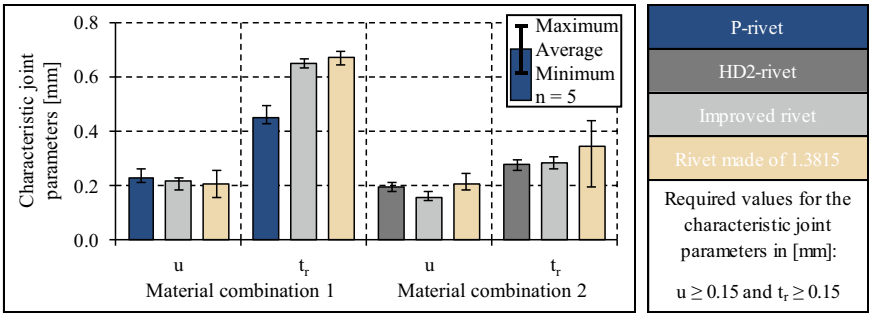

Fig. 8 Characteristic joint parameters achieved with different rivets. (Color figure online)

4 Summary and Outlook

Based on the improved rivet geometry of [4], a forming concept for the manufacture of rivets in stainless steels 1.3815 and 1.4541 was elaborated in [14]. The present investigation focusses on the properties of these rivets and their deformation behaviour during the joining process by comparison to conventional rivets made of treatable steel. Stopping the joining process at several different stages for a detailed analysis of the joint formation contributes to a deeper process understanding regarding the joining with rivets made of stainless steel with high strain hardening. The experimental tests are analysed on the basis of determined geometrical parameters, the measured hardness, and checks for cracks. The results confirm the assumption that the strength of stainless steel 1.4541 is not sufficient for its use as rivet material. Rivets in this material are not able to create an interlock and only facilitate process faults. With rivets made of high nitrogen steel 1.3815, by contrast, it is possible to create joints of the required quality. It can thus be stated that the capability of these rivets is essentially comparable to the capability of conventional rivets made of treatable steel. However, since the characteristic joint parameters are a good indicator of the expected strength of the joint, it must be noted that, despite the equal values achieved by the rivet in 1.3815, the deviations of the rivet caused by the challenging forming process are critical with regard to the attainable joint strength with the punch-sided aluminium in material combination 2. The results of the investigation presented in [10] indicate that especially the smaller rivet head diameter is problematic and leads to a reduction of the joint strength. Based on these insights and the findings of the present investigation, it is planned to further enhance the existing solution for the use of rivets in high nitrogen steel 1.3815. This will focus, in particular, on improving the joint properties through the use of a more accurate rivet geometry and the systematic local adjustment of the material hardness within the rivet during the forming process. In addition, an evaluation of the corrosion resistance of the rivets and the riveted joint with conventional coated rivets and uncoated rivets in stainless steel is to be conducted in future.

Acknowledgments The authors would like to thank the German Research Foundation (DFG) for its support of the research project “Forming and joining of semi-tubular self-piercing rivets made of high-strength steel with adapted mechanical properties and numerical analysis of the process chain” (ME 1840/8-1), on which this paper is based.

Numerical and Experimental Investigations on Riveting Assembly Processing Parameters of Hub Bearing Unit

You Wang, Wei Xiong, Jia-hua Zhou, and Peng Ren

Abstract Applying the rotary forging process (RFP) to the shaft-end riveting assembly of hub bearing units (HBU) is an important technological innovation with promising application prospect. Due to its advantages of stable pre-tightening, low cost and high integration, shaft-end riveting assembly have become a vital process in assembling the third generation HBU. However, due to the lack of systematic application research on RFP, there are still gaps between the domestic hub bearings and the imported products especially in terms of accuracy and consistency of performance. In the study, a numerical simulation platform (NSP) was adopted to simulate the assembling processes of HBU, in which the interference assembly, loading, and unloading of RFP were simulated with ABAQUS/Standard, ABAQUS/Explicit, and ABAQUS/Standard, respectively. The influence of processing parameters on product quality has been carried out by investigating several levels of feed displacement and feed rate, and relevant experimental research has also been conducted. It is found that the experimental results are in consistence with the numerical simulation results, demonstrating that the NSP adopted could be an alternative in determining and optimizing the processing parameters of RFP.

Keywords Hub bearing unit · Rotary forging · Riveting assembly · Numerical simulation

1 Introduction

Rotary forging process (RFP) has been successfully adopted into shaft-end riveting assembly of hub bearing units (HBU) due to its merits of high efficiency, energy saving, low cost, and low noise [1–4]. In shaft-end riveting process, the shaft end

of inner flange is flanged gradually and finally pressed against the upper surface of inner ring for the purpose of assembling and axial clamping. In the past decades, with the imperious demands on lightweight, high integration and reliability of automobile parts, researchers and engineers engaged in hub bearing manufacturing have dedicated in exploring systematic application, mainly involving forming apparatus, test equipment, forming principles, design, and optimization of processing parameters through numerical simulation [5].

Yin explored the effects of processing parameters, such as feed speed of riveting head, thickness, and height of shaft end, on pre-tightening force, outside diameter change of inner ring, and geometrical shape of final riveted product [6]. Xiao and his coworkers carried out design of riveting machine tool and theoretical analysis of riveting force, which pointed out that the feed speed of riveting head should be determined in view of impact effect and production efficiency [7]. Qu et al. systematically studied the influence of initial axial distance, friction factor, radius ratio, and maximum inclination angle on pre-tightening force and energy consumption [8, 9]. Similarly, Li et al. explored the influence of inclination angle and feed speed on riveting force and pre-tightening force [10]. Yang et al. systematically studied the effects of riveting head movement trajectory, inclination angle, and dwell time on riveting force, pre-tightening force, inner ring deformation, and product performance [11]. Shu et al. studied the deformation characteristics of shaft end and explored the influence of feed displacement of riveting head and tempering temperature [12].

The research mentioned above has been carried out detailed investigations on the main processing parameters of shaft-end riveting assembly, involving inclination angle and feed speed of riveting head, material, and structure of shaft end and lubrication state between riveting head and shaft end. The results are of great significance for engineering application. However, inevitable deviations in predicting key performance indexes of HBU would be occurred as only dynamic explicit algorithm was employed without considering the interference assembly and the unloading of RFP [13]. Therefore, the study will rely on the basis of the authors' previous research to carry out numerical and experimental investigations on riveting assembly process of HBU, mainly exploring the influence of feed displacement and feed speed of riveting head.

2 Forming Apparatus and Test Platform

The riveting machine comes from SCFA Company (shown in Fig. 1), which is driven by electromagnetic force and its maximum vertical riveting force is 300 kN. The displacement of the riveting head is controlled and detected by a grating sensor during shaft-end riveting assembly. Testing samples are all provided by NTP Company and the main dimensions are denoted as shown in Fig. 2.

The shaft-end riveting process can be concluded into four stages, as shown in Fig. 3. Firstly, the riveting head is rapidly pushed downward to establish contact with the shaft end. Secondly, the riveting head is continuously pushed downward to the

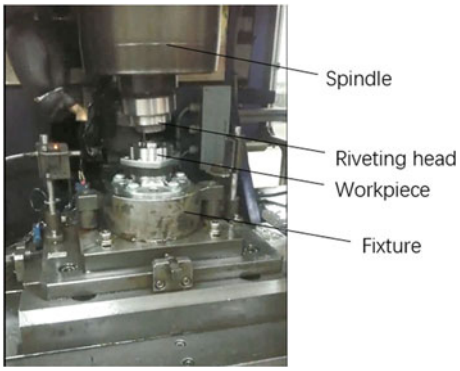

Fig. 1 Riveting machine. (Color figure online)

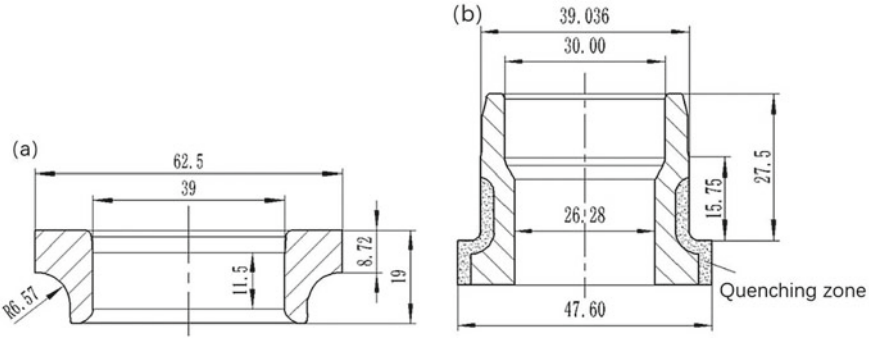

Fig. 2 Main dimensions of testing sample. **a** Inner ring, **b** inner flange

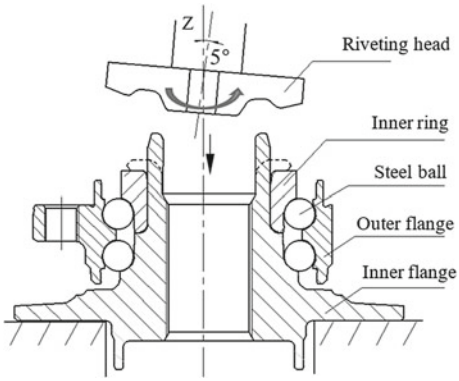

Fig. 3 Schematic of riveting assembly process

pre-set location with a constant lower speed. And then, the third stage is also referred to the smoothing stage, in which the displacement of riveting head remains constant for several rotations to flatten the shaft end. Finally, with the riveting head lifting up quickly to its initial position, the inner ring and the inner flange are undergoing unloading process. In the study, it is noted that the steel balls and the outer flange are excluded as their influence on employed indexes could be ignored. Moreover, it is noted that the riveting force is measured through a built-in pressure sensor, and the other employed indexes are all measured by micrometers.

3 NSP Modeling

The NSP was established based on the general finite element (FE) software ABAQUS. Specific steps concluded are as follows. Firstly, the interference fit between inner ring and inner flange was simulated by utilizing ABAQUS/Standard module. Then, the riveting loading process was conducted with ABAQUS/Explicit, by taking the simulation result of the interference fit as its predefined stress field. Finally, the springback analysis of RFP was conducted in ABAQUS/Standard, by taking the simulation result of the previous step as its predefined stress field. The FE model of HBU is given in Fig. 4, where the linear reduction integration element C3D8R was adopted to mesh the inner flange, inner ring, and riveting head. In order to speed up the simulation process, the riveting head was constrained into rigid. The friction coefficients at the interfaces were set to be 0.15 and assumed to follow the Coulomb friction model.

The materials adopted for the inner ring and inner flange are quenched GCr15 bearing steel and quenched and tempered 65Mn spring steel, respectively. Their mechanical properties are illustrated in Fig. 5 and Table 1. The stroke of riveting

Mechanical property	Density (Kg/m^3)	Young's modulus (GPa)	Poisson's ratio	Yield strength (MPa)
65Mn	7800	212	0.288	1400
GCr15	7800	220	0.3	1700

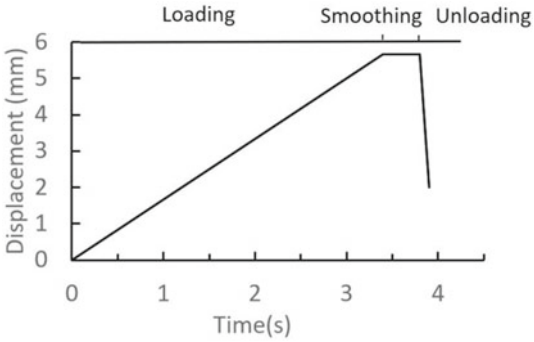

Fig. 6 Stroke of the riveting head

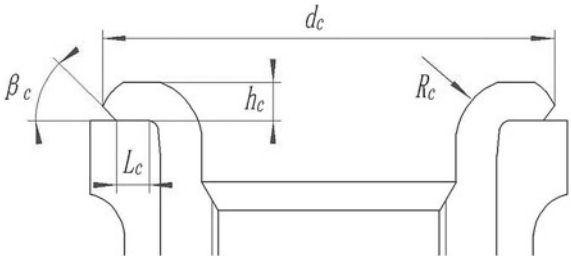
head during the shaft-end riveting assembly is defined as shown in Fig. 6. To save computation time, the mass scaling strategy was also adopted and the reliability of numerical results was evaluated through the ratio of kinetic energy to internal energy.

4 Results and Discussion

In terms of product performance, HBUs are required to have high stiffness, long life, and low noise. Reflecting on the riveting process, it is required that the riveted products have proper clearance and pre-tightening force. However, the two parameters



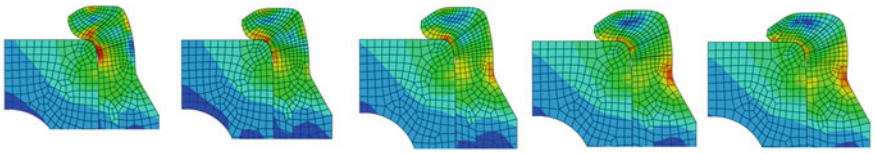


Fig. 7 Main parameters of the shaft end after riveting assembly

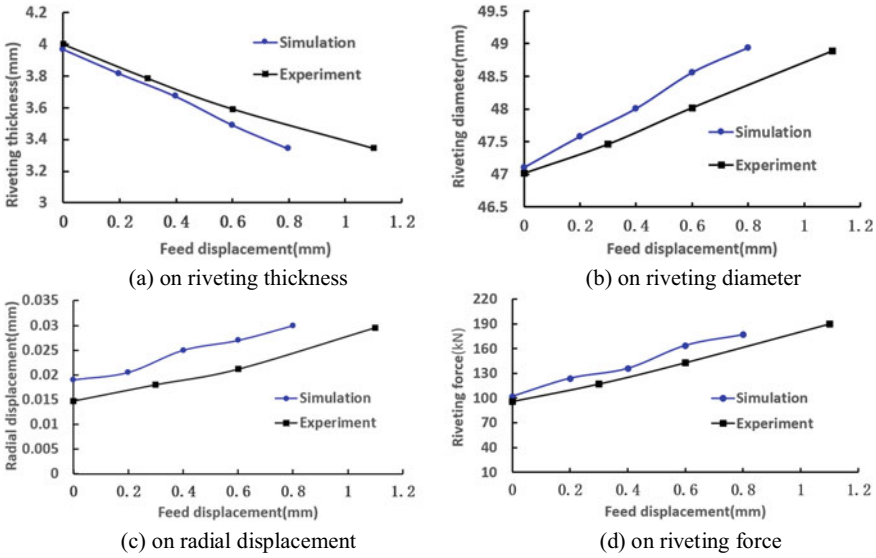
could not be easily measured especially for mass production. Therefore, it is of practical significance to establish the relationship between the geometrical dimensions of the riveted products and their performance indexes and to monitor and evaluate the shaft-end riveting process by controlling the geometric parameters. The main parameters are indicated in Fig. 7, where d_c, β_c, h_c, R_c, L_c refers to riveting diameter, throat angle, riveting thickness, riveting filet, and contact length, respectively. In the study, riveting diameter, riveting thickness, radial displacement of inner ring, and riveting force were employed to evaluate the influence of processing parameters. Here, the riveting force refers to the force that the riveting head exerted on the inner flange.



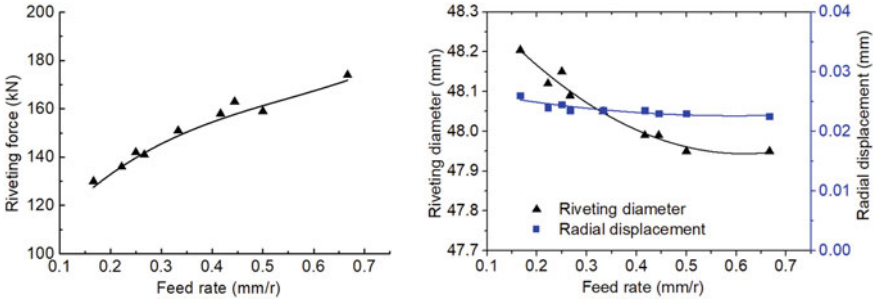
4.1 The Influence of the Feed Displacement

Five levels of feed displacements, i.e., 0, +0.2 mm, +0.4 mm, +0.6 mm, +0.8 mm relative to a reference value, are designed to explore the feed displacement on the riveted products. The configurations of the shaft end after riveting assembly are given in Fig. 8, which indicates that the riveting thickness decreases with the feed displacement increased. In order to investigate the effects of feed displacement quantitatively, the relationships between the employed indexes and the feed displacements are illustrated in Fig. 9. From an overall perspective, the riveting diameter, the radial displacement, and the riveting force are all increased with the increasing of feed displacement. Specifically, it can be seen from Fig. 9a that the ratios of feed displacement change to riveting thickness change approximately stand at 1:0.9 and 1:0.6 for

a) 0 b) +0.2 mm c) +0.4 mm d) +0.6 mm e) +0.8 mm

Fig. 8 Configuration of the shaft end under different feed displacements. (Color figure online)

(a) on riveting thickness (b) on riveting diameter



(c) on radial displacement (d) on riveting force

Fig. 9 Effects of feed displacement. (Color figure online)

the simulation result and for the test result, respectively, indicating that deformation recovery occurred after the unloading process. On the other hand, the ratio of feed displacement change to riveting diameter change approximately stands at 1:2.2, indicating that the feed displacement on riveting diameter is more sensitive than that on riveting thickness. Therefore, it is drawn that the riveting diameter would be more suitable as index in view of processing control. Then, it can be seen from Fig. 9c that the radial displacement increases with the feed displacement increased, meaning that the shaft-end riveting assembly not only compresses the inner ring axially but also enlarges the inner ring radially. Moreover, it is seen from Fig. 9d that the riveting force shows an increasing trend, indicating the deformation of shaft end increases with the increase of feed displacement. Finally, experimental tests are performed and the results are in good agreement with their relative numerical results, indicating that NSP is solid in predicting geometrical and performance indexes.

4.2 The Influence of the Feed Rate

Firstly, it should be noted the feed rate of riveting head p refers to the ratio of its axial displacement to its rotational speed per unit time, which can be expressed as $p = 60v/n$. Where v and n refer to feed speed and rotational speed of the riveting head, separately. Figure 10a illustrates the distribution of riveting force under different feed rates. It is clear that the riveting force indicates an increasing trend with the feed rate increased, showing the same trend to the previous studies conducted by

(a) on riveting force (b) on riveting diameter and radial displacement

Fig. 10 Effects of feed rate. (Color figure online)

Zhang, Marcinik, Slater, and Appleton [14]. The reason is that the contact area rate is increased with the increase of feed rate, and the greater the contact area rate is, the greater the riveting force is. At meanwhile, a higher contact area rate would also cause more power consumption for the riveting machine. To quantitatively analyze the feed rate on riveting diameter and radial displacement, Fig. 10b shows their distributions under different feed rates. With the feed rate change from 0.167 to 0.667 mm/r, it is seen that the riveting diameter is fluctuated from 48.20 to 47.95 mm and the radial displacement is varied between 0.02 and 0.03 mm, meaning the effects of feed rate on riveting diameter and radial displacement could be ignored at the same pre-set axial displacement of the riveting head.

5 Conclusions

Based on the NSP of HBU, the study explored the influence of processing parameters on the assembly quality of the riveted product. Five levels of feed displacements and nine levels of feed rates were designed to simulate their influence on key performance indexes of HBU. Moreover, the relevant experimental tests were carried out to consolidate the simulation results. The main conclusions are included as follows:

(1) The experimental results demonstrate that NSP built by the joint use of ABAQUS/Standard and ABAQUS/Explicit is valid and precise in predicting the key performance indexes of HBU, providing an effective way for hub bearing analysis.
(2) Besides riveting thickness, the riveting diameter, radial displacement, and riveting force are all increased with the increase of feed displacement. It is also drawn that the riveting diameter is more suitable in processing control as it is more sensitive to changes in feed displacement.
(3) The riveting force increases with the feed rate increased, but the influence of feed rate on riveting diameter and radial displacement is so small as to be negligible.

Lubrication and Surface Effects

Evaluation of Lubricant Performance for Thick Sheet Ironing Process by Ball Ironing Test

Nuttakorn Sae-eaw and Yingyot Aue-u-lan

Abstract A thick sheet ironing process is normally used to manufacture a uniform wall thickness of products. To evaluate the performances of lubricants by conventional tests, such as Ring Compression Test (RCT) is not suitable due to the limitation in low levels of contact pressure, surface expansion ratio, and relative velocity. In this research, Ball Ironing Test (BIT) was proposed as a new simulative tribo-test to evaluate the lubricants of the thick sheet ironing process. Finite Element Modeling (FEM) together with statistical analysis was employed to determine a frictional indicator (i.e., maximum load and final height of specimen). According to the results, the maximum load is very sensitive to the friction and used as an indicator to evaluate and approximate the friction coefficient via Frictional Calibration Curve (FCC). Different types of lubricants were tested experimentally and demonstrated different performances by the BIT. In conclusion, the BIT is suitable for evaluating the lubricants of the thick ironing process.

Keywords Ball ironing test · Tribo-test · Friction evaluation

1 Introduction

Nowadays, time and cost savings in production are the main challenges for engineers. For metal forming processes, Flow Control Forming process (FCF) was proposed by combining the advantages of sheet and bulk metal forming processes to reduce the material waste, load, and forming steps [1]. A thick sheet is formed by drawing and, later on, ironing process to produce a controlled thickness cup shape. It is called thick sheet ironing process. Nowadays, most of the pulleys are produced by this process instead of the backward extrusion process. The tribological conditions of the forming processes are the important factors which have effect on the forming results such as forming load, shape, and dimension on the workpiece [2]. For ironing process, if the

G. Daehn et al. (eds.), *Forming the Future*, The Minerals, Metals & Materials Series,
https://doi.org/10.1007/978-3-030-75381-8_126

friction as a result of the tribological conditions is increased, the forming load and the cup height will increase. The high friction may lead to a thinning problem because of the high tensile stress acting on the workpiece's wall [3]. Therefore, the lubricant is applied for controlling or reducing the friction level in the forming process.

A simulative tribo-test is used as a tool for evaluating the performance of the lubricant or the tribological conditions. The test should provide the same process conditions, i.e., contact pressure, surface expansion ratio and relative velocity, as the actual process [4]. Ring Compression Test (RCT) was accepted as the standard tribo-test for bulk metal forming processes [5]. The change in diameter of the disc-shaped specimen was used as the friction indicator. However, this test provided the low process conditions compared with the conditions of common forged products. Therefore, the new tests are always proposed to design the proper conditions for their products. Spike Forging Test (SFT), T-shape compression test, and Double Cup Extrusion Test (DCET) are the examples of the tests developed for forging processes. The tests for sheet forming processes, Strip ironing and Drawing and ironing tests [6, 7] were similar to the ironing process. For Strip ironing test, the thickness reduction of the specimen was controlled by the constant load. The friction coefficient can be evaluated by the ratio of the pulling force and the applied constant load. However, this test still provided the low contact pressure because it was a thin sheet. Moreover, the uniaxial tension stress was the main stress stage of this test in which was not the same as that of the real ironing process. Therefore, the drawing and ironing test was proposed by considering the condition near the actual ironing process. A cup-shaped specimen was formed by drawing process and the thickness was reduced by ironing process. The difficulty of this test was specimen preparation, because there were 2 steps of forming dies, including machining step. These 2 forming steps are deep drawing and later on ironing process, and they need to perform separately. These tests are not suitable for thick sheet ironing process. The suitable tribo-test should reproduce the same characteristics as the existing process. The process conditions, the stress stage, and the gradient of surface expansion would be considered for determining the suitable tribo-test. For that test, the lubricants can be applied easily for lubricant screening test. The results of the test should provide the good friction sensitivity.

The aim of this research was to propose the new tribo-test named "Ball Ironing Test (BIT)" that can be used to evaluate the performance of the lubricant with the same tribological conditions as the thick sheet ironing process. Finite Element Modeling (FEM) was used as a tool to investigate the friction indicator and to develop the Friction Calibration Curve (FCC). The new test will be validated by the experiment with different types of the lubricants. The friction coefficients of the selected lubricants will be determined.

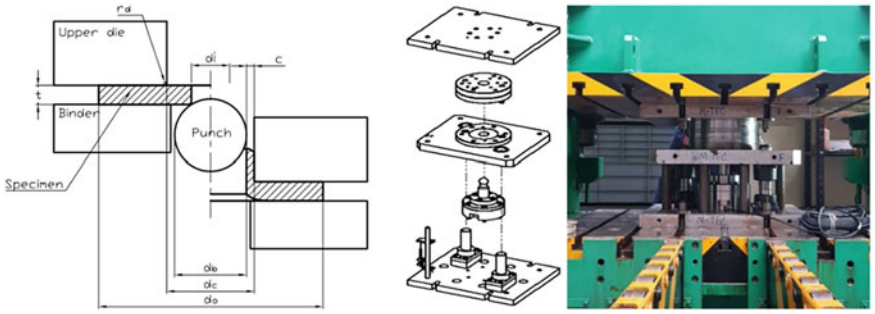

Fig. 1 Ball ironing test; **a** schematic of the BIT and **b** BIT die set. (Color figure online)

2 Ball Ironing Test

To select a suitable simulative tribo-test for the thick sheet ironing process, their process characteristics and process conditions were considered. At the existing process, the contact pressure was around 800-1,400 MPa and the surface expansion ratio was around 3.5–4.5. These conditions were depended on the thickness reduction of the specimen. Moreover, the gradient of new generated surface from the workpiece is demonstrated as the uniform area due to the ironing process. Therefore, the Ball Ironing Test (BIT) was proposed as a suitable test because it can duplicate these specific conditions of the thick sheet ironing process.

The schematic of the BIT is shown in Fig. 1a. The main components consisted of a specimen, a ball-shape punch, an upper die, and a binder. The specimen was a thick disc-shape. It was clamped by the upper die and the binder. The clamped specimen was pushed through the fixed lower punch. The deformation zone was designed only at the inner diameter of the specimen. In the beginning, the material was deformed by drawing process and, later on, ironing process. The clearance between punch and die was used to control the final thickness of the tested specimen.

3 Methodology

3.1 Ball Ironing Test Simulation

The simulation model is shown in Fig. 2a. Due to the symmetrical geometry of the test, 2D model was used for reducing time in calculation. The specimen was assumed as plastic material. The number of mesh were 10,000 elements created on specimen by quadrilateral elements. The SPHC steel with outer diameter at 5 mm and height at 10 mm was compressed to determine the mechanical property. In Fig. 2b,

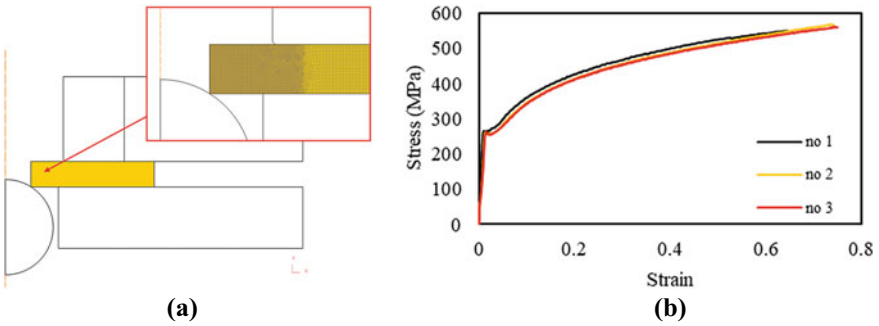

Fig. 2 Finite Element Modeling (FEM) of the BIT; **a** 2D simulation model and **b** stress-strain curve of the SPHC steel. (Color figure online)

these stress–strain curves were input into FEM code, Deform2D version 10.2. The tool components were assumed as a rigid body. Shear friction model was selected because of the high level of normal contact pressure of the thick sheet ironing process as shown in Eq. (1).

$$\tau = mk \tag{1}$$

where shear friction coefficient (m) was a fraction of shear strength of material (k) [8]. In this research, the shear friction coefficients were varied from 0 to 0.4 to evaluate the friction effect on the BIT results.

The flow behavior and strain distribution of the specimen will be illustrated by FEM to confirm the process conditions of the BIT. Moreover, friction indicator of the test will be determined and used to create the Friction Calibration Curve (FCC) for friction evaluation.

3.2 Tooling Setup

In this study, the specimen was the SPHC steel widely used to produce the common automotive parts. For the die set of the BIT as seen in Fig. 1b, most of the tool components are made of the S45C steel. The upper die was made of the SKD11 steel with the hardness value of 58 HRC. The die surface was prepared by grinding and polishing processes controlled the average surface roughness value at 0.15 μm. The ball-shape punch was made of the JU2 bearing steel with the hardness of 60 HRC. This die set was conducted on the single action with cushion hydraulic press machine. The maximum press capacity was at 200 tons. The clamping force was applied by the cushion pins at 13 tons. The testing speed was set at 1 mm/s and the total displacement was at 60 mm. Table 1 shows the tooling geometries of the BIT.

Table 1 Tooling geometries of ball ironing test

Workpiece		
Inner diameter (d_i)	24	mm
Outer diameter (d_o)	140	mm
Thickness (t)	12	mm
Tooling		
Bearing ball diameter (d_b)	45	mm
Die clearance (c)	4.8	mm
Upper die radius (r_d)	1	mm

4 Experiment Procedure

Different types of the lubricants will be tested such as dry, solid, and liquid lubricants. Dry lubricant condition was the metal-to-metal contact at the surfaces of the die and the workpiece. Zn-Ph coating was the solid lubricant normally used in the common cold forging processes. For the experiment, the combined lubrication layer weight of this solid lubricant was more than 8 g/m^2. The oil with EP (Extreme Pressure additives) was selected as liquid lubricant that the viscosity was at 480 cSt@40 °C. At the specimen surfaces, the oil was applied by brushing technique which the oil quantity was controlled at 5 ml per specimen.

The BIT was performed for evaluating the performances at various lubricants. The results, the final height of specimen (h_f) and the maximum load (L_{max}), were measured and used to indicate the friction effect. The comparison of the BIT results will be used to rank their performances.

5 Results and Discussion

5.1 Simulation Results

The flow behavior during the test is shown in Fig. 3. The deformed grids created on the specimen can confirm the location of the deformation that was occurred only at the inner diameter of the specimen. At the first step, it was drawing process, the specimen was bent and drawn by ball-shape punch into the die cavity. Next step,

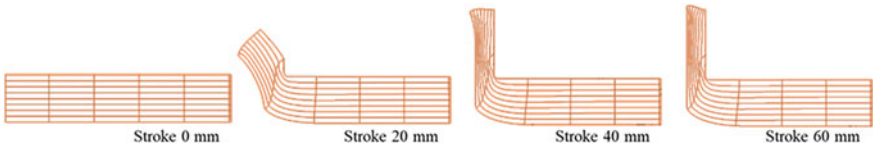

Fig. 3 Flow behavior of the BIT specimen. (Color figure online)

the thickness was reduced by ironing process. Amount of deformed material was used to create the wall of the specimen. When the stroke was increased, the height of specimen was also increased.

Moreover, the effective strain distributions on the BIT specimen are shown in Fig. 4a. It can be seen that the location of the most deformation was at the inner surface of the specimen's wall. The gradient of the strain showed as the uniform area was suitably used to study the surface defects; such as wear and galling. From the FEM calculation, the process conditions of the BIT were determined. The level of the normal contact pressure was around 1,200 MPa at the maximum load and surface expansion ratio was around 4. The uniform surface expansion distributions are shown in Fig. 4b. This test can duplicate the specific conditions of the thick sheet ironing process.

The shear friction coefficients were varied in FEM model. In Fig. 5, the effects of friction were determined on the BIT results. When the friction was increased, the height of specimen and load were increased. However, it was clearly seen that the maximum load was highly sensitive to friction. The wider range of the response,

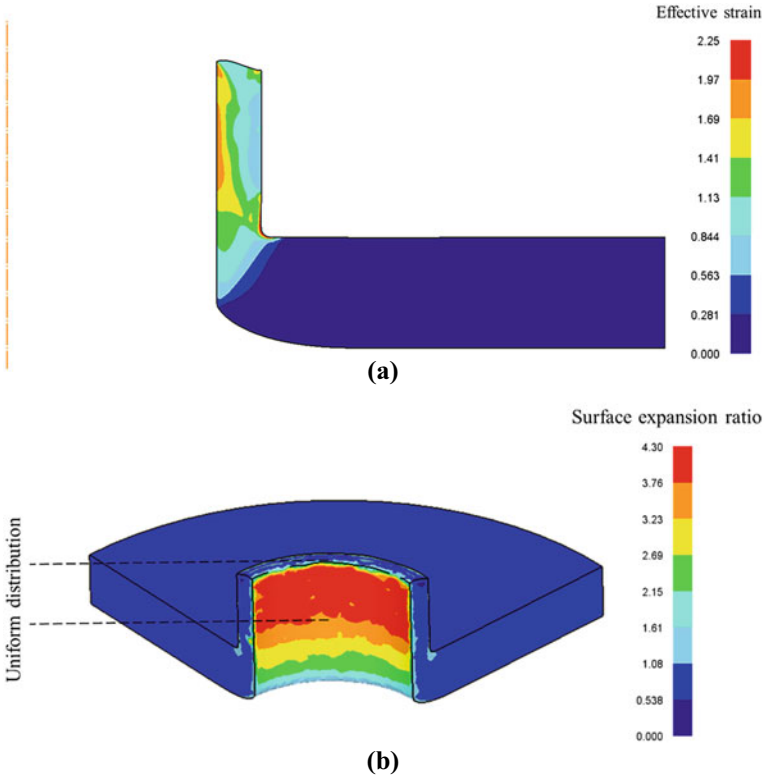

Fig. 4 FEM results; **a** effective strain distribution and **b** surface expansion distribution. (Color figure online)

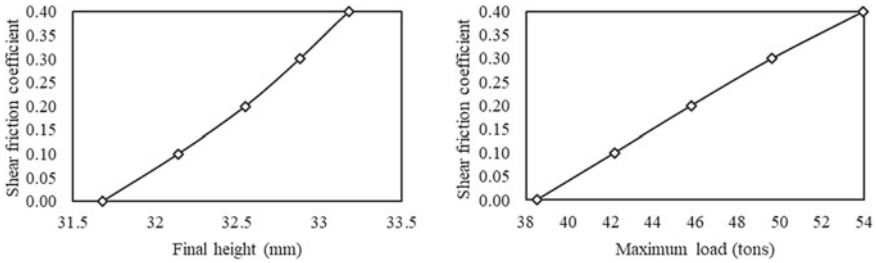

Fig. 5 BIT results with various shear friction coefficients; **a** final height and **b** maximum load

maximum load, can be used to approximate the friction value easily. The linear relationship between shear friction coefficient and maximum load is shown in Fig. 5b. So, the Friction Calibration Curve (FCC) was fit as shown in Eq. (2).

$$m = 0.026(L_{\max}) - 0.9989 \tag{2}$$

5.2 Experimental Results and Validation

The specimens after BIT testing are shown in Fig. 6. Only the dry lubricant cannot be formed successfully. At the wall of specimen, the fracture was found due to the high contact pressure from the metal-to-metal contacting. Solid and liquid lubricants, Zn-Ph coating and oil with EP, showed the excellent performances. The specimen can be formed without any surface defects. In Fig. 7, the maximum load comparison was presented. BIT can use to rank the performances of the lubricants. The lowest testing load was Zn-Ph coating. For friction evaluation, these maximum load values were input to predicted mathematical model, and the results showed that the approximated shear friction coefficients were 0.025 and 0.067 for Zn-Ph coating and oil with EP, respectively.

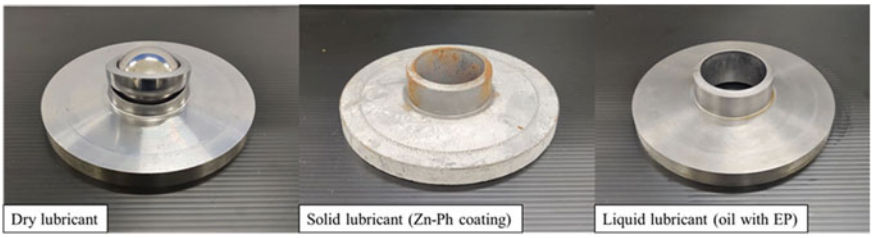

Fig. 6 Specimen after Ball ironing test. (Color figure online)

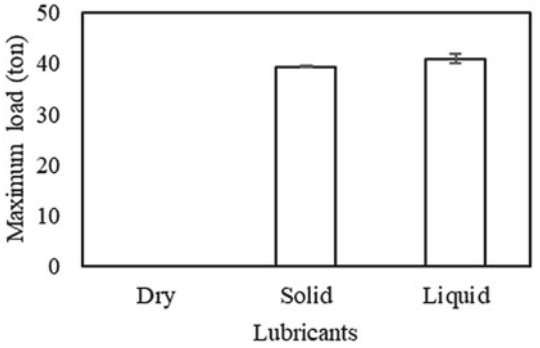

Fig. 7 Maximum load comparison

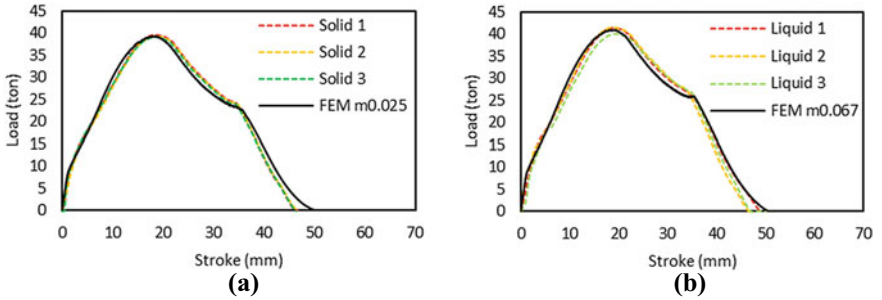

Fig. 8 Load profile compassion; **a** solid lubricant and **b** liquid lubricant. (Color figure online)

To validate the experimental results, these approximated shear friction coefficients were input to FEM code for simulation. The load-stroke curves calculated from FEM were compared with the experiment as seen in Fig. 8. The result comparison between the FEM and the experiment showed the perfect match of the load-stroke profiles.

6 Conclusions

1. Ball Ironing Test (BIT) was proposed for evaluating the tribological conditions of the thick sheet ironing processes. BIT can provide the same tribological conditions as that of the actual process.
2. According to the simulation results, when the friction was increased, the final height of specimen and the maximum load were increased. It was clearly seen that the maximum load had good sensitive to friction, so it was used as friction indicator. For friction evaluation, the shear friction coefficient (m) was determined by using a simplified mathematical model.

3. The performances of various lubricants were determined by the BIT. The fractured specimens were found for dry lubricant, while the solid lubricant (Zn-Ph coating) and liquid lubricant (oil with EP) presented the excellent performances to protect the specimen without any surface defect. The maximum load of Zn-Ph coating was lower than that of the oil with EP. From the maximum load comparison, BIT can obviously rank the performances of each lubricant.
4. The approximated shear friction coefficients were evaluated. There were 0.025 and 0.067 for Zn-Ph coating and oil with EP, respectively.

Development of Oil-Type Lubricants for Cold Forging Using Phase Transition Behavior Under High-Pressure Conditions

Tomoaki Okano, Nobuhide Tanino, and Kazuhiko Kitamura

Abstract In the cold forging process, lubricants are essential because they prolong die life and improve product surface quality. In contrast, it is well known that lubricants are exposed to very severe conditions such as high contact pressure and processing-induced high temperatures. Oil-based cold forging lubricants induce processing defects when the oil film is insufficient. In the search for better alternatives, we explored the possibility of phase transition materials that changeover from liquid to solid under high-pressure conditions. In this study, we developed new oil-type cold forging lubricants with phase transition material additives. Moreover, we found that these hybrid materials show superior lubricating performance in the cold forging process to conventional lubricants. These results indicated that phase transition behavior under high-pressure conditions supports more efficient cold forging process lubrication.

Keywords Lubricants · Cold forge · Phase transition · High-pressure conditions

1 Introduction

From a plastic working process viewpoint, including forge and press work, lubricants assume a very important role in limiting tool wear and seizure prevention. An appropriate lubricant choice contributes to improved final product surface finish, precision, and accuracy [1, 2]. Among them, the cold forging process is especially severe and lubrication is difficult due to exposure to high surface pressure conditions and excessive temperatures caused by work hardening and die friction with the work product [3, 4].

Referring to cold forging process lubricants, those chemical conversion coating-types, such as phosphate film have been in the mainstream since they were developed more than half a century ago [5, 6]. Conversely, chemical conversion coatings have industrial waste problems due to numerous processing steps. So, most new chemical conversion coating-type lubricants that reduce industrial wastes are being developed and practicalized for these reasons [7].

On the other hand, oil-type lubricants for cold forging processes do not lubricate as well as chemical conversion coating-types because oil film is thinner and cannot easily be sustained under severe conditions. However, oil-type lubricants have high potential because they do not need nearly as much processing as chemical conversion coatings and have less industrial waste [8]. So, if we develop new oil-type lubricants with equivalent lubricating properties, they will become more popular.

To solve these problems, we found new materials that phase transition from liquid to solid under high-pressure conditions and infused oil-type lubricants with them. In this work, we evaluate oil-type lubricants containing phase transition materials using a ball penetration test that determines lubrication properties for cold forging processes [9]. As a result, we found that phase transition materials have better lubricity in cold forging processes compared to lubricants without it.

2 Experimental Details

2.1 Phase Transition Behavior Observations of Lubricants

We evaluated phase transition behavior of samples using a plunger-type high-pressure vessel observation system, developed in-house, as shown in Fig. 1 [10]. The observation window inside the cylinder is made of sapphire glass and is built in the middle of a high-pressure vessel. An LED light source was installed on one side of the observation window, and an optical microscope was installed on the other side. Optical micrographs obtained from this device were recorded on a PC and by synchronizing the applied pressure data recorded by a data logger, visualized the phase transition behavior under various pressure conditions and determined the phase transition pressure values.

2.2 Ball Penetration Test

We evaluated the lubricating properties of lubricants for cold forging processes using a ball penetration test, as shown in Fig. 2. High carbon chromium steel balls (hardness, 58 HRC; surface roughness, $R_a < 0.05$ μm) were used with 0.1% C carbon steel workpieces (hardness, 119 HV; surface roughness, $R_{max} = 1$–5 μm). After both the ball and the workpiece were dipped in the prepared sample oils and set up in a

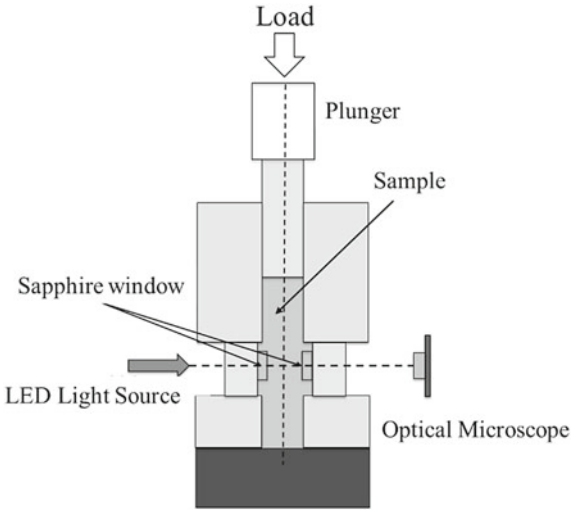

Fig. 1 Schematic drawing of our high-pressure vessel

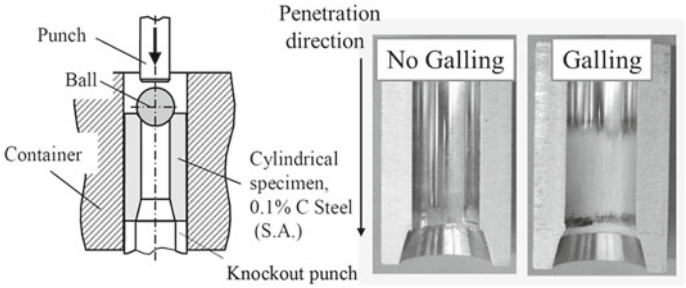

Fig. 2 Schematic drawing of our ball penetration test and result examples about galling

container, the ball was forced to penetrate the cylindrical workpiece. The tests were carried out using a mechanical press and severity is determined by cross-sectional area reduction and ball diameter, as shown in Table 1. A larger reduction in the

Table 1 Reduction by ball penetration test

R (%)	D_b (mm)	D_i (mm)
4	15.88	15
6	15.88	14.5
8	16.67	15
10	16.67	14.5
D_b: Ball diameter		
D_i: Inside diameter of workpiece		

Table 2 Formulation and properties of sample oils

	Oil A	Oil B	Oil C	Oil D
High Viscosity B/O	remain	remain	remain	remain
Low Viscosity B/O	–		–	–
Fatty Acid Type Additive	5.0	5.0	5.0	5.0
Sulfur Type EP Additive	25.4	25.4	25.4	25.4
Other Additives (Ester, etc.)	15.0	15.0	–	–

Phase Transition Material Y	–	–	–	15.0
Kinematic Viscosity (40°C), mm^2/s	130.1	61.02	64.05	60.84

workpiece cross-sectional area means a more severe condition. The galling prevention ability of the sample oils was evaluated from the maximum reduction (Max *R*) determined by the workpieces surface after the ball penetration test.

2.3 Lubricants Formulation

We formulated four sample oils for evaluation as described in Table 2 and divided them into the following four types. Oils A and B are the same additive formulation but have different viscosity and do not include phase transition materials. The viscosity of Oils C and D is identical to that of Oil B; however, Oils C and D contain two different types of phase transition materials; that are ester-type lubricant additives. Kinematic viscosity of these lubricants was measured by the procedures determined by ASTM D445.

3 Results and Discussion

3.1 Direct Observations of Phase Transition Behavior

We evaluated the phase transition behavior using phase transition materials diluted with paraffinic base oil. As shown in Fig. 3a, the samples condition before testing was at a liquid state. Figure 3b–d displays the optical photomicrographs of phase transition behaviors of each of the phase transition materials under several pressure conditions. Here, phase transition pressure is determined by measurement pressure when the phase transition behavior occurs on the optical photomicrographs.

It is clear in Fig. 3 that the phase transition behavior from liquid to solid occurred under high-pressure conditions. All of these materials formed needle-like crystals and their shape was different based on the material type and dilution rate.

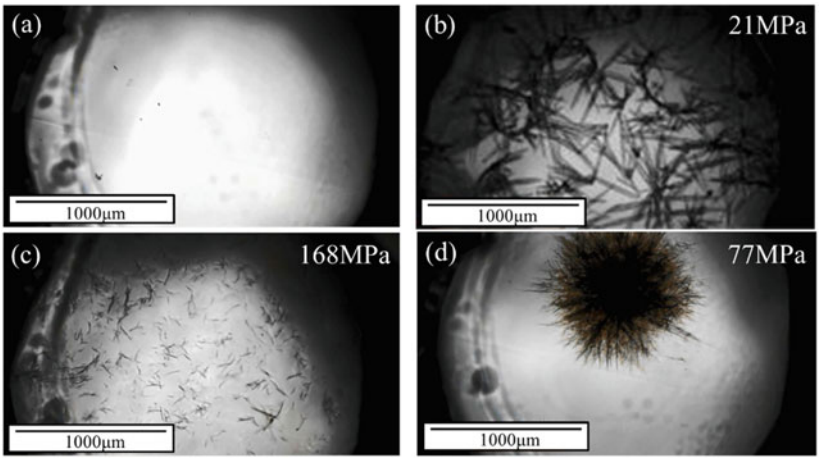

Fig. 3 Optical photomicrographs under optional pressure conditions of **a** Before Testing (No pressure), **b** Phase transition material X 100%, **c** Phase transition material X 20% (Diluted with paraffinic base oil), **d** Phase transition material Y 20% (Diluted with paraffinic base oil). (Color figure online)

Hereafter, we focus on the phase transition materials dilution rate effects based on phase transition pressure. Figure 4 shows the phase transition pressure of phase transition materials as a function of their paraffinic base oil dosage. Here, Phase transition material Y precipitated at just over 40 wt%; indicating the phase transition pressure decreases with an increase of phase transition material dosage. In addition, phase transition pressure of Phase transition material Y is lower than that of Phase

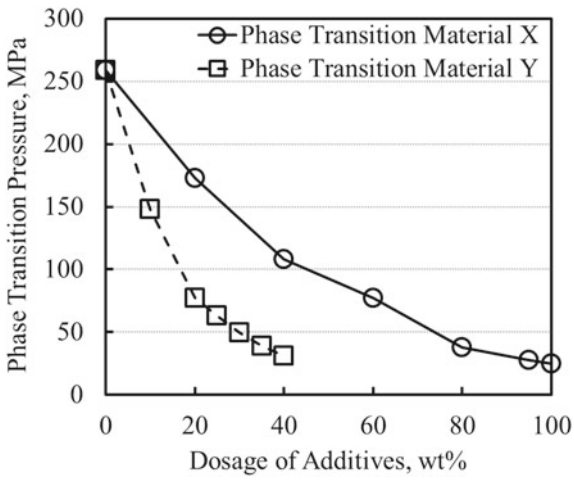

Fig. 4 Effects of dilution rate of phase transition materials on phase transition pressure. (Diluted with paraffinic oil)

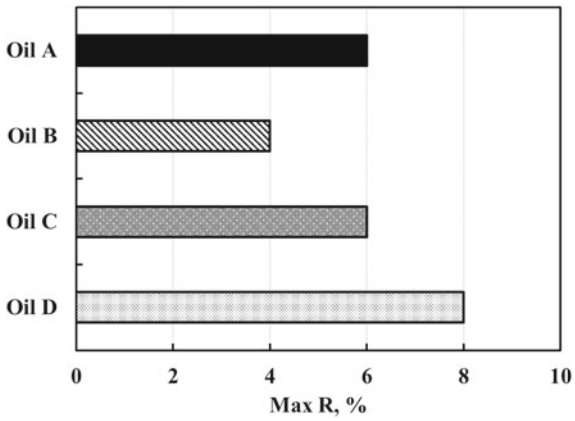

Fig. 5 Lubrication properties of sample oils in ball penetration test

transition material X. These results mean that Phase transition material Y is prone to phase transition from liquid to solid under lower pressure conditions.

3.2 Lubrication Properties of Phase Transition Materials for Cold Forging Processes

Figure 5 shows the ball penetration test results using each sample oil. Comparing Oil A to Oil B, Oil A has better lubricity. It is speculated that the difference between Oils A and B is attributed to its viscosity; because high viscosity lubricant makes a thicker oil film between workpieces and prevents workpiece galling more effectively than lower viscosity oil.

On the other hand, Oils C and D show better lubrication properties compared to Oils A and B even though these lubricants had low viscosity. We suggest that these lubricity improvements are supported by the lubricant phase transition behavior as discussed in Sect. 3.1. In summary, the phase transition pressure of Phase transition material Y is lower than Phase transition material X, and the lubricity of Oil D is better than Oil C.

As shown in Fig. 6, general oil-type lubricant causes oil film shortage between workpieces, but lubricant with applied phase transition materials causes phase transition from liquid to solid under high-pressure conditions and creates a solid film between them. For these reasons, phase transition materials improve lubricity effectiveness for oil-type lubricants.

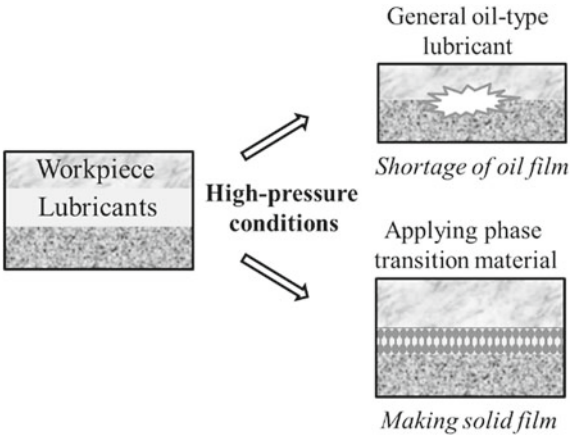

Fig. 6 Schematic drawing of lubrication image by phase transition materials

4 Conclusions

In this study, we investigated the phase transition behavior of lubricants and their possibility for application to cold forging processes. We derived the following findings from this study:

(1) We succeeded in direct observation of lubricant phase transition behavior from liquid to solid under high-pressure conditions.
(2) Oil-type lubricants that include phase transition materials showed improved lubricity for cold forging processes even at low viscosity.
(3) The lubrication properties of phase transition materials for oil-type lubricants depended on their phase transition pressure and a lower pressure at transition is better.

These results led us to deduce that phase transition behaviors under high-pressure conditions enhance lubricity for cold forging processes. In conclusion, we succeeded in development of new oil-type lubricants using phase transition materials.

Analysis of Work Hardening and Tribological Changes After a Gap Controlled Drawbead Passage

Harald Schmid and Marion Merklein

Abstract In deep drawing processes, drawbeads are frequently used to control the material flow while forming. It is well known that material parameters are changed significantly after a drawbead passage. Also, there are many references that the tribological system after a drawbead is changed and that this has influences on the ongoing forming process. In this study, the connection between work hardening and the tribological system after a drawbead is analyzed with respect to the initial state. Therefore, sheets are drawn through a gap controlled drawbead passage while parameters like the gap between blank holder and die or the materials are varied. Afterwards, hardness measurements will be carried out as well as 3D surface measurements to correlate them. For these investigations, three different sheet metals are used: a conventional deep drawing steel, an advanced high strength steel AHSS, and an aluminum alloy, as they represent the variety of industrial used sheet metal.

Keywords Deep drawing · Drawbead · Work hardening · Surface modification · Friction

1 Introduction

Functional integration of modern deep drawing parts, for example, in the automotive industry, leads to complex design in modern forming processes [1]. As consequence, forming operations of sheet metal face demanding geometries. Failure and defects are possible as well as unwanted thinning. Therefore, material flow control in a deep drawing process is important. In literature [2], different types of material flow control are described: Firstly, the adjustment of the blank holder force to control the flow

in the flange area. In addition, the sheet metal layout can be changed and double-checked in simulations. Also, a change of the lubrication system, most of the times by changing the oil type or the oil amount is possible. For higher retention forces, drawbeads are used usually. Drawbeads do not only affect the material flow, but also have impact on mechanical properties [3] and tribological characteristics [4]. On the mechanical sector, work hardening and the significance of the Bauschinger effect was investigated and proven before [5]. Also the failure behavior is changed, according to Ke et al. [6], what was examined in tensile tests with material preloaded in a drawbead. This was also investigated by the authors in [7], and it was demonstrated that important material parameters are changed significantly. Next to that, there are also indications for tribological changes. For example, Staeves [8] showed an effect by drawbeads on the topography and Green [9] demonstrates that every contact of the drawbead has influences on the material itself. Trzepiecinski and Lemu [10] are analyzing a 5xxx-series of Aluminum and parameters like the rolling direction (R.D.) or the lubrication. Trzepieciński et al. [11] show various topographies of material in the initial state and after a drawbead passage and also differences compared to the bounder area. In addition, significant differences in the smoothening can be seen by the preloading direction. Azushima et al. [12] analyze the behavior of aluminum in bending tests and investigate a combination of roughening and smoothing effects. [13], a roughening effect on the outside of free bending is observed. According to the authors, smoothing takes place especially under high loads, and the differences on the surface of both sides of the sheet are also described. In [14], a change of friction coefficients after a drawbead is proven. By the authors, it was shown in [15] that an effect of the drawbead is evident for S_a and V_{cl} and it needs to be distinguished between the in- and outside of the sheet metal after a drawbead passage. The abrasive behavior of aluminum and the oil distribution after the drawbead is discussed. It is determined that steel materials are smoothened significantly while aluminum is roughened on the outside. Also, the coefficient of friction is influenced by pre-stretching in the forming area. To summarize this, a change of the mechanical and the tribological system is stated in many scientific publications. Until now, there is no cause-dependent correlation and therefore no physical explanations of these effects. Therefore, strip drawing tests with drawbead geometry are analyzed on the mechanical and tribological side. As a result, retention forces are evaluated as well as the surface topography on the in- and outside as a characteristic value for the tribological behavior. Variation is done for the tool distance of the drawbead and the material itself. Hardness measurements are performed for one tool distance variation. Analysis and discussion is done to find or determine if there is any direct connection between the parameters and the effect variables that can influence the tribological behavior.

2 Materials and Experimental Setup

In this chapter, the used materials and the experimental setup as well as the applied methodology are named. One material investigated is the aluminum alloy EN AW AA6014-T4 according to EN 573-1:2005-02, which was aged to a stable condition for six months. These sheets are mostly used in body shell or structural components as a lightweight material because of the low density and high strength compared to other materials. Also a deep drawing steel CR 3 GI 50/50-U [16] with 50 g/m^2 of hot-dip zinc coating is analyzed and will be called DC04. In addition, the material AHSS CR 440Y780T-DP GI40/40 [16] as a representative for a high strength steel is analyzed and will be called DP800. All sheet metals are delivered in the initial thickness $t_0 = 1.0$ mm. In Table 1, the material parameters derived, from uniaxial tensile tests A_{50} and from results of confocal microscopy, are presented.

As expected, DP800 has the highest yield strength YS and tensile strength TS. In comparison, the uniform elongation ε_u of DP800 is smaller compared to AA6014 and DC04. The confocal microscopy was used to describe the surface topography of the applied materials. Therefore, similar to the methodology in [15], the parameter S_a of the analyzed area as the mean arithmetic height is chosen to quantify the surface globally. S_a as the arithmetic mean height is able to describe the overall roughness and is, for example, also applied in commercial tribological software like TriboForm [17]. It can be seen that the surface of aluminum before forming is smoother compared to the steel. With these initial values, different behavior in mechanical and tribological changes can be expected. The drawbead geometry and the tool are shown in Fig. 1.

The nominal thickness of the material is $t_0 = 1.0$ mm; in reality, the materials AA6014 and DC04 are slightly thicker (~1.02 mm) while DP800 is a little bit thinner (0.96 mm). As mentioned before, strip drawing tests with drawbead geometry and a constant tool distance d between die and blank holder are used in the setup. The drawbead chosen has a height of h = 5.0 mm. The tool distance d is varied between 1.05, 1.10 and 1.15 mm as these are common values. The gap is defined by an adaptive system with two rails to fulfill an exact distance when closing with forces up to 100 kN. The gap to be set is double-checked with gauge-blocks and repeatable adjusted with a tolerance of +0.01 mm. All drawbead tests are performed with a drawing velocity of v = 50 mm/s and a lubrication of 2.0 g/m^2 KTL N 16, the oil amount was controlled with an optical system INFRALYTIC NG 2 (Infralytic GmbH), that was

	Tensile strength TS [MPa]	Uniform elongation ε_u [%]	Mean arithmetical height S_a [µm]
AA6014	249.6 ± 1.7	20.0 ± 0.2	0.72 ± 0.01
DC04	303.7 ± 0.3	25.7 ± 0.6	1.31 ± 0.03
DP800	808.2 ± 3.4	12.9 ± 0.3	1.28 ± 0.02

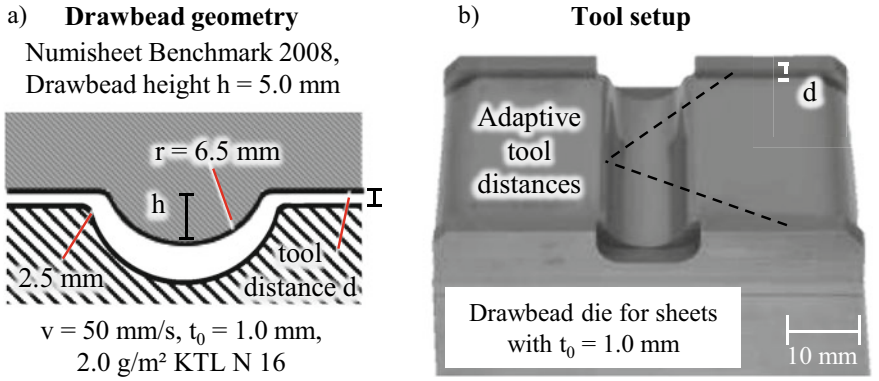

Fig. 1 **a** Details of drawbead geometry and **b** drawbead die with applied tool distancing. (Color figure online)

calibrated before. For every variation, n = 5 repetitions are drawn through the drawbead. Before and after the drawbead preloading, Brinell hardness measurements are performed. In pretesting, it was found that Vickers measurements are not suitable as the imprint was not evaluable after preloading due to the springback and deformation of the strips. So, Brinell hardness with circular imprints is determined by using the so-called Testor (Instron-Wolpert GmbH) with a loading of HBW 2.5/62.5 according to DIN EN ISO 6506-1:2014 with a ball diameter of 2.5 mm and a measuring force of 62.5 kP corresponding to 612.9 N. This evaluation is used to determine the surface hardness and was found to work suitable on the in- and outside and differentiate the hardening. The hardness is measured on every specimen on the in- and outside. Due to the deformed specimen after a drawbead, the sheet metal was clamped. In Fig. 2, the Brinell hardness measurements and the 3D-surface measurement by using Nanofocus µsurf are shown.

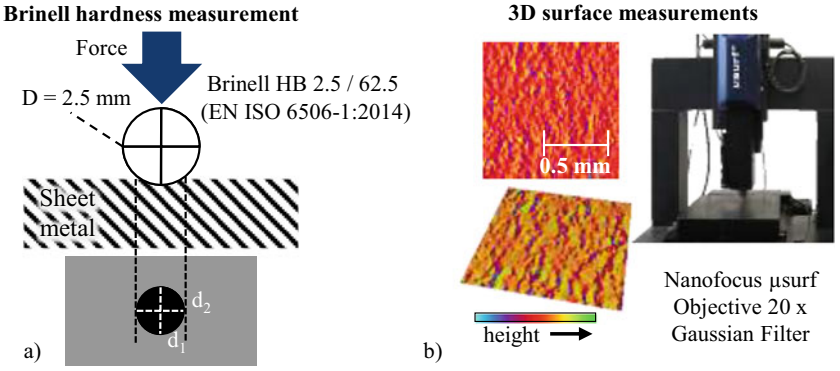

Fig. 2 **a** Process of hardness measurements Brinell HBW2.5/62.5 and **b** process for confocal microcopy of sheet metal after a drawbead preloading. (Color figure online)

For the confocal measurements, an objective with 20× magnification and a measuring size larger than 2 × 2 mm^2 was used and a Gaussian filter is applied. Every specimen was measured on the in- and outside after a drawbead passage for three times: left side, middle, right side. This is to guarantee repeatable values and to prevent any deviations between right and left sides. This means, every single specimen was measured by confocal microscopy six times, one variation is measured 30 times in total. In the following chapter, the results of the different measurements are presented.

3 Results of Drawbead Preloading

In this chapter, the results of the mentioned experimental setups are shown: the specific retention forces for different drawbead and material variations, confocal microscopy results and the corresponding Brinell hardness measurements.

3.1 Strip Drawing Tests and Retention Forces

In Fig. 3, the specific retention force, defined as the retention force related to the strip width, is shown as subject to the material and the applied tool distance d. The standard deviations are varying about maximum of 3.5% around the average and are therefore reasonable. A first observation is that AA6014 has specific retention forces up to 100 N/mm, DC04 up top 150 N/mm and DP800 up to nearly 300 N/mm. This is also due to the varying material strength as can be seen in Table 1. It is also obvious that the specific retention force is maximum for a tool distance of 1.05 mm. The rise of the retention force is between 5 and 7.5% for a step of 0.05 mm in the tool distance. The highest changes can be seen for AA6014, as also having the lowest

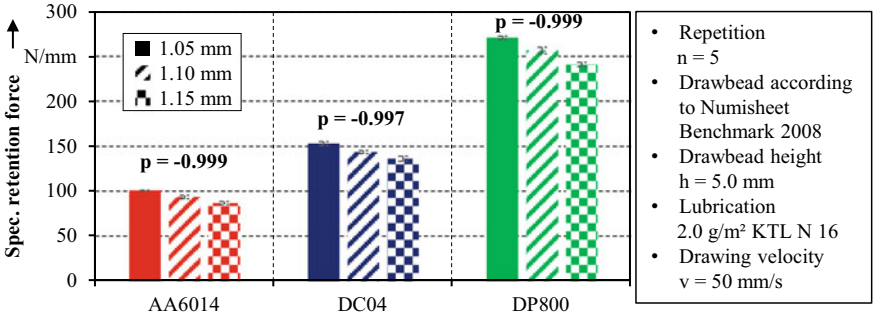

Fig. 3 Specific retention forces for AA6014, DC04 and DP800 when varying the tool distance d between 1.05, 1.10 and 1.15 mm. (Color figure online)

yield strength YS. When correlating the tool distances with the specific retention forces, Pearson's correlation coefficient can be evaluated to $p_{AA,DP} = -0.999$ for AA6014 and DP800 and $p_{DC} = -0.997$ for DC04. This means a nearly perfect negative linear relationship between the tool distance and the specific retention force. This relationship is expected to be valid in a defined range of d, as the geometrical conditions might change otherwise.

With the tool, various tool distances d can be realized by changing the rails. The tool distance d was set to match all materials. After the investigation of the retention forces as a specific value for the drawbead, the surface topography will now be considered.

3.2 *Confocal Microscopy After a Drawbead Passage*

Figure 4 shows the results for the arithmetic mean height S_a by confocal microscopy that was explained in chapter "A Vision of Numerically Controlled, Autonomous Manufacturing and Metal Forming". All of the different variations of Fig. 4 were tested on the in- and outside as well as the initial state.

Each bar represents the average of five specimen with each three measurements on the in- and outside. First of all, the initial arithmetic mean height S_a is lowest for AA6014 with 0.8 µm followed by DP800 with 1.2 µm and DC04 with about 1.3 µm. This could be also a result of the zinc coating on the steel materials. For AA6014, changes can be seen after a drawbead passage compared to the initial state, which was already stated in [14, 15]. On the outside, a roughening is apparent after the drawbead, which becomes more noticeable with higher tool distancing to a rise of nearly 20%

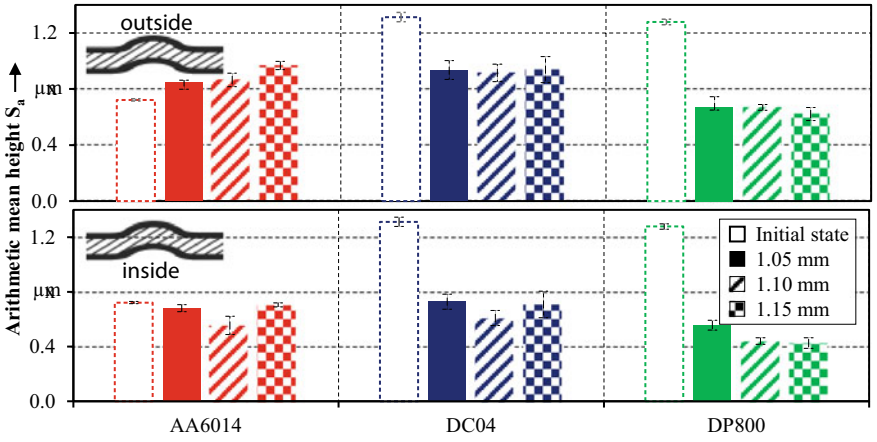

Fig. 4 Arithmetic mean height S_a for the initial state and after a drawbead passage for different variations of the tool distance d, the materials and the in- and outside for n = 5 specimen for each variation. (Color figure online)

at 1.15 mm. On the inside of AA6014, a smoothening is visible and S_a is reduced about 30%. Interestingly, smoothing is not maximum for the smallest tool distance. This could indicate different stress states according to the changed geometry. For DC04, the changes for S_a are even higher. The smoothing on the outside leads to a value of $S_a = 0.9\ \mu m$ and results in a reduction of 30% which is constant in between the standard deviation. The arithmetic mean height on the inside of DC04 is reduced between 44 and 53%. Also here, the reduction is maximum for the tool distance of d = 1.10 mm what was also seen for the inside of DC04. The material DP800 shows the highest reduction of S_a in general. The inside value is reduced up to 40%, the outside even to 64%. For the smoothing behavior, higher S_a values for smaller tool distances are the outcome. Regarding retention forces, expectation would have been also the other way round. In general it can be stated, that surface parameters after a drawbead passage are not clearly predictable by the geometrical value tool distance but a smoothing is expected for steel materials.

3.3 Hardness Measurements After Drawbead Preloading

For a better understanding of the work hardening effects on the sheet metal surface, Brinell hardness measurements were done on the in- and outside. Brinell's hardness was chosen to measure directly on the surface. This is also due to spring back effects when evaluating the imprint optically. The specimen were clamped on a metal plate. To measure the inside of the specimen, a formed tool with a smaller radius than the strip was used to ensure the planar measurement without any suspensions. In Fig. 5, the results for the Brinell hardness measurements are shown.

First of all, the initial hardness of the three materials varies: the hardness of AA6014 values is located around 60 HB in the beginning while DC04 locates around

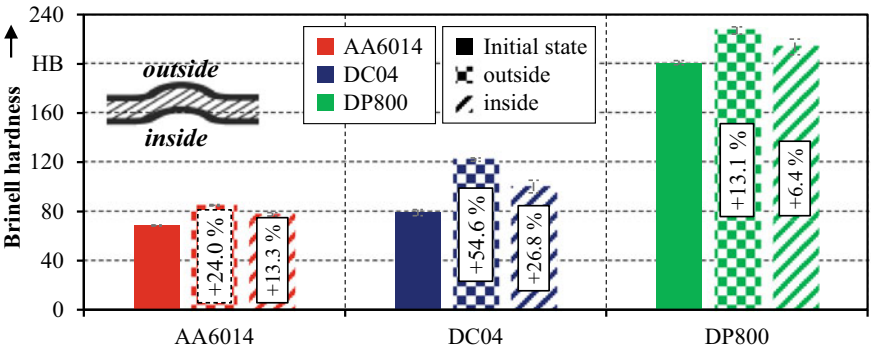

Fig. 5 Brinell hardness measurements for AA6014, DC04 and DP800 before and after a drawbead passage at d = 1.10 mm and grouped by in- and outside with n = 3 specimen measured. (Color figure online)

80 HB, DP800 has more than the doubled initial hardness with nearly 200 HB before the forming process. After the geometrically identical drawbead passage, a rise of the hardness between 6% up to 55% can be observed. In addition, on the outside the hardness is higher, what was also investigated for a another drawbead geometry by microhardness measurements in [3]. For AA6014 a rise of 24.0% on the outside and of 13.3% on the inside are visible. The final hardness locates around 80 HB. The initial hardness of DC04 is also located at 80 HB, the outside is hardened to 120 HB and the inside to 100 HB. For the deep drawing material DC04, the work hardening effects are the highest compared to the others. DP800 rises its hardness between 6 and 13%. In the following chapter, results will be correlated and discussed by giving possible explanations.

4 Discussion

First of all, a correlation between the specific retention force and the surface parameter S_a as a characteristic value for the tribological changes is discussed. Therefore, in Fig. 6, the forces and the surface parameters on the in- and outside after a drawbead preloading are shown normalized.

The retention forces were normalized to the value of the variation d = 1.15 mm, and the surface values were normalized to its initial state. The retention forces follow a linear correlation with the tool distance d, what could be possible due to a linear rise of friction and bending forces in this range of d what was also shown in Fig. 3. On the other hand, the surface parameter S_a does not behave the same way. Depending on the material, the smoothing on the inside is most significant for d = 1.10 mm and the inside is smoothened higher compared to the outside. DP800 has the highest retention forces but also has the lowest values for S_a compared to its initial state. Considering the materials only, a negative correlation between the smoothing and the forces can be drawn. Higher retention forces for each material are followed by more

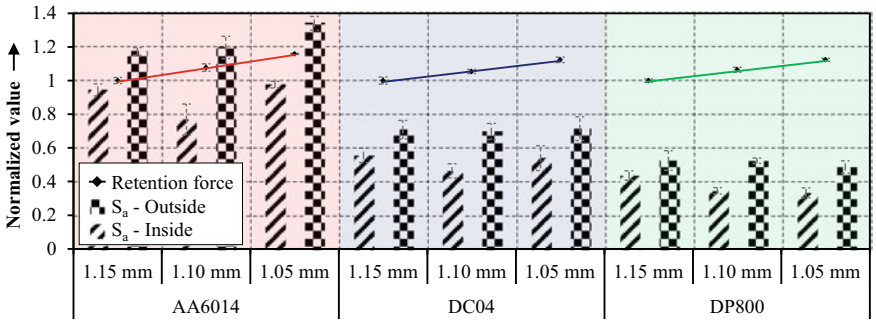

Fig. 6 Retention forces correlated and normalized with the arithmetic mean height S_a on the inside and outside. (Color figure online)

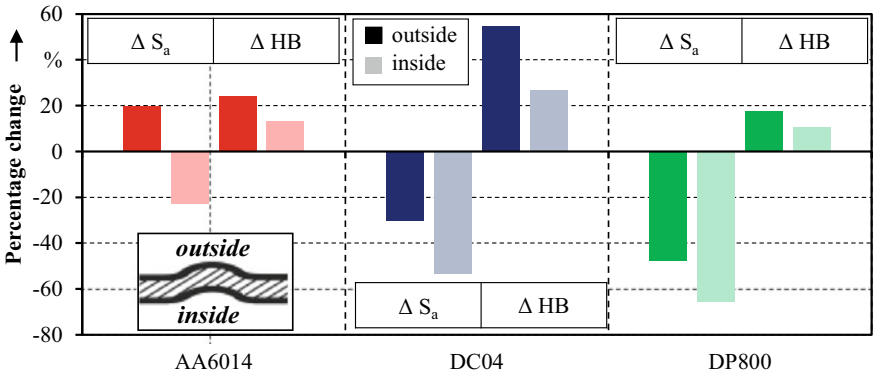

Fig. 7 Percentage change of the arithmetic mean height S_a and the Brinell hardness HB for the tool distance variation of d = 1.10 mm and the materials AA6014, D0C4 and DP800. (Color figure online)

significant smoothing, what could also be said in connection to the yield strength YS. After considering the surface and the retention forces for all the variations, a connection between the Brinell hardness results for the tool distance d = 1.10 mm and the surface parameter S_a will be drawn. Therefore, the percentage change of both values compared to the initial material value is shown in Fig. 7.

For all materials, except for the outside of AA6014, a smoothing simultaneously with a hardness increase is certifiable. The smoothing is also higher on the inside while the rise of hardness is higher on the outside. For aluminum, a statement is hard to make. The outside of AA6014 is the only area to roughen in a drawbead passage while the hardness is increased. In general, for AA6014, the arithmetic mean height S_a and the hardness are changed with a maximum of about 20–30%. The roughening effect for AA6014 compared to the steel seems to be interesting for further investigations. For DC04, the percentage change is located between 50 and 60% considering maximum values. In opposite, the material DP800 has only a rise lower than 20% looking at the hardness but a reduction of S_a of over 60% for the inside. That means, the material with the smallest rise in hardness has the highest reduction in its surface parameter S_a. Correlating these results to DC04, the changes seem to be more balanced there. A geometrical explanation of the correlation of hardness and smoothing behavior can not be drawn directly. Here, different approaches for an explanation are possible: The contact on the inside in a drawbead passage seems to provoke a higher smoothing effect for every material. Otherwise, on the outside the hardness is increased higher compared to the inside after a drawbead passage. An idea could be that the contact conditions are playing a key role for the behavior. A longer contact area with lower values on the inside could lead to higher smoothing effects while higher contact pressure located in a smaller area follow in a more significant increase of hardness. This would also be dependent on the geometrical circumstances of the alternating bending the location of contact areas. Also, the used aluminum and steel materials having different coating and therefore most possible

different friction and smoothing behavior. Next to the contact pressure, the effect of topography changes due to tension, compression, or bending effects needs to be considered. According to Wechsuwanmanee et al. [18], the surface roughness plays an important role on the bending behavior and a difference to an ideal smooth surface is existent. For example, Muhamad et al. [13] show the increase of roughness during a wrap-bending process on the outside for a extruded aluminum and analyze material related reasons. For an integrated understanding of the topography changes in a drawbead, the combination of alternating bending processes with overlying tension needs to be investigated in detail step by step, also differentiating between the in- and outside. As an example, in investigations from Jonasson et al. [19] a direct correlation between the friction coefficient and common surface parameters was not found and can also not expected. As only the tool distance d is varied in a range of $\Delta d = 0.1$ mm, the variation of surface parameters in between one material is expected to be most likely a reason top different contact pressure effects. Also the yield strength YS and the hardening coefficient n could also influence the hardness behavior, which was also described in [7]. While YS and the work hardening coefficient n are quite similar for AA6014 and DC04, these two values are differing significantly for DP800. The influence of an oil reduction after a drawbead passage was also varying [15]. It seems that the oil reduction is high on the outside, where also the highest hardness increase takes place. This could also indicate a connection between the applied contact pressure, the oil reduction, and the final hardness. Unfortunately, this effect is very difficult to investigate in an experimental setup in a drawbead geometry although experimental setups like Filzek's [20] with respect to the Hertzian stress seem as a good start for further investigations.

5 Summary and Outlook

In this publication, the specific retention force, the surface parameter S_a as a value representing the tribological condition of sheet metal and the Brinell hardness were investigated before and after a drawbead passage and correlated. Therefore, the Numisheet Benchmark 2008 drawbead geometry was used with a drawbead height of $h = 5.0$ mm and tool distancing d was varied in three steps from 1.05 to 1.15 mm for the materials AA6014, DC04, and DP800. The most distinctive findings are

- There is a clear linear correlation evidenced by Pearson with $p = -0.99$ between the specific retention forces and the tool distance d for all investigated materials. This is expected to be valid in a specific range only.
- A correlation between the tool distance d and the surface parameter S_a could not be drawn clearly.
- Smoothing is visible for all materials and preloaded surfaces except for the outside of AA6014. This could be explained by the aluminum oxide layer and its special

reaction to alternating bending with overlying tensions. Next to the contact pressure variation, the influence of alternating bending and tensions on the surface roughness needs to be mentioned.

- Smoothing effects are more significant on the inside than on the outside after a drawbead passage. The reduction of the arithmetic mean height are up to - 60% for DP800.
- Hardness is increased on the in- but more significantly on the outside of sheet metal after a drawbead. While the outside hardness increased, the smoothing effect is more significant on the inside. An interesting observation is that low hardness changes are corresponding with high reductions of S_a for DP800. This could be due to higher contact pressure in combination with a higher yield strength of DP800.
- A significant influence on the tribological behavior is expected for every material deriving from the changes in hardness and surface values. Regarding the value S_a, the highest change is expected for DP800. Also considering the surface hardness, a tribological transition is probable for the mild steel DC04, too. After the results for the same blank holder force in [15], an integrated approach of the mechanical and tribological behavior taking in account all parameters is indicated.

In general, a geometric correlation between the hardness and the mean arithmetic height by varying the tool distance d could not be proved, a direct relationship could not be drawn. The influence of the same tool distancing on the materials was shown. As an outlook, the findings need to be connected in detail using other methodologies in further investigations. The connection between surface changes by contact pressure and forming effects by tension, compression and bending need to be separated in detailed investigations and step by step. This would also help to improve simulations and also to identify the contact pressure height and its distribution. On the experimental side, an idea would be to preload materials with a specific tool radius only and calculate the Hertzian stresses and the final surface parameters. The following hardness and surface changes could be combined with the results above. Comparing the materials, higher specific retention forces seem to lead to higher surface changes, what might be due to the contact pressure. The interaction between the mechanical and tribological system represented by the surface values seems to interact in a complex way that needs to be investigated furthermore.

Investigations on Dynamic Characteristics of a Mechanical Press Considering Both Translational Clearance Joint and Lubrication Effect

Xuze Wu and Yu Sun

Abstract The existence of clearance in the joints of multibody systems can significantly influence the system behaviors. The introduction of joint clearance in the dynamic analysis of the mechanical press can generally lead to a higher analysis precision. In this paper, a lubricant revolute joint and a translational clearance joint are conducted in the dynamic model of a mechanical press, to identify their combined influence on the system dynamics. The Pinkus and Sternlicht approach is employed to obtain the hydrodynamic forces, while the IMPACT function is used to evaluate the contact forces. Simulations are carried out in the cases where the translational joint is assumed to be ideal or with clearance. The results show that the lubricated revolute joint presents practically similar to an ideal one in the global responses while the existence of the translational joint will lead the slider trajectory into chaos. Moreover, the translational clearance joint seems to have little influence on the local dynamics of the lubricated joint, due to the limited amount of contacts resulted from a low input crank speed. This observation indicates that in the dynamic analysis of heavy-load mechanical presses with a low operation speed, the effects of these two joints can be analyzed separately.

1 Introduction

The effects of clearance joint on the dynamics of multibody systems have received much attention over the decades. In the literature, the contact model and the lubrication model are widely applied to describe the clearance joint [1]. The nonlinear damping spring model, which was proposed by Lankarani [2] and comprehensively analyzed by Flores et al. [3], has been proved to be consistent with the experiments. In engineering applications, the clearance joint is extensively described by hydrodynamic forces, due to the existence of lubricating oil. Moreover, one of the key points in the present work focuses on the influence of multiple clearance joints. Erkaya et al. [4] analyzed the vibrations and noise in the slider-crank mechanism with both revolute and translational clearance joints. In the same mechanism, Ma et al. [5] conducted three revolute clearance joints by dry contact models and suggested that the interactions of the joints with clearance should be carefully studied. A slider-crank mechanism with one and two clearance joints was studied by Megahed and Haroun [6]. They pointed out that when the mechanism works in the horizontal plane, the rate of impacts at each clearance joint increase, compared with the vertical plane operation condition. The presented research shows that the existence of multiple clearances will tend to complicate the system responses.

The mechanical press, which could be regarded as a practical application of the slider-crank mechanism, has been analyzed in numerous studies, considering the effects of clearance. A high-speed press system with flexible bodies and revolute

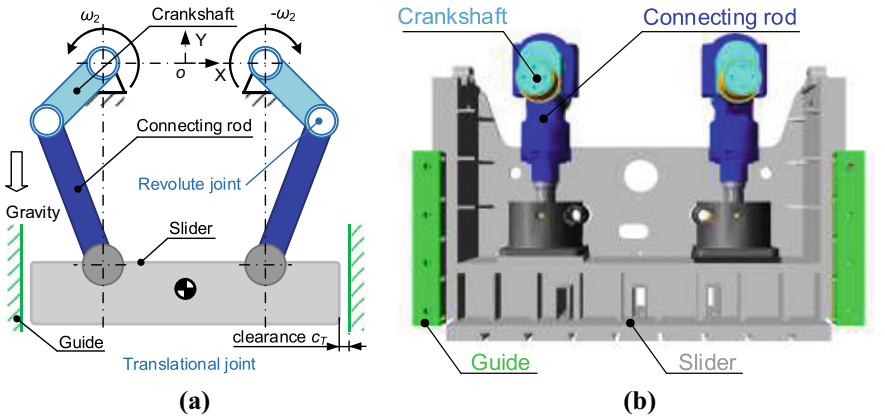

Fig. 1 Configuration of the mechanical press: **a** the kinematic sketch; **b** dynamic model of the press with clearance joints conducted in MSC.ADAMS package. (Color figure online)

joints was modeled in Zheng et al.'s work, where the lubrication forces and dry contact forces were considered in the model [7]. Chen et al. [8] proposed planar analysis models for a heavy-load press with a revolute clearance. Numerical and experimental methods are both employed to describe the effects of clearance on the system performance.

As far as the authors are concerned, there are few studies concerning the effect of translational clearance joint on the dynamics of the mechanical press. In addition, the combined influence of translational clearance joint and the lubricated revolute joint is virtually unknown in the literature. Thus, the presented work is aimed at the combined action and interaction of the two clearance joints. Figure 1a illustrates the configuration of the planar motion mechanism of the press, where the two symmetrical cranks possess the opposite constant rotational speed. The mechanism is regarded to be over-constraint when all the joints of the mechanism are perfect. The introduction of planar joint clearance will remove two degrees of freedom in every joint. However, we assume that the cranks rotate strictly synchronously and no external distribution is applied on the slider, thus the rotational degree of the slider is supposed to be constrained. Figure 1b depicts the dynamic model of the press conducted in MSC.ADAMS package. The model is first built in the software SolidWorks and then transferred to ADAMS for dynamic simulations. The mass centers of the parts are all located in the XOY plane. The revolute clearance joint between the crankshaft and connecting rod is conducted as a lubricated joint. The simulations are carried out in the cases with translational clearance joint or ideal translational joint. Additionally, motion trajectories and Poincaré portraits are employed to characterize the joint dynamics and global responses.

2 Dynamics of Joints with Clearance

2.1 Dry Contact Model for the Translational Clearance Joint

The existence of clearance in a planar translational joint will introduce two extra degrees of freedom to the slider and remove two kinematic constraints in the dynamic formulations. Hence, instead of kinematic constraints, the dynamic responses of the joint are governed by the developed contact-impact forces. In this paper, it is assumed that when the collision occurs, the colliding bodies penetrate with each other in a dry contact manner.

Considering the energy loss and the nonlinear nature of contact forces, the normal component of the generalized impact force can be represented by [7].

$$F_N = K\delta^{1.5} + C(\delta)\dot{\delta} \quad (\delta > 0) \tag{1}$$

The contact stiffness K is determined by the geometric shape of the contact region. When the inclination angle of the slider is rather small (minor than 0.1 degree), the influence of the slider's rotation on the system response might be negligible. Therefore, when the contact region is characterized by a rectangular surface with length l_a and width l_b, the area of contact region can be predetermined and the stiffness is obtained from [9],

$$K \approx \frac{\sqrt{S_c}}{(\sigma_i + \sigma_j)} \frac{1}{11.15(l_a/l_b + 15.72)^{-1} + 0.2854} \tag{2}$$

where and denote the material parameters of the colliding bodies i and j, respectively.

$$\sigma_k = \frac{1 - \upsilon_k^2}{E_k} \quad (k = i, j) \tag{3}$$

In Eq. (1), the instantaneous damping coefficient $C(\delta)$ is presented by a cubic step function of the penetration [7, 8],

$$\begin{aligned} C(\delta) =& STEP(\delta,\ 0,\ 0,\ d_{\max},\ c_{\max}) \\ =& \begin{cases} 0 & if\ \delta \le 0 \\ c_{\max}(\delta/d_{\max})^2(3 - 2\delta/d_{\max}) & if\ 0 < \delta \le d_{\max} \\ c_{\max} & if\ \delta \ge d_{\max} \end{cases} \end{aligned} \tag{4}$$

where $c_{\max}$ is the damping coefficient when δ reaches the maximum depth $d_{\max}$.

In the clearance joints, the friction force is likely to play a vital role in system responses. To avoid some integral difficulties caused by the sudden transformation of the direction in friction forces, the modified Coulomb method is adopted in this paper [10],

$$\mathrm{F}_T = -c_f c_d \|\mathrm{F}_N\| \mathrm{v}_T \big/ \|\mathrm{v}_T\| \tag{5}$$

where $\mathbf{F}_N$ is the normal contact force vector, $\mathbf{v}_\mathrm{T}$ represents the tangential velocity vector, and c_f is the friction coefficient. The dynamic correction coefficient c_d is obtained from,

$$c_d = \begin{cases} 0 & if \ \|v_T\| \le v_0 \\ \frac{\|v_T\| - v_0}{v_1 - v_0} & if \ v_0 \le \|v_T\| \le v_1 \\ 0 & if \ \|v_T\| \ge v_1 \end{cases} \tag{6}$$

where v_0 and v_1 represent the given tolerances for the tangential velocity.

Generally, the conduction of contact model is based on the kinematic analysis of the clearance joint. In the previous studies, Flores had proposed a comprehensive formulation to describe the kinematics of planar translational clearance joints [11]. Hence, the kinematics of the joints will not be presented here in detail. To embed the normal contact forces and friction forces estimated by Eq. (1) and Eq. (5), respectively, the IMPACT function is acted between the colliding bodies in the model established in MSC.ADAMS.

2.2 *Lubricated Model for the Revolute Joint*

This section briefly describes the hydrodynamic force model adopted in the revolute clearance joint, which connects the crank and connecting rod. The revolute joint with clearance is generally modeled by contact models or lubricated models. The engineering application of the revolute joint in the mechanical press requires the lubricant to cool down the joint and reduce friction. When the space between the journal and bearing is filled with lubricant, hydrodynamic forces originated from both the wedge and squeeze actions will dominate the dynamic response of the joint. During the running of the mechanism, the dynamic load applied to the journal will vary in both magnitude and directions, which leads to the fluctuation of the film thickness.

Figure 2 shows a generalized smooth dynamically loaded journal-bearing. The hydrodynamic force components, which consist of the tangential component F_t and the radial force F_r along the direction of the eccentricity, are illustrated in the schematic representation. Margarida [12] analyzed the effect of three classical hydrodynamic force models in the system responses of the slider-crank mechanism. He emphasized that the film evolutions vary from the selections of the models. The Pinkus and Sternlicht approach for long journal-beading is employed here to obtain the generalized forces in the revolute joint, due to its regular and steady behaviors in the system response, i.e., this model features higher stability. The hydrodynamic forces are obtained from [13],

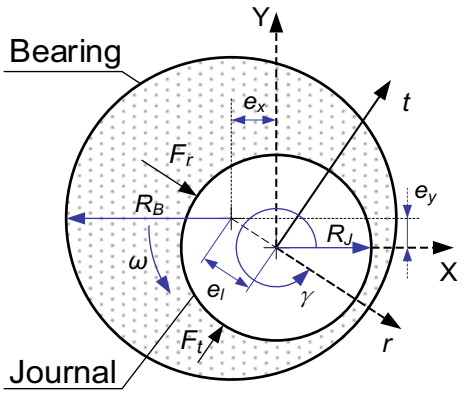

Fig. 2 Cross section of a smooth dynamically loaded journal-bearing. (Color figure online)

$$
\begin{aligned}
F_r &= -\frac{\mu L R_J^3}{c^2}\frac{6}{\left(2+\varepsilon^2\right)\left(1-\varepsilon^2\right)^{1.5}}\left[4k\varepsilon^2+\left(2+\varepsilon^2\right)\pi\left(sign(\dot{\varepsilon})+\frac{3}{2k+3}\right)\right]\\
F_t &= \frac{\mu L R_J^3}{c^2}\frac{6\pi\varepsilon(\omega-2\dot{\gamma})}{\left(2+\varepsilon^2\right)\left(1-\varepsilon^2\right)^{0.5}}\left(sign(\dot{\varepsilon})-\frac{3}{2k+3}\right)\\
\varepsilon &= e_l/c
\end{aligned}
\tag{7}
$$

where c presents the radial clearance between the journal and bearing. The parameter k and the sign function are, respectively, defined as

$$
k^2=\left(1-\varepsilon^2\right)\left[\left(\frac{\omega-2\dot{\gamma}}{2\dot{\varepsilon}}\right)^2+\frac{1}{\varepsilon^2}\right] \tag{8}
$$

$$
sign(\dot{\varepsilon})=\begin{cases}\dot{\varepsilon}/|\dot{\varepsilon}| & if\ \dot{\varepsilon}\neq 0\\ 0 & if\ \dot{\varepsilon}=0\end{cases} \tag{9}
$$

The time derivation of angle γ is calculated by

$$
\dot{\gamma}=\frac{d\left(\tan^{-1}\left(e_y/e_x\right)\right)}{dt}=\frac{e_x\dot{e}_y-\dot{e}_x e_y}{e_l^2} \tag{10}
$$

Finally, to employ the hydrodynamic forces obtained from Eq. (7) to the dynamic model of the mechanism, the radial and tangential force components should be projected onto the X- and Y-directions, and are given by

$$
\begin{bmatrix}F_x\\F_y\end{bmatrix}=\begin{bmatrix}\cos\gamma & -\sin\gamma\\ \sin\gamma & \cos\gamma\end{bmatrix}\begin{bmatrix}F_r\\F_t\end{bmatrix} \tag{11}
$$

The minimum film thickness, which can indicate the load-bearing capacity of oil film, is defined as

$$h_{\min} = c(1 - \varepsilon) \tag{12}$$

Within the application of hydrodynamic bearings in engineering, it is suggested that the safe minimum film thickness should be greater than 1.5×10^{-4} mm/mm of the bearing diameter to ensure good operation conditions [12].

3 Simulation and Discussions

The dynamic simulations of the mechanical press are carried out and analyzed in this section. Considering the influence of clearances and lubrication effect, the dynamic model with imperfect joints is constructed in MSC.ADAMS package, as presented in Fig. 1b. The simulation characteristics and properties of the components in the system are listed in Table 1. With the consideration to achieve higher simulation precision, the integration formulation (SI1) is chosen, which takes the constraint derivatives into account [14].

During the simulations, the translational joint is first assumed to be ideal, while the hydrodynamic forces are always applied in the revolute joint. Simulations are carried out with different crank speeds. The motion trajectories of the journal center with respect to the bearing are shown in Fig. 3a to c, where the geometrical limits defined by the clearance are plotted by dashed lines. And the results are obtained from the four full crank rotations after the steady states have been reached. It indicates that the shapes of the trajectories vary with the crank speed, and the journal basically approaches the bearing boundary as the speed increases. As the crank speeds up, the inertia forces of the bodies are intensified, which develops the greater dynamic loads on the revolute joint. Consequently, the lubricant film becomes thinner to achieve a greater load-bearing capacity. Meanwhile, we chose the time delay equal to the

Table 1 Simulation characteristics of the mechanical press

Nominal radius of journal R_J	0.12 m	Clearance size c_t	0.2 mm
Width of the bearing L_b	0.21 m	Friction coefficient c_f	0.02
Fluid viscosity μ	320 cP	Mass of crankshaft	447.55 kg

Elastic module of slider	207 GPa	Length of guide	1050 mm
Poisson's ratio	0.3	Width of guide	80 mm

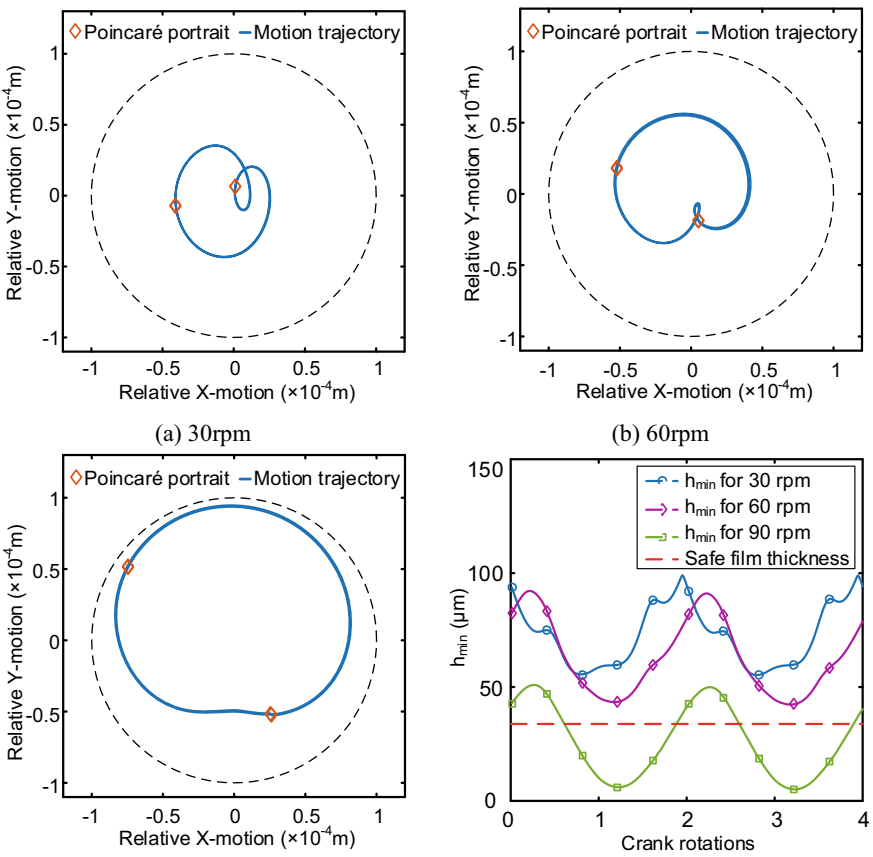

Fig. 3 Dynamic characteristics of the lubricated joint: **a**, **b**, and **c** motion trajectories and Poincaré portrait for different crank speeds; **d** minimum film thickness. (Color figure online)

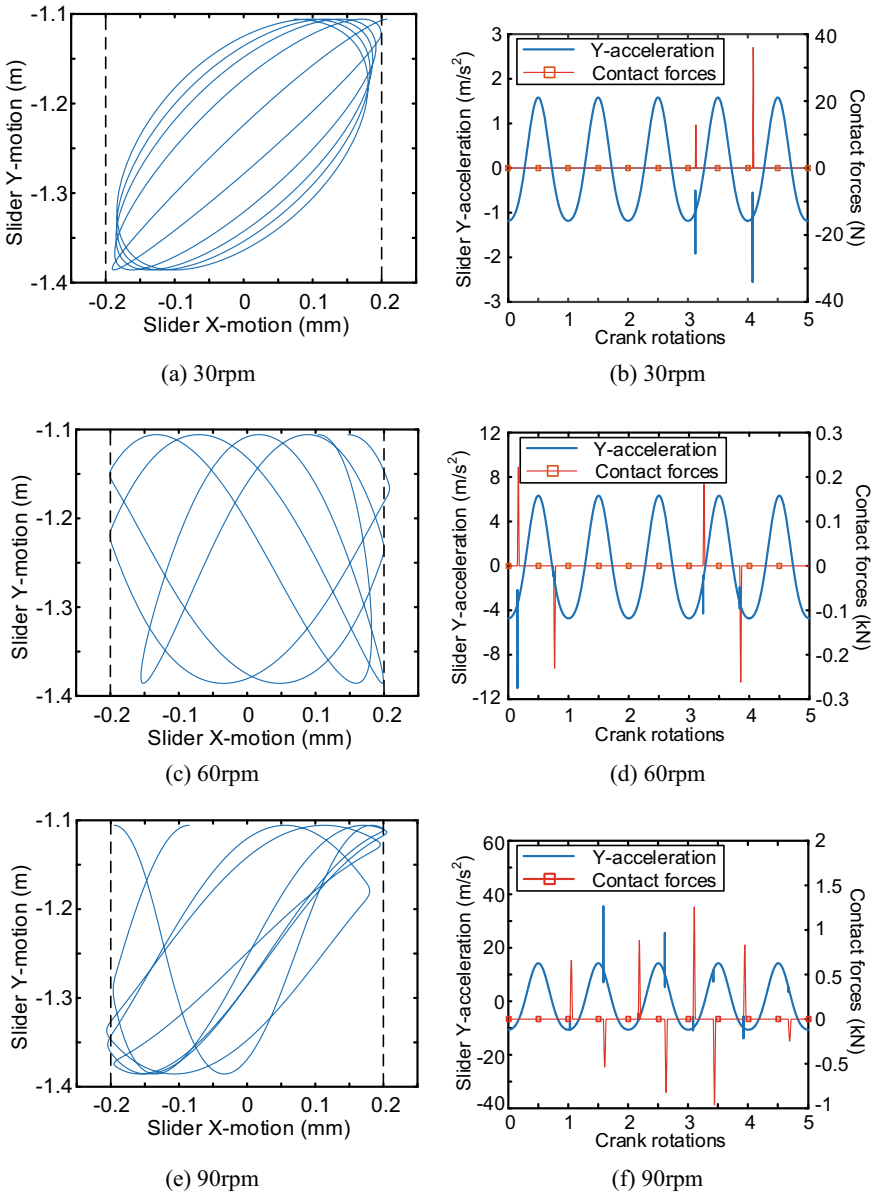
period of crank speed to conduct the Poincaré portrait of the trajectory. It appears that the journal position varies twice the cycle times of the crank rotation. However, the hydrodynamic forces in the joint share the same period time with the crank. In the work proposed by Machado et al. [12] and Zheng et al. [7], where the lubricant joint between the slider and connecting rod was investigated, such an unusual phenomenon was not observed.

The minimum film thickness for different crank speeds is displayed in Fig. 3d. It is demonstrated that the increase in speed can cause less fluctuation in the film thickness. For the maximum value of the speed, the minimum film thickness is even below the recommended safe value. Moreover, during the post-processing of the simulations, the global system responses of the mechanism, including the driving torque applied on the crankshaft, the acceleration and displacement of the slider, are observed no obvious difference with those obtained from ideal joints only. The



lubricated joint performs similarly to the ideal joint when investigating the local performance of the slider. The subsequence is also affirmed by the previous studies according to the reference [1].

Considering the combined effect of the lubricated joint and translational clearance joint, the system responses of the mechanical press are then investigated. The motion trajectories of the slider for different crank speeds are depicted in Fig. 4a, c, and e, which indicate irregular or chaotic behaviors of the system. As the crank speeds up, the motion trajectories become rather irregular and the maximum penetration depth magnifies. Moreover, high peaks in the slider acceleration along the Y-direction are observed. It shows that there is a direct connection between these peaks and the contact forces developed in the translation joint, as shown in Fig. 4b, d, and f. The growth of crank speed leads to the increase of slider acceleration spikes both in quantity and magnitude. It has been proofed by Flore et al. that the existence of clearance can disturb the slider acceleration with high peaks [15], which is also observed in this work.

However, the relative motion trajectories in the journal-bearing joint are found no significant differences when the translational joint is assumed to be ideal or a clearance one. This may result from the weak effects of short-term and small quantities of collisions on the slider displacement and velocity along the Y-direction. Therefore, according to Eq. (7), the hydrodynamic forces that dominate the dynamic responses of the lubricant revolute joint are almost unaffected.

4 Conclusions

The consideration of joint clearance in the dynamic analysis of the mechanical press can generally lead to a higher simulation precision. In this paper, a lubricant revolute joint and a translational clearance joint are simultaneously conducted in the model to identify their combined influence. The results show that the lubricated revolute joint presents practically as an ideal one in the global responses, with the parameters chosen in this paper. The minimum lubricant film thickness decreases as the crank speeds up, which indicates a strict control to the crank speed. The combined effect of the two clearance joints shows that the translational clearance joint could influence the system response significantly, leading to undesirable peaks in slider accelerations. However, it seems that the translational clearance joint has little influence on the dynamics of the lubricated joint, due to the limited amount of contacts under a low input crank speed. This observation implies that the effects of the two joints can be analyzed separately, for the dynamic analysis of heavy-load mechanical press with a low operation speed.

Microstructure and Damage Development and Characterization

Temperature-Dependent Fracture Loci of AZ31 Magnesium Alloy Sheets

R. Bertolini, Q. Wang, A. Ghiotti, and S. Bruschi

Abstract Magnesium alloys have been used in the automotive and aerospace industry for several years, thanks to their high strength-to-density ratio. Their mechanical characteristics at room and even at elevated temperature have been well studied, whereas, when it comes to temperatures lower than room one, only a few studies are available in the literature. To this aim, the present paper investigates the mechanical behavior of AZ31 magnesium alloy sheets deformed at different temperature regimes. Tensile tests till fracture were carried out at room temperature, −100, −50, 100, and 300 °C using different specimen geometries in order to vary the stress triaxiality. The fracture strain values were identified making use of a combined numerical–experimental approach, whereas the fracture surfaces were qualitatively characterized by means of stereoscopy and scanning electron microscopy. Finally, the AZ31 fracture locus as a function of the stress state and temperature was constructed.

Keywords Magnesium alloys · Cryogenic · Fracture locus · Fracture surface

1 Introduction

Magnesium alloys can be used in many structural and non-structural applications thanks to their high specific strength, high specific stiffness, and good damping capacity [1]. Nevertheless, the major limitation to their widespread application is represented by the poor formability characteristics of their hexagonal close packed (HPC) crystalline structure. In fact, in magnesium alloys, non-basal slip planes are hardly operative at room temperature since their critical resolved shear stress (CRSS) is much higher compared with one of the basal planes [2]. In addition, in case of sheets, the rolling process generally introduces a strong basal texture, aligning the hexagonal structure mostly normal to the rolling plane [3]. This confers a high anisotropy to the sheet and increases the difficulty in deformation accompanied with thickness reduction and consequently leads to very limited formability at room

temperature [4]. For these reasons, magnesium alloy sheets are generally formed within the warm/hot temperature regime and a lot of research works are available on this topic [5].

Magnesium alloys can be exposed to very low temperatures when used for aerospace, satellite parts, or tanks for liquefied gases. Some studies are available in the literature addressing their mechanical behavior at cryogenic temperatures, which may also useful to evaluate if an increase of ductility can be obtained at those temperatures, with the aim of proving the feasibility of cryogenic forming.

Bussiba et al. [6] studied the uniaxial mechanical response of round specimens made of ZK60 and AZ31 magnesium alloys at temperatures of 123 and 296 K. A completely different behavior was found for the two materials, namely ductile in the case of ZK60 and semi-brittle for the AZ31. This was attributed to the presence of different second phases, which were found to be responsible for controlling both the non-basal and basal plane slip activities. Jiang et al. [7] evaluated the strategy of applying a cryogenic treatment (CT), namely cooling the material to 77 K at a rate of 2 K per minute, as a strategy to increase both the tensile strength and ductility of the AZ31 magnesium alloy. Different soaking times were applied. The obtained results showed that the highest increase in mechanical performance (+42%) was found for the sample soaked for 2 h. The contribution of CT was identified on two levels: (i) the formation of a frame-like twinning due to the movement of grains as a consequence of thermal contraction at low temperatures and (ii) the development of a compressive residual stress state. Different conclusions were achieved by Wang et al. [8], who studied the tensile deformation behavior of the Mg–3Al–1Zn alloy at low temperatures ranging from 300 to 77 K at different strain rates. By reducing the temperature, the yield stress and ultimate tensile stress increased while the strain to failure was found to decrease. It was argued that the dislocation motion changed with temperature. Specifically, above 173 K, the interaction between dislocations and forest dislocations was dominant, whereas at temperature below 173 K, the dislocation motion was governed by the interaction with local lattice friction.

It is worth noting that in all these studies, the mechanical performances of magnesium alloys were evaluated in a wide range of temperatures, including that below room temperature, but solely under uniaxial loading conditions, without considering different stress states. In this framework, the present paper investigates the mechanical behavior of the AZ31 magnesium alloy at different temperatures and stress triaxiality conditions. For each experimental condition, the strain at fracture was identified by means of a combined experimental–numerical approach, whereas the fractured surfaces were inspected using a scanning electron microscope (SEM) at different magnifications.

Table 1 Chemical composition (% mass) of the AZ31 magnesium alloy sheets

Element	Aluminum	Zinc	Manganese	Magnesium
Content	3	1	0.2	Bal

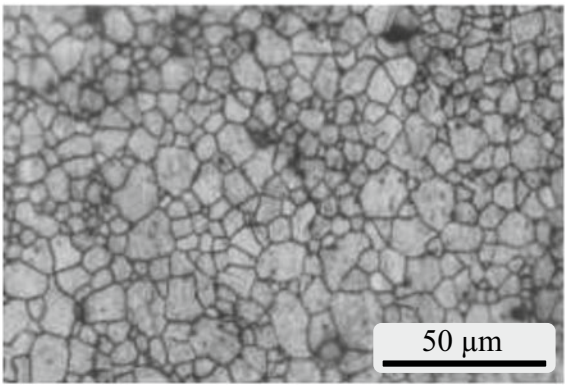

Fig. 1 Microstructure of the AZ31 magnesium alloy sheets in the as-delivered condition

2 Experimental

2.1 Material

The material under investigation is the AZ31 magnesium alloy provided in form of 1 mm thick sheets. The chemical composition of the alloy in the as-delivered condition is reported in Table 1, whereas its microstructure is shown in Fig. 1. The latter was obtained by cutting the sheet along with its thickness, then polishing, etching, and inspecting the sample through a Leica DMRE™ optical microscope equipped with a high-definition digital camera. The microstructural analysis revealed that the as-delivered material was characterized by a dual grain size distribution, a possible consequence of the dynamic recrystallization phenomenon during hot rolling. The resulted average grain size was calculated to be equal to 9 ± 4.8 μm. The AZ31 sheets were laser-cut along the rolling direction to provide specimens for the mechanical tests. Afterward, a finishing milling step was carried out to avoid any influence of the laser heat-affected zone on the experimental results.

2.2 Mechanical Testing

Tensile tests were carried out on the MTS™-322 hydraulic wedge shown in Fig. 2a, equipped with an environmental chamber that allowed setting the testing temperature in a range from –130 (±2) to 315 (±2) °C. To control the temperature during testing, a k-thermocouple was spot-welded on each specimen, as can be seen in Fig. 2b. Each

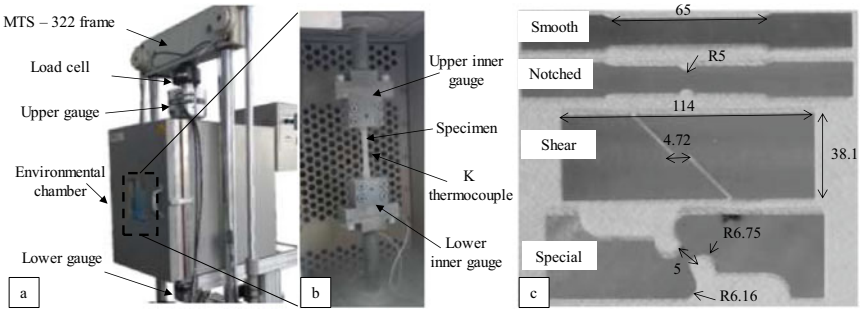

Fig. 2 **a** MTS™-322 hydraulic wedge equipment, **b** experimental setup configuration for testing smooth specimens, and **c** geometry of samples used in this study (measures are given in mm). (Color figure online)

test was carried out at a fixed strain rate of 0.1 s^{-1} and repeated three times to assure reproducibility of the results.

The effect of the testing temperature and stress triaxiality was investigated. To this aim, five different temperatures, namely −100, −50, 25, 200, and 300 °C, as well as four different stress triaxiality states were adopted. The latter was achieved by changing the specimen geometry: besides the classical dog bone sample, a 5 mm notched sample, a shear sample, and a special one, which accounts for a shear–tension state according to [9], were selected. The nominal stress triaxiality values are 0.1, 0.17, 0.33, and 0.47 for shear, special, smooth, and notched, respectively [10]. Figure 2c shows the specimen geometries considered in this paper and highlights their main geometrical features.

2.3 Procedure to Identify the Fracture Strain

The determination of the fracture strain is always a challenging issue in mechanical testing. It is generally recognized that its evaluation by measuring the specimen cross-section area through a microscope leads to some uncertainties due to the high level of strain attainable especially in hot conditions [11]. Nevertheless, the presence of the environmental chamber makes impossible the use of any kind of optical technique for its direct measure. For these reasons, in the present study, a hybrid experimental–numerical method was used to assess the strain at fracture.

The numerical simulations were performed as implicit analysis using the Ls_Dyna™ code version R9.1.0 (Ls_Prepost V4.7) with shell elements. The results of the tensile tests in terms of flow stress as a function of the temperature were used to calibrate the hardening law. The developed FEM model was validated using experimental data other than the ones used for its calibration.

Figure 3 illustrates the procedure used in this paper in the case of a shear specimen tested at −100 °C, as a reference example. The experimental and simulated force

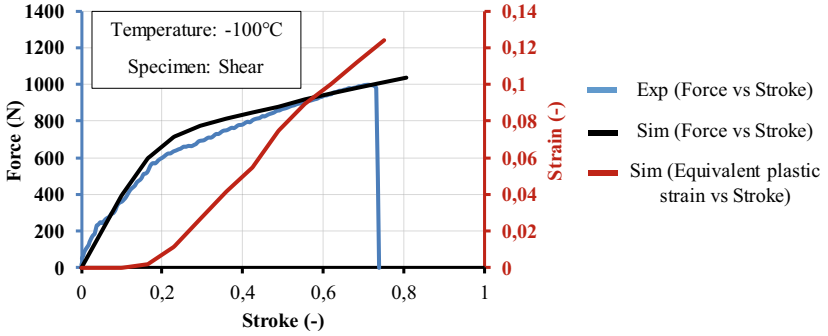

Fig. 3 Calculation of the equivalent plastic strain at fracture using the hybrid experimental–numerical method (case of a shear specimen deformed at −100 C). (Color figure online)

versus stroke curve is represented in the same figure, as well as the equivalent plastic strain versus stroke curve. It can be observed that the simulated force–stroke curve agrees with the experimental one with a good level of accuracy. The strain at fracture was assumed to be the maximum equivalent plastic strain at the experimental fracture stroke.

2.4 Characterization After Mechanical Testing

After mechanical testing, the specimen fracture surfaces were analyzed using the FEI™ QUANTA 450 scanning electron microscope (SEM) equipped with the Everhart–Thornley Detector (ETD). Images at 2000X and 5000X magnifications were acquired in different zones of the samples for each testing condition.

3 Results and Discussion

3.1 Mechanical Behavior

The force versus stroke curves for the investigated experimental conditions are reported in Fig. 4. Both the temperature and specimen configuration played a significant role in affecting the alloy mechanical behavior.

For a given stress triaxiality, the force increased as the testing temperature was reduced. On the contrary, the stroke at fracture diminished by deforming the specimen at temperatures lower than room one compared to tests conducted at higher temperatures. It is worth noting that for the special and shear samples, no sensible differences were seen between tests performed at 25, −50, and −100 °C. The smooth

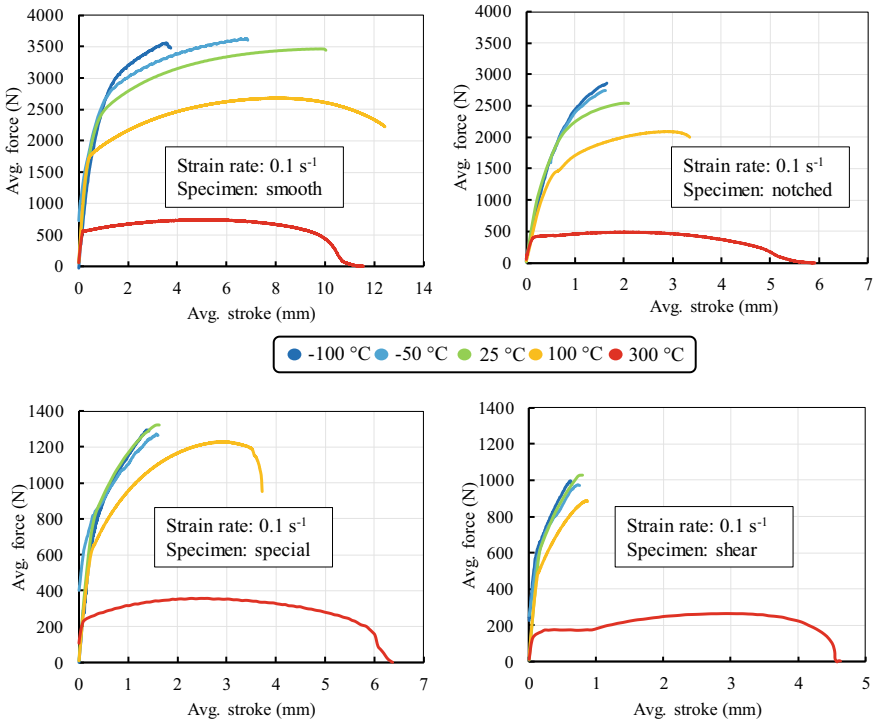

Fig. 4 Force versus stroke curves at varying testing temperature and stress triaxiality. (Color figure online)

specimen was characterized by the highest recorded forces, whereas the shear specimen by the lowest ones. Similarly, the stroke at fracture gradually decreased from smooth, notched, special to shear specimens.

Similar results in terms of force sensitivity to temperature can be found in Jiao et al. [12], where the AZ31B magnesium alloy was tested at −230, −196, −73, and 27 °C, but under uniaxial testing conditions. The specimen deformed at the lowest temperature showed an increase in the ultimate tensile strength and yield strength over 60% compared with the one deformed at room temperature. This was attributed to the reduced solubility of aluminum and zinc atoms at low temperatures, which are the main strengthening elements of the AZ31 alloy, inducing the formation of a fine distributed second phase in the matrix, which reinforced the alloy.

The AZ31 fracture loci as a function of the temperature and stress triaxiality are reported in Fig. 5. As an example, in case of smooth specimens, the maximum fracture strain value (identified on the basis of the procedure described in Section 2.3) was exhibited by the specimen deformed at the highest testing temperature, with an increase up to 1000% compared with the specimen deformed at the lowest temperature. This indicates the activation of additional deformation mechanisms above 200 °C. The fracture strain gradually decreases from 300, 100, 25 to −50 °C.

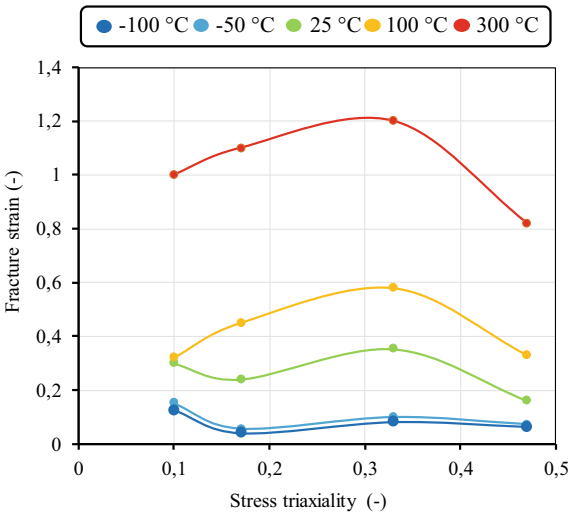

Fig. 5 AZ31 fracture loci at varying testing temperature and stress triaxiality. (Color figure online)

However, the fracture strain at −50 °C nearly overlapped the one at −100 °C, regardless of the stress triaxiality indicating the presence of a threshold temperature value below which the alloy ductility is no more sensitive to the testing temperature.

It is worth noting that the fracture strains of the shear and special specimens tested at room temperature are 50 and 81% higher compared with the ones obtained at low temperature, even if the same maximum load was reached during mechanical testing.

3.2 Fracture Surfaces

Figures 6 and 7 show the SEM images of the AZ31 specimens fractured at 300, 25, and −100 °C at magnifications of 2000X and 5000X, respectively. In Fig. 6i–l, wide and deep dimples structures, indicative of a ductile fracture mode, can be seen in the specimens deformed at 300 °C. On the contrary, at the lowest testing temperature, no ductile fracture features can be seen, since the dimples disappeared in favor of elongated fluted that are known to be symptomatic of a brittle fracture [10] (see Fig. 6a–d). In addition, on the fracture surfaces of Fig. 6(c and d), cracks along the grain boundaries can be observed, which is another typical brittle fracture structure. The fracture surfaces of the specimens deformed at room temperature have features in the middle, being a mixture of ductile and brittle type of fracture. Even if not here reported, the fracture surfaces of the specimens deformed at −50 °C are similar to those obtained at −100 °C, thereby confirming a fragile rupture when testing below the room temperature.

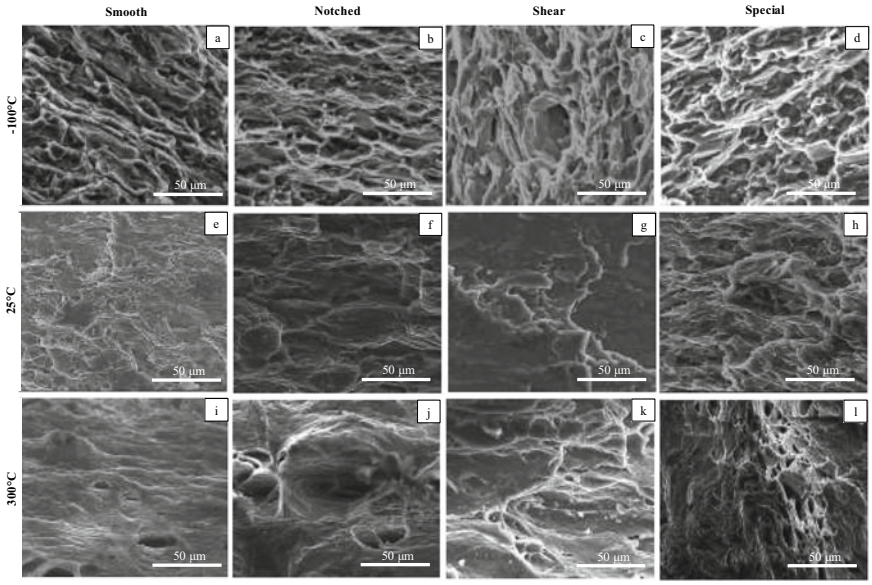

Fig. 6. 2000X SEM magnification of the AZ31 fractured surfaces as a function of the temperature and stress triaxiality

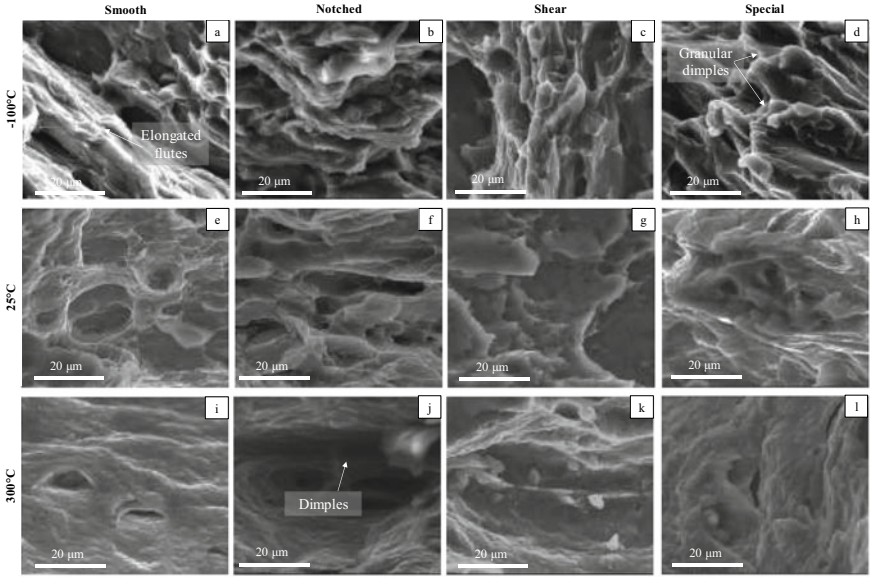

Fig. 7 5000X SEM magnification of the AZ31 fractured surfaces as a function of the temperature and stress triaxiality

4 Conclusions

In this work, tensile tests till fracture and SEM observations of the fracture surfaces were employed to characterize the mechanical properties and fracture morphology of the AZ31 magnesium alloy deformed in a wide range of temperature and stress triaxiality.

The main conclusions can be summarized as follows:

- The force increased monotonically by decreasing the temperature for the smooth and 5 mm notched samples. In the case of shear and special samples, at temperatures below than room one, the force was no longer sensitive to the testing temperature.
- Higher fracture strains were obtained at elevated temperatures, whereas no sensible differences were shown between tests carried out at −50 and −100 C.
- The reduction of temperature favored a brittle mode of fracture. The fractured surfaces of the specimens deformed at −50 and −100 C were in fact characterized by the presence of elongated flutes and intergranular cracks.

Influence of Specimen Preparation Methods on the Mechanical Properties and Superplastic Behavior of AA5083 Sheets

Mohammad S. Dastgiri, Leo Kiawi, Iman S. Sarraf, Eugene Ryzer, and Daniel E. Green

Abstract The process used to fabricate tensile specimens inevitably introduces imperfections at their edges, which can affect the resulting experimental mechanical properties. It has been reported that, for ambient temperature testing, tensile specimens prepared by less aggressive machining methods yield more accurate data due to the absence of plastic deformation at the edges. However, for superplastic forming (SPF) where forming is performed at elevated temperatures, the results are different. In this study, AA5083 sheet specimens were prepared using different machining methods: wire-electro-discharge machining, waterjet cutting, and conventional milling. Mechanical properties were determined from tensile tests carried out at 450 °C and at a quasi-static strain rate. The edges of tensile specimens were observed under optical and scanning electron microscopes (SEM) both before and after testing. It was found that milled specimens resulted in greater values of total elongation. The microscopic investigation revealed that specimens whose edges have a lower arithmetic mean roughness (Ra) have greater values of elongation. The SEM investigation also revealed that micro-cracks are more prevalent at the edges of specimens that have a greater surface roughness. Therefore, tensile specimens used to characterize sheet mechanical properties in view of SPF applications should be fabricated by a process that yields a lower surface roughness, such as conventional milling.

Keywords SPF · Superplastic forming · Surface roughness · Tensile testing · Aluminum AA5083

1 Introduction

Aluminum AA5083 is a non-heat-treatable aluminum alloy with excellent cold formability and can reach moderate levels of superplasticity [1]. This alloy is affordable and has reasonable environmental resistance and good mechanical properties, which make it ideal for aerospace, marine, and automotive applications [2].

Tensile testing is the most common way to determine mechanical properties. Experimental mechanical characteristics can be used to compare different batches and for input in numerical simulations of forming or post-forming operations. It has been reported that specimen preparation methods can affect the specimen edge quality and consequently affect reported mechanical properties for steels at ambient temperature [3, 4]. Although the mechanical properties of aluminum AA5083 have been investigated by many researchers [5–7], there is a striking lack of information regarding the specimen preparation methods in most of these publications. Since the machining method can affect the results of tensile testing makes it difficult to use these published results. Computer numerical controlled (CNC) waterjet cutting (WJet), wire-electro-discharge machining (WEDM), and milling are among the most common machining methods used to prepare tensile specimens. Therefore, this research focuses on investigating the effects of these specimen preparation methods on the results of tensile tests carried out on AA5083 aluminum sheet specimens at 450 °C in view of superplastic forming applications.

2 Experimental Procedures

2.1 Specimen Preparation

In this research, three types of preparation methods were used to cut tensile specimens, namely milling, WEDM, and WJet. Specimen dimensions were selected according to the ASTM E2448 standard, which does not provide any recommendations as to the machining method that should be used. However, ASTM E2448 requires that the gauge width and thickness be measured at a minimum of four locations within the gauge area, and the measurement tolerance should not exceed 1% or 12 μm. AA5083 sheets with a thickness of 1.42 mm were cut in such a way that there was no thickness reduction at the edge. In order to reach this tolerance, process parameters were selected as follows: for milled specimens, machining was carried out with a 1/8-inch diameter tool rotating at 7500 rpm with a feeding rate of 30 mm/min. The full sheet thickness was machined in two successive passes. For WEDM, a 0.0254-inch diameter wire was tensioned at 17 N and fed at a rate of

8.1 mm/min. The cutting rate was 0.01 Versus and the electrical current was AC 28 Hz, 17Amp. For WJet, the nozzle diameter was 0.030 inch, distant at 0.080 inch and the average cutting rate was 1200 mm/min.

2.2 Roughness Evaluation

Before performing the tensile tests, all the specimens underwent a surface roughness evaluation. The ISO 4287:1997 standard was employed to determine the arithmetic mean surface roughness (R_a), the maximum height of the assessed profile (R_z), the maximum peak height (R_p), and the maximum valley depth (R_v) [8]. The surface that was evaluated was the edge of the specimens where each machining method left a different surface roughness. In this research, two-dimensional and three-dimensional arithmetic mean roughness (R_a) was measured. Two-dimensional data were extracted from perpendicular to cutting edge optical images taken with an Olympus GX51 at 50X magnification, and each profile covered 1760 ± 3 μm. For each tensile specimen, three profiles were measured and analyzed. For three-dimensional surface roughness measurements, back-scattered electron (BSE) images of the specimen edge were calibrated with BSE image of the reference specimen.

2.3 Scanning Electron Microscopy

Test specimens were investigated for surface morphology using scanning electron microscopy, and this was carried out with a FEI Quanta 200 FEG scanning electron microscope (SEM).

2.4 Tensile Tests

Quasi-static tensile testing was conducted using an MTS Criterion® model 45. For better accuracy, an additional "Strainsert FL1U(C)-2SGKT" load cell with a maximum capacity of 1Kip was employed. Strains were recorded using an MTS integrated video extensometer. The high-temperature environment was generated using a tubular radiant furnace with an additional controlled conductive heater located at lower specimen holder. Two contacting thermocouples were used to record the temperature at both ends of the specimen and another thermocouple was located near the middle of the gauge length. The temperature was controlled using a PID controller, which allowed the temperature gradient from one end of the specimen to the other to remain within 2 °C throughout the test.

3 Results and Discussion

3.1 Surface Roughness

The arithmetic mean surface roughness (Ra) of the specimen edges prepared with different machining processes is summarized in Table 1 and Fig. 1. The Ra values clearly show that milled specimens had the lowest surface roughness ($R_a = 0.45$ μm, on average). The Ra value increases 18 and 24 times, in WEDM and WJet specimens, respectively, compared to milled specimens. It can be seen that 3D and 2D surface roughness parameters are slightly different; 2D roughness measurements were obtained from profiles taken parallel to the specimen loading direction. However, 3D surface roughness measurements were calculated across selected 1 mm × 1 mm areas. Therefore, the orientation of the 2D surface roughness profiles parallel with the specimen loading direction is no doubt the cause of these minor differences.

3.2 Surface Morphology

Figure 2 presents the surface profile of the edge of the three types of specimens prior to tensile testing, and the scale of *Z*-axis was kept identical for all three machining methods. WJet specimens are characterized by deep markings (Fig. 3) that show the abrasive nature of the waterjet cutting process. These marks are oriented perpendicular to the loading direction of the tensile specimen. These abrasion marks are potential regions for crack nucleation, and in some areas, it appears that microcracks already exist. During a tensile test, the applied load effectively opens any cracks, causing further damage to the edge of the specimen.

In contrast to WJet specimens, the surface morphology of the edges of WEDM specimens is non-directional and is characterized by rounded globules that are a residue of local melting caused by electrical sparking. Figure 4 shows a secondary electron image of the edge of a WEDM specimen prior to testing. The size of the globules appears to be randomly distributed. Furthermore, the local melting and solidification also cause shrinkage of the base metal that leaves a conical dimple under each globule. These shrinkage dimples are susceptible to stress concentrations, which may become crack nucleation sites during tensile testing.

The edges of milled specimens exhibit a uniformly directional pattern, as seen in Fig. 5. This pattern appears as shallow score marks that are oriented parallel to the loading direction of the tensile specimen. According to Table 1, the maximum height of these machining marks ($R_z = 3.2$ μm) is considerably less than those at the edge of WJet specimens ($R_z = 31.1$ μm). In addition, even if these milling marks led to the initiation of edge cracks, these cracks would not be responsible for the final failure and fracture of the specimen because they lie parallel to the loading direction.

3.3 Effect of Preparation Method on the Yield Stress

The effect of the machining process on the yield stress of AA5083 specimens loaded in tension at 450 °C is presented in Fig. 6a. It appears that the yield stress remains virtually unchanged for each machining method. However, the range of measured yield stress values differs for each specimen preparation method. The range of recorded yield stress values is very small (±) for milled specimens whereas the range for WJet samples is greatest. Figure 7 compares the engineering stress–strain curve of the most representative specimens for each type of machining method. During high-temperature superplastic forming, this aluminum alloy exhibits a softening behavior and therefore the yield stress is also the maximum stress before fracture. A comparison of the stress–strain curves in Fig. 7 shows that the machining method only affects the total elongation and practically has no effect on the elastic modulus and flow behavior of AA5083.

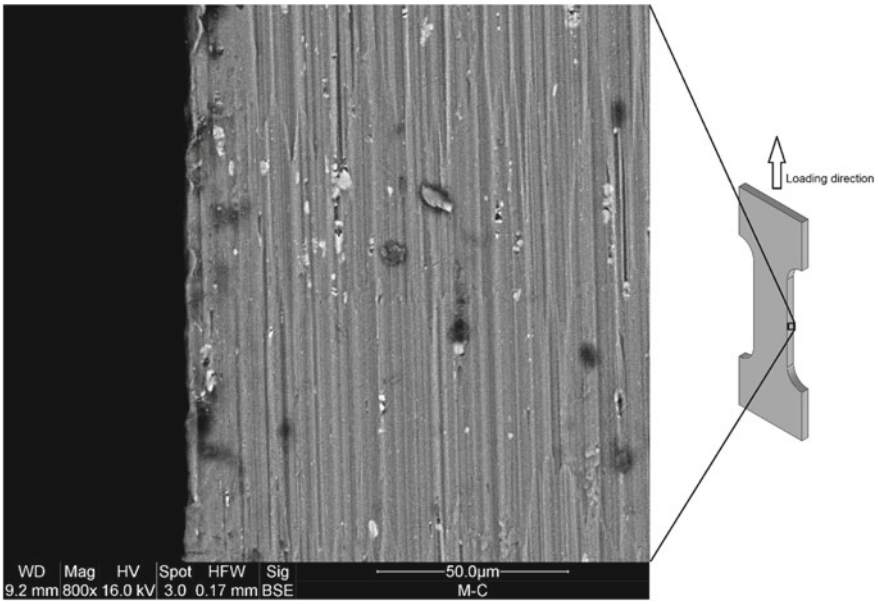

Fig. 5 SEM-BSE image of the edge of a milled specimen prior to tensile testing

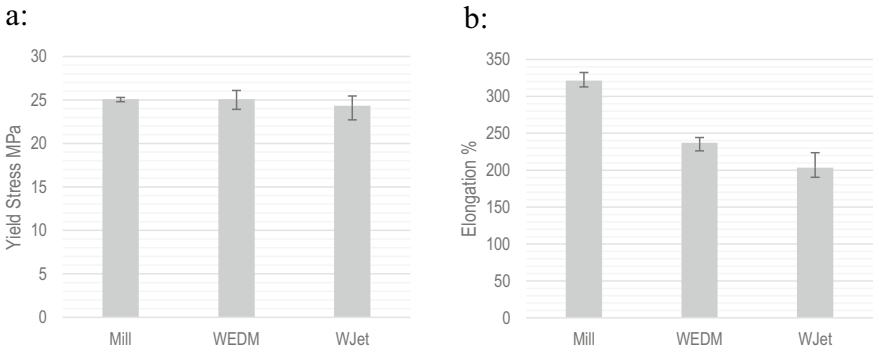

Fig. 6 Effect of machining process on mechanical characteristics of AA5083 at 450 °C

3.4 Effect of Preparation Method on the Total Elongation

Figure 6b shows the sensitivity of the total elongation to the specimen preparation process. Milled specimens deformed in tension at 450 °C exhibit a total elongation of 3.1, which is, on average, 30 and 59% more than that of WEDM and WJet specimens, respectively. The range of measured elongation values is presented in the form of error bars in Fig. 6b, and it is evident that the range is greatest for WJet specimens compared to the other machining processes. In order to better understand the reasons

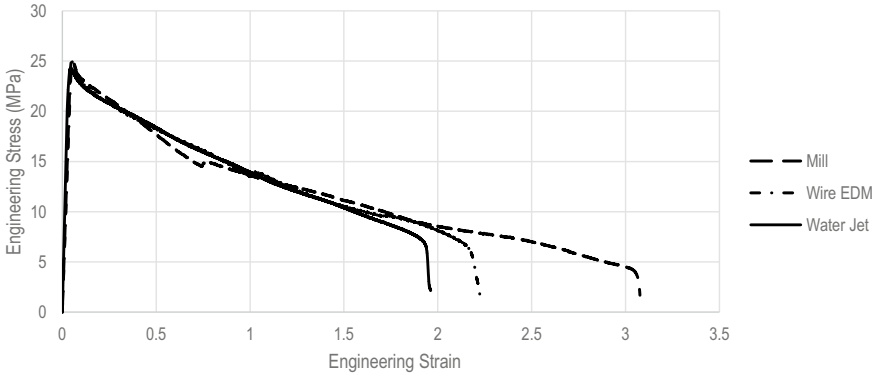

Fig. 7 Engineering stress–strain curve of AA5083 specimens loaded in tension at 450 °C and prepared with different machining methods

for the differences in the ranges of measured elongation values, the edge of deformed specimens was also observed using macro SEM imaging (see Fig. 8). These images were taken within the gauge length and approximately 5 mm away from the fracture site. Figure 8.a shows that the edges of milled specimens deformed uniformly in high-temperature tensile testing. Due to the decreased surface roughness and the absence of sites of potential crack nucleation, the deformation reached greater values before the onset of fracture. In contrast, Fig. 8b, c shows increased non-uniformity of the through-thickness strain in WEDM and WJet specimens, respectively, compared to the milled specimen. All the specimens that were prepared by waterjet cutting were observed to fracture by the propagation of a crack that started at one of the two edges. This trend was also observed in the case of WEDM specimens. Even though the width strain of WEDM specimens is more uniform than that of WJet specimens, all the WEDM specimens also failed because of a crack that started from the machined edge.

4 Conclusions and Recommendations

The microscopic investigation that was carried out indicated that the three different machining methods used to prepare AA5083 tensile specimens resulted in very different surface roughness parameters. Conventional milling had the lowest surface roughness ($R_a = 0.46\,\mu m$) whereas WEDM and WJet resulted in considerably greater surface roughness ($R_a = 8.28\,\mu m$ and $R_a = 10.85\,\mu m$, respectively). Moreover, three-dimensional surface mapping showed the presence of micro-cracks in undeformed specimens that were prepared using waterjet cutting.

High-temperature tensile test data showed that milled specimens, which had the lowest surface roughness, exhibited the greatest values of total elongation (ε_f = 3.1) compared to specimens machined by wire-EDM and waterjet cutting (ε_f =

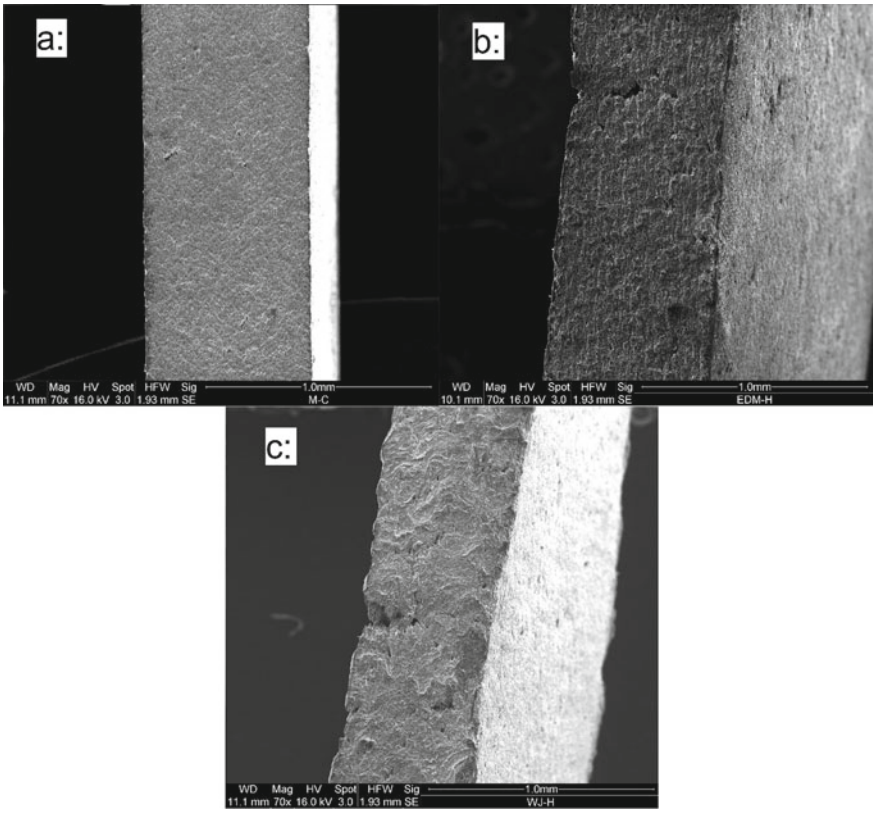

Fig. 8 SEM-SE images of the edge of (**a**) milled, (**b**) WEDM, and (**c**) WJet specimens after tensile testing

2.38 and $\varepsilon_f = 1.95$, respectively). However, the yield stress remained essentially unchanged for each of the machining methods considered. Microscopic investigation also confirmed that milled specimens deformed more uniformly in their gauge length compared to WEDM and WJet specimens.

This work shows that the type of machining method can significantly affect the values of the total elongation, which are measured in high-temperature tensile tests. The following recommendations can be made:

- The recommended method for preparing tensile specimens for the characterization of high-temperature mechanical properties of superplastic aluminum sheets is by conventional milling: this is due to the smoother surfaces imparted to the edges of the specimen.
- If experimental fracture strain data obtained from high-temperature tensile tests are intended to validate the outcome of numerical simulations of a superplastic forming process, it is recommended that the tensile specimen preparation method should be selected in such a way that the resulting surface roughness corresponds

as closely as possible with that of the edge of the sheet metal blank that will be used in the actual forming process.

- Finally, it is recommended that the machining method used for tensile specimen preparation and the corresponding surface roughness measured at the specimen edges be reported in publications, with the high-temperature experimental mechanical properties that are obtained from these specimens: this will avoid inappropriate utilization of experimental tensile data for superplastic aluminum alloys. Similarly, comparisons between high-temperature tensile data obtained from different laboratories should only be done after careful consideration of the surface roughness at the specimen edges prior to tensile testing.

Acknowledgments The authors would like to thank AEM Power Systems Inc. for sponsoring this research, and the Great Lakes Institute for Environmental Research (GLIER) at the University of Windsor is acknowledged for the use of their scanning electron microscope.

Application of the Nondestructive Evaluation (NDE) Method to Evaluate the Sheared Edge Quality and Edge Cracking

J. Gu, N. Pathak, S. Freed, E. Todorov, and H. Kim

Abstract Evaluating the shear edge quality and edge cracking is important in forming the advanced high-strength steel (AHSS) for automotive structural parts. This paper introduces the eddy current-based NDE method to evaluate the sheared edge quality. Different shear clearances from 5 to 25% of the sheet thickness were used to create different work-hardening levels on the sheared edges, which change the local formability. The NDE sensor scanned the sheared DP780 blanks to obtain the NDE data. The micro-hardness at the sheared edge was measured to compare the NDE data to the work-hardening level of the sheared edge. The edge formability was evaluated using the half specimen dome test (HSDT) with digital image correlation (DIC). The measured HSDT failure strain was correlated with the NDE data. The NDE result showed a good correlation with the DIC measured failure strain and micro-hardness. With further development effort, the eddy current-based NDE method can be implemented to inspect the sheared edge quality in a production environment.

1 Introduction

Eddy current (EC) technology is widely used as one of the nondestructive evaluation (NDE) methods. The EC is the induced current with closed contour patterns generated by alternating the magnetic field in a conductive material by Faraday's law of induction [1]. The contour of the EC signal is affected by sample electromagnetic property, standoff distance of the sensor, and sample geometry [2]. Discontinuity of conductivity from microcracks can distort the eddy current contour [3]. Therefore, EC is often used to detect structural defects that can be used to evaluate the work-hardening level from the shearing process. The effect of structural defects on EC contour is shown in Fig. 1.

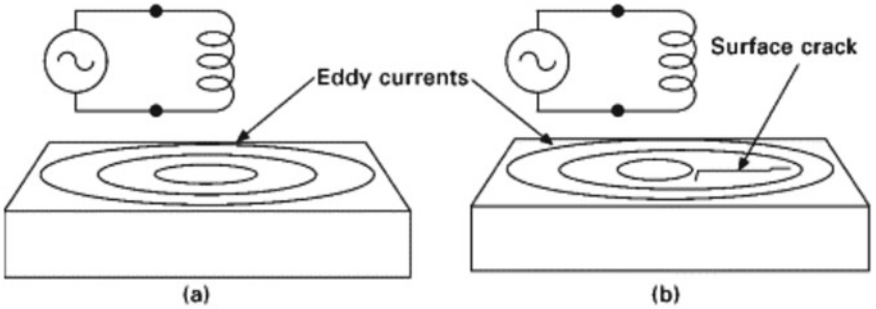

Fig. 1 Schematic of EC (L) and detecting surface crack (R) [1]

A sheared edge stretching operation involves a two-stage, nonproportional loading process that includes through-thickness shearing followed by in-plane stretching under uniaxial tensile loading. Various research has been conducted on evaluating and predicting edge cracking on AHSS. The critical parameters affecting edge local formability were investigated by Pathak et al. [4]. The study concludes that the edge local formability is mainly affected by the work-hardening introduced during the shearing process. To evaluate the edge formability, various destructive tests [4–6] were used to evaluate the edge work-hardening and sheared edge stretchability by measuring grain rotation and micro-hardness testing. However, most lab-scale tests cannot be used for real-time assessment of the edge formability in a production environment.

Following up the previous work on this topic at EWI [8], this study contributed further improvements in using an EC NDE tool to evaluate edge local formability. The previous experimental setup and EC scanning result are shown in Fig. 2 [8]. However, the previous NDE setup was found very sensitive to edge alignment. In this study, the NDE setup was upgraded with a high-resolution EC probe and improved fixture to obtain more accurate NDE data by directly scanning the sheared edge in the thickness direction. Multiple stacked samples with spacers were scanned in one path with the new scanning setup. Other validation tests, HSDT and micro-hardness testing, were conducted to correlate with the NDE result.

2 Objective

The objective of this study was to develop and validate an NDE method to evaluate the sheared edge quality in sheet metal forming.

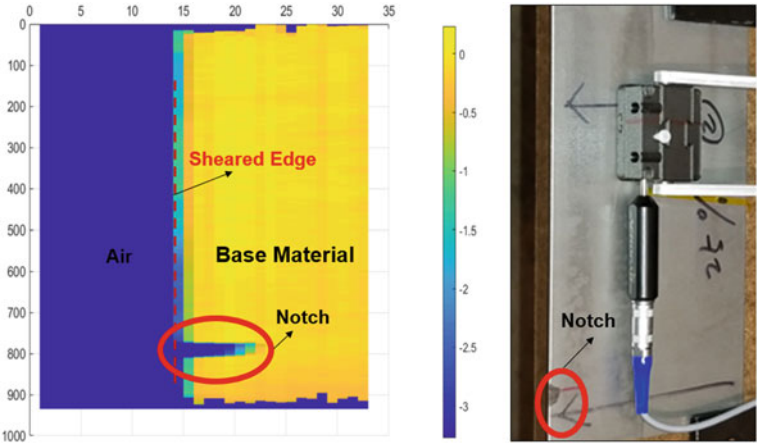

Fig. 2 Eddy current measurement result colormap (L) and setup (R) from the previous study [8]. (Color figure online)

3 Approach

This study was conducted on the basis of previous work published by EWI [8]. DP780 material with 1.2-mm thickness was selected for this study. The following various conditions were used to create different work-hardening levels on the sheared or machined edge:

- 5%: Die shearing at 5% die clearance
- 10%: Die shearing at 10% die clearance
- 15%: Die shearing at 15% die clearance
- 20%: Die shearing at 20% die clearance
- 25%: Die shearing at 25% die clearance
- Milling: machined edge
- Sheared: Sheared using a conventional lab shear machine with unknown shear clearance.

The die clearance is calculated by the percentage of breakage with respect to material thickness (1.2 mm). The shearing with precisely controlled shear clearance was performed by US Steel, and the other edge conditions are prepared by EWI.

a. **NDE Measurement Setup**
A small size surface probe was used to measure the eddy current signals as shown in Fig. 3. The probe is attached to the fixture that has CNC control in *x* and *y* directions horizontally as shown in Fig. 4. The interested edges were aligned facing up vertically and the stacked samples were separated layer by layer with non-conductive material.

b. **NDE Measurement**

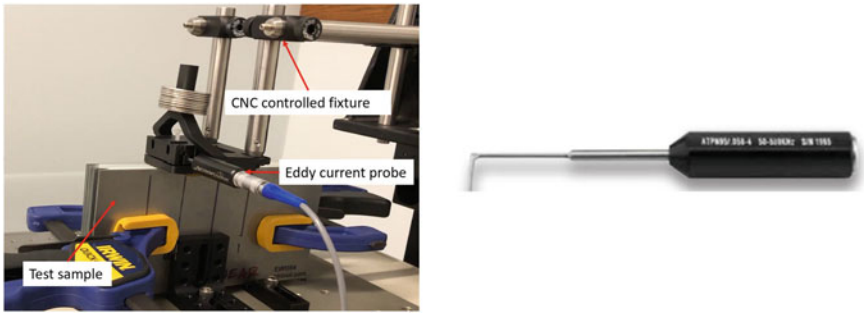

Fig. 3 Eddy current probe setup and the eddy current probe. (Color figure online)

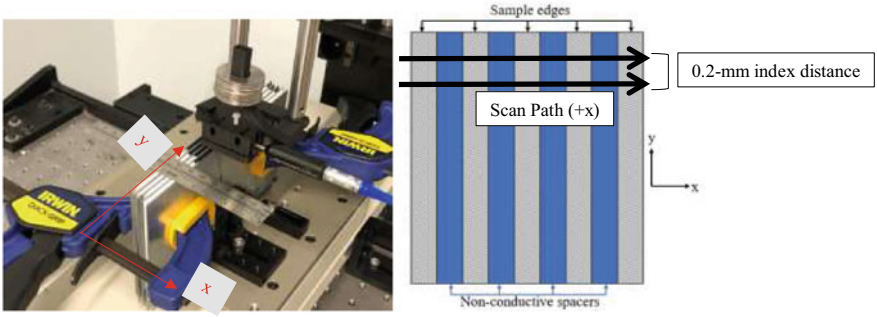

Fig. 4 Measurement setup and schematic of sample layout. (Color figure online)

In this study, the EC measurement frequency was set to be 500 kHz to obtain high-resolution EC data. The NDE measurement system was calibrated for the selected DP780 material. The NDE probe was set to travel 25 mm in *x*-direction using the CNC-controlled fixture as indicated in Fig. 4. 1000 data points were collected in each second. In each scan path, approximately16,000 data points were collected. A total of 200 scan paths in *x*-direction were conducted for each set of the stacked five samples as shown in Fig. 4. The probe position was incrementally changed with 0.2-mm in *y*-direction after finishing each scan path. The three scan data from different scan paths were selected to calculate an average NDE data for each sheared sample. The signal component that is sensitive to work-hardening level is isolated, which is called the vertical component. The NDE scan data reported in this study are referred to as the vertical component.

c. **HSDT and hardness tests**

Two different tests, HSDT and micro-hardness testing, were used to establish a relationship between NDE data and the edge quality. HSDT evaluates the straight sheared edge by stretching the sheared edge with a 100-mm diameter dome punch shown in Fig. 5 [7]. Three samples were repeated in HSDT for each representative edge condition. The local strain distribution of the sheared edge

Fig. 5 HSDT setup, HSDT tested sample, and DIC strain contour. (Color figure online)

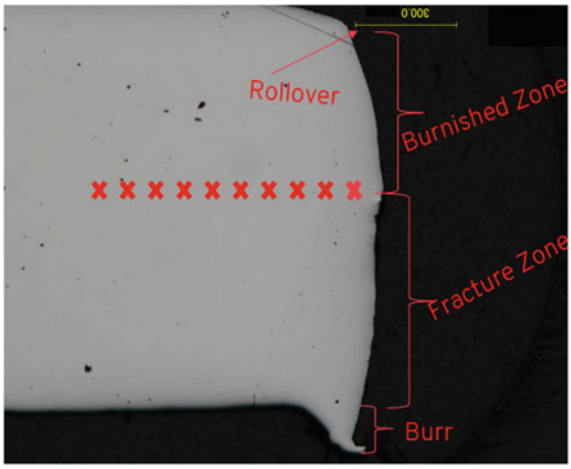

Fig. 6 Schematic of indentation locations of micro-hardness testing. (Color figure online)

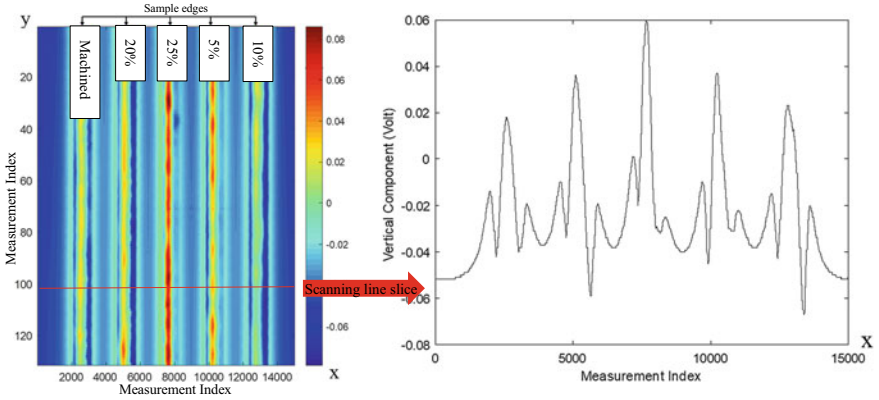
was measured using DIC cameras. The equivalent failure strain before initiation of edge cracking was recorded as shown in Fig. 5.

A micro-hardness test was also conducted to evaluate the work-hardening introduced by different edge conditions. Ten indentations were made for each measured sample from the sheared edge to the base metal as shown in Fig. 6. The starting point of indentation was selected at the transition between the burnished zone and fracture zone since the work-hardening was known to be more pronounced in this transition area. The first indentation was 100 μm from the sheared edge, and the subsequent indentations had 150-μm step pitch.

4 Results

4.1 EC results

Figure 7 shows a contour plot of the NDE data distribution of five samples that had different edge conditions from shearing and machining. The red color indicates the



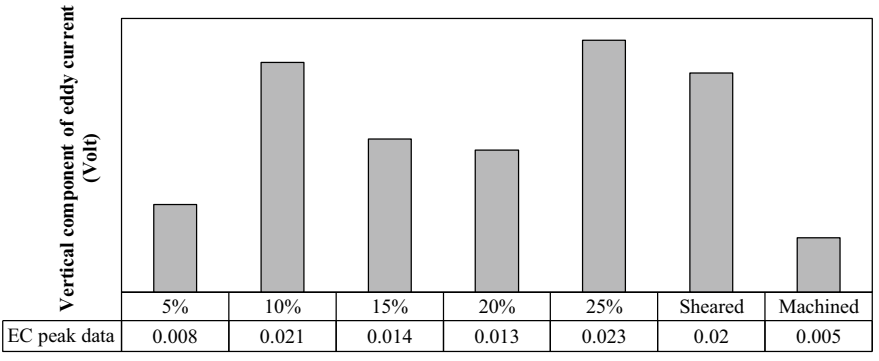


Fig. 7 Colormap and schematic of selection of data slices from EC scanning of machined edge, 20, 25, 5, and 10% sheared clearance (L–R), and example of peak data across the thickness in the same order. (Color figure online)

maximum NDE signal that was measured on the sheared edges. Each sample has different work-hardening levels from shearing at different clearances. The NDE scan data were sliced horizontally as shown in Fig. 7. Due to the limitation of the fixture, only five samples can fit in one scan. The five local peak values of the continuous NDE data correspond to the five stacked samples during scanning. The scanning direction is along the $+x$ direction, which is the same as the thickness direction. Peak value occurs around the middle point of the sample thickness.

The EC peak values of the sample in all edge conditions are compared in Fig. 8.

	5%	10%	15%	20%	25%	Sheared	Machined
EC peak data	0.008	0.021	0.014	0.013	0.023	0.02	0.005

Fig. 8 Summary of EC peak value of different edge conditions

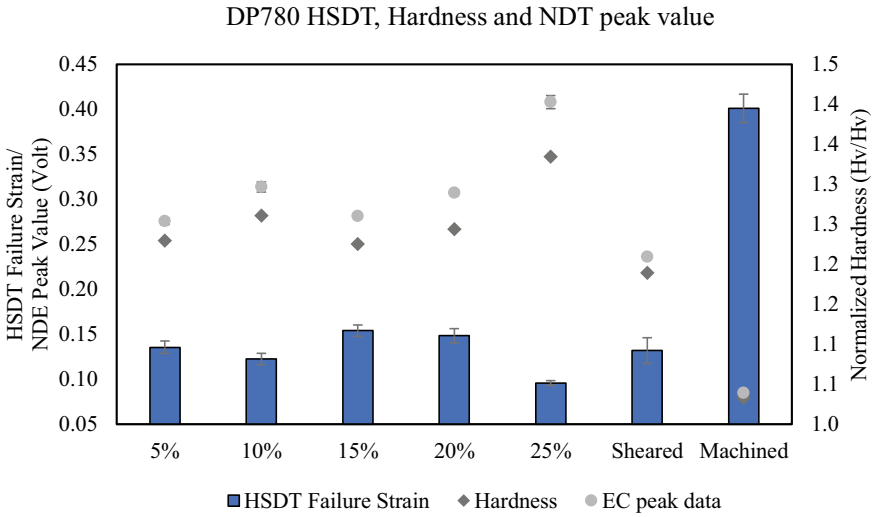

Fig. 9 Comparison of NDE result and destructive evaluations of edge formability. (Color figure online)

4.2 Correlation of NDE result with HSDT and hardness results

The NDE result was compared with the equivalent strain for the onset of edge cracking from HSDT and the normalized edge hardness from Vickers micro-hardness measurement. Figure 9 compares the NDE and destructive evaluation of edge quality. The higher equivalent failure strain in HSDT indicates the more formable edge condition. The lower hardness represents the better edge quality.

The critical hardness value was calculated using Eq. 1. HV_{edge} was obtained from the first indentation at the edge. HV_{base} was the average hardness value of the last four indentations of the measurement array.

$$\text{Normalized Hardness} = HV_{Edge} / HV_{base} \tag{1}$$

A correlation between NDE and destructive tests can be modeled using the power regression method as shown in Fig. 10. The regression model between NDE result and normalized hardness shows R-squared value over 94%, which indicates good reliability of the model. The regression model between NDE result and average HSDT failure strain shows R-squared value around 80%, which indicates relatively less correlation. Therefore, more experiment data should be considered to improve the correlation.

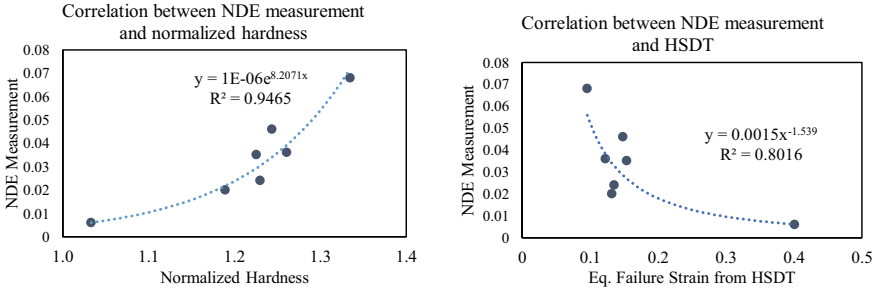

Fig. 10 Potential correlation of NDE measurement with destructive measurements. (Color figure online)

5 Conclusions

The following conclusions can be made from this study:

- The eddy current NDE tool can be used to measure the work-hardening level on sheared edges.
- The NDE data show a strong correlation with the edge quality evaluation results of HSDT and micro-hardness test.
- The NDE value increases as the HSDT strain decreases or hardness increases.
- As future work, NDE data can be attempted for predicting the edge failure by correlating with the formability test results such as hole expansion test and HSDT.

An Extended Ductile Fracture Prediction Model Considering Hydrostatic Stress and Maximum Shear Stress

Zhe Jia, Lei Mu, Ben Guan, and Yong Zang

Abstract An uncoupled ductile fracture model, based on Mu–Zang model, is extended by incorporating a hydrostatic stress term. An aluminum alloy material (Al 6016-T6) is selected with a series of static ductile fracture tests performed on four different specimens, which can cover a wide range of stress states. A robust simulation-experiment approach is adopted to characterize the correlation between the material's ductility and distinct stress states. The extended model is then calibrated using least-squares optimization. The resulting 3D fracture surface demonstrates acceptable deviations from the tested data, manifesting a promising capability of the extended model to describe the ductility of the considered material within a wide stress state range. In addition, the comparison against other representative ductile fracture models further confirms a good prediction performance of the model proposed.

Keywords Ductile fracture · Hydrostatic stress · Stress triaxiality · Lode parameter

1 Introduction

Aluminum alloys with a high strength-to-weight ratio are being increasingly used in the automobile industry due to the demand for weight reduction, fuel efficiency, and environmental friendliness. Accordingly, it is an urgent issue to accurately predict the ductile fracture behavior of aluminum alloys during the forming process.

For the last decades, various ductile fracture models have been developed, which have been classified into two major types: coupled models and uncoupled models [1]. In the framework of a coupled model (i.e. GTN model), the ductile damage-induced material strength degradation is elaborately considered, whereas an uncoupled model

(i.e. MMC model, Lou–Huh model) ignores the interaction between ductile damage and material constitutive model by empirically or semi-empirically formulating the damage accumulation in a specialized function containing several macroscopic variables (such as equivalent plastic strain, tensile stress, hydrostatic stress, etc.) [2–4]. In the past decade, many extensive efforts have been made in the development of modern uncoupled models, which demonstrate sensitivities to both stress triaxiality and Lode parameter. These novel models have been successfully used to characterize the formability of various materials, including DP590, Al 2024-T351, and 5083-O [4–7]. The prediction accuracy of proposed models on ductile fracture behavior needs to be further improved from the perspective of void evolution. Mu et al. recently proposed a new phenomenological fracture model, considering the two well-known void deformation modes, viz., void dilation and void elongation/rotation [5, 6]. In the Mu–Zang model, the normalized first principal stress ($\sigma_1/\overline{\sigma}$) is used to characterize the void dilation, whereas the normalized maximum shear stress ($\tau_{\max}/\overline{\sigma}$) is used to characterize the void elongation/rotation. However, the void dilation theoretically determines how the volume of voids enlarges due to all-sided (triaxial) tension conditions and is caused by hydrostatic tensile stress [8]. Thus, the current paper has been proposed to modify Mu–Zang model through characterizing the void dilation mode using stress triaxiality, which is defined by the ratio of hydrostatic stress to von Mises stress. A hybrid experimental-simulated method is used to calibrate the model under a large range of stress state. The results show that the proposed model has a good ability of prediction for aluminum alloys.

2 A Modified Ductile Fracture Model

The void dilation part of Mu–Zang model is slightly modified by using a normalized hydrostatic tensile stress term, as shown in Eq. (1). C_1 and C_2 indicate the sensitivities of various materials to the two major void deformation modes, namely, void dilation and void elongation/rotation, respectively; C_3 represents the effect of superposition of two void modes; C_4 expresses the threshold value of ductile fracture; D_n takes a form of $D_n = R_n(\overline{\varepsilon}^p)^m$ according to [6].

$$C_4 = \int_0^{\overline{\varepsilon}^f} \left\langle C_1 \frac{\sigma_m}{\overline{\sigma}} + C_2 \frac{\tau_{\max}}{\overline{\sigma}} \right\rangle^{C_3} D_n d\overline{\varepsilon}^{\mathrm{p}}. \tag{1}$$

When using an uncoupled ductile fracture model to capture the occurrence of ductile fracture during a certain form process, researchers generally reformulate the selected model in the space of stress triaxiality (η), Lode parameter (L), and fracture strain ($\overline{\varepsilon}^f$) based on a linear loading assumption, constructing a 3D fracture surface function [9, 10]. Then the constructed 3D fracture surface function is used in a linear ductile damage indicator framework to define the ductile damage evolution. Likewise, Eq. (1) is reformulated in the space of (η, L, $\overline{\varepsilon}^f$), as follows,

Table 1 Material parameters of hardening model

	A/MPa	ε_0	n	Q_s/MPa	Q_0/MPa	V_0/MPa	h
AA 6016-T6	475.5	0.025	0.126	380.93	299.31	5819.32	0.1

$$\bar{\varepsilon}^f = C_{4N}\left\langle \frac{\sqrt{L^2+3}}{C_1\eta\sqrt{L^2+3}+C_2} \right\rangle^{C_{3N}} \tag{2}$$

where

$$C_{3N} = \frac{C_3}{m+1}, C_{4N} = \left[\frac{C_4(m+1)}{R_m}\right]^{\frac{1}{m+1}}. \tag{3}$$

3 Model Calibration

3.1 The Stress–Strain Curve of AA 6016-T6

In this study, an aluminum alloy sheet (AA 6016-T6) with a thickness of 1.5 mm is selected to verify the predictive ability of the modified model. Its stress–strain curve is obtained by performing several uniaxial tension tests on the dog-bone specimens cut along the rolling direction. The Swift-Voce combined model (Eq. 4) is used to describe the stress–strain curve, with the identified parameters listed in Table 1.

$$Y\left(\bar{\varepsilon}^p\right) = h\left[A\left(\varepsilon_0+\bar{\varepsilon}^p\right)^n\right] + (1-h)\left[Q_s - (Q_s - Q_0)e^{\left(-\frac{V_0}{Q_s}\bar{\varepsilon}^p\right)}\right] \tag{4}$$

where A, ε_0, n, Q_s, Q_0, and V_0 are material constants, h denotes the superposition coefficient of two hardening models.

3.2 Experiments and Simulation of Ductile Fracture

Four different specimen geometries, which can cover a wide range of stress states (from simple shear to balanced biaxial tension), are carefully designed, as illustrated in Fig. 1. Each specimen is extracted from the same sheet along the rolling direction. Tension tests on No. 1, No. 2, and No. 3 are conducted on a universal testing machine with the cross-head traveling at a speed of 1 mm/min. Nakajima tests (on specimen No. 4) are performed on Zwick-BUP 600 testing machine with the punch traveling at

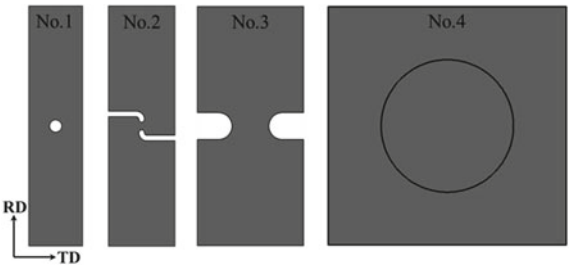

Fig. 1 Specimens with different geometries: (1) specimen with a central hole (No. 1); (2) simple shear specimen (No. 2); (3) plane strain tension specimen (No. 3); (4) specimen for Nakajima test (No. 4, the solid line stands for draw-bead)

a speed of 0.5 mm/s. To capture the surface strain field of each specimen, the Digital Image Correlation (DIC) technique is utilized. Besides, the load–displacement curves of specimens Nos.1–3 are obtained using a DIC-based extensometer. Each test is repeated three times to ensure the reliability of the results.

Parallel simulations are carried out using ABAQUS/Explicit 6.14. All specimens are meshed by C3D8R elements, meanwhile loading condition is achieved by applying displacement control to each loading unit. The duration of each simulation is carefully defined to assure a quasi-static condition. Considering the fact that ductile fracture propagates very quickly after its onset, the fracture moment is identified as the one corresponding to the sudden drop in the measured load–displacement curve for each simulation. The simulated and measured force–displacement curves and surface strain fields are compared to validate the corresponding simulations, as demonstrated in Fig. 2.

3.3 Construction of 3D Ductile Fracture Surface

As postulated by other researchers [11, 12], the element presenting the highest strain is identified as the critical location where the ductile fracture initiates for each simulation. Figure 3 shows the η and L evolutions of each specimen at the critical location before the identified fracture moment. It is obvious that the values of η and L keep changing during the deformation process. Therefore, we average these values by using Eq. (5), and the results are shown in Table 2.

$$\eta_{\text{av}} = \frac{1}{\overline{\varepsilon}^f} \int_0^{\overline{\varepsilon}^f} \eta \mathrm{d}\overline{\varepsilon}^p, \; L_{\text{av}} = \frac{1}{\overline{\varepsilon}^f} \int_0^{\overline{\varepsilon}^f} L \mathrm{d}\overline{\varepsilon}^p. \tag{5}$$

Then the least-square method is used to identify a group of model parameters, which can minimize the accumulation between the targeted 3D fracture surface and the ductile fracture data points shown in Table 2. The resulting 3D surface and the calibrated parameters are shown in Fig. 4. It is clear that the constructed 3D fracture surface can well describe the correlation between material ductility and stress state for AA 6016-T6. Figure 4 shows that fracture strain $\overline{\varepsilon}_f$ is a decreasing function with

respect to stress triaxiality for a given Lode parameter. The reason for this trend is that a higher stress triaxiality promotes void dilation, resulting in a poor ductility.

4 Comparison of Three Ductile Fracture Models

MMC model (Eq. 6) and Lou–Huh model (Eq. 7) have been deemed as typical representatives of modern uncoupled ductile fracture models [3, 4].

$$\bar{\varepsilon}_{f-MMC} = \left\{ \begin{array}{l} \dfrac{A}{C_6}\left[C_7 + \left(2+\sqrt{3}\right)(1-C_7)\left(\sqrt{L^2+3}-\sqrt{3}\right)\right] \\ \left[\sqrt{\dfrac{1+C_5^2}{L^2+3}} + C_5\left(\eta - \dfrac{L}{3\sqrt{L^2+3}}\right)\right] \end{array} \right\}^{-\frac{1}{n}} \tag{6}$$

$$\overline{\varepsilon}_{f-Lou} = C_{10}\left(\frac{\sqrt{L^2+3}}{2}\right)^{C_8}\left[\frac{3(1+C_{11})\sqrt{L^2+3}}{3(\eta+C_{11})\sqrt{L^2+3}-L+3}\right]^{C_9}. \quad (7)$$

For the purpose of comparison, these two models and three aluminum alloys (Al 6016-T6 of the current study, 2024-T351 [4], and 5083-O [7]) are selected. Following the same calibration procedure, the results are given in Figs. 5 and 6. It is observed that using the same model, the constructed 3D fracture surfaces of different materials differ from each other in surface height and surface curvature, representing differences in ductility. Also, different models demonstrate varying levels of error from the tested data for the same material: for 6016-T6 and 5083-O, the minimized error by the modified model is the smallest one, followed by Lou–Huh model and MMC model; as for 2024-T351, MMC model yields the smallest minimized error, followed by Lou–Huh model and the modified model. Regardless of the observed differences in the model performance, these three models all can work well for the selected aluminum alloys with acceptable errors (Fig. 7).

5 Conclusion

An extended ductile fracture prediction model is proposed by considering hydrostatic stress that controls the behavior of void dilation. Four specimens with various shapes are employed to achieve different stress states ranging from simple shear to biaxial tension. The comparison between experiments and predicted results shows a good prediction performance of the proposed model. Meanwhile, the proposed model has a good applicability for the aluminum alloys selected.

Full-Field Strain Measurement in Multi-stage Shear Cutting: High-Speed Camera Setup and Variational Motion Estimation

Christoph Hartmann and Wolfram Volk

Abstract Shear cutting is a prominent process in the chip-less separation of metallic sheet materials. The cut surface characteristics have been the basis for quality assessment but the shear-affected zone becomes increasingly important with regard to the functionality of the produced components, such as further processing or its final application. Multi-stage shear cutting processes may be used to specifically adjust the mechanical and geometrical properties of shear cut edges. Originally, multi-stage shear cutting was aimed at producing smooth and clean-cut surfaces with high-dimensional accuracy and improved load capacity. However, nowadays, it is also used to reduce the sensitivity to edge cracking, for example. In this paper, we present a novel approach for the experimental analysis of multi-stage shear cutting as a basis for advanced process analysis and validation. Moreover, the achieved results may serve for future database process design, modeling, and control. We developed an in-situ test design and measurement setup that preserves the real process boundary conditions of shear cutting. An enhanced high-speed optical full-field evaluation method based on optical flow methods allows local and time-resolved measurement of strain fields and strain rate fields for each shear cutting stage. A mapping of these state variables between the individual cuts enables us to analyze consistently the shear-affected zone throughout the whole multi-stage process and thus to characterize the final state of the shear-affected zone experimentally.

1 Introduction

Shear cutting represents the most prominent, chip-less separation process for sheet metal. Two-stage shear cutting consists of a conventional shear cutting stage and a second stage, which we denote the shaving[1] stage throughout this work. Multi-stage shear cutting extends this concept and applies several shaving stages. The guideline VDI2906-1 defines shaving as trimming of narrow edges of semi-finished sheet metal [1]. As originally stated by Kuhlmann, the process was aimed at producing smooth and clean-cut surfaces that were as free of tears and cracks as possible with high-dimensional accuracy and improved load capacity [2, 3]. However, for example, Pätzold et al. and Feistle et al. also used multi-stage shear cutting to reduce the sensitivity to edge cracking [4, 5]. The use of shaving operations to prevent edge cracking is only one example that emphasizes the rising importance of the shear-affected zone when assessing the quality of shear cutting processes. In general, the shear cutting process strains and damages the material in the shear-affected zone at the component's edge, which impedes further processing or lifetime use and application. Weiss et al. showed the effect of internal stresses in the shear-affected zone on the magnetic loss in electrical sheet metal processing or Hamada et al. its influence on fatigue crack propagation [6, 7]. Hence, and in contrast to typical procedures that entirely rely on the cut surface characteristics, the induced pre-straining and pre-damaging in the shear-affected zone should be taken into account for advanced process design, whether or not shear cutting or multi-stage shear cutting is used.

Today's process design heavily incorporates numerical models to predict part properties and to size the manufacturing equipment. However, the simulation of the shear cutting process alone remains a challenging task for its multiscale characteristics, large deformations, localization, damage, and thermomechanical interactions, as reported exemplarily by Bolka et al. and Sonkamble et al. [8, 9]. Due to error propagation and mapping dependencies, the numerical analysis of the multi-stage shear cutting process presents even more challenging, as shown in the investigations of Wang et al [10]. In essence, the experimental validation of this simulation model faces the same major challenges, especially regarding the development of the shear-affected zone, see for example Wang et al. [11]. To evaluate experimentally the development of the shear-affected zone, highly resolved full-field measurements are necessary. Furthermore, these measurements should be carried out under the natural process boundary conditions that are assumed plane strain in classical shear cutting processes, as for example stated by Aoki and Takahashi as well as Manopulo [12, 13].

In this investigation, we, therefore, propose an experimental setup to observe the shear cutting under plane strain conditions in high spatial and temporal resolution using a tailored precision shear cutting tool equipped with a high-speed camera and a microscope lens, see Fig. 1a. We further present an evaluation procedure for the robust calculation of displacements, strains, and strain rates from the high-speed image sequence. To enable a multi-stage analysis, we incorporated a mapping of the

[1] The term *shaving* commonly is limited to small cutting offsets.

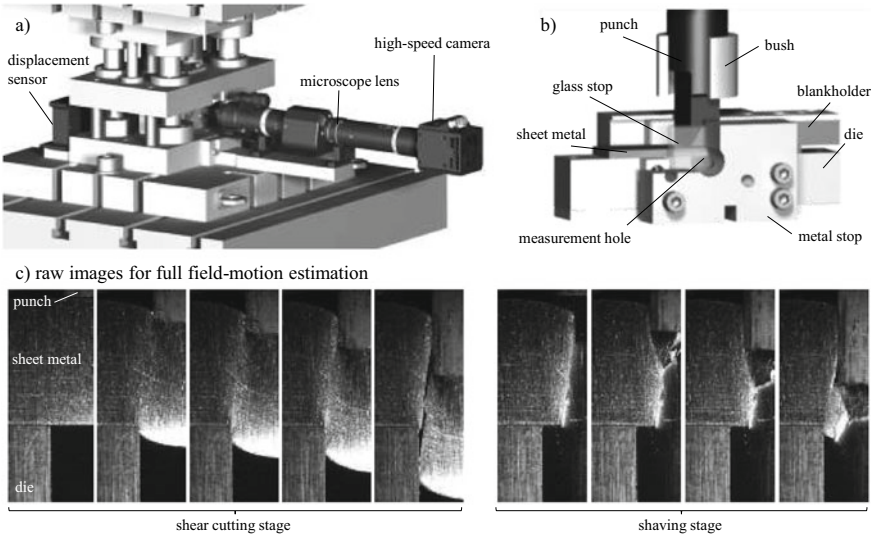

Fig. 1 **a** Precision shear cutting tool equipped with displacement sensor, microscope lens, and high-speed camera. **b** Free-cut view on the sheet metal specimen, the glass stop (supported by a metal stop), and the active elements of the shear cutting tool [16]

measured state fields between the subsequent cutting stages. Finally, two variants of a two-stage shear cutting process are subject to the evaluation.

2 Approach

In order to observe the shear cutting process under its natural boundary condition that is plane strain, we follow the tool setup proposed by Takahashi and Aoki using glass stops at the sheet metal edge [14]. Figure 1b illustrates the arrangement of the active elements, the sheet metal specimen, and the glass stop in the shear cutting tool. In previous work, our coworkers and we validated that the glass stops prevent bulging and thus maintain the plane strain boundary condition present inside the sheet material [15]. Next to the high-speed camera with the microscope lens, the shear cutting tool is also equipped with a laser displacement sensor and a load cell to measure punch travel and cutting force. A single trigger ensures synchronous recording of all measurement signals [16].

We utilized the acquired high-speed camera images, see Fig. 1c, to calculate the deformation fields during the shear cutting process. The classic way to do this motion estimation in engineering practice is digital image correlation (DIC), introduced by Yamaguchi as well as Peters and Ranson [17, 18]. Besides its many advantages, like flexibility, reliability, and simplicity, DIC has some drawbacks, such as, for example, the handling of discontinuities, described by Hassan [19] and Balle et al. [20], density

of the motion field, or the subsequent calculation of derivatives as our coworkers and we showed [16, 21].

3 Full-Field Motion Estimation

We implemented an alternative approach for full-field motion estimation based on optical flow methods, which are popular for object tracking in the field of computer vision but rarely used in experimental mechanics. We did not apply any artificial speckle pattern, as common in DIC analysis, since it would smear in the contact area with the glass stop. However, we achieved to use the material texture from machining specimen preparation for the deformation measurement algorithm. We validated the general usability of the machined specimens in a detailed analysis, where we compared them to polished and etched specimens that provide speckle-like patterns due to the grain structure of the material [22]. In contrast to etched and polished samples, machined specimens are suitable for experimental parameter studies, since they can be produced in large quantities without great effort.

The core of optical flow methods is a variational formulation with respect to the digital image intensity values (8-bit grey values in our case) over the region of interest Ω defined in the image domain. Based on this variational formulation, optical flow methods obtain the motion field[2] $\boldsymbol{u}$, where $\boldsymbol{u} = (u_1, u_2)$ for plane motion, by minimizing the energy functional $E(\boldsymbol{u})$, which is often split into a data term $D(\boldsymbol{u})$ and a regularization term $R(\boldsymbol{u})$. The data term D proposes the interaction of the motion field and the provided image data, while the regularization term R models the structure of the motion field. In general form, the energy functional reads

$$E(\boldsymbol{u}) = D(\boldsymbol{u}) + \alpha R(\boldsymbol{u}) \tag{1}$$

where α is a positive scalar weighting factor. Various approaches exist for modeling the data term D and the regularization term R. For example, Baker et al draw a comparison of different methods [23]. We utilize a combination of spatial and temporal regularization [16, 24]. Therefore, we combined the recursive regularization approach by Hewer et al. [25] and the trajectorial, temporal regularization proposed by Volz et al. [26]. The energy functional in Eq. (1) thus takes the following form

$$E(\boldsymbol{u}) = D(\boldsymbol{u}) + \alpha_t R_t(\boldsymbol{u}) + \alpha_s R_s(\boldsymbol{u}), \tag{2}$$

where R_t and R_s are the temporal and spatial regularization terms with the respective weighting factors α_t and α_s. The data term D contains a combination of the image intensity consistency assumption and the spatial gradient consistency assumption, as

[2] We use the term motion field here for consistency with the computer vision literature, which is known as the displacement field in the engineering discourse.

proposed, for example, in [27]. To couple five consecutive images also in the data term D, it consists of a sum of four respective data terms D_i, where $i = 1, 2, 3, 4$. The target displacement $\boldsymbol{u}$ is the displacement $\boldsymbol{u}_2$ and may be used analogously. The weighting of the penalty between both assumptions is controlled by the positive scalar factor β, and contribution of each data term D_i by the scalar factors γ_i.

$$D(\boldsymbol{u}) = \sum_{1}^{4} D_i(\boldsymbol{u}) = \sum_{1}^{4} \gamma_i \int_{\Omega} \psi\left(|I_{i+1}(\boldsymbol{u}) - I_i|^2 + \beta|\nabla I_{i+1}(\boldsymbol{u}) - \nabla I_i|^2\right)\mathrm{d}\omega. \quad (3)$$

The function $\psi\left(x^2\right) = \sqrt{x^2 + 0.001^2}$ introduces a regularized L_1-norm minimization for convexity of the optimization objective [27]. Applying this generic framework of Hewer et al. [25], the spatial regularization term inherently provides a predetermined n-th order smoothness of the motion field $\boldsymbol{u}$. We applied a regularization term R_s of 3rd order. Again, the total term R_s results from the sum over four consecutive images.

$$R_s(\boldsymbol{u}, \boldsymbol{A}, \boldsymbol{B}) = \sum_{1}^{4} R_{s,i}(\boldsymbol{u}, \boldsymbol{A}, \boldsymbol{B}) = \sum_{1}^{4} \int_{\Omega} \delta_1\left(|\boldsymbol{A}_i - \nabla \boldsymbol{u}_i|^2 + \delta_2\left(|\boldsymbol{B}_i - \nabla \boldsymbol{A}_i|^2 + \delta_3\left(|\nabla \boldsymbol{B}_i|^2\right)\right)\right)\mathrm{d}\omega \quad (4)$$

Here, the factors δ_1, δ_2, and δ_3 weight between the spatial smoothness terms. $\boldsymbol{A}$ and $\boldsymbol{B}$ represent auxiliary variable to introduce the prior information on the smoothness of the displacement field. Furthermore, the formulation in Eq. (4) allows for direct calculation of displacement gradients, hence strains, using the auxiliary variable $\boldsymbol{A}$ also as an output. We implemented a trajectorial regularization term R_t of second order, which results in piecewise linear displacement trajectories. The temporal regularization term reads

$$R_t(\boldsymbol{u}) = |\boldsymbol{u}_1 - 2\boldsymbol{u}_2 + \boldsymbol{u}_3|_1 + |\boldsymbol{u}_2 - 2\boldsymbol{u}_3 + \boldsymbol{u}_4|_1. \quad (5)$$

The temporal regularization enables the robust computation of strain rates and, more important in the present investigation, also stabilizes the calculations of the other deformation fields. To cope with large deformations in the evaluation of the high-speed camera images, we implemented a coarse-to-fine image pyramid framework according to Burt and Adelson [28]. To reduce the data, we furthermore implemented an adaptive selection procedure to evaluate a minimum number of images but accordingly prevent linearization errors using predefined maximum displacement and strain increments. For detailed description of the algorithm implementation, parameter selection, and detailed derivation, we refer to our respective references [16, 24].

In general, we emphasize that spatio-temporal regularization is a promising technique to integrate physical relationships and assumptions in optical full-field evaluation. The presented variational model yields third spatial order smoothness and second-order temporal smoothness of the motion field. Besides the incorporation

of prior knowledge, the full-field measurement results are dense and allow further processing without the use of filters or hole-filling algorithms.

4 Experiments

The shear cutting experiments have been carried out on universal tension–compression testing machine of type 1484/DUPSM by Zwick GmbH & Co.KG, Ulm, Germany. We used specimens of the micro-alloyed fine-grained structural steel S355MC in the dimension 100 mm by 25 mm and 4 mm thickness. A cutting clearance of 10% and a punch velocity of 1 mm/s were set for all tests. The cutting edge geometry was equal at the punch and the die (50 µm radius).

First, the desired contour is pre-cut by conventional shear cutting leaving a narrow strip on the sheet metal component. The narrow strip is removed in the subsequent shaving stage. Shaving has different boundary conditions compared with conventional shear cutting and almost resembles a machining process. The die-side sheet metal represents the component; the punch-side material of both cuts is considered waste. As common in industrial practice, we used a closed cutting line setup on the first stage. After the first cut, tailored stops in the die allow to move the two sheet metal strips by the cutting offset in preparation of the second stage. We analyzed two different cutting offsets. Cutting offset 1 is 2 mm and cutting offset 2 is 1 mm.

5 Results and Discussion

Table 1 summarizes the resulting cut surface characteristics according to the guideline VDI2906-2 [28] for the two-stage processes. It also contains the values for the first shear cutting stage. Both two-stage strategies reduce the edge draw-in height, where offset 2 has a higher impact on this cut surface characteristic. Offset 2 yields an increase in the clean-shear share, where offset 1 leads to earlier fracture.

Table 1 Tactile measurements of the cut surface characteristics for the first shear cutting operation and the subsequent second stage operations. h_i represents the heights of the draw-in (d), the clean-shear (c), the fracture (f), and the burr (b), w_i the respective heights and α_i the respective angles. All values are based on five tests and five measurements for each test along the cutting line

	h_d in %	h_c in %	h_f in %	h_b in µm	w_d in µm	w_b in µm	α_c in °	α_f in °
Pre-cut	12.2 ± 2.1	23.4 ± 1.1	64.4 ± 1.7	51 ± 13	2259 ± 103	49 ± 9	90 ± 0.2	81 ± 1.1
Offset 1	7.3 ± 1.9	20.0 ± 1.7	72.7 ± 1.9	32 ± 16	1877 ± 59	46 ± 15	90 ± 0.1	81 ± 0.2
Offset 2	6.5 ± 2.3	34.0 ± 2.1	59.5 ± 2.1	49 ± 11	1606 ± 36	51 ± 16	90 ± 0.1	80 ± 0.1

In addition to the manipulation of the cut surface geometry, the multiple-stage shear cutting processes increasingly focus on the specific modification of the shear-affected zone, as we briefly explain above. The local analysis of the conducted two-stage shear cutting experiments, therefore, centers on the representation of the accumulated deformation in the shear-affected zone after the second shear cutting operation. For this purpose, we mapped the state variables between the two stages. The mapping represents a straightforward intermediate step in the evaluation algorithm, which carries out a rigid body translation. The rigid body translation describes the displacement of all material points during the sheet metal feed. We computed the displacement fields from the last image of the first cutting operation and the first image of the second cutting operation. The allocation of all information of a tracked material particle is, therefore, preserved and may be seamlessly used in the evaluation.

Figure 2 shows the equivalent strain E_{eq} distribution in the shear-affected zone for the first shear cutting stage, the two-stage shear cutting process using offset 1, and the two-stage shear cutting process using offset 2. We use the classical strain measure E_{eq}, although other possibilities are present, as, for example, the thermodynamic consist measure is derived by Butcher and Abedini [29]. We calculated the equivalent strain fields E_{eq} according to

$$E_{\mathrm{eq}} = \int_0^t \sqrt{\frac{1}{2}\left(\frac{\partial}{\partial t}\boldsymbol{A} + \frac{\partial}{\partial t}\boldsymbol{A}^{\mathrm{T}}\right) \cdot \frac{1}{2}\left(\frac{\partial}{\partial t}\boldsymbol{A} + \frac{\partial}{\partial t}\boldsymbol{A}^{\mathrm{T}}\right)}\,\mathrm{d}t \tag{6}$$

where t represents the shear cutting process time.

We visualized the strain distribution in two different color scales to give a better overall impression of the deformation state. In addition, the diagram of the principle strains E_1 and E_2 is shown next to the shear-affected zone graphs, whereby the color of each single coordinate reflects its probability density. The first-stage experiment, see Fig. 2a, shows a high straining along the clean-shear share and along the fracture surface. A strong gradient in vertical direction exists that starts from the cut surface and leads to smaller pre-deformation inside the sheet metal. Already ~0.8 mm away from the cut surface, the equivalent strain E_{eq} values decrease by at least 80%. The pre-deformation is higher in the edge draw-in region than on the underside of the sheet metal part. The imaginary connecting line from the beginning of the edge draw-in to the burr covers the area of moderate pre-deformation geometrically.

The shear-affected zone of the two-stage shear cutting with offset 1 has a similar strain distribution appearance as the first-stage experiment, when considering the coarser color scale, see Fig. 2b. The offset 1 experiment comes close to shear cutting with an open cutting line, which, however, the sheet metal material processed is already affected. Although the areas near the cut surface experience similar deformation, but with reduced peak values. In total, pre-deformation is reduced, with the change from closed to open cutting line. Especially on the burr side of the sheet metal component, the affected zone becomes thinner. The width of this zone at the edge

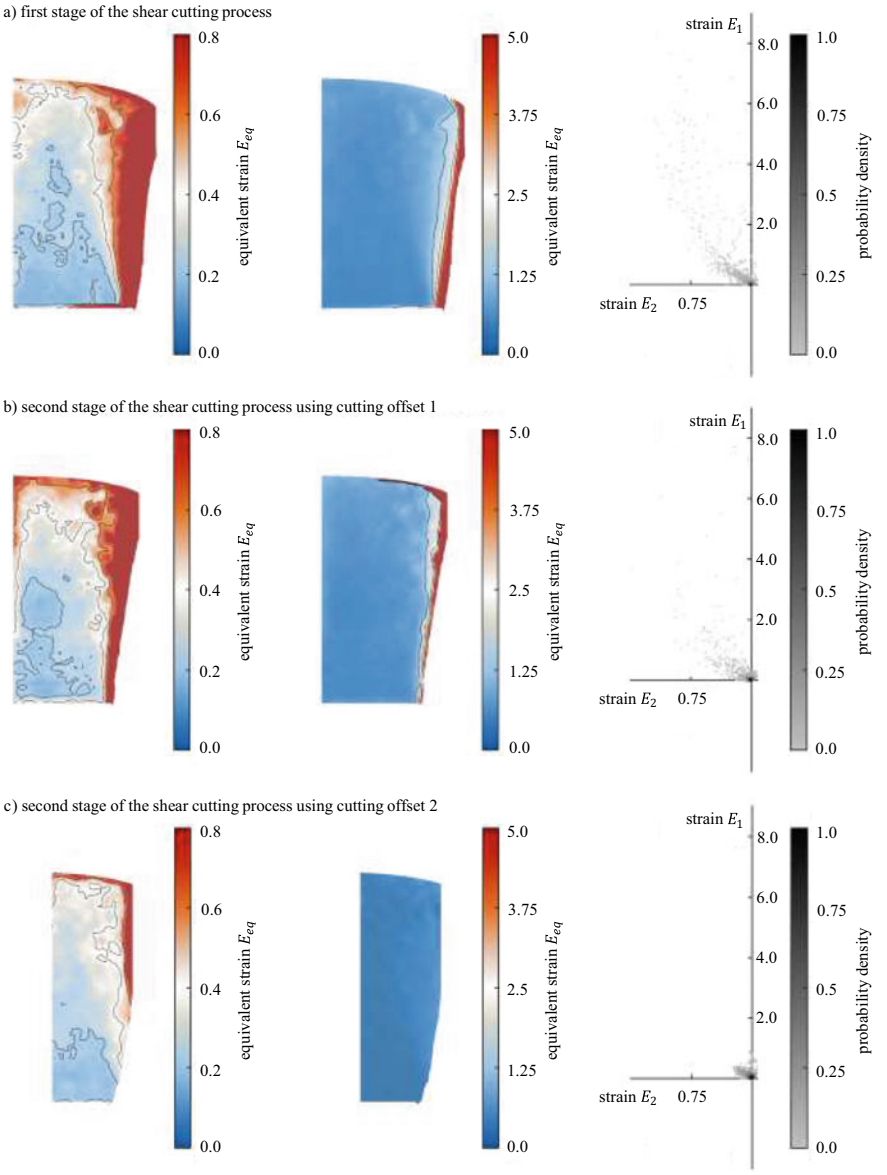

Fig. 2 Experimental measurement results for the conducted shear cutting processes. **a** Shear-affected zone after the first shear cutting operation. **b** Shear-affected zone after the second shear cutting operation using cutting offset 1. **c** Shear-affected zone after the second shear cutting operation using cutting offset 2. Please note that the principle strain diagrams may not be interpreted similar to the well-known pendant from sheet metal forming, the FLD, since deformation boundary conditions are different. (Color figure online)

draw-in is 0.8 mm and decreases to 0.4 mm at the burr. In the diagram of principal strains, this leads to lower probability densities for increased principal strain values compared to the reference experiment. Moderate pre-deformation distributes in a region spanned between the beginnings of the edge draw-in to the die edge.

The two-stage shear cutting with offset 2 results in a different shear-affected zone condition, see Fig. 2c. The deformation processes take place almost exclusively in the waste part of the sheet metal, so that hardly any additional deformation affects the sheet metal component. This becomes particularly clear when looking at the shearing influence zone with the coarse color scale. The pre-deformed areas that are already severely affected are separated from the waste and only regions that suffered moderate deformation remain in the part. The shear-affected zone, therefore, reveals lower equivalent strain values in its final state. The highly pre-deformed edge zone along the cut surface is almost completely eliminated. The shear zone shows only moderate deformation, which is also apparent in the diagram of the principal strains in comparison to the reference experiment and the two-stage shearing with cutting offset 1. The material particles occupied by the shear-affected zone using cutting offset 2 concentrate around the coordinate origin. Here, the principal strain distribution comes closer to that in the origin region of the reference experiment than that of the two-stage shear cutting using offset 1. In this sense, two-stage shear cutting with offset 2 eliminates the large scatter of pre-deformation and expands the diagram by certain portions along the E_1-axis, which mainly originate from shear deformation along with the clean-shear share of the second shearing stage.

6 Conclusion and Outlook

We proposed an experimental setup that is suitable to study multi-stage shear cutting processes under real process conditions. The conducted measurement equipment provides high temporal and spatial resolution data. Our full-field motion estimation approach based on variational methods can handle the raw images from the high-speed camera in a robust way and delivers full-field strain and strain rate information. By mapping the computed fields between the different stages, eventually a combined strain measure field for evaluation, analysis, and comparison of different process variants was possible. Based on the straightforward mapping between different process stages, also other multi-stage processes may be tested in the same way, such as combined shear cutting, forming, and stamping operations.

With the analysis of the two-stage shear cutting process, we have experimentally proven the effectiveness of shaving in reducing pre-deformations and pre-damage introduced in the first stage using full-field information. The choice of the cutting offset controls the process characteristics of the second stage that ranges from open cutting (offset 1) to machining-like boundary conditions (offset 2).

The high-resolution experimental data in the future can be used to validate and enhance numerical models, serve as a basis for inverse analysis and parameter identification, or offer a labeled information for database modeling.

A Novel Continuum Damage Constitutive Model for Predicting the Formability of AA7075 Alloy at Elevated Temperatures

Hai Rong, Liang Ying, Ping Hu, and Wenbin Hou

Abstract Hot forming has been proposed to improve the formability of high-strength aluminum alloys. The main objective of this paper is to formulate a continuum damage model and to describe the damage evolution features of AA7075 alloy at elevated temperatures. Hot uniaxial tensile tests and hot Nakajima tests were conducted. Subsequently, a novel continuum damage model was proposed and incorporated into a set of multi-axial visco-plastic constitutive equations to describe the thermal flow behaviors and predict the thermal forming limit diagram (TFLD) of AA7075. Material constants were determined based on the experimental data with a genetic algorithm. Moreover, the TFLD of AA7075 was numerically simulated by implementing the multi-axial continuum damage constitutive equations (CDCEs) via the user material subroutine VUMAT in commercial software ABAQUS. Simulation results agree well with experimental results and theoretically predicted results, which indicates the set of multi-axial CDCEs is capable of predicting the formability of AA7075 at elevated temperatures.

Keywords Continuum damage model · Forming limit diagram · Visco-plastic constitutive model · AA7075 aluminum alloy · VUMAT

1 Introduction

Lightweight and high-strength aluminum alloys such as AA7075 are greatly needed in automotive industries to reduce vehicle mass. Forming at elevated temperatures is an effective way to improve the formability of high-strength aluminum alloys [1].

The thermal formability of aluminum alloys is commonly evaluated by thermal forming limit diagram (TFLD), which reflects the maximum deformation capacity of materials before failure appears. Lots of investigations have been conducted on TFLDs of aluminum alloys in experimental, theoretical, and numerical methods [2]. Lin et al. [3] first proposed a set of multi-axial continuum damage constitutive

equations (CECEs) to predict the TFLD of AA5754, where the effect of stress states on the damage evolution was discussed in detail. Subsequently, the set of multi-axial CDCEs was formulated for various alloys [4, 5]. The results proved that the multi-axial CDCEs are capable of describing damage evolutions and predict forming limits of aluminum alloys at elevated temperatures.

In this paper, a set of multi-axial CDCEs was established to predict the TFLD of AA7075 at elevated temperatures. Moreover, the thermal forming limits of AA7075 were numerically simulated with commercial software ABAQUS via subroutine VUMAT.

2 Experimental Procedures

The commercial AA7075-T6 alloy sheet produced by Kaiser Aluminum Corporation with a thickness of 1.6 mm was investigated in this paper. The weight fraction of additive chemical compositions is listed as: 5.48%Zn, 2.3%Mg, 1.52%Cu, 0.01%Zr, 0.16%Fe, 0.03%Mn, 0.21%Cr, 0.03%Ti, 0.11%Si. Hot uniaxial tensile tests and Nakajima tests were conducted within the temperature range of 300–400 C at different deformation rates. Specimens were heated to the target temperature and soaked for 10 min and then deformed to fracture. Strain histories were recorded by the ARAMIS™ 4 M optical measuring system.

3 Establishment of Multi-axial Continuum Damage Constitutive Equations

3.1 Continuum Damage Model

A modified continuum damage model was proposed in this paper and formulated as Eq. (1). The first item represents the nucleation and growth rate of micro-voids in the earlier deformation stage, and the second item reveals the growth and coalescence rate of micro-voids in the later and final deformation stages. Macroscopic cracks are considered to appear once ω reaches a critical value of 0.7.

$$\dot{\omega} = D_1(1-\omega)\dot{\varepsilon}_p^d + \frac{D_2\dot{\varepsilon}_p^{D_3}\cosh(D_4\varepsilon_p)}{(1-\omega)^{D_5}}. \tag{1}$$

3.2 Multi-Axial Continuum Damage Constitutive Equations

To describe the visco-plastic flow behaviors and predict fractures of AA7075, a set of multi-axial CDCEs were established [3] and formulated as Eqs. (2)–(7). Traditional power-law formula is chosen to describe the constitutive relation between equivalent plastic strain rate $\dot{\varepsilon}_e^p$ and equivalent stress σ_e, as given in Eq. (2). Equation (3) reveals the associated flow rule based on Mises yield criterion, where $\dot{\varepsilon}_e^p$ is plastic strain rate tensor and S_{ij} is stress deviator. Normalized dislocation density rate $\dot{\overline{\rho}}$ and dislocation-based isotropic hardening rate $\dot{R}$ are given in Eqs. (4) and (5), respectively. In order to correct the damage evolution features in different stress states, a multi-axial correction formula was introduced, as given in Eq. (6), where σ_1 and σ_H are major principle stress and hydrostatic stress, respectively. The flow stress σ_{ij} is calculated by generalized Hooke's law as shown in Eq. (7), where ε_{kl} and ε_{kl}^p are strain tensor and plastic strain tensor.

$$\dot{\varepsilon}_e^p = \left\langle \frac{\sigma_e/(1-\omega) - R - k}{K} \right\rangle^n \tag{2}$$

$$\dot{\varepsilon}_{ij}^p = \frac{3}{2}\frac{S_{ij}}{\sigma_e}\dot{\varepsilon}_e^p \tag{3}$$

$$\dot{\overline{\rho}} = A(1-\overline{\rho})\left|\dot{\varepsilon}_e^p\right| - C\overline{\rho}^{n_2} \tag{4}$$

$$\dot{R} = 0.5B\overline{\rho}^{-0.5}\dot{\overline{\rho}} \tag{5}$$

$$\dot{\omega} = \Delta\left(\frac{a_1\sigma_1 + 3a_2\sigma_H + a_3\sigma_e}{(a_1+a_2+a_3)\sigma_e}\right)^{\varphi}\left(D_1(1-\omega)(\dot{\varepsilon}_e^p)^d + \frac{D_2(\dot{\varepsilon}_e^p)^{D_3}\cosh(D_4\varepsilon_e^p)}{(1-\omega)^{D_5}}\right) \tag{6}$$

$$\sigma_{ij} = D_{ijkl}(1-\omega)(\varepsilon_{ij} - \varepsilon_{ij}^p). \tag{7}$$

In the multi-axial CDCEs, d, n_2, a_1, a_2, and a_3 are material constants, $k, K, n, A, C, B, D_1, D_2, D_3, D_4, D_5, \Delta$, and φ are material variables expressed by the corresponding material constants, as listed in Table 1. R, T, and $\dot{\varepsilon}$ represent gas constant, absolute

Table 1 Material variables in the multi-axial CDCEs

$K = K_0\exp(Q_K/RT)$	$n = n_0\exp(Q_n/RT)$	$A = A_0\exp(Q_A/RT)$
$C = C_0\exp(-Q_C/RT)$	$B = B_0\exp(Q_B/RT)$	$D_1 = D_{10}\exp(-Q_{D1}/RT)$
$D_2 = D_{20}\exp(Q_{D2}/RT)$	$D_3 = D_{30}\exp(Q_{D3}/RT)$	$D_4 = D_{40}\exp(Q_{D4}/RT)$
$D_5 = D_{50}\exp(Q_{D5}/RT)$	$\Delta = \Delta_{11} + \Delta_{21}\exp(\Delta_{22}/\dot{\varepsilon})$	$\varphi = \varphi_{11}\exp(-\varphi_{12}/T)$
$E = E_0\exp(Q_E/RT)$	$k = k_0\exp(Q_k/RT) + k_1\exp(k_2/\dot{\varepsilon})^{k_3}$	

temperature, and strain rate, respectively.

4 Calibration of Multi-axial Continuum Damage Constitutive Equations

All of the material constants were calibrated with the Non-dominated Sorting Genetic Algorithm II (NSGAII) based on the experimental results. The determined material constants have been listed in Table 2.

Good agreement has been found between experimental and predicted results, as shown in Fig. 1. The larger elongation and higher forming limit curves show that the formability of AA7075 is improved with temperature and strain rate increasing.

5 Numerical Simulation for Thermal Forming Limit Prediction of AA7075

Numerical simulations of the hot Nakajima test were carried out using commercial software ABAQUS. The set of multi-axial CDCEs was implemented into ABAQUS/Explicit via the user material subroutine VUMAT. One quarter symmetry simulation model was established based on the experimental Nakajima device and specimens, as shown in Fig. 2a. The C3D8R element type with the size of 0.5 mm was chosen to mesh specimens. The punch, die, and blank holder were modeled as rigid bodies. Figure 2b shows that the forming limits (400 °C, 0.1 s^{-1}) of AA7075 obtained from numerical simulations are in good agreement with the forming limit curve predicted by multi-axial CDCEs and experimental results. Damage parameter ω accelerates rapidly around the center of specimens in the final deformation stages resulting in fractures ultimately.

6 Conclusions

The set of multi-axial CDCEs was established and calibrated based on experimental results. Good formability of AA7075 is found at relatively higher temperatures and strain rates. The calibrated set of CDCEs was implemented in ABAQUS via VUMAT to obtain the TFLD of AA7075. Simulation results show good agreement with experimental results and predicted results by CDCEs, which proves the multi-axial CDCEs can be used to predict the formability of AA7075 at elevated temperatures.

The Influence of Temperature and Strain Rate on the Superplastic Deformation Behavior and Microstructure Evolution of TNW700 Alloy

Lixia Ma, Min Wan, Weidong Li, Jie Shao, and Xuepiao Bai

Abstract TNW700 titanium, as a new near-α high-temperature titanium alloy, is designed to work at 700 °C for a short-term service. Superplastic deformation behavior of TNW700 alloy at 900–975 °C and strain rate of 0.0005–0.01 s^{-1} was investigated to identify the optimum deformation temperature and strain rate. The microstructure evolution after high temperature tensile was investigated using scanning electron microscope. The research found that TNW700 alloy has an excellent superplasticity. The elongation exceeds 200% at various deformation conditions except 975 °C with higher strain rate of 0.005 and 0.01 s^{-1}, and the maximum elongation of 613% was obtained at a temperature of 925 °C and strain rate of 0.001 s^{-1}. The flow stress is sensitive to temperature and strain rate, and it increases with decreasing temperature and increasing strain rate. In addition, the flow stress exhibits strong work hardening with increase in true strain, and the instantaneous work hardening exponent n as well as critical hardening strain is accelerated as the strain rate decreases. The strain rate sensitivity exponent (m) is higher than 0.4 when the temperature is lower than 975 °C, which corresponds to dynamic recrystallization and grain boundary sliding mechanisms. The m is 0.229 at temperature of 975 °C, corresponding to dynamic grains growth mechanism. The deformed microstructure of TNW700 alloy consists of β grains and equiaxed α grains. Increasing the temperature is beneficial to the transformation of α phase into the β phase, which resulted in an increase in the volume fraction of the β phase. The β grains grow rapidly at higher temperatures and lower strain rates due to the higher diffusion coefficient.

1 Introduction

Titanium alloy has been widely utilized in aerospace, chemical, and biomedical engineering industries for its high specific strength, good corrosion resistance and biocompatibility, and excellent high-temperature performance [1–3]. Superplastic forming is a promising process to achieve complex shape parts forming, material saving, part accuracy and quality improvement, and weight reduction. Near-α and α titanium alloy are attractive because of their lightweight, excellent fatigue and creep properties, and appropriate strength; meantime, they are commonly shaped for complex jet engines components by high-temperature superplastic forming due to their low machinability and poor cold formability [4, 5].

Depending on the temperature, strain rate, and strain, titanium alloys display different microstructural evolutions, such as α/β phase transformation, precipitation of the second phase (silicide and Ti_3X), grain coarsening, and grain refinement with dynamic recrystallization (DRX) [6, 7]. However, different microstructures, in turn, affect titanium alloy deformation behavior and formability. The microstructure and texture evolution of a near-α Ti–6Al–1.21Nb–9.04Zr–3.88Sn–1.59W–0.28Si alloy were investigated by Lin et al. at 900 °C and strain rates of 3×10^{-3} and 3×10^{-2} s^{-1} [8]. It was found that work hardening and softening reach a dynamic equilibrium at strain rate of 3×10^{-3} s^{-1}, and DRX is the main softening mechanism accompanied by weakening of the initial texture. Liu et al. [9] systematically studied superplastic behavior and microstructure evolution of the Ti55 alloy, and they showed that work hardening predominates at the initial deformation stage, then the flow stress decreases rapidly and reaches a quasi-steady state before fracture. In addition, grain boundary sliding (GBS) and grain rotation are the primary and auxiliary deformation mechanisms, respectively, and the main softening mechanism is discontinuous dynamic recrystallization (DDRX). Mikhaylovskaya et al. [5] researched the superplastic deformation behavior of Ti–2.5Al–1.8Mn alloy and found that the strain hardening coefficient increases with increase in temperature resulted from dynamic grains growth.

Although the superplastic deformation behavior and microstructure evolution of some near-α titanium alloys have been extensively investigated, however, few literatures have been reported regarding the superplasticity of TNW700 alloy. To accurately and deeply study the superplastic and work hardening behavior, and determine the internal mechanism of TNW700 alloy, high-temperature tensile tests and the microstructure evolution observation were performed in this work.

2 Experimental Description

The TNW700 alloy with the composition shown in Table 1 was produced by Baoji Titanium Industry Co., Ltd. with a thickness of 0.71 mm. Adding α phase stabilizing elemental Al can increase tensile strength, creep resistance, and reduce alloy density.

Table 1 Nominal chemical composition of the TNW700 alloy (wt%)

Element	Al	Sn	Zr	Nb	W	Si	Ti
Wt.%	5.86	3.4	5.56	1.15	1.6	0.19	Balance

The neutral elementals Sn and Zr have large solid solubility and can form high-strength compounds with Al, playing a complementary and strengthening role. Si is an important element to enhance high-temperature strength and creep resistance. The elements Nb and W can improve the oxidation resistance and heat resistance, respectively.

Mechanical tests were conducted using specific electronic uniaxial testing machine (Fig. 1a) with four different temperatures (900, 925, 950, and 975 °C) and four different constant strain rates (0.0005, 0.001, 0.005, and 0.01 s^{-1}). Tensile specimens with gauge length, width, and thickness of 10 × 6 × 0.71 mm were machined from sheets along the rolling direction. The specimen coated with Ti-1 antioxidant was clamped in a tensile testing machine, then was heated to a predefined temperature and maintained under isothermal conditions for 10 min to ensure a heat balance before the tensile test. The specimen deformation distance was accurately recorded with extension poles and grating rulers, and the specimen deformation force was recorded by S-type force sensor. Tensile test scheme and partially deformed specimens are shown in Fig. 1b, c respectively.

After tensile deformation, the specimens were water quenched as quickly as possible, to avoid microstructure modification during slow cooling from the testing temperature. Then, the sections were mechanically ground, polished, and

etched in a 10%HF:10%HNO_3:80%H_2O mixed solution. The microstructures were characterized by Zeiss Supra55 scanning electron microscope (SEM).

3 Results and Discussion

3.1 Initial Microstructure

The SEM micrograph of the initial microstructure is shown in Fig. 2a. The microstructure mainly composed of dark α phase and small amounts of bright intergranular β phase. Figure 2b is the typical XRD diffraction pattern of as-received materials. Obviously, α phase diffraction peaks, such as (100), (002), (101), (102), (110), (103) etc. were observed, and there are no β phase diffraction peaks. In addition, α-phase diffraction peak deviates from the ideal diffraction peak (as highlighted by brown dashed line). This is related to the dissolution of the alloying element Zr with large atomic radius in α-phase matrix.

3.2 Plasticity Flow Behavior

Figure 3a and b show flow stress–true strain curves at 925 °C with different strain rates and at strain rate of 0.001 s^{-1} with different temperatures, respectively. Obviously, the flow stress of TNW700 alloy is highly dependent on deformation temperature, strain rate, and strain. Higher flow stress is exhibited at higher strain rates and lower temperatures, and it decreases remarkably with increasing temperature and decreasing strain rate. This phenomenon is consistent with the previously reported results of other titanium alloys [1, 5]. Meanwhile, the all flow stress curves manifest remarkable work hardening phenomenon with long period, namely, all curves reach

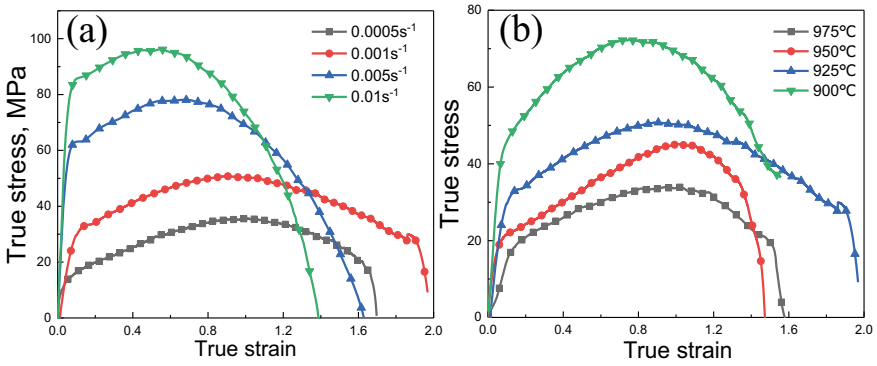

Fig. 3 Flow stress–strain curves obtained at different strain rates and temperatures, (**a**) 925 °C, (**b**) 0.001 s^{-1}. (Color figure online)

a peak stress at higher strain, then followed by the flow softening, which is the result of α grain refinement.

Quantitative data can more intuitively reflect the alloy flowing behavior. Figure 4a and b show- the variation of peak stress and elongation, respectively. Evidently, the peak stress decreases with increasing temperature at a constant strain rate, which is related to the enhancement of the thermal activation effect, the increase in the atomic kinetic energy and the weakening of the critical shear stress at high temperature. Meanwhile, another factor affecting peak stress is the increase of β phase volume fraction, which has more slip systems than α phase. The peak stress increases significantly with increase in strain rate at a constant temperature. This is because the time required for unit strain is shortened, and the dislocation density, motion speed, and the probability of dislocation tangle increase at higher strain rate, all of those leading to an increase in critical shear stress. Undoubtedly, the largest and smallest

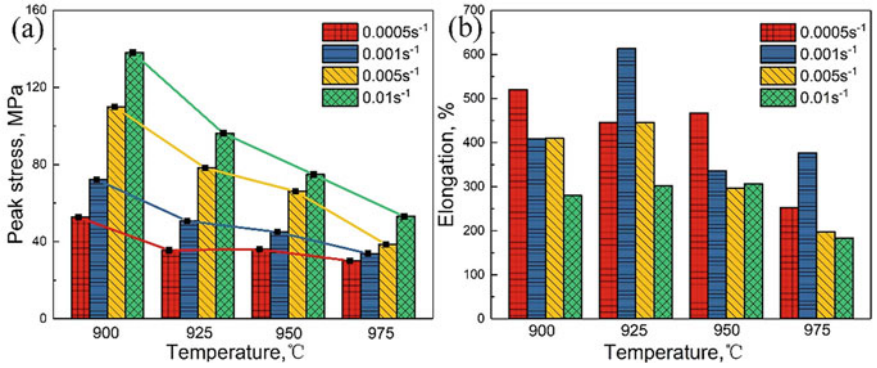

Fig. 4 Peak stress and elongation of the TNW700 alloy at different strain rates and temperatures, (**a**) peak stress, (**b**) elongation. (Color figure online)

peak stresses were observed at 900 °C/0.01 s^{-1} and 975 °C/0.0005 s^{-1}, respectively, with values of 138 MPa and 30 MPa, respectively.

The specimen elongation was calculated according to the following equation

$$\text{Elongation} = 100\left(\frac{\Delta l}{l_0} + 1\right)\% \tag{1}$$

where l_0 and Δl are the specimen initial gauge length and deformation length respectively. This study corresponds to average displacement of grating rulers when the specimen fracture force/stress is zero. The variation of elongation under different conditions is shown in Fig. 4b, demonstrating that most of the specimens exhibited excellent superplasticity. No distinct relationship was found between elongation and temperature or strain rate. The maximum elongation of 613% occurs at 925 °C and 0.001 s^{-1}, and the lower elongation of 183% is acquired at 975 °C and 0.01 s^{-1}. Overall, high temperature of 975 °C and high strain rate of 0.01 s^{-1} are not conducive to obtaining large elongation, which may be related to grain coarsen.

3.3 Work-Hardening and Strain Rate Sensitivity Exponent

To quantify the superplastic deformation behavior of TNW700 alloy, the variation of work hardening and strain rate sensitivity exponent were respectively analyzed, as shown in Fig. 5. The instantaneous work hardening exponent (n) and strain rate sensitivity exponent (m) were calculated from the slope of the $\ln\sigma - \ln\varepsilon$ and $\ln\sigma - \ln\dot{\varepsilon}$ according to the following equations,

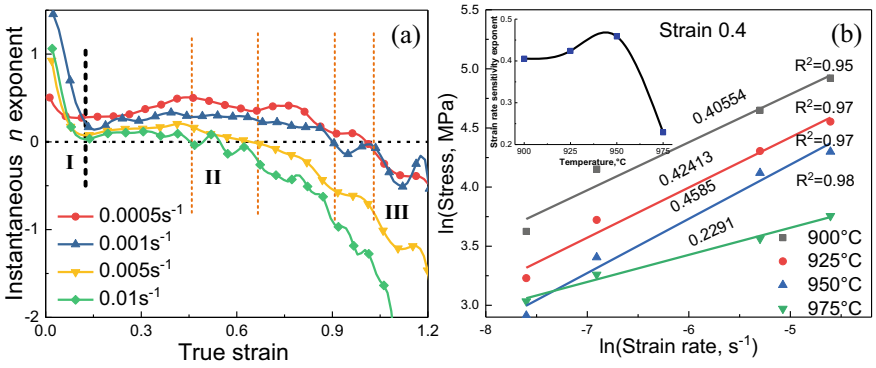

Fig. 5 **a** Instantaneous n exponent of the TNW700 alloy for different strain rates at 925 °C; **b** strain rate sensitivity exponent at a strain of 0.4. (Color figure online)

Table 2 Relationship between average n value in stage II and strain rate at 925 °C

Strain rate	0.01 s^{-1}	0.005 s^{-1}	0.001 s^{-1}	0.0005 s^{-1}
Average n value in stage II	0.096	0.162	0.272	0.379

$$n = \left.\frac{d(\ln \sigma)}{d(\ln \varepsilon)}\right|_{\dot{\varepsilon},T} \tag{2}$$

$$m = \left.\frac{d(\ln \sigma)}{d(\ln \dot{\varepsilon})}\right|_{\varepsilon,T} \tag{3}$$

where σ, ε, $\dot{\varepsilon}$, and T are the true stress, true stain, strain rate, and deformation temperature, respectively. Positive and negative n values represent work hardening and softening, respectively. At low strain condition, the positive n decreases rapidly with increasing true strain, as shown in stage I of Fig. 5a. Then, the n value curves displayed a slight increase, a steady state and a slight decrease in stage II with a relatively long period. In addition, the average n value at the steady stage decreases from 0.379 to 0.096 with the increase in strain rate from 0.0005 to 0.01 s^{-1}, as shown in Table 2. Lager n value and critical hardening strain (marked as short brown lines) are manifested at small strain rate of 0.0005 s^{-1}, and the critical hardening strain decreased from 1 to 0.45 as strain rate increased from 0.0005 to 0.01 s^{-1}. The longer work hardening period may be related to β grain coarsening and silicide precipitation. The n value is lower than 0 in stage III, which corresponds to the flow softening.

The m values are the slopes of the $\ln \sigma - \ln \dot{\varepsilon}$ lines obtained by linear regression method at various temperatures in the plots of Fig. 5b, and the inset exhibits the variation tendency of m value. Obviously, the m values first increase with increasing deformation temperatures, and achieved the maximum value at 950 °C, then decrease. The m values are 0.405, 0.424, 0.458, and 0.229, when the temperature range is 900–975 °C and the interval is 25 °C. Based on Ma et al. [1], the deformation mechanism corresponds to DRX and GBS in the temperature range of 900–950 °C and may correspond to the dynamic grains growth at 975 °C.

3.4 Microstructure Evolution

The microstructure evolution after superplastic deformation at a temperature of 925 °C with different strain rates was analyzed by SEM to determine the causes of work hardening behavior of TNW700 alloy. Obviously, the deformed microstructure contains more β grains than the initial TNW700 alloy, which is related to the transformation of α to β at high temperature. In addition, the volume fraction and average grain size of β phase and α phase are heavily dependent on strain rate, respectively. When the strain rate was reduced from 0.01 to 0.0005 s^{-1}, the average

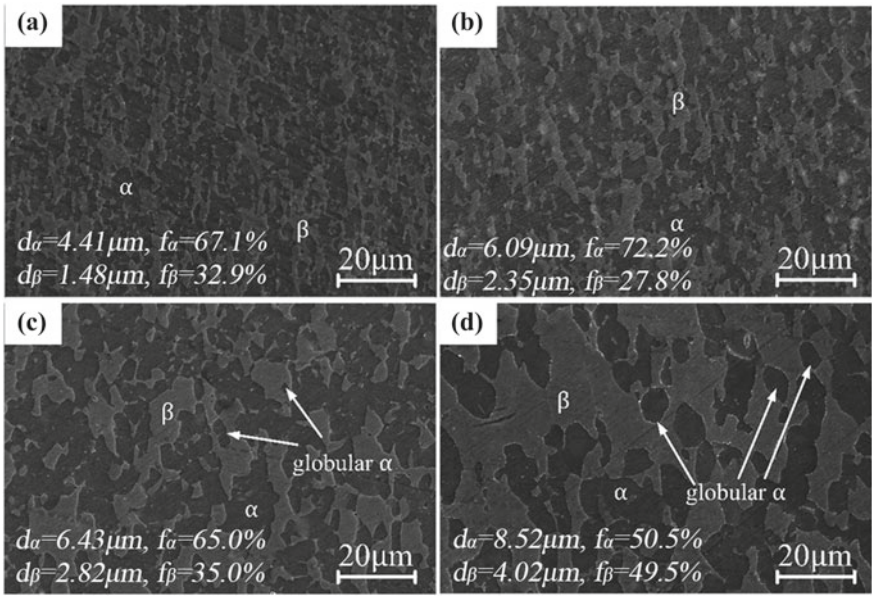

Fig. 6 The microstructure evolution of the TNW700 alloy after tensile deformation for different strain rates at 925 °C. **a** 0.01 s^{-1}, **b** 0.005 s^{-1}, **c** 0.001 s^{-1}, **d** 0.0005 s^{-1}

grain size of α grains increased from 4.41 to 8.52 μm, and the size of β grains increased from 1.48 to 4.02 μm with volume fraction increased from approximately 32.9 to 49.5%. Just as superplastic deformation is a diffusion-controlled hot deformation process, the β grains with higher diffusion coefficient grow up rapidly when deformed at low strain rates and high temperature. Therefore, the instantaneous n coefficient increases with a decrease in the strain rate from 0.01 to 0.0005 s^{-1} is mainly related to the grain growth effect. In addition, although a small amount of α grains spheroidization were observed at low strain rate, the geometric morphology of α grains got less morphological change at various strain rates (Fig. 6).

4 Conclusions

The superplastic deformation behavior and microstructure evolution of TNW700 alloy subjected to high temperature tension deformation were investigated in this study. The main conclusions of this study are as follows:

(1) During the superplastic tension test, the flow stress is sensitive to the deformation temperature and strain rate, and the peak stress increases with decrease in

strain rate and increase in temperature. The maximum peak stress and elongation were respectively obtained at 900 °C/0.01 s^{-1} and 925 °C/0.001 $s^{-1}$with the value of 138 MPa and 613%.

(2) The TNW700 alloy has a longer work hardening period due to second phase and grain growth. The positive n value and critical hardening strain increase with decrease in strain rate. A negative n value corresponds to flow softening caused by grain refinement.

(3) The microstructure of the TNW700 alloy is consisted of β and equiaxed α phase after deformation at high temperature, and the β grain size and volume fraction increase with decreasing strain rate. The α grain spheroidizes at lower strain rate.

Finite Element Simulation of Edge Fracture by Mapping the Shear-Induced Ductile Damage into Hole-Expansion Simulation

Lei Mu, Zhe Jia, Ben Guan, and Yong Zang

Abstract A ductile fracture criterion (uncoupled type, originally presented at ICTP2017), which is endowed with both stress triaxiality (T) and Lode parameter (L) dependence, is selected to define the ductile damage accumulation from hole-blanking simulation to the subsequent hole-expansion simulation for a DP780 sheet. The calibrated ductile fracture criterion yields an asymmetric 3D fracture surface, which can well describe the material's ductility within a wide range of stress states from simple shear to balanced biaxial tension. With the help of a fully integrated simulation framework, the ductile damage induced by the hole-blanking is completely mapped into the hole-expansion simulation to incorporate the pre-damage field for the sheared edge. We find that after considering the pre-damage field, the accuracy of edge fracture simulation is significantly improved in terms of both hole-expansion ratio and fracture propagation path.

Keywords Ductile fracture · Uncoupled model · Edge fracture · Hole expansion

1 Introduction

Advanced high-strength steels (AHSS) have been deemed as promising materials to fabricate modern vehicles, which are aimed at a reasonable balance between light weight, cost efficiency, durability, and good looks. Mechanical shearing (such as blanking and trimming) is an important process to prepare sheet metal blanks that are subsequently formed to fabricate a variety of vehicle body components through various stamping processes. However, the mechanically sheared edges of AHSS sheets have been reported to exhibit a strong tendency to rupture at the strains, which are lower than the predictions given by the traditional forming limit approach [1].

One of the important indicators characterizing the edge formability of a certain sheet metal is the hole-expansion ratio (HER), which can be obtained through performing a standard hole-expansion test, as detailed by ISO/TS16630. Wang et al. [2] tested HERs of different edge conditions for a dual phase (DP) steel sheet. They found that the HER of a milled edge was much higher than that of the sheared edge prepared by hole-blanking. Taylor et al. [3] successfully improved the edge formability of DP980 steels by hardening the ferrite microstructure and meanwhile softening the martensite microstructure. The experimental study performed by Teng et al. [4] pointed out that the edge fracture of a DP980 sheet indeed originates from the pre-existing micro-crack induced by the prior mechanical shearing. This study indicates that the pre-existing ductile damage caused by shearing process should be carefully considered when trying to accurately predict edge fracture behavior for DP steel sheets.

Thanks to the relatively simple forms and comparatively fewer number of parameters to be calibrated, uncoupled ductile fracture (DF) criteria have been widely adopted in various sheet metal forming applications, including fracture forming limit curve [5–8] and edge fracture phenomenon of AHSS steels [9, 10]. Through mapping, the simulated ductile damage field from a 2D hole-blanking simulation to the subsequent 3D hole-expansion simulation, Wang et al. [9] successfully predicted HERs of a DP780 sheet using the famous MMC criterion [11]. It should be mentioned that the edge fracture phenomenon involves a non-linear loading path from shear state to tensile state. Therefore, it is crucial to select a reasonable DF criterion for a reliable edge fracture prediction, as discussed in our previous work [10], in which various uncoupled DF criteria (Lou-Huh [12], Oh [13], and Brozzo [14]) are selected. It was found that Lou–Huh criterion [12] yielded the best HER prediction. Accordingly, it was concluded that a preferred model should be the one, which is capable of capturing DF in a wide range of stress states.

The current work has been proposed to test the performance of a novel uncoupled DF criterion in edge fracture prediction, serving as a follow-up study of the criterion presented at ICTP 2017 [15]. To consider the effects of the pre-existing ductile damage, a fully integrated simulation framework is used, through which the pre-damage fields from 3D hole-blanking simulations are completely mapped to the following hole-expansion simulations. Meanwhile, a user-defined material subroutine of Abaqus-Explicit is coded with the considered DF criterion integrated. It should be mentioned that the material considered in this study is a DP steel (DP780) sheet with a thickness of 1.6 mm. For the detailed information concerning the ductile fracture and hole-expansion tests of this DP780 sheet, readers are referred to Wang et al. [2, 9].

2 Ductile Fracture Criterion and Calibration

2.1 Ductile Fracture Criterion

The DF criterion used in this study is a micromechanically motivated uncoupled model, which was first developed by considering two major void deformation modes (void dilation and elongation/rotation) [15] and further improved by integrating with a void nucleation term [16], as follows,

$$C_3 = \int_0^{\bar{\varepsilon}^f} \left\langle C_1 \frac{\sigma_1}{\sigma_{\text{eq}}} + (1 - C_1) \frac{\tau_{\max}}{\sigma_{\text{eq}}} \right\rangle^{C_2} D_n \mathrm{d}\bar{\varepsilon}^p, \text{ with } D_n = R_n \left(\bar{\varepsilon}^p\right)^m. \tag{1}$$

In Eq. (1), $\sigma_1 / \sigma_{\text{eq}}$ is the normalized first principal stress (σ_1) by equivalent stress (σ_{eq}), characterizing the void dilation mode; $\tau_{\max} / \sigma_{\text{eq}}$ is the normalized maximum shear stress ($\tau_{\max}$) by σ_{eq}, characterizing the void elongation/rotation mode; C_1 modulates material's sensitivity to different void deformation modes, ranging from 0 to 1; C_2 controls the effect of the linear combination of the two void deformation modes; D_n is a power function quantifying the number of the nucleated voids with respect to equivalent plastic strain ($\bar{\varepsilon}^p$). Equation (1) originally assumes that DF occurs when C_3 is reached by Eq. (1). Researchers in the DF community usually make the use of the so-called linear ductile damage indicator framework to define ductile damage evolution during a certain plastic deformation process, as follows,

$$\mathrm{d}D = \frac{\mathrm{d}\bar{\varepsilon}^p}{\bar{\varepsilon}^f(T, L)}. \tag{2}$$

In Eq. (2), dD stands for the increment in damage indicator (D). To simulate DF initiation and propagation in a sheet metal forming simulation, the element deletion approach is frequently implemented to remove the critical element whose D value reaches at 1. The term, $\bar{\varepsilon}^f(T, L)$ in Eq. (2), is a 3D fracture surface function defined in the space of stress triaxiality (T), Lode parameter (L), and fracture strain ($\bar{\varepsilon}^f$). The form of $\bar{\varepsilon}^f(T, L)$ varies with the selection of DF criterion. Generally speaking, $\bar{\varepsilon}^f(T, L)$ can be derived from a certain DF criterion using a linear loading path assumption. The specific $\bar{\varepsilon}^f(T, L)$ corresponding to Eq. (1) is as follows,

$$\bar{\varepsilon}^f(T, L) = a \left[\frac{3\sqrt{L^2 + 3}}{C_1 \left(3T\sqrt{L^2 + 3} - L\right) + 3} \right]^b, \; a = \left[\frac{C_3(m + 1)}{R_n} \right]^{\frac{1}{m+1}}, \; b = \frac{C_2}{m + 1}. \tag{3}$$

2.2 Model Calibration

According to Eqs. (2) and (3), a, b, and C_1 are the three parameters to be calibrated (C_3, R_n, and m merge into a; C_2 and m merge into b). To this end, the least-squares optimization is performed to identify a pair of (a, b, and C_1), which can minimize the accumulated error of the targeted 3D fracture surface as compared to each DF data point, as listed in Table 1. It should be mentioned that the DF data of the DP780 sheet considered were initially obtained by Wang et al. [2, 9] and later converted into the space of (T, L, $\overline{\varepsilon}^f$) by Mu et al.[10]. The optimized pair of (a, b, and C_1) is (0.1115, 3.2186, 0.1273) with the resultant 3D fracture surface given in Fig. 1. It is observed that the constructed 3D fracture surface can well demonstrate the distribution of the DF data points in the space of (T, L, $\overline{\varepsilon}^f$) with acceptable deviations. Moreover, the 3D fracture surface exhibits two special features: (a) the surface is asymmetric with respect to the plane of $L = 0$; (b) the L sensitivity of the surface increases with a decrease in T. These two features have been confirmed from the results yielded by the well-established unit cell approach, as reported by Dunand and Mohr [17] and Luo and Gao [18].

Table 1 DF data points in the space of (T, L, $\overline{\varepsilon}^f$)[10]

Specimen no.	Specimen type	T (averaged)	L (averaged)	$\overline{\varepsilon}^f$

3 Simulation Framework

To predict the edge fracture behavior of a blanked circle hole during the subsequent hole-expansion test, the simulation framework of the current study is proposed to comprise two sub-simulations, namely, hole-blanking simulation and hole-expansion simulation. For the purpose of enabling the hole-expansion simulation to consider the shear-induced ductile damage field, three Python scripts are coded to process the results from the hole-blanking simulation: (a) the first Python script is specialized to remove all the nodes, whose displacements (in the blanking direction) are larger than the sheet thickness (1.6 mm), thereby removing the circular sheet cut out from the original material; (b) the second Python script rebuilds the elements based on the remained nodes, thereby constructing the geometry model for the hole-expansion simulation with the morphology of the sheared edge inherited; (c) the third Python script extracts $\overline{\varepsilon}^p$ and D fields from the hole-blanking simulation, which are further prescribed as the initial state variable fields for the hole-expansion simulation.

$$Y_{\text{Swift}}\left(\overline{\varepsilon}^p\right) = A\left(\overline{\varepsilon}^p + \varepsilon_0\right)^n \tag{4}$$

$$Y_{\text{Voce}}\left(\overline{\varepsilon}^p\right) = Y_s - (Y_s - Y_0)e^{\left(-\frac{H_0}{Y_s}\overline{\varepsilon}^p\right)} \tag{5}$$

$$Y_{\text{Swift - Voce - combined}}\left(\overline{\varepsilon}^p\right) = \alpha Y_{\text{Swift}}\left(\overline{\varepsilon}^p\right) - (1-\alpha)Y_{\text{Voce}}\left(\overline{\varepsilon}^p\right) \tag{6}$$

$$f\left(\sigma_{ij}\right) = \sqrt{F\left(\sigma_{yy}-\sigma_{zz}\right)^2 + F\left(\sigma_{zz}-\sigma_{xx}\right)^2 + H\left(\sigma_{xx}-\sigma_{yy}\right)^2 + 2\left(L\sigma_{zy}^2 + M\sigma_{zx}^2 + N\sigma_{xy}^2\right)} \tag{7}$$

The plastic properties of the DP780 sheet are characterized using Swift-Voce-combined hardening law (Eqs. 4–6) and Hill's 1948 quadratic yield function (Eq. 7), with the relevant parameters given in Table 2 and Table 3, respectively. The Young's modulus and Poisson's ratio of the DP780 are set to be 200 GPa and 0.3, respectively.

Table 2 Strain hardening parameters [2, 9]

Swift law			Voce law			Weight factor α(–)
A (MPa)	ε_0 (–)	n (–)	Y_s (MPa)	Y_0 (MPa)	H_0 (MPa)	
1460.3	0.0024	0.1943	1020	507.9	19,321	0.7

Table 3 Parameters of the Hill's 1948 quadratic yield function [2, 9]

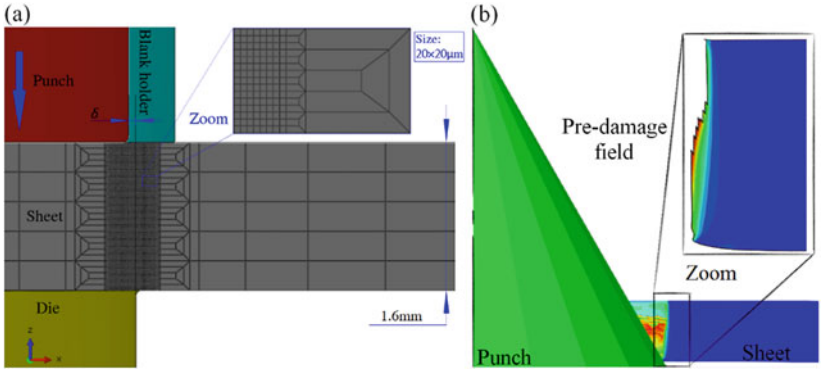

Fig. 2 Simulation configurations: **a** hole-blanking simulation; **b** hole-expansion simulation. (Color figure online)

A user-defined material subroutine (VUMAT) compatible with Abaqus/Explicit is coded to describe the abovementioned elastic–plastic characteristics with the ductile damage evolution law defined by Eq. (2) embedded. In addition, C3D8R elements are used to discretize the DP780 sheet with the shear zone assigned fine elements; tools are all assumed to be rigid bodies; a quarter of the sheet is modeled to make use of the symmetric nature of the problem; Coulomb friction model is used to describe the friction of each contact pair with the friction coefficient set to be 0.1. Simulation configurations of the hole-blanking and hole-expansion processes are illustrated in Fig. 2a, b, respectively. Note that in Fig. 2b, the pre-damage (denoted by D value) field, which is defined by Eq. (2) and inherited from the prior hole-blanking simulation, is prescribed as an initial state variable field. Also, the clearance ratio (δ) in Fig. 2a is defined as the blanking clearance divided by the sheet thickness.

4 Results and Discussion

The hole-expansion simulation results corresponding to a δ value of 5% are given in Fig. 3. Figure 3a shows the case where the shear-induced pre-damage is considered, whereas Fig. 3b shows the case without considering the pre-damage. It is observed from Fig. 3a that the predicted cracks initiate from the middle of the sheared edge, where there are relatively higher values of D. As the punch further travels upward, the initial cracks primarily propagate at 45° with respect to the sheet thickness direction. This is in accordance with the experimental observation, as shown in Fig. 4a. When the occurrence of the first through-thickness fracture is captured, the corresponding HER value is identified to be 0.13, which is slightly larger than the experimental value (0.12). However, when the pre-damage field is ignored (Fig. 3b), the prediction yields unacceptable errors: (a) the propagation direction of the through-thickness fracture is not 45° with respect to the thickness direction; (b) only one crack initiates and

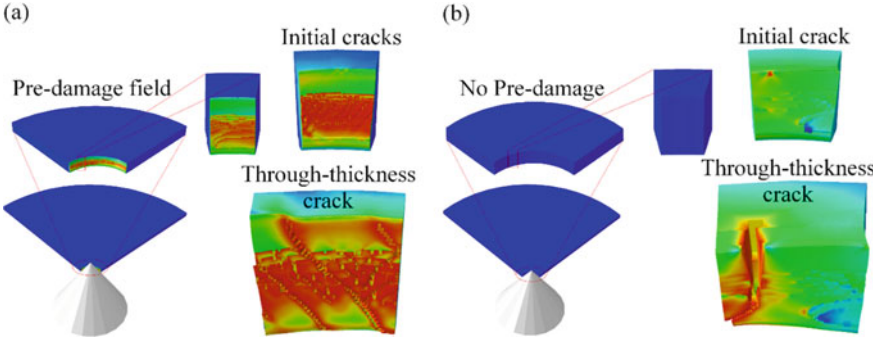

Fig. 3 Simulated evolution of macroscopic cracks: **a** with pre-damage; **b** without pre-damage. (Color figure online)

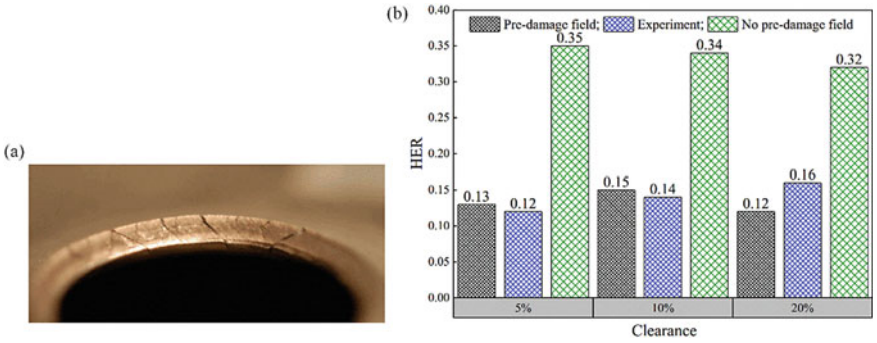

Fig. 4 Experimental observations: **a** observed crack initiation and propagation (δ: 5%) [9]; **b** HERs. (Color figure online)

grows; (c) the predicted HER is 0.35, which is much larger than the tested value (0.12).

It should be mentioned that the predicted crack initiations and propagations of other δ values (10% and 20%) are similar to those shown in Fig. 3. Meanwhile, the predicted HERs of different δ values are compared with experimental ones in Fig. 4b. Obviously, a careful consideration of the pre-damage field can significantly improve the HER predictions of different blanking clearances for the DP780 sheet. Also, the used DF criterion is able to give reliable predictions in terms of not only the HER values but also the crack initiations and propagations.

In addition, the performance of various DF criteria is compared as shown in Fig. 5. Here, only the case of 5% δ is considered because the experimental HER shows minor changes with a varying δ from 5 to 20% as shown in Fig. 4b. For the detailed prediction results by Lou–Huh criterion [12], Oh criterion [13], and Brozzo criterion [14], readers are referred to one of our previous works [10], in which an identical simulation framework was used except for the DF criterion. It is

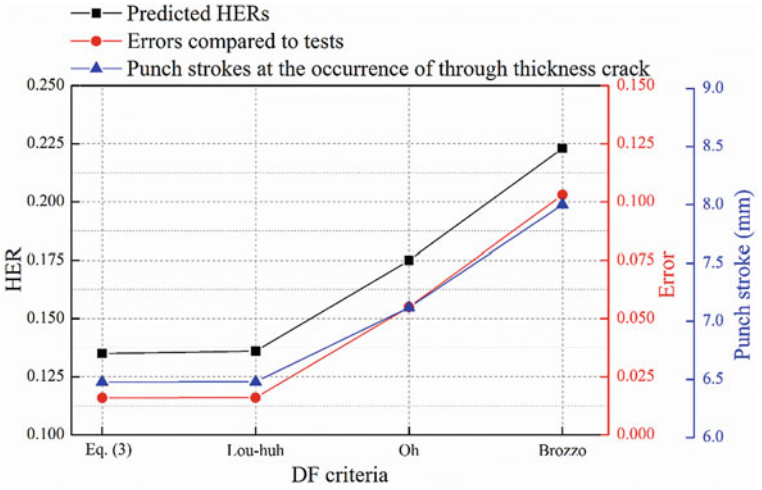

Fig. 5 Comparison of HER predictions between various DF criteria (the predictions by Lou–Huh, Oh, and Brozzo criteria are cited from Ref. [10]). (Color figure online)

found that Lou–Huh criterion and the one described in Section 2.1 produce the best predictions as compared with the experimental data. This could be contributed to the fact that these two criteria are able to accurately characterize the ductility of the DP780 sheet in a wide range of stress states from simple shear to balanced biaxial tension. This lines up with the conclusion made in [10]. Also, we find that the HER predictions by these two criteria are almost the identical, which could be explained by the following aspects: (a) The crack initiation and propagation are simulated based on the element deletion operation, which is executed according to the ductile damage accumulation defined by a 3D fracture surface through Eq. (2); (b) Since the 3D fracture surfaces defined by the currently selected criterion (Eq. 3) and Lou–Huh criterion only demonstrated minor deviations, the resultant crack initiation and propagation predictions are similar between these two criteria, contributing to the identical HER predictions. (c) It should be also mentioned that the crack initiation and propagation simulations are also sensitive to the mesh size in a FE simulation. The identical HERs predicted could also imply that the mesh size used in this study cannot distinguish the minor deviations between these two criteria.

5 Conclusion

In the current study, a newly proposed DF criterion is selected to define the ductile damage evolution from hole-blanking simulation to the following hole-expansion simulation. The shear-induced pre-damage is elaborately considered through a fully integrated simulation framework. The model calibration result points out that this

criterion can well describe the ductility of the DP780 in a wide range of stress states. It is also confirmed by the comparison between the simulation and experimental observation that the shear-induced pre-damage plays an important role in an accurate HER prediction for the DP780 sheet considered. Again, after considering the pre-damage, the selected DF criterion can well predict the edge fracture behavior of the DP780 sheet.

Relaxation Characteristics of Creasing Process of Scored Paperboard for Liquid Container

Shigeru Nagasawa, Takaomi Nagumo, Azusa Sakamoto, and Kazuki Umemoto

Abstract In this work, dynamic creasing characteristics of liquid-container-purpose paperboard of basis weight 313 g/m^2 (a thickness of $t = 0.47$ mm) were investigated, when varying the holding time of two creasing knives (a round edge and/or a flat edge) at an indentation depth of $d = 0.8$ mm. In a scoring process, the relationship between the time-dependent behavior of reaction force f and the permanent scored depth d_{as} was approximately linearized with a logarithmic function of the elapsed holding time $t_{ep} =$ 0-60 s. When using the paperboard scored with the specified indentation depth and varying the tracking holding time T_{ep}, the relationship of the bending moment M and the rotation angle θ was investigated. The effects of the tracking holding time at the scoring process on the bending moment resistance (as the maximum strength) $M_{90}(0)$ at $\theta =$ 90° and the initial gradient $C_1 = \partial M/\partial\theta(\theta = 0–5°)$ were characterized with a logarithmic function of T_{ep}, and also an explicit expression of C_1 with $M_{90}(0)$ was revealed. Namely, a time-dependent relaxation of scoring reactional force f and the time-dependent relaxation of C_1 (and/or $M_{90}(0)$) in a folding process has occurred with a logarithmic term of the holding time.

1 Introduction

Coated paperboard is a fundamental raw material for various printed-decorated packaging and transport packaging industries due to its advantages such as high strength-to-weight ratio, high surface smoothness, printability, sustainability, and recyclability [5]. If any cracks occur on the outside of the folded parts of paperboard, which is used for making a cabinet, the mechanical strength of the cabinet is weakened, and also folded parts are inferior in decorative aspects. The actual creasing range was investigated based on the relationship between the crease depth and crease width

[3]. Carey [1] and Carlsson [2] explained about the bending behavior of the creased part as composed of two parallel beams. There are several reports for estimating the anisotropic properties of the paperboard and the delamination-based folding resistance in the creasing process [15]. Nagasawa et al. [6–10] reported about the quasi-static folding stiffness and bulging profile with respect to the indentation depth of the creaser and also discussed about a fundamental crease deviation effect on the folding deformation characteristics, by the use of a creasing strength tester CST-J-1, which was based on a cantilever type [4], namely a single-point method (TAPPI, T-556 om-11). Empirically, the folding performance of the creased part is estimated using the relative creasing strength (*RCS*, a ratio of bending peak maximum resistance of the creased sheet by that of uncreased sheet) or the folding factor *F* (decrease rate of bending moment resistance) defined as 1-*RCS.* The bending strength of creased part was generally based on the quasi-static solid mechanics, while a real scoring of the paperboard was processed under various dynamic conditions: a high velocity for making a high productivity, a trial low velocity in a laboratory. Since the paperboard has time-dependent behaviors (e.g., visco-elasticity), the velocity effect on the folding factor seems to be changed. Sakamoto et al. [14] reported the stress relaxation response of liquid container board during a scoring process. However, the effects of stress relaxation on the bending stiffness (as the bending moment resistance) were not sufficiently pursued. The relationship between the dynamic scoring of creasing knife against the paperboard and the quasi-static folding factor (the bending moment resistance acting on a hinge) is important in order to adjust mechanical conditions for boxing a paperboard. In this work, therefore, in order to reveal the dynamic creasing characteristic of a liquid container board, when the holding time of a creasing knife was changed at each pushed position, the reaction force of scoring at the specified indentation depth was observed and its effect on the bending moment resistance was investigated.

2 Experimental Condition and Method

2.1 Pre-processing of Specimen

The chosen paperboard was popular for making a milk carton box, which had a thickness of 0.47 mm and a basis weight of 313 g/m^2. In-plane tensile test properties in the Machine Direction (MD) and Cross machine Direction (CD) are shown in Table 1. As for the pulp combination ratio of the paperboard, a broad-leaved lumber of 60.3% and a needle-leaved lumber of 39.3% were measured by a fiber analyzer Kajaani-FS300. From this fiber analysis, it was confirmed that the paperboard was made from virgin softwood and hardwood fibers. Figure 1 shows a sectional view of the liquid container sheet across the fiber grain machine direction. The wetted (inside) surface of the liquid container sheet had a thickness 28–29 μm of polyethylene, and the printed (outside) surface had a thickness 16–17 μm of polyethylene, respectively.

Table 1 In-plane tensile properties of liquid container sheet. Humidity: 50%RH, temperature: 296 K

Breaking true stress σ_B (MD/CD) MPa	40.72/18.77
At feed velocity 0.33 mm/s	
Breaking true strain ε_B (MD/ CD) %	1.96/4.55
Young modulus E (MD/ CD) GPa	4.40/1.86
0.2% proof stress (MD/ CD) MPa	26.64/11.75

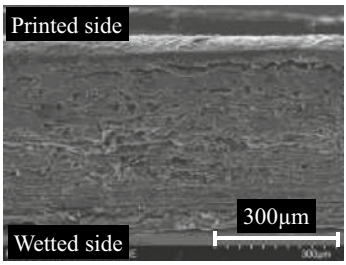

Fig. 1 SEM photograph of sectional view across the fiber grain machine direction of liquid container sheet of 313 g/m^2

The specimens were kept in a room, which had a temperature of 296 K and a humidity of 50% RH. The scoring test pieces were prepared as eight pieces of the rectangle formed liquid container sheet, which had a width of $W_S = 15$ mm, a length of 60 mm, and a thickness of $t = 0.47$ mm for each mechanical condition: (1) two kinds of creasing knives (flat-edge and round-edge) and (2) the holding time of scoring from 1 to 60 s at the specified bottom position. Chosen three pieces from these specimens were examined in the bending resistance test with respect to the mechanical condition. The specimens were scored on the printed surface with an indentation velocity of 0.0167 mm/s using rubber blocks and a creasing knife (flat-edge or round-edge) against a grooved counter face plate as shown in Fig. 2. The creasing knife was set across MD of the specimen. When the knife was indented to the specimen with the indentation depth d, the normalized indentation depth $2d/B = \gamma$, a kind of average shearing strain, was chosen as a certain range (Nagasawa

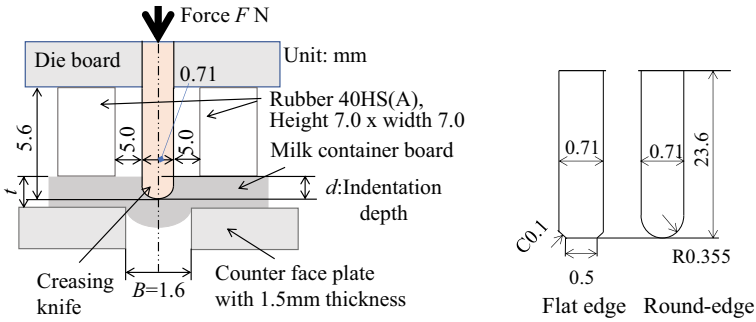

Fig. 2 Layout of out-of-plane scoring by creasing knife, and profile of knife edges. (Color figure online)

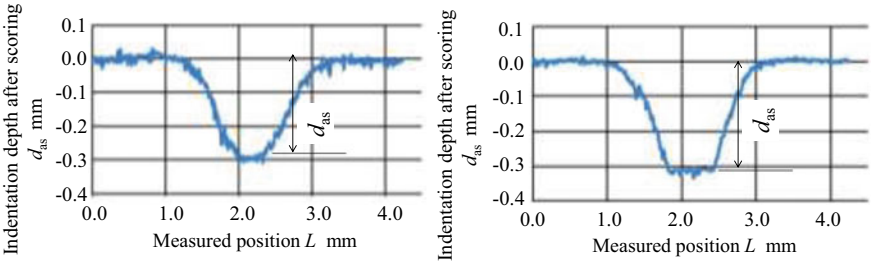
2001). The groove width B was empirically chosen as 1.6 mm ($\approx 2t + b$). Here, a thickness of knife body $b = 0.71$ mm and a thickness of specimen $t = 0.47$ mm were considered.



In the previous report [14], a range of $\gamma = 0.4$–2.0 ($d/t = 0.68$–3.4) was used for investigating the spring back effect when the holding time of scoring was zero. The permanent depth after scoring d_{as} was experimentally approximated as Eqs. (1) and (2) for the round-edge and the flat-edge knife, respectively. Defining the spring back $SP = 1 - d_{as}/d$ when choosing $\gamma = 1.0$ ($d/t = 1.7$), that of round-edge and flat-edge was 0.58 and 0.56, respectively. Namely, the spring back of flat-edge scoring seemed to be a little smaller than that of round-edge scoring. Figure 3 shows a representative two-dimensional profile, which was measured at the middle zone of the specimen by a laser microscope, on the printed surface of the specimen scored (at a holding time of zero) by the round-edge and the flat-edge knife, respectively.

$$d_{as}/t = 0.699(d/t) - 0.474 \tag{1}$$

$$d_{as}/t = 0.704(d/t) - 0.451. \tag{2}$$

Obviously, since the minimum distance (clearance) of flat-edge type between the edge of creasing knife and the groove edge of counter face plate was the smaller than that of round-edge type against the specified indentation depth d, the strain state of the flat-edge type is severer than that of the round-edge type. In this work, the holding time of scoring at the bottom end position ($\gamma = 2d/B = 1.0$, $d/t = 1.7$) was chosen as $T_{ep} = 1, 2, 5, 10, 20$ and 60 s. According to a preliminary experiment, seeing both sides of the printed surface and wetted surface of scored part by the flat-edge type, a permanent depth d_{as} of wetted surface was almost equal to that of printed surface, although distributed profiles of scored zone were different with each other.

Figure 4 illustrated a response of scoring line force $f = F/W_S$ with the elapsed time t_{ep}. The creasing knife was initially indented to the specimen until reaching

(a) In case of round-edge knife (b) In case of flat-edge knife

Fig. 3 Representative 2 dimensional profile of permanent depth on printed surface when choosing $\gamma = 1.0$ ($d = 0.8$ mm), scanned by a laser microscope. Here, the holding time of scoring was zero. (Color figure online)

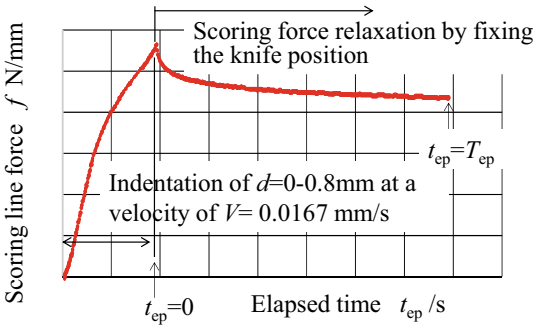


Fig. 4 Scoring load response model and holding time zone. (Color figure online)

the position of $d = 0.8$ mm ($\gamma = 1.0$) at a velocity of $V = 0.0167$ mm/s. At that position, the creasing knife was locked and the reaction line force f was recorded with the elapsed time $t_{ep} = 0 - T_{ep}$. After releasing the knife from the specimen, the permanent depth d_{as} was measured with the specified T_{ep}, using the laser microscope.

2.2 *Measurement of Bending Moment Resistance*

Figure 5 shows a schematic diagram and a general view of the experimental apparatus [4] used for the folding motion test. A clamped specimen on the right side as a cantilever beam (sheet) was rotated at the hinge (the center of rotation) while the left side of specimen was fastened by the load cell edge. The fixture (right side) rotated from $\theta = 0$ up to $\theta = 90°$ at a rotation velocity of $\omega = 0.2$ rps. Figure 6 shows the examples of the relationship between the folding angle θ and the bending moment resistance M per unit width Nm/m. As for characteristic parameters of the bending moment resistance, the initial gradient $C_1 = \partial M/\partial\theta$ ($\theta = 0$–$5°$), the bending moment $M_{90}(0)$ at the tracking position of $\theta = 90°$, and the initial release angle $\theta_{2,1}(0)$ were experimentally collected when varying the holding time of scoring T_{ep}. Here, $M_{90}(0)$ denotes a moment resistance when the stopping time was zero at the tracking position of 90° [11, 12]. Since the maximum peak bending moment resistance of non-scored specimen was $M_{p1,0} = 1.61$ Nm/m in across MD, the ratio of $M_{90}(0)/M_{p1,\gamma=0}$ as *RCS*

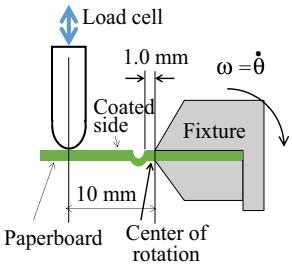

Fig. 5 Bending test apparatus. (Color figure online)

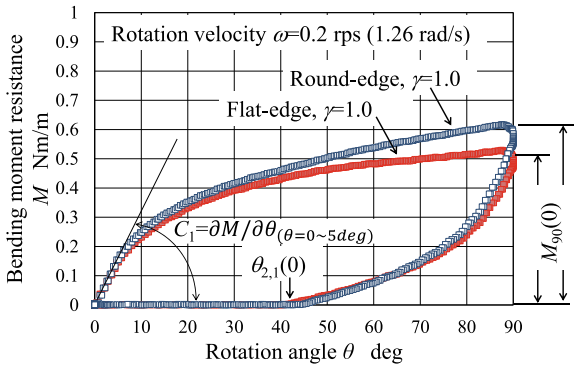

Fig. 6 Analysis parameters on folding resistance diagram. (Color figure online)

was estimated as 0.37, 0.31 for the round-edge and flat-edge, respectively when $T_{ep} = 0$. The initial gradient of non-scored $C_{1,\gamma=0}$ was 0.123 Nm/m/degree.

3 Results and Discussion

3.1 *Relaxation of Scoring Line Force and Permanent Indentation Depth*

Figure 7 shows the line force of scoring $f = F/W_S$ with the elapsed time $t_{ep} =$ 0–60 s after fixing the creasing knife at a specified indentation of $d/t = 1.7$ ($\gamma =$ 1.0). Here, two dashed lines were linear approximations with a logarithmic term $\ln(t_{ep})$ expressed by Eq. (3). Two relaxation coefficients a_1, a_0 were experimentally determined for the round-edge and flat-edge knife, respectively.

$$f = -a_1 \ln(t_{ep}) + a_0 = a_0\left(1 + \ln(t_{ep})^{-a1/a0}\right). \tag{3}$$

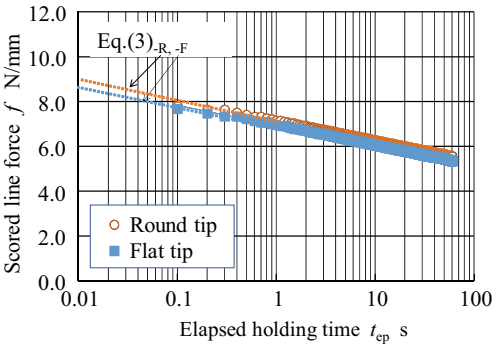

Fig. 7 Relationship between scored line force and elapsed holding time when $\gamma = 1.0$ across MD. (Color figure online)

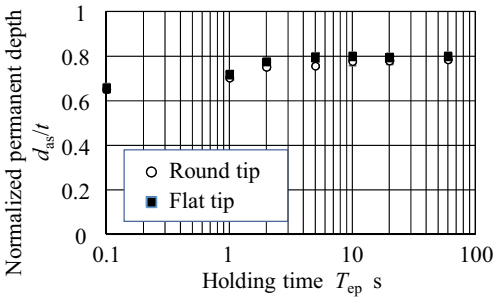

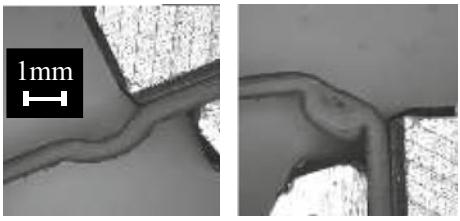

Fig. 8 Effect of holding time on permanent indentation depth when $\gamma = 1.0$ across MD. (Color figure online)

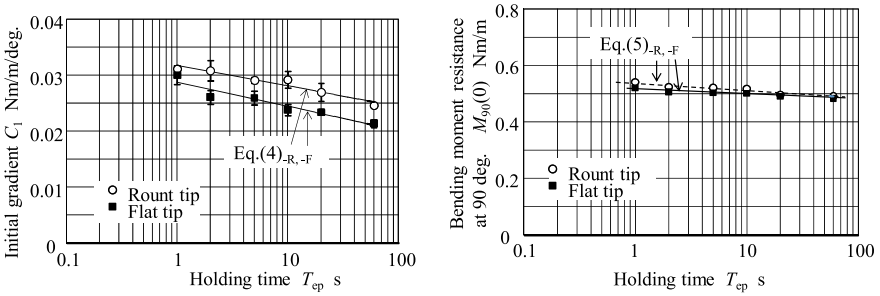
Seeing $t_{ep} = 0.1$–60 s, the index ratio a_1/a_0 and the coefficient a_0 (=f at $t_{ep} = 1$ s) were 0.054, 7.2 for the round-edge, and 0.056, 6.9 for the flat-edge, respectively. According to Sakamoto's report [13], the relaxation index ratio of a_1/a_0 with in-plane MD tensile test was 0.046 (for 0.1–60 s). Hence, the relaxation of scoring reaction force appeared to be larger than that of in-plane simple tensile stress.

Figure 8 shows the permanent indentation depth d_{as} with respect to the holding time $T_{ep} = 1$, 2, 5, 10, 20 and 60 s. Here, dots at $T_{ep} = 0.1$ s were referenced data when the scoring was executed without any holding time. The value of d_{as} transiently increased and appeared to be saturated for $T_{ep} > 5$ s. Assuming that the time-dependent response of d_{as} was described as the first-order delay model, the time constant was roughly estimated as 2 s (up to 63.2% of total variance).



3.2 *Effects of Holding Time on Bending Relaxation Characteristics*

Figure 9 shows an example of photographs of side views of scored zone of the specimen at $\theta = 0$, 90°. Here, the state of the paperboard at $\theta = 0°$ was the same as that of Fig. 5. The relationship between the bending moment resistance per unit width M and the rotation angle θ, as shown in Fig. 6, was measured when T_{ep} was chosen as 1, 2, 5, 10, 20, and 60 s, using two creasing knives. Figure 10a shows the

(a) θ=0° (b) θ=90°

Fig. 9 Photographs of bending process after flat-edge scoring across MD at $\gamma = 1.0$, $T_{ep} = 0$

(a) Initial gradient C_1=$\partial M/\partial\theta$ (θ=0-5°) (b) Bending moment resistance at θ=90°.

Fig. 10 Effect of holding time on folding factors in the bending moment response. (Color figure online)

initial gradient $C_1 = \partial M/\partial\theta$ ($\theta = 0$–5°), while Fig. 10b shows the bending moment resistance at the tracking position $\theta = 90°$ with respect to T_{ep}. In these graphs, lines described approximations with a logarithmic term $\ln(T_{ep})$ as expressed in Eqs. (4) and (5).

$$C_1 = -c_{11}\ln(T_{ep}) + c_{10} = c_{10}\left(1 + \ln(T_{ep})^{-c11/c10}\right) \tag{4}$$

$$M_{90}(0) = -m_{90.1}\ln(T_{ep}) + m_{90.0} = m_{90.0}\left(1 + \ln(T_{ep})^{-m90.1/m90.0}\right) \tag{5}$$

here, the coefficient $c_{10} = C_1(T_{ep} = 1\text{ s})$ was 0.032, 0.029 Nm/m/deg. for the round-edge and the flat-edge, while the index ratio c_{11}/c_{10} was 0.063, 0.069 for the round-edge and the flat-edge, respectively. The RCS factor (at $\gamma = 1.0$) $c_{10}/C_{1,g=0}$ was 0.26, 0.24 for the round-edge and the flat-edge knife, respectively. Similarly, the coefficient $m_{90.0}$ was 0.54, 0.52 Nm/m for the round-edge and the flat-edge, while the index ratio $m_{90.1}/m_{90.0}$ was 0.022, 0.015 for the round-edge and the flat-edge, respectively. The time-dependent response of C_1 was fairly sensitive, because the ratio c_{11}/c_{10} was larger than a_1/a_0. On the other hand, the value of $M_{90}(0)$ was relatively insensitive with T_{ep} owing that a large deformation of $\theta = 90°$ reduces the residual strain state with the holding time, although there was a small effect of T_{ep} on the bending stiffness at $\theta = 90°$. The RCS factor (at $\gamma = 1.0$) $m_{90.0}/M_{p1,0}$ was 0.34, 0.32 for the round-edge and the flat-edge knife, respectively. Seeing C_1 and $M_{90}(0)$, they were similarly varied with T_{ep}. Figure 11 shows a scatter plot of C_1 and $M_{90}(0)$ when changing the parametric T_{ep}. Also, a monotonous, static relationship Eq. (6) was derived from Eqs. (4) and (5).

$$C_1 = \frac{c_{11}}{m_{90.1}}M_{90}(0) + c_{10} - \frac{c_{11}}{m_{90.1}}m_{90.0}. \tag{6}$$

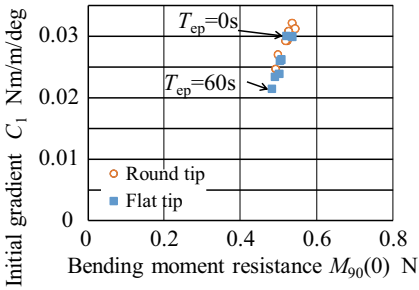


Fig. 11 Variation of folding parameters C_1, $M_{90}(0)$ in the bending moment response when increasing the holding time. (Color figure online)

It was found that C_1 decreased with 30% (23%) and $M_{90}(0)$ decreased with 10% (8%) when changing $T_{ep} = 0$–60 s with respect to the flat-edge (round-edge) knife. Namely, a positive holding time of scoring at the bottom end position promotes an additional indentation depth equivalently.

As for a spring back deformation of folded hinge, the initial release angle $\theta_{2,1}(0)$ was measured and about 42–44° when changing T_{ep}. Any monotonous correlation was not detected between $\theta_{2,1}(0)$ and T_{ep}. Dependencies of the rotational velocity of ω and the stopping time at a folded angle of $\theta = 90°$ on $\theta_{2,1}(0)$ were already reported using a white-coated paperboard [12]. Since this work was carried out under keeping $\omega = 0.2$ rps and the stopping time of folded angle as zero, the effect of T_{ep} on $\theta_{2,1}(0)$ seemed to be sufficiently negligible.

4 Conclusions

In a scoring process using two kinds of creasing knives (round-edge and flat-edge), when increasing the holding time T_{ep} of the creasing knife up to 60 s, at a specified indentation depth of $\gamma = 2d/B = 1.0$, one-loop bending characteristics of a creased liquid container sheet of 0.47 mm thickness were investigated by using a crease stress tester. Obtained results were as follows.

(1) Considering the holding time T_{ep}, the permanent depth increases in the scoring process. As the result, the bending characteristics (as the relative creasing strength) such as the initial gradient $C_1 = \partial M/\partial\theta$ ($\theta = 0$–5°) and the bending moment resistance at the right angle $M_{90}(0)$ decrease in a certain level.

(2) The difference between a round-edge and a flat-edge knife almost does not affect the relaxation coefficient (the index ratio of scoring force: a_1/a_0, that of initial gradient: c_{11}/c_{10}), but the difference affects the permanent depth and the intercept values a_0, c_{10}.

(3) The permanent depth against the specified indentation depth or the spring back of scored depth apt to be saturated when setting the holding time larger than 5 s. The estimated time constant of first-order delay model was 2 s. However, the time-dependent relaxation of scoring reaction force and the time-dependent

relaxation of the initial gradient of the folding process occurred with a logarithmic term of the holding time T_{ep} = 1–60 s. Namely, the relaxation of bending moment resistance does not disappear for T_{ep} = 1–60 s.

Abbreviations: t: a thickness of paperboard 0.47(mm); W_S: a width of paperboard 15(mm); B: a width of groove on a counter (mm); b: a thickness of body of creasing knife 0.71 (mm); F: a force applied to a creasing knife (N); $f = F/W_S$: a line force (N/mm); d: a displacement of creasing knife (= an indentation depth to a paperboard) (mm); d/t: a normalized indentation depth of creasing knife against the specified thickness (–); $\gamma = 2d/B$: a normalized indentation depth of creasing knife as an average shear strain (–); d_{as}: a permanent indentation depth of a paperboard after releasing the creasing knife, a scored depth on a paperboard (mm); t_{ep}: an elapsed holding time at the bottom end position $0 - T_{ep}$ (s); T_{ep}: a (tracking) holding time (s); V: a velocity of a creasing knife (mm/s); θ: a rotation angle of fixture arm (degrees); $\omega = \partial q/\partial t/360$: a rotation velocity of fixture arm (in this work, $\omega = 0.2$rps = 72°/s/360); M: a bending moment resistance per unit width (N mm/mm = N m/m = N); $C_1 = \partial M/\partial q$: an initial gradient of the bending moment M with θ (for θ = 0–5°) (N/deg.); $M_{90}(0)$: a bending moment at the tracking position of $\theta = 90°$ when the elapsed time of folded state was zero at θ = 90°. $\theta_{2,1}(0)$: an initial release angle after releasing the fixture arm (degrees); $M_{p1,0}$: the maximum peak of bending moment during a folding process when choosing $\gamma = 0$; $SP = 1 - d_{as}/d$: a spring back of indentation depth in a scoring process; $RCS_{(90)} = M_{90}(0)/M_{p1,0}$: a relative creasing strength at $\theta = 90°$; A classical/original RCS is defined as $M_{p1}/M_{p1,0}$ (a ratio of the peak maximum bending moment of creased sheet by that of uncreased sheet); $F_{(90)} = 1 - RCS_{(90)} = 1 - M_{90}(0)/M_{p1,0}$: a folding factor at $\theta = 90°$. MD: a Machine (transferred) Direction for papermaking, a fiber grain making direction; CD: a Cross machine Direction; a_0, a_1: Coefficients of Eq. (3) ; c_{10}, c_{11}, $m_{90,0}$, $m_{90,1}$: Coefficients of Eqs. (4) and (5).

Hot Cutting of Press-Hardened Parts in Different Heat Treatment Regimes

R. Schmidt, A. Rautenstrauch, and V. Kräusel

Abstract Parts made of press-hardened steel are cut in general by laser cutting. Shear cutting at room temperature of materials with a tensile strength above 1,500 MPa is not an alternative due to insufficient tool life quantity. The presented investigation relates to the hot cutting of press-hardenable materials such as 22MnB5 and 34MnB5 and includes the determination of the cutting parameters (measuring rate of 100,000 Hz), the temperature, the formation of the microstructure, and the dimensional accuracy of the cut parts during different heat treatments. The results of this investigation show that, when comparing two process routes, the maximum cutting force was reduced to approximately 70 % when cutting in the austenitic range, the acceleration during the cutting impact was close to zero and the deviations from the target geometry were very small. With regard to the measurement results, hot cutting can be an alternative to laser cutting.

Keywords Hot cutting · Press-hardened steels · Thermal treatment

1 Introduction

In recent years, the use of high-strength press-hardened steel has increased, especially for structural parts of the car body. This is due to the increasing need for weight savings while maintaining the same safety requirements in the automobile. The use of press-hardenable boron–manganese steels offers a promising approach to further optimize the lightweight design of structural components. If a critical cooling rate is taken into account during the hot forming of these steels and the targeted quenching in the cooled forming tool, a martensitic structure with strengths >1,200 MPa is obtained [1].

Due to the high tensile strength, press-hardened parts are difficult to cut with mechanical cutting tools due to high abrasive tool wear and even complete tool breakage. Mechanical cutting represents a conventional shear cutting operation. The

greatest challenge in the processing of press-hardened sheet metal parts is the very high cutting force and the resulting cutting impact. This results in a high alternating load on the cutting tools, which is manifested as heavy wear on the active cutting elements. As a result, the cutting tools require frequent maintenance, which is associated with high operating and maintenance costs. Laser cutting is currently the most widely used method for cutting press-hardened steel parts. However, laser cutting as a flexible thermal cutting process is very cost-intensive as well as time and energy-consuming [2–4].

The following optimization potentials for the processing of press-hardened steels can be derived from these facts: One approach that is examined in this article is the substitution of the complex laser cutting after press hardening by hot cutting the component in the austenitic state. Currently, only limited experience is available regarding the hot cutting of sheet metal parts made of boron–manganese steels and the corresponding process parameters. Hot cutting offers the possibility to reduce time and operating costs by simultaneously cutting and quenching during forming after previous heating above the austenitizing temperature. Direct quenching in the tool leads to an increase in the tensile strength of the heat-treated and sheared sheet metal part. At the same time, however, the ductility also decreases [5, 6].

In this paper, the influence of the thermal treatment and carbon content of the press-hardenable material on cutting force, cutting impact, part quality, and mechanical properties of hot cut boron–manganese steels is examined. The approach of this work is to punch the sheet metal part in a ductile state to avoid the high dynamic stress on the cutting punch and thus achieve a longer tool life quantity. Of course, the tool heats up with the number of cuts with a consequent change in its strength properties, but this will be initially neglected in this study.

2 Experimental Details

2.1 Selection of Alloys

In this work, a selected group of steel alloys were investigated based on their similarities, e.g. their similar chemical compositions, which are summarized in Table 1. Strip samples with dimensions of 400 × 30 × 1.5 mm were used for all experiments. The manganese–boron steel alloys 22MnB5 and 34MnB5 in supply condition, i.e. cold-rolled, show a ferritic–pearlitic microstructure with the presence of some carbides.

Table 1 Nominal composition of the studied alloys (wt%)

Steel alloy	C	Si	Mn	P	S	Cr	Mo	B	Ti
22MnB5	**0.17**	0.22	1.19	0.01	0.008	0.12	0.01	0.001	0.03
34MnB5	**0.35**	0.29	1.28	0.01	0.01	0.17	0.01	0.004	0.03

The 22MnB5 has a carbon content of about 0.17 % and the material 34MnB5 of about 0.35 % (Table 1).

2.2 Punching Tool and Measurement Concept

The tool has two tool halves, which are guided with four columns and dimensioned primary for cutting of ultra-high-strength steels. The tool material Böhler K890 was used for the punch and the selected material for the die was a Böhler S600. The tool has an integrated cutting shock absorption, which was in tests always enabled. The stripes were 5 mm above the cutting die and the distance to the next support surface was 60 mm. Therefore, the cooling of the strips on contact with the tool is negligible. The manual transport of the stripes from the oven to the cutting process needs around about 2 seconds. The diameter of the punch is 10 mm and the constant cutting clearance is 0.2 mm. A constant blank holder force of 90 kN was set and the punch velocity was adjusted with an industry-relevant value of 50 mm/s. The tool was moved path-controlled by a servo-driven spindle press of the company Dunkes [7] (Fig. 1).

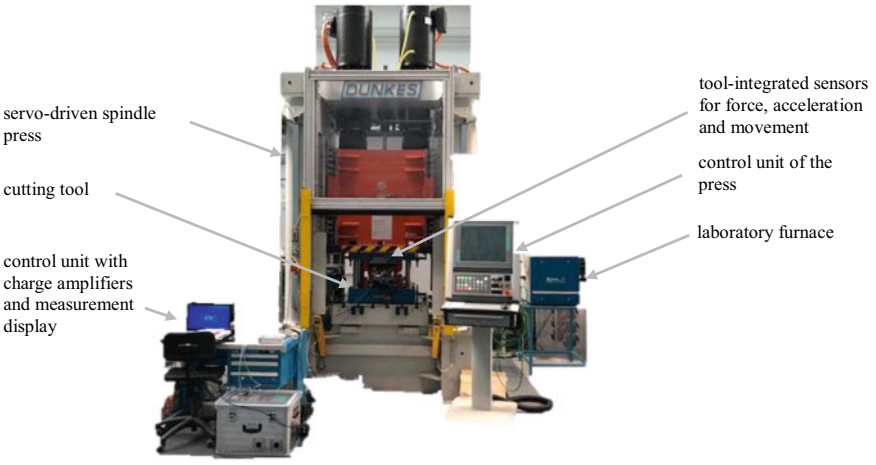

Fig. 1 Experimental setup with the position of measurement sensors. (Color figure online)

Tool-integrated sensors measure the cutting force, acceleration, and movement. The force sensor is positioned directly above the punch in a special construction to measure the pure cutting force without force shunt and other influencing factors. The position of the sensors for acceleration and movement is near the cutting zone. The controlling and saving of the measurement values implement with a control unit of National Instrument. The selected measurement frequency of 100,000 Hz is necessary to obtain a sufficient resolution of the measurement values, especially in

the area of the cutting impact, and to be able to execute a frequency filtration of the measurement values.

2.3 Thermal Treatments

Two different heat treatments were carried out in this work. The first heat treatment route (HTR 1) starts with an austenitization of the test samples at a temperature of 1,000 °C during 10 min and quenched in water by a cooling rate of approximately 10,000 K/s. The hardened strips are then tempered in a furnace in a temperature range between 600 °C and 400 °C for 6 min. The next step is the transfer of the sheet metal strips from the furnace to the cutting tool for punching in the temperature range between 540 °C and 320 °C. After the hot cutting, the tool is opened and the punched sheets are removed for subsequent air cooling to room temperature (Fig. 2).

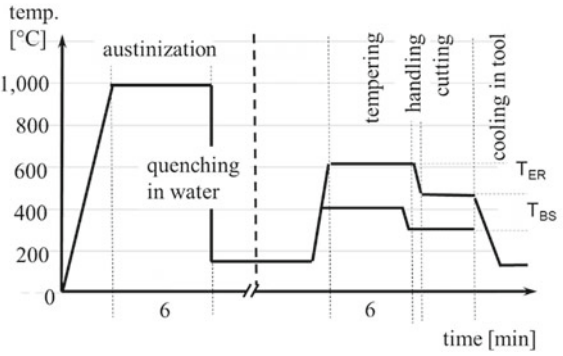

Fig. 2 Heat treatment route 1—HTR 1

In the second heat treatment route HTR 2, the samples are heated at a temperature of 1,000 °C for 10 min. Afterward, the austenized samples are transferred from the furnace to the cutting tool and cut between 800 °C and 600 °C. During handling, the samples cool down from the furnace temperature to the cutting temperature at a cooling rate of approximately 14 K/s (Fig. 3).

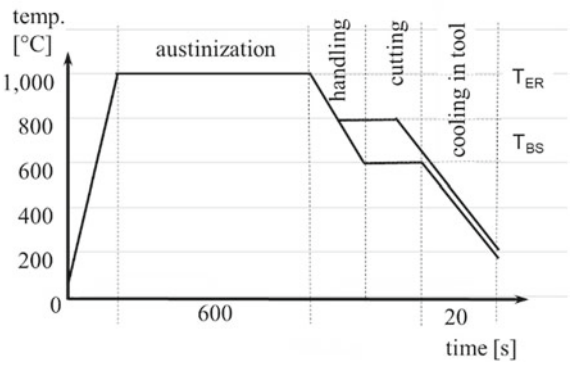

Fig. 3 Heat treatment route 2—HTR 2

3 Results

3.1 Determination of Cutting Performance

The measurement values were evaluated with a self-developed algorithm in the software MATLAB R2019b and filtered against the noisy frequency with a standard MATLAB filter function. To prepare a comparison of different force–displacement curves, the beginning of the curves with the first increase in cutting force is determined for further investigation. In Fig. 4, three typical force–displacement curves

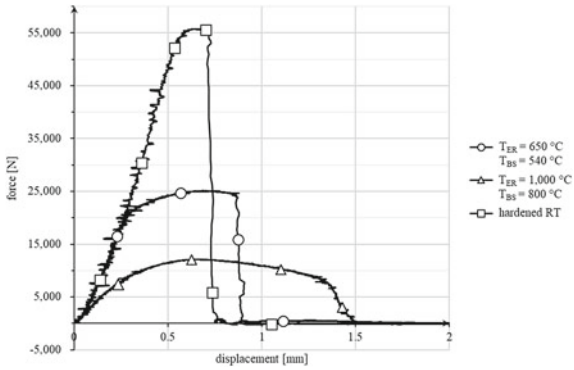

Fig. 4 Typical force–displacement curves for punching of strips made of 34MnB5

are shown as an example of the tested material 34MnB5 with three different heat treatment routes.

The highest cutting force and the shortest flush-cut amount can be determined when cutting from the hardened strip. The abrupt dropdown of the force by approximately 0.7 mm punch penetration results in the highest measured cutting impact in this study. In comparison, a much more pronounced shear zone can be seen on the hot cut sample due to the better forming capacity and thus material flow. Especially, the

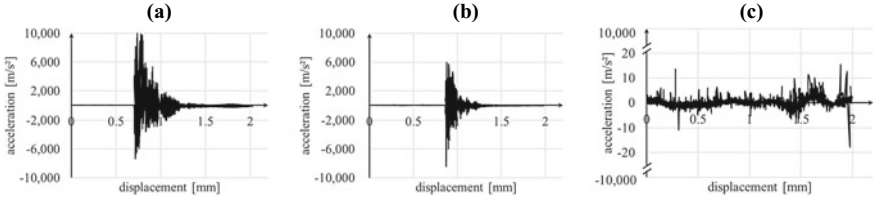

Fig. 5 Acceleration–displacement curves for punching of strips made of 34MnB5 of (**a**) hardened RT; (**b**) $T_{ER} = 650$ °C; $T_{BS} = 540$ °C; (**c**) $T_{ER} = 1{,}000$ °C; $T_{BS} = 800$ °C

material 34MnB5 shows an elastic behavior at 800 °C up to a displacement of 0.2 mm. Afterward, the plastic deformation proceeds until the end of the cutting process with a smooth run-out of the force–displacement curve without any recognizable cutting influence (Fig. 5).

As shown in Fig. 6, after punching a hole with a diameter of 10 mm, the punch enters the die 1 mm and remains at the bottom dead center for one second. Then the punch moves out of the die and the sheet strip while the blank holder continues to press the workpiece onto the die. At this point, the material cools to martensite start temperature and hardening occurs. This is followed by the opening of the tool and the sheet strip is removed. For both the HTR 2 and the uncured material, an increase in retraction force was noticeable after cutting. This suggests that at the time of cutting, no hardening of the material took place during the process route HTR 2 because the martensite start temperature has not yet been reached.

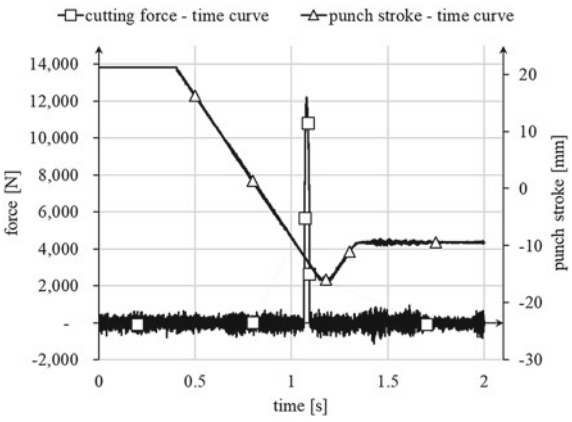

Fig. 6 Development of cutting force for cutting of 34MnB5 at HTR 2

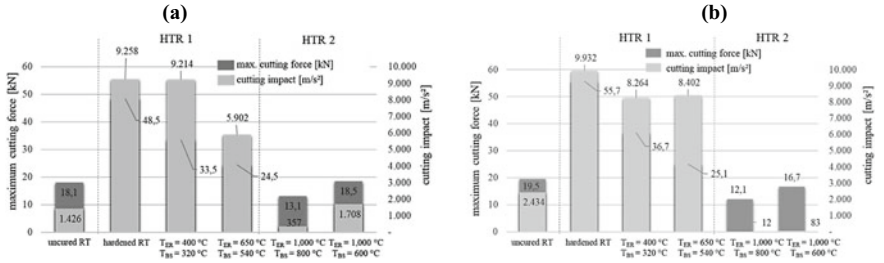

Fig. 7 Maximum cutting force and cutting impact of **a** 22MnB5; **b** 34MnB5

3.2 Determination of the Maximum Cutting Force and Cutting Impact

To determine the maximum cutting force and the cutting impact, the interference signals are filtered with the MATLAB filter function. The cutting impact values after the break are included in the evaluation. The results in Fig. 7 show that the highest maximum cutting forces correlate with the highest measured cutting impact values. Furthermore, it is found that the lowest cutting forces show a correlation with the lowest measured cutting impact values. The results were found to be independent of the material. When cutting hardened steels according to heat treatment route 1, higher cutting forces and higher cutting impact values are recorded compared with heat treatment route 2. In contrast, the lowest maximum force of 12.1 kN was obtained during hot cutting of the material 34MnB5 along HTR 2 at a cutting temperature of 800 °C. The cutting impact could not be measured for this low cutting force.

3.3 Determination of Cutting Quality

In addition to the investigation of Neumayer et al. [6] and So et al. [8], the diameters of the round holes are measured optically with a Keyence microscope VHX-600 with a deviation of about 0.02 mm. The following Fig. 8 shows the diameter of the hole from the punch side compared to the punch diameter.

For both investigated materials, a similar diameter of the perforated stripe on the side of the punch could be measured for the respective heat treatment routes. The hole in the hardened stripe increased significantly after cutting, which is why no retraction forces were measured. In contrast, the hole in the hardened stripe, which was reheated to 650 °C and cut at 340 °C, was reduced to 9.94 and 9.97 mm respectively. As a result of HTR 1, a retraction force of approximately 500 N could be measured during cutting for both materials examined. In particular, the diameters determined according to HTR 2 scarcely changed compared to the punch diameter, taking into account the measurement inaccuracy. Since no retraction forces greater

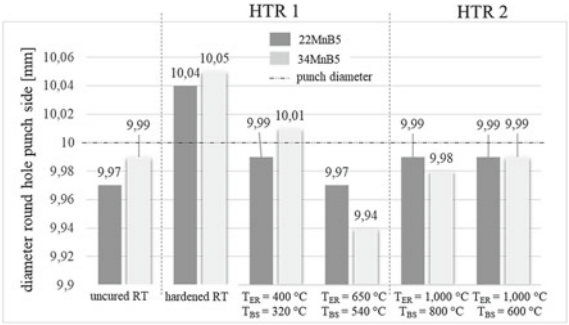

Fig. 8 Round hole diameter versus punch diameter

than 100 N were measured, no abrasive wear at higher stroke rates is likely to be detected.

3.4 Determination of the Mechanical Properties

To investigate the influence of the heat treatment routes on the mechanical properties, the cut specimens were embedded, subjected to a hardness test and metallographic examination. Vickers Hardness tests were performed using the load range HV 1. The experimentally determined Vickers hardness of the heat-treated sheets is shown in Fig. 9. The samples were prepared for micrographs. Microstructural analysis was performed using optical microscopy from ZEISS.

Samples were chemically etched using 3 % Nital solution. In heat treatment route 1 after austenitization followed by quenching in water, both materials show a clear hardening, for the 22MnB5 of 640 HV1 and for the 34MnB5 of 738 HV1. The microstructure of both hardened materials shows martensite (Figs. 10 and 11). Because of reheating to 650 and 400 °C, the material relaxes and after cooling, it has a reduced hardness. The material 22MnB5 shows 365 HV1 at 650 °C and 484 HV1 at 400 °C. In addition, a hardness of 332 HV1 for the material 34MnB5 after heat treatment at 650 °C and 528 HV1 after 400 °C (Fig. 9) was measured. The

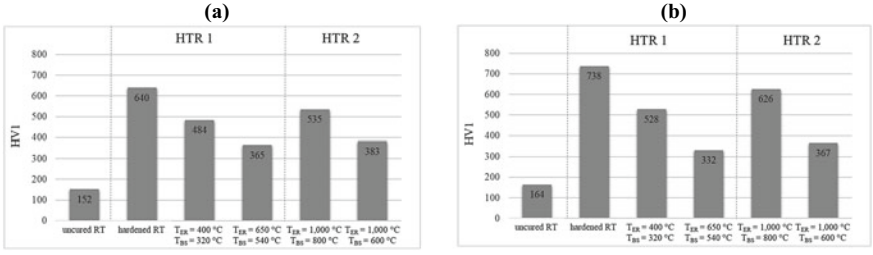

Fig. 9 Hardness values HV1 for **a** 22MnB5; **b** 34MnB5

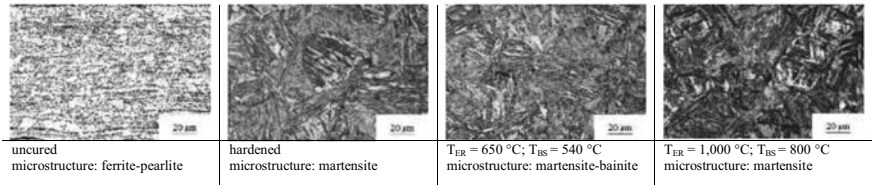

Fig. 10 Microstructure development for 22MnB5

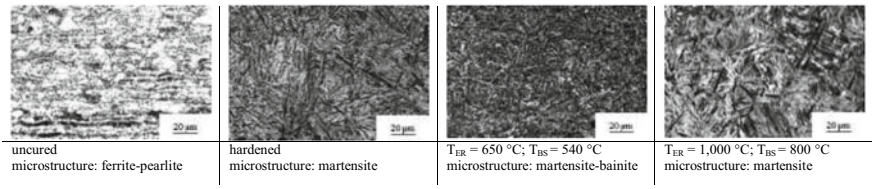

Fig. 11 Microstructure development for 34MnB5

microstructure showed a martensitic–bainitic structure in both materials due to the subsequent tempering (Figs. 10 and 11).

Along heat treatment route 2, the materials 22MnB5 and 34MnB5 are heated to 1,000 °C in the furnace, hot cutting in the tool, and cooled to room temperature. After heat treatment and cutting, the material 22MnB5 has a hardness of 535 HV1 at 800 °C and 383 HV1 at a cutting temperature of 600 °C. Because of the heat treatment, the material has a martensitic structure after treatment. The material 34MnB5 shows, after austenitization and hot cutting a hardness of 626 HV1 at 800 °C and a hardness of 367 HV1 at a cutting temperature of 600 °C. The microstructure shows also here a martensitic structure due to the heat treatment (Figs. 9, 10, and 11).

4 Conclusions and Outlook

The presented results show that the maximum cutting force as well as the cutting impact are considerably reduced due to the hot cutting of boron–manganese steels. Along heat treatment route 1, an improvement in mechanical cutting for press-hardened materials could be achieved. For example, for the press-hardened 22MnB5, a reduction of the cutting force by up to 50 % was achieved by cutting at a cutting temperature of 650 °C.

The measured cutting impact close to zero has no influence on the tool life quantity. With regard to tool production, it can be deduced for hot cutting to use a tool material with higher heat resistance. Small deviations in the cutting clearance are negligible in route 2 and allow a greater margin with regard to the tool tolerances.

With the heat treatment route 2, proof could be provided that in a direct heat treatment process, the process heat can be used for hot cutting and a martensitic microstructure can be set. For this purpose, approaches are being pursued to combine the hot cutting with the press-hardening process in one step and to integrate the hot cutting in a press-hardening tool.

Acknowledgments The authors acknowledge Salzgitter Flachstahl GmbH, especially Dr. Stefan Mütze, for providing the 34MnB5 material and acknowledge AWEBA Werkzeugbau GmbH Aue, especially Dipl.-Ing Thomas Aurich, for providing the cutting tool.

High-temperature Properties of Hot-Work Tool Steel (AISI H13) Deposited via Direct Energy Deposition

Jongyoun Son, Gwangyong Shin, Kiyong Lee, Chang-hwan Choi, and Dosik Shim

Abstract Conventionally, a defected tool steel is repaired by welding; however, that repairing does not guarantee homogeneous quality. Hence, this study focused on developing an alternative repairing technique using direct energy deposition (DED) to minimize thermal effects. To investigate a repair using powder-fed DED, AISI H13 powder was deposited onto heat-treated JIS SKD61. The deposited material was observed through scanning electron microscopy and its hardness and tensile properties were determined at 25, 200, 400, 600, and 800 °C. The deposited material showed different hardness distributions in its cross-section, revealing four representative features. The deposited region and dilution showed a hardness of 620 HV with a dendrite structure. The hardness decreased to 490 HV in the heat-affected zone, revealing a tempered martensite structure; however, it increased to 550 HV in the substrate and revealed a typical martensite structure. At all temperatures, the deposited material showed higher hardness than heat-treated SKD61. Moreover, it showed higher ultimate tensile strength and lower elongation in the deposited region. Therefore, this result indicates that without pre- or post-heat treatment, a part repaired using powder-fed DED can have better mechanical properties than heat-treated SKD61.

1 Introduction

AISI H13 and JIS SKD61 steels have been typically used as hot-work tool steels, and they are heat-treated with quenching and tempering to improve their mechanical properties at high temperatures [1]. In hot-working processes, such as die-casting and forging, tool steels are exposed to severe working conditions at high temperatures; they are partially heated by molten or heated metals and cooled using lubricants or coolants repeatedly. These partial heating and cooling processes generate thermal stresses inside of these hot-work tool steels, and repeated thermal stresses eventually cause fatigue cracks and fractures on the inside and outside of the tool steels [2–4].

Defective tool steels with cracks and fractures resulting from thermal fatigue are typically repaired by welding; the repairing processes involve pre-machining, buildup welding, post-machining, and finishing [5]. However, this conventional repairing method with welding causes excessive thermal effects, which partially anneal the heat-treated tool steel; these repairing techniques are performed manually by skilled craftsmen based on their individual experiences. Therefore, repairing tool steels using these conventional methods cannot guarantee a homogeneous quality in the repaired part.

Therefore, this study focused on developing an alternative repairing technique using direct energy deposition (DED). DED is a three-dimensional (3D) printing technique; it deposits metal powder or wire using a laser heat source. DED can minimize the thermal effects on metal depositions, and it enables the fabrication of various shapes with precise control. To investigate repairing with DED, AISI H13 powder was deposited onto heat-treated JIS SKD61, and the deposited material was observed via scanning electron microscopy (SEM); its hardness and tensile properties were examined at 25, 200, 400, 600, and 800 °C.

2 Materials and Methods

2.1 Description of the Powder-Fed DED Process

The DED process is typically used with metals and metal-based hybrids in the form of either wire or powder [6]. Figure 1 shows a schematic of the powder-fed DED process. In this process, a substrate is irradiated by a laser beam, and a pool of molten material forms on the substrate. Then, a metal powder is simultaneously fed into the melting pool, and a single bead is deposited onto the substrate. Another bead is deposited right next to the deposited single bead; these two deposited beads overlap one another. In this way, a single layer is formed with depositions of multiple beads and is then built upon additively, layer-by-layer, to deposit multiple layers.

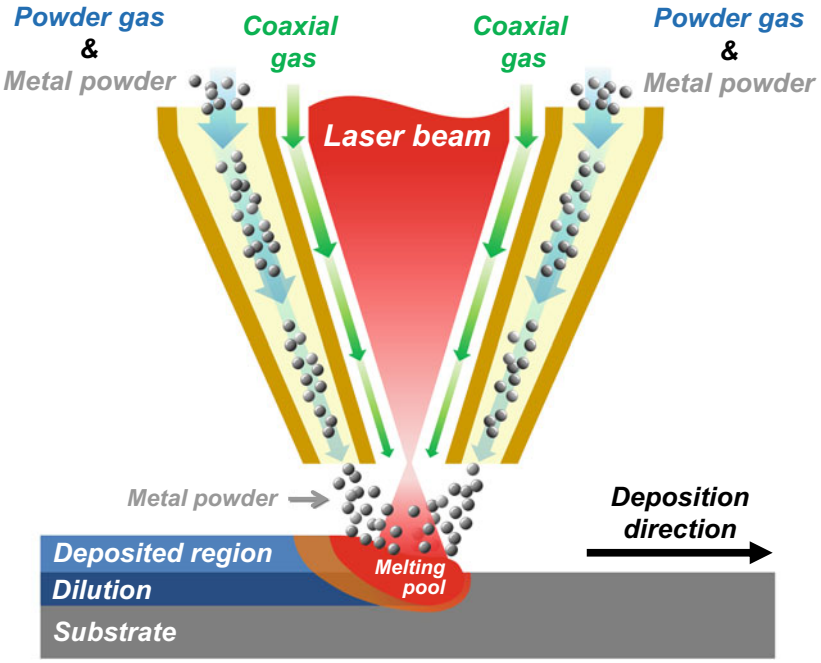

Fig. 1 Schematic of metal deposition in the DED process. (Color figure online)

2.2 Powder-Fed DED Equipment

Figure 2 shows the direct metal tooling (DMT) MX3 laser-assisted metal deposition device. This device is mainly composed of a 4 kW CO_2 laser, metal powder feeder, and computer numerical controller, and it uses argon (Ar) as the carrier gas for injecting the metal powder and as the shielding gas to protect the workpiece from oxidation. The processing head of this device is equipped with a laser beam nozzle, powder feeding nozzles, and charge-coupled device cameras. During depositions, the working distance between the processing head and the workpiece is set at 9 mm to focus the laser spot having a diameter of 1 mm on the workpiece.

2.3 Deposition Process and Experimental Specimen Preparation

Table 1 presents the chemical composition of the AISI H13 powder and the JIS SKD61 material. The H13 powder comprises spherical particles with diameters of 50–160 μm, as shown in Fig. 3. This H13 powder was used as the deposition material, and heat-treated SKD61 was used as the substrate with dimensions of 100

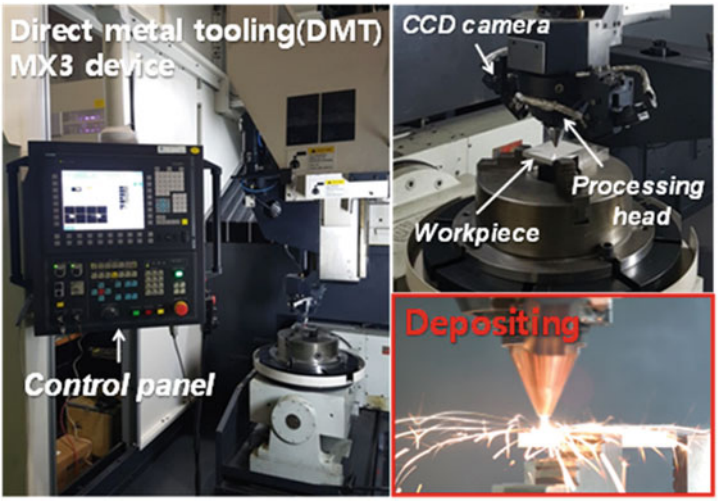

Fig. 2 Direct metal tooling (DMT) MX3 device. (Color figure online)

Table 1 Chemical composition of the JIS SKD61 and AISI H13 materials [wt%]

Material	C	Si	Mn	P	S	Mo	Cr	Ni	N	V	O

× 50 × 15 mm^3. Every single bead was deposited and overlapped in a width of 0.5 mm with the adjacent bead. Multiple layers were deposited through back-and-forth motion in a fixed direction following a "zigzag" path, and the final heights of the deposited layers were 2 mm (0.25 mm for each layer) for tensile test specimens and 3.25 mm for hardness test specimens. The specimens for the tensile tests were cut such that they included the substrate and deposited region using wire electrical discharge machining, as shown in Fig. 4a; the tensile test specimens were cut to have equal thicknesses of the substrate and deposited regions, as shown in Fig. 3b. Table 2 lists the main parameters used in the powder-fed DED process for the deposition of the H13 material; these parameters were established through preliminary experiments.

Coaxial gas (fixed)	8.0 L/min

3 Results and Discussion

3.1 Microstructures of the Deposited Material

To observe the microstructure of the deposited material, it was cut perpendicular to the substrate and the deposited region. The cut samples were etched using Nital etchant (nitric acid 5% + ethyl alcohol 95%) and then observed via field emission SEM (FE-SEM; JEOL Ltd., 7100f).

Figure 5 shows SEM micrographs of the cross-section of the deposited material. The deposited material reveals four different features; these features are identified in the deposited region, dilution, heat-affected zone (HAZ), and substrate. Figures 5a and b show the microstructures of the deposited region and dilution, and these revealed typical dendrite structures. During laser irradiation, the H13 powder, having a ferrite phase in its microstructure, reaches the homogeneous austenite temperature (1020 °C) in a short time. Then, if the metal at its austenite temperature cools

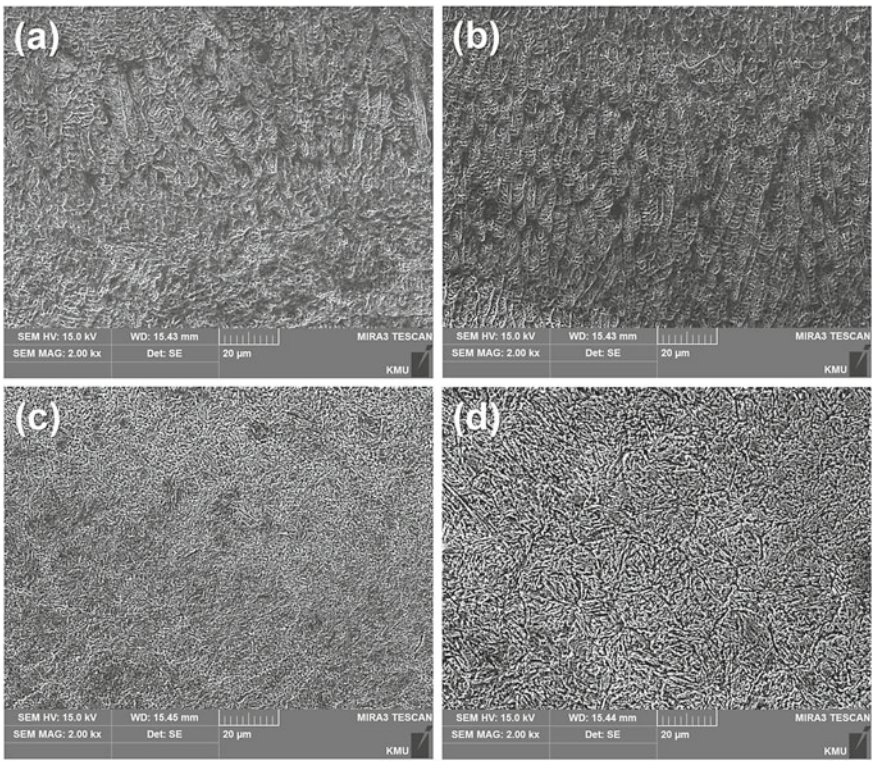

Fig. 5 SEM micrographs showing the microstructures of **a** deposited region, **b** dilution, **c** HAZ, and **d** substrate

rapidly, a martensite phase is formed, and the deposited metal is further strengthened. However, deposited beads or layers overlap previously deposited layers/beads during powder-fed DED, and the temperature in the deposited region remains below the austenite temperature during deposition. Therefore, the deposited region and dilution cannot cool as rapidly as required for full transformation to the martensite phase; this assumes to be the reason for the formation of dendrite structures, partially including martensite phases and retained austenite phases [7–10]. Figures 5c and d, respectively, shows the microstructure of the HAZ and the substrate. The substrate, heat-treated SKD61, shows martensitic phases in its microstructure, typical of a quenched material. However, the HAZ reveals a tempered martensite phase, also called the troostite phase. During metal deposition, the part of the substrate adjacent to the dilution was heated by the deposited metal, instantly molten and solidified, and the temperature of this heated area was just below the molten temperature. Then, the heated area in the substrate with martensitic phases was tempered; these martensitic phases were assumed to be transformed to troostite phases.

3.2 Hardness Tests

Depth-sensing microindentation tests were performed using AAV-502 tester to examine the hardness distribution of the deposited material and Nikon QM-2 tester to evaluate its hardness at elevated temperatures. In the hardness tests, a load of 1.9 N was applied to each indentation for 15 s, in accordance with the ASTM E384 test method.

To examine the hardness distribution of the deposited H13 on heat-treated SKD61, the deposited specimens were linearly indented in a 4 mm length along the deposition direction on the substrate; the indentations were evenly spaced at 100 μm intervals from the center of the previous indentation. This test was repeated thrice. Figure 6 shows the hardness distribution on the cross-section of the deposited material. The hardness of the substrate, typically quenched and tempered SKD61, was around 550 HV. The hardness decreased to around 490 HV in the HAZ, but it increased to around 620 HV in the deposited region and dilution. These results indicate that different microstructures of the deposited material led to different hardness values. The substrate revealed a typical martensite structure with fine carbides, but The HAZ had tempered martensite structures. From this result, it is assumed that the martensite structure in the substrate was partially tempered by the thermal effect from the laser irradiation, and this partial tempering resulted in slightly decreased hardness in the HAZ. The deposited region and the dilution, rapidly molten and solidified by the laser, had a dendrite structure with extremely fine carbides [5]; this structure and finer carbides than in the other areas were considered to lead to the highest hardness. Figure 7 shows the hardness graphs of the heat-treated SKD61 and the deposited H13 on heat-treated SKD61 at 25, 200, 400, 600, and 800 °C. The hardness of the deposited H13 was identical to that of the heat-treated SKD61 at 25 and 200 °C. The deposited H13 revealed slightly lower hardness than that of the heat-treated SKD61

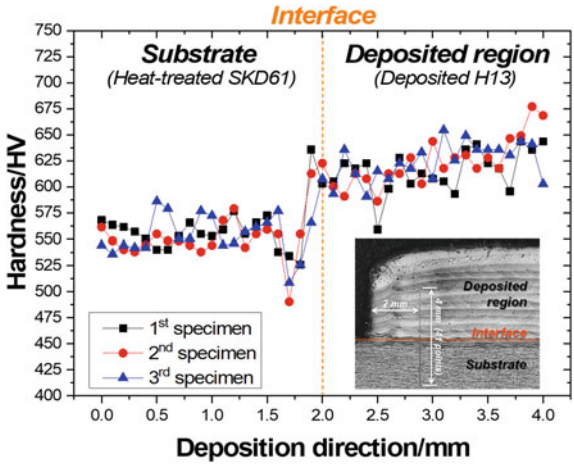

Fig. 6 Hardness distributions on the cross-section of deposited H13 on heat-treated SKD61. (Color figure online)

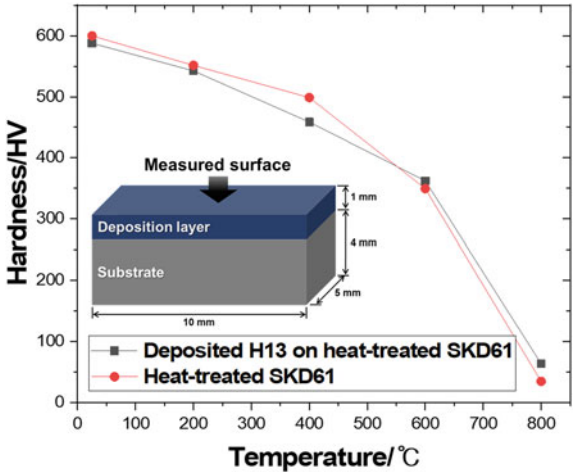

Fig. 7 Hardness of deposited H13 on heat-treated SKD61 and heat-treated SKD61 at 25, 200, 400, 600, and 800 °C. (Color figure online)

at 400 °C; however, the deposited H13 showed a higher hardness at 600 and 800 °C. These results reveal that the hardness of the deposited H13 had an identical tendency as the heat-treated SKD61 at elevated temperatures.

3.3 Tensile Tests

The tensile tests at elevated temperatures were performed using MTS 810 material testing machine and a heating furnace, as shown in Fig. 8. Tensile specimens were placed in the heating furnace at the tested temperatures for 20 min to stabilize their

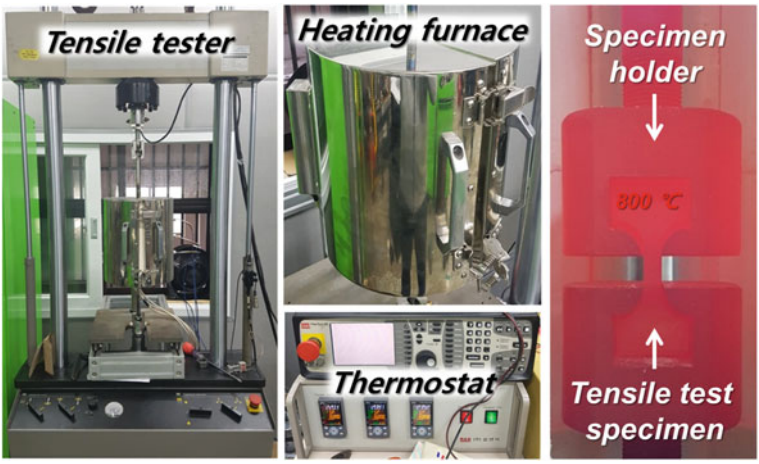

Fig. 8 Tensile testing machine and heating furnace. (Color figure online)

thermal expansion. The tests were conducted with a cross-head speed of 2 mm/min at 25, 200, 400, 600, and 800 °C and repeated thrice.

Figures 9 and 10 represent the true stress and true strain curves for the deposited H13 on heat-treated SKD61 and the heat-treated SKD61 at various temperatures. At 25 °C, the heat-treated SKD61 showed ultimate tensile strength (UTS) of 1798 MPa and elongation of 0.175, and the deposited H13 showed UTS of 1807 MPa and elongation of 0.085. These UTS values of both specimens were very close; however, the deposited H13 had two times lower elongation than that of the heat-treated SKD61. At 200, 400, 600, and 800 °C, the deposited H13 shows higher UTS values than the heat-treated SKD61. However, elongations of the deposited H13 were all lower than those observed on heat-treated SKD61 at elevated temperatures; these differences of

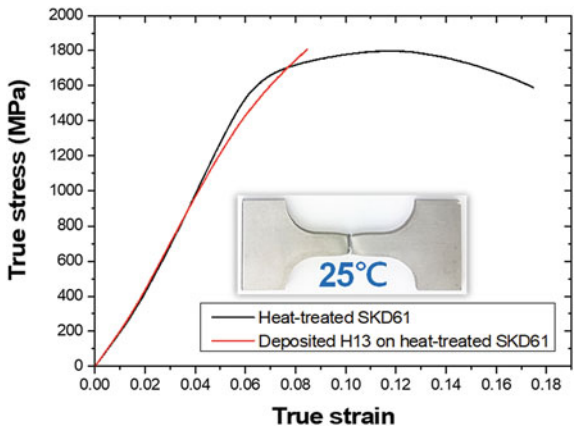

Fig. 9 True stress and true strain curves for deposited H13 on heat-treated SKD61 and heat-treated SKD61 at 25 °C. (Color figure online)

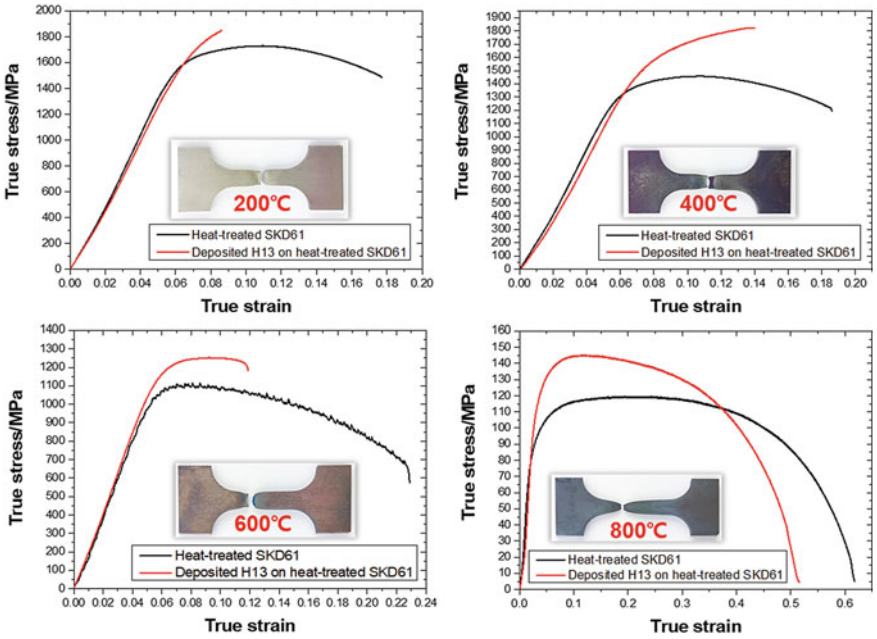

Fig. 10 True stress and true strain curves for deposited H13 on heat-treated SKD61 and heat-treated SKD61 at 200, 400, 600, and 800 °C. (Color figure online)

the elongations between the deposited H13 and the heat-treated SKD61 decreased with an increase in temperature.

In addition, fractured surfaces of the tensile tested specimens were observed via FE-SEM to examine the failure modes of the specimens. Figure 11 shows SEM images of fractured planes at 600 °C. The heat-treated SKD61 showed a dimple-like appearance typical of ductile fractures. In contrast, the deposited H13 on heat-treated SKD61 showed a flat-fractured surface, indicating a brittle fracture, in the deposited region and a dimple-like appearance on the substrate area. Moreover, the fractured area of the heat-treated SKD61 was smaller than that of the deposited H13 on heat-treated SKD61. This result indicates that the deposited H13 had not shrunk much in the plastic deformation by tensile loading, and then it was suddenly fractured. Thus, it is assumed that the brittleness of the deposited materials led to the lower elongations of the deposited H13 as compared with the heat-treated SKD61, as shown in Fig. 10.

4 Conclusions

In this study, H13 powder was deposited onto heat-treated SKD61, and the microstructures of the deposited material were observed via FE-SEM; its mechanical properties were evaluated by performing hardness and tensile tests at elevated

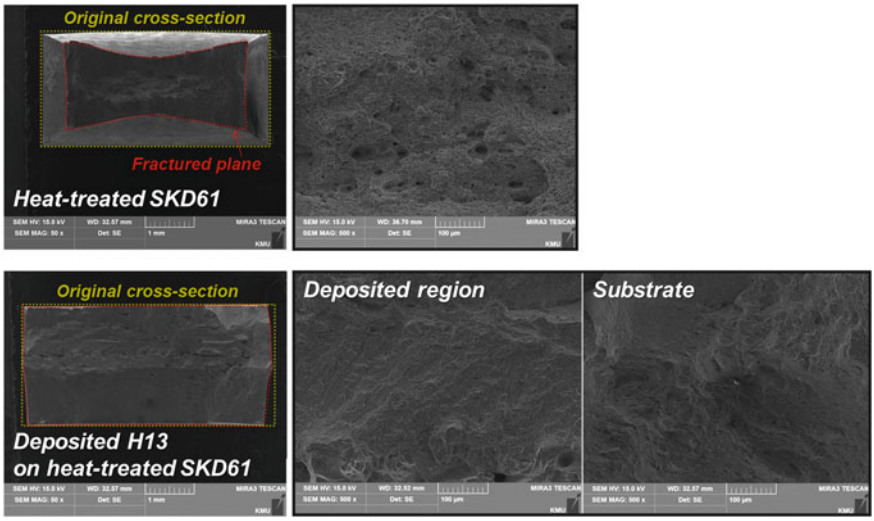

Fig. 11 SEM micrographs of fracture planes of tensile tested specimens at 600 °C. (Color figure online)

temperatures to demonstrate the effectiveness of powder-fed DED as an alternative repairing method.

The deposited material exhibited four representative features with different microstructures, and these different microstructures led to different hardness values. The deposited region and the dilution had the highest hardness; their hardness was higher than that of the heat-treated SKD61, a conventional hot-working tool steel. However, the hardness of HAZ was lower than the heat-treated SKD61, but the substrate showed identical hardness as compared with that of the heat-treated SKD61. The deposited H13 on heat-treated SKD61 had similar hardness as compared to the heat-treated SKD61 at high temperatures. Tensile test results showed that the deposited H13 on heat-treated SKD61 and the heat-treated SKD61 had similar UTS values at 25 °C, whereas the elongation of the deposited H13 was two times lower. At 200, 400, 600, and 800 °C, the deposited H13 on heat-treated SKD61 showed higher UTS values than the heat-treated SKD61. The elongations of the deposited H13 were lower than those of the heat-treated SKD61 at all temperatures; however, differences in the elongations between the deposited H13 and the heat-treated SKD61 rather decreased with an increase in temperature. Therefore, the heat-treated SKD61 can be repaired using powder-fed DED without pre- or post-heat treatments, and moreover, the repaired parts could have improved mechanical properties compared with typical hot-work tool steels. This study only examined fundamental properties of the deposited H13; however, there are other crucial properties, such as wear and thermal fatigue life. In the future, further crucial properties of deposited materials will be investigated.

The Study of Energy Absorption of Dual-Material Tailored Plane Strain Sheet

Pengfei Ying, Yulong Ge, and Yong Xia

Abstract In this paper, new tailored structure design has come forward based on ultra-high-strength steel (UHSS) material properties. The analytical model and finite element model are established in this study for the investigation of the energy absorption properties of the plane strain sheet. Via analytical calculation, the mechanical characters of the tailored sheet are deeply investigated before fracture initiation under extreme conditions. An optimized structure geometry configuration is obtained according to the quantity of structural energy absorption. The promotion of energy absorption of the tailored structure before fracture initiation is not obvious comparing with the pure material ones. In the FE model, the properties of the energy absorption of the tailored sheet after fracture initiation are investigated. Under a designed geometry setting, the energy absorption of the tailored sheet can provide 135% and 77% promotion, respectively, compared with the pure material ones. Besides, the designed configuration can also provide a good effect of crack inhibition, which shows great potential for further engineer applications.

Keywords Tailored sheet · Plane strain structure · Energy absorption · Analytical model · Finite element model

1 Introduction

The high strength steel is widely applied in the automotive industry [1]. The tensile strength of the UHSS sheet has reached more than 1500 MPa now [2]. The outstanding properties of UHSS have spawned a lot of new design of engineering structures. However, this material has some non-negligible defects compared with conventional steel such as low ductility, brittle failure, etc. [3, 4]. As to fully utilize the UHSS and avoid the defects, the concept of tailored properties structure is becoming more and more popular as different material area function differently in structure [5, 6]. Laser quenching is a technology that is applied for structure manufacturing with

tailor properties [7]. Creating a selected quenched area structure with a homogeneous material distribution originally, the structure performance is decided by the configuration of the quenched area and the mechanical properties of the material before and after processing.

In the study of structure mechanics, the energy absorption structures are widely investigated. As the macro structure is an integration of material elements, each element is under a uniform loading state approximately [6]. It is reasonable to improve the structural performance by adjusting the performance of each material element delicately, and this is also the fundamental idea of the tailored structure. As the plane strain condition is one of the basic loading conditions for functional structure [8], this study is focusing on a plane strain sheet with a combination of different material properties. The material properties are based on the simplified ideal elasto-plastic model obtained from tension tests of 22MnB5 [7]. The maximum effective plastic strain criterion for fracture is applied. An analytical model is established to analyze material behavior before the fracture initiation. An FE model is also established to provide more analysis of the fracture characters of the structure.

2 The Analytical Modeling of Tailored Sheet

We will focus on the energy absorption ability of the sheet with different geometry configurations under certain material properties. The analytical model will be used for the optimization of the energy absorption of the tailored plane strain sheet and the investigation of the mechanical properties of the sheet. With the help of this model, some interesting numerical phenomena are revealed under several cases for the understanding of the structural response. Besides, the basic configuration of the sheet is a stripy distribution along the loading direction.

2.1 Hypotheses and Methodology

Considering a simple configuration of tailored dual-material sheet with manufacture possible, Figure 1a shows the stripy distribution of the conceptual design. As to fully understand the mechanical performance of this structure, more constraints are required, and mechanical hypotheses are also required for the analytical modeling.

Three hypotheses and two boundary conditions are made for the analytical model:

Hypotheses:

1. The material follows the ideal elasto-plastic material behavior hypothesis
2. The material follows the maximum effective plastic strain fracture criterion
3. The structure is a thin wall structure: no stress distribution in the out-of-plane direction

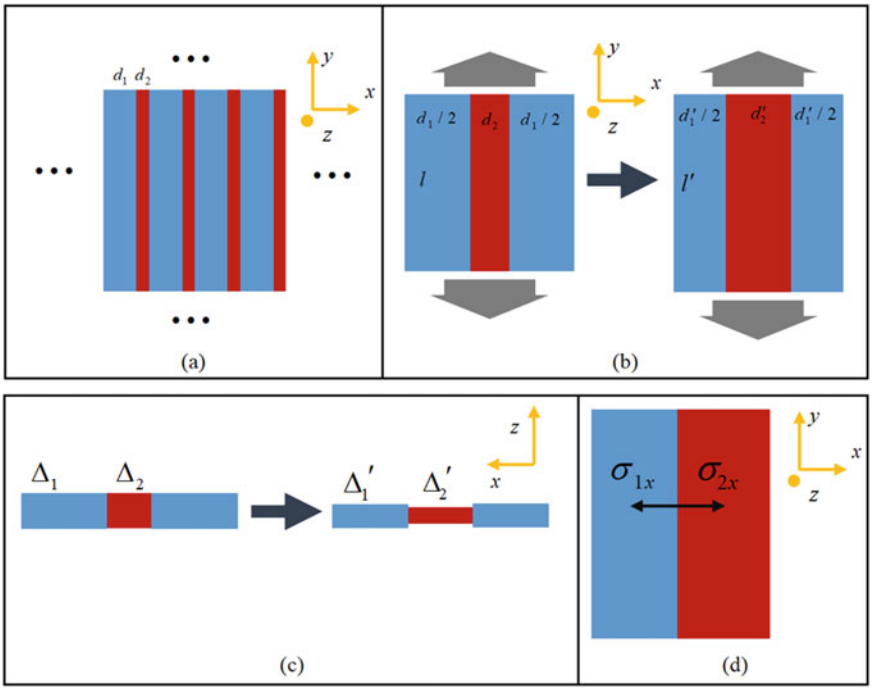

Fig. 1 The schematic of (**a**) the infinite periodic condition sheet, (**b**) the extracted analysis area and the deformation process, (**c**) the cross-section, and (**d**) the interface balance condition. (Color figure online)

Boundary conditions:

1. The sheet is under an infinite periodic boundary condition
2. Longitudinal quasi-static loading only

Figure 1a demonstrates the structure configuration. The materials are distributed in a stripy arrangement. According to the infinite boundary condition, we can use the area showed in Fig. 1b as a representative element of the plane strain sheet. The blue color blocks represent the soft material (low yield stress), the red blocks represent the strong material (high yield stress). Assuming the initial width of soft material and strong material is d_1, d_2 separately, the initial length of the representative element is l.

Because of the length limitation of this paper, some mathematical derivation of the iteration process and the energy accumulation process are omitted. Here only provides the basic functions for the calculation and the flow chart is shown for explanation.

As to interpret the possibility of the mathematical operation of this model, all the unknowns and the numbers of the equations are listed below. Necessary explanations are provided.

According to the structural symmetry, we may assume each material bar has the uniform distribution of stress and strain, which provide 24 unknowns for stress and strain during the loading process. However, the boundary condition 2 eliminates the shear stress and the shear strain, which reduced the unknowns to 12.

The relations between geometry and strain can be established as follow:

$$\varepsilon_{1x} = \ln\left(d_1'/d_1\right) \tag{1}$$

$$\varepsilon_{2x} = \ln\left(d_2'/d_2\right) \tag{2}$$

$$d_1 + d_2 = d_1' + d_2' \tag{3}$$

$$\varepsilon_{1y} = \varepsilon_{2y} = \ln\left(l'/l\right). \tag{4}$$

The strain along the out-of-plane direction of the two materials is different during the deformation as shown in Fig. 1c, which will influence the consistency of the material near the interface. However, hypothesis 3 provides two more equations for the deformation incompatibility.

$$\sigma_{1z} = 0 \tag{5}$$

$$\sigma_{2z} = 0. \tag{6}$$

Besides, the balance condition requires the stress along the x-direction should be the same for both materials as shown in Fig. 1d:

$$\sigma_{1x} = \sigma_{2x}. \tag{7}$$

For constitutive relations, the ideal elasto-plastic model is applied. The fracture criterion is based on the maximum effective plastic strain theory. Thus, there are three strain unknowns and three stress unknowns for two materials separately, and the material widths are also unknowns. Thus, 14 unknowns are included in this problem. Equations 1–7 provide eight independent equations. The constitutive relations always provide three independent equations for each material. Thus, 14 independent equations will be provided for the 14 unknowns theoretically.

According to the previous studies [5, 7], the yield stress of the original material of 22MnB5 is approximate to 500 MPa, and the yield stress of the material after laser quenching is approximate to 1500 MPa. The fracture strain is close to 0.3 for the original material, but the fracture strain of 22MnB5 after processing is approximate 0.1.

Thus, a simplified stress–strain curve is obtained as shown in Fig. 2. As materials perform differently in elastic stage and plastic stage, we divide the loading into three stages for ease of calculation:

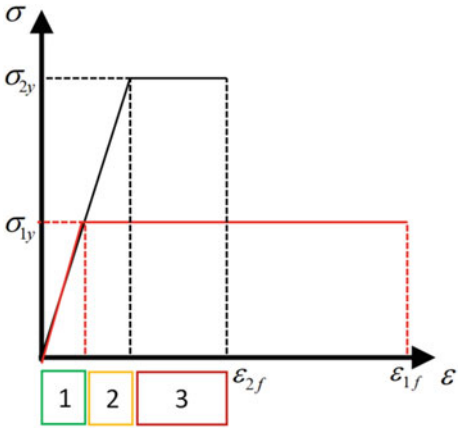

Fig. 2 The schematic of materials response and the loading stage classification. (Color figure online)

Stage 1: Both materials stay in the elastic state.

Stage 2: The soft material yields and the strong material stays in the elastic state.

Stage 3: Both materials yield.

Stage 1 provides explicit expressions for materials response, but the numerical iteration calculation is required for stage 2 and stage 3. The mathematical process of the derivation is omitted for stage 1 and all the calculation processes of stage 2 and stage 3 are omitted.

Here provides the expression of the final states of the materials at stage 1:

$$\ln\left(\frac{l_{ter}}{l}\right) = \frac{1-\upsilon^2}{E}\sqrt{\frac{1}{\upsilon^2-\upsilon+1}}\sigma_{1y} \tag{8}$$

where *lter* is the terminal length of the sheet of stage 1, σ_{1y} is the yield stress of soft material under uniaxial tension test. Besides, the energy absorption of stage 1 can be written as follow:

$$E_{Stageone} = e^{-\frac{\upsilon}{1-\upsilon}}\Delta\frac{E}{1-\upsilon^2}(d_1+d_2)l^2\left[\frac{1}{2}\left(\frac{l_{ter}}{l}\right)^2\ln\left(\frac{l_{ter}}{l}\right)-\frac{1}{4}\left(\frac{l_{ter}}{l}\right)^2+\frac{1}{4}\right]. \tag{9}$$

For stage 2 and stage 3, as the explicit form is unobtainable, a system of numerical explicit iteration equations is derived for the calculation. Figure 3 shows the flow chart of the subroutine of all the calculations included in this model.

Besides, the energy accumulation of stage 2 and stage 3 is based on the increments of input energy:

$$dE_{stagetwo\&three} = \left(\Delta_1'\sigma_{1y}d_1' + \Delta_2'\sigma_{2y}d_2'\right)dl'. \tag{10}$$

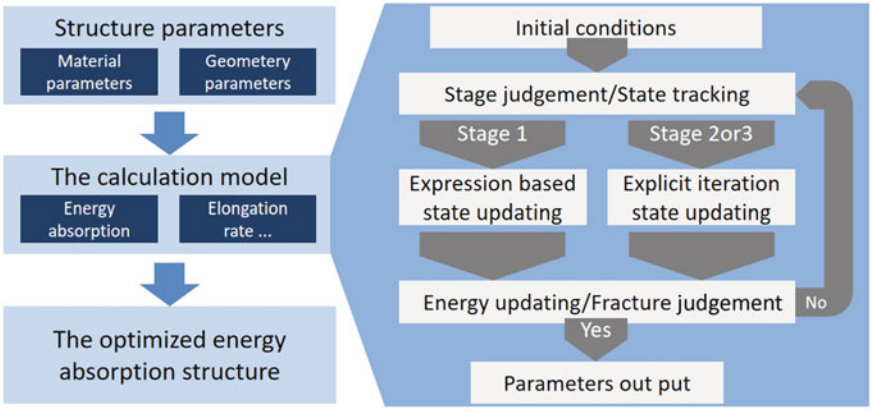

Fig. 3 The flow charts of the analytical model. (Color figure online)

2.2 Results Analysis and Discussion

2.2.1 The Description of Analytical Model

Three groups of system input parameters are variable for the initial conditions: the calculation-related parameters, the geometry-related parameters, and the material property-related parameters. As the influence of the geometry configuration is discussed in this paper, the geometry-related parameter is the default. The calculation-related parameter is also default as the convergence test will be conducted later.

All the parameters contained in this model are shown in Table 1. Some values of parameters are also provided. The unit is ignored as the analytical model is a

Table 1 The initial value and the name for all the parameters contained in this calculation mode

Calculation related	Material properties related	Geometry related
Step length: $dl' = default$	Young's modulus: $E = 210$	The length of the structure: $l = 1$
	Poisson ratio: $\upsilon = 0.3$	Thickness of the structure: $\Delta = 0.01$
	Yield stress of soft material: $\sigma_{1y} = 0.5$	Width of the soft material: $d_1 =$ default
	Yield stress of strong material: $\sigma_{2y} = 1.5$	Width of the strong material: $d_2 = 1 - d_1$
	Fracture strain of soft material: $\varepsilon_{1fra} = 0.3$	
	Fracture strain of strong material: $\varepsilon_{2fra} = 0.1$	

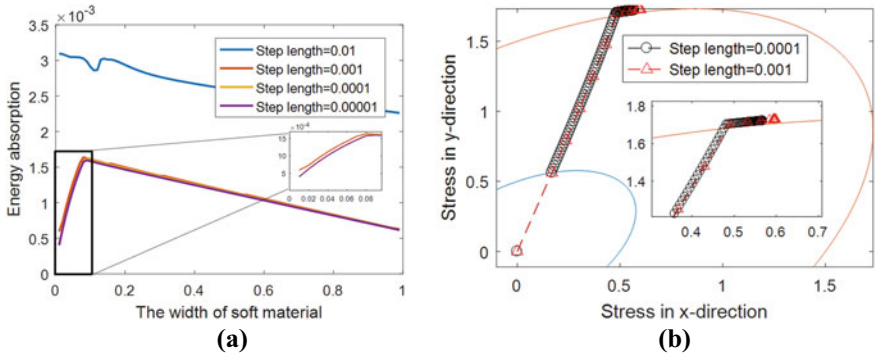

Fig. 4 **a** The convergence results with different calculation step length (**b**) the trace of the stress of strong material with different calculation step length ($d_1 = 0.05$). (Color figure online)

normalized system. The calculation results contained below are a direct calculation output from the parameters inputted as shown in Table 1.

To decide a proper step length for the calculation, a convergence test was conducted. The curve of energy absorption versus width of soft material is shown in Fig. 4a and the curve of y strain vs x strain for strong materials is shown in Fig. 4b, in which the fine lines represent the yield surface of materials.

For explanation, Fig. 4b is the state tracking of the calculation process with certain structure geometry, $d_1 = 0.05$.

The commercial software MATLAB is applied for the establishment of this model. According to the results in Fig. 4a, the energy absorption curve can reach convergence with step length lower than 0.001. The results of time length lower than 0.0001 are overlapped with each other. However, this step length may cause a sparse calculation point distribution of material stress in stage 2 and stage 3. Thus, the step length of 0.0001 is chosen for calculation step length for the balance of computational accuracy and computational economy.

2.2.2 The Results of the Analytical Model

Figure 5a shows the calculation results. The dashed line (fracture index) represents the fracture type. The upper platform represents the fracture initiation of strong material, and the lower platform represents the fracture initiation of soft material.

According to the results shown in Fig. 5a, an optimized geometry configuration is obtained to maximize energy absorption. The width ratio of d_1:d_2 is approximate to 1:9. Under this setting, the tailored plane strain sheet can provide the highest energy absorption before the fracture initiation.

As to deeply understand the material behavior, the extreme conditions (extreme material distribution) are calculated and their state tracking results are shown in Fig. 6. The extreme conditions are defined as follow:

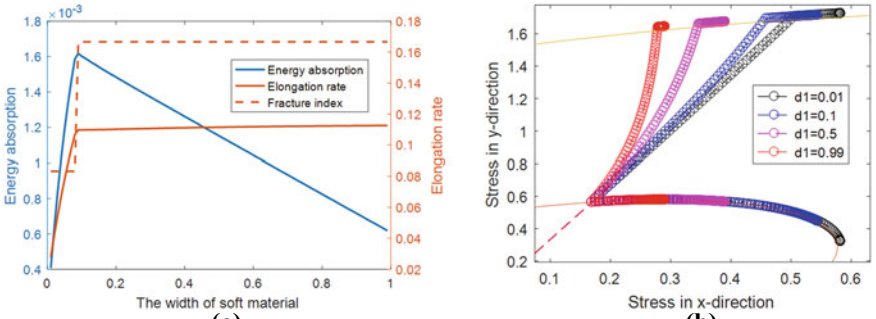

Fig. 5 (**a**) The structural properties of different structure geometry (**b**) the stress states of two materials under different structure geometry. (Color figure online)

Limit on the left: $d_1$close to 0.
Limit on the right: $d_1$close to 1.

The energy absorption and elongation of the pure material sheet and the optimized sheet are shown in Table 2. The effective stiffness is defined as the ratio of energy absorption and elongation. The unit is ignored too.

2.2.3 Results Analysis and Discussion

Under plane strain condition, as the transverse deformation of sheet is limited, the summation of transverse deformation for each periodic structural unit is equal to zero.

Figure 5a is an exhibition of the final calculation results. According to the fracture index, the fracture transformation decides the local maximum of the energy absorption. Figure 5b shows the stress in the *x*-direction is gradually released with the increase of the width of the soft material. As the response of the sheet is influenced by many parameters, it is necessary to fully analyze the material behavior during the deformation process. The extreme conditions are very helpful for the understanding of material behavior. Here provide results' analysis:

Considering the limit on the left. In Fig. 6a, b, the strong material shows a stable stress response under tension. However, the fracture strain of structure is positively correlated with the width of soft material. According to Fig. 6c, d, the first principle strain is in the transverse direction, which contributes to the effective plastic strain significantly and leads to the earlier fracture. If the width of soft material is close to zero, the limit of elongation is close to 0.01, where the strong material just steps into stage 3. It means that within the decrease of the width of soft material, the plastic stage of strong material will be shortened. What is more, the plane strain loading condition for pure material sheet provides a stress ratio (Stress-*y* vs. stress-*x*) of 2. But for the tailored sheet at the limit on the left, the soft boundary can release the transverse constraint a lot and the stress ratio is decreased to 3.

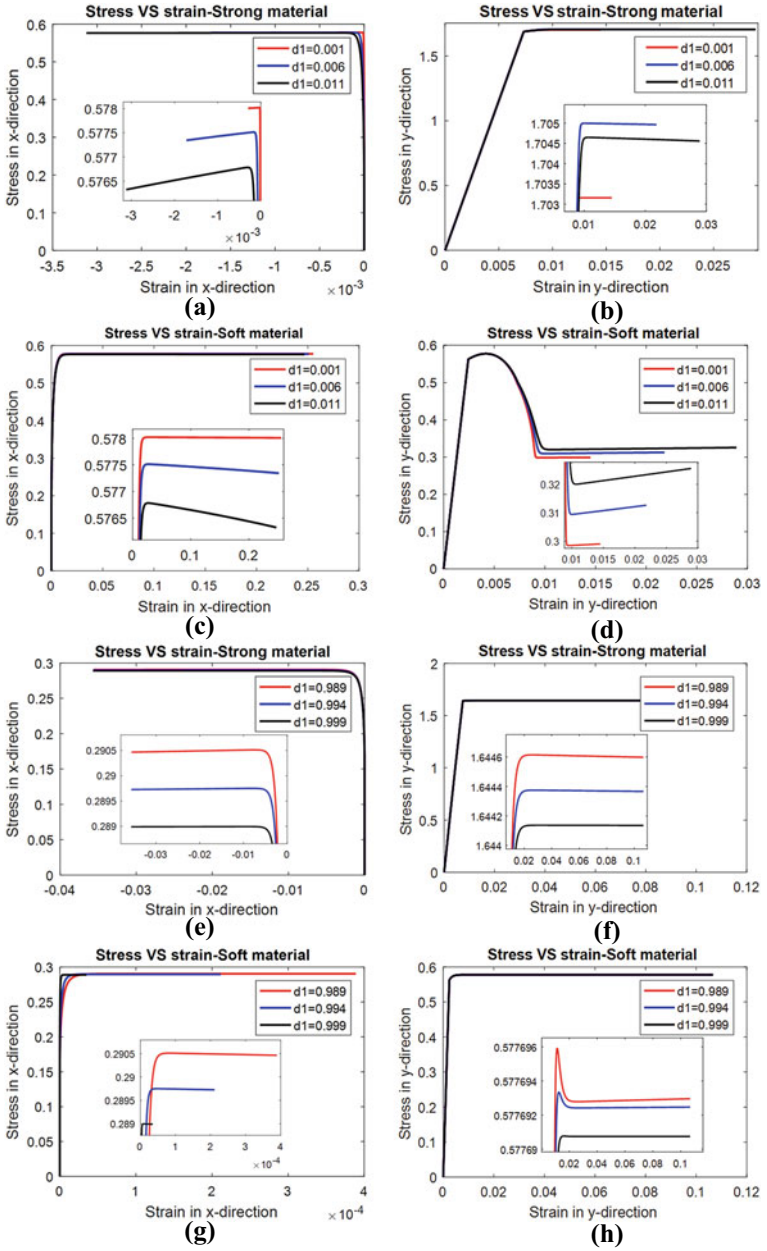

Fig. 6 The stress–strain state tracking of the material under extreme geometry setting. (Color figure online)

Table 2 The energy absorption of sheet with different combination of materials

Type of sheet	Strong material	Soft material	Tailored
Energy absorption	1.57e−3	1.55e−3	1.62e−3
Elongation	0.10	0.30	0.11
Effective stiffness	1.57e−2	5.17e−3	1.47e−2

Considering the limit on the right. At this condition, the fracture is dominated by strong material. Figure 6e, f, h shows the stable stress and strain response of both materials. It means that the strong material cannot be stretched by the soft material transversely, the fracture is mainly caused by the longitudinal deformation. Besides, as the strain of strong material in the x-direction has no correlation with the material width, and the strain of soft material in the x-direction is approximate to 0, it provides a plane strain condition for soft material and the stress ratio is equal to 2.

The analysis of extreme conditions not only provides a deeper understanding of the mechanical behavior of the tailored sheet but also represents engineering practices. For example, if an area for plane strain loading is expected for quenching strengthening, but a narrow area is left without quenching because of the machining precision, the sheet strength may become much lower than expected. The strong doping material could also influence the elongation of the sheet then cause performance reduction.

As shown in Table 2, the increment of energy absorption of the tailored sheet is not significant. However, two advantages are expected. First, comparing with the soft sheet, the stiffness of the tailored sheet is higher, which is good for the resistance of constant loading. Second, the high-strength steel has a bad fracture character as the fracture process is very brittle. However, the design of the striped structure can inhibit the propagation of brittle crack and improve energy absorption after fracture initiation. This phenomenon will be discussed later in detail.

3 The FE Model of Tailored Sheet

3.1 Description of FE Model

The previous model investigated the energy absorption of the tailored sheet before fracture and the material performance inside the sheet. The results show that the energy absorption for this optimized tailored sheet has not been promoted obviously comparing with the pure material ones. The energy absorption after fracture initiation was also ignored.

As the structure behavior after fracture initiation is too complex to establish an analytical model, the commercial software is used for the investigation of the crack propagation and the energy absorption after fracture initiation.

The software LS-DYNA was applied for this study. The keyword *MAT_PIECESISE_LINEAR_PLASTICITY is used for the ideal elasto-plastic

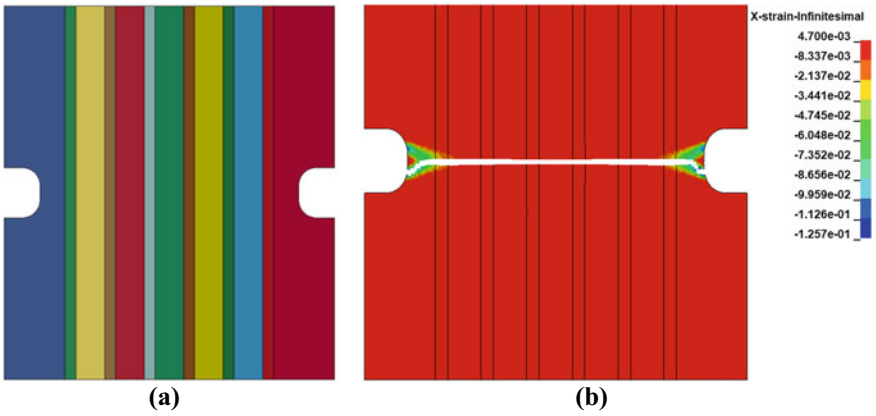

Fig. 7 **a** The FE model of the plane strain sheet **b** the transverse strain contour of soft material sheet. (Color figure online)

material model. The effective plastic strain at failure is 0.1 and 0.3 respectively. The yield stresses are 500 MPa and 1500 MPa separately. The thickness of this model is 1 mm. The soft material is 3 mm wide and the strong material is 8 mm wide. The geometry of the structure is shown in Fig. 7a. The element size is 0.5 mm.

As to verify the plane strain loading condition, the post-fracture contour for the transverse strain of soft material is shown in Fig. 7b. A similar distribution can be observed in the strong material sheet. Those simulations are quasi-static simulations as scarcely kinematic energy was observed in the data of energy output.

3.2 Results and Discussion

Fig. 8a–c represents the fracture morphology and the effective plastic strain contour of the different sheet.

Considering the pure material sheets, according to Fig. 8a, b, the fracture is a highly localized behavior. With the crack propagation, the geometry near the crack may experience a large distortion. What is worse, the strong material has a high yield stress and low failure plastic strain. Once if the fracture is initiated, the crack propagates at a very fast speed and the structure just lost all the ability of force maintenance.

For the tailored sheet shown in Fig. 8c, a much better energy absorption form is observed. First, according to the contour, the distribution of plastic strain is relatively uniform for most of the material, which is good for the improvement of the structural ability to absorb energy. Second, according to Fig. 8d, the crack propagates in a very limited way in this structure. The crack still propagates very quickly in strong material, but the soft material will stop the crack propagation, which provides a

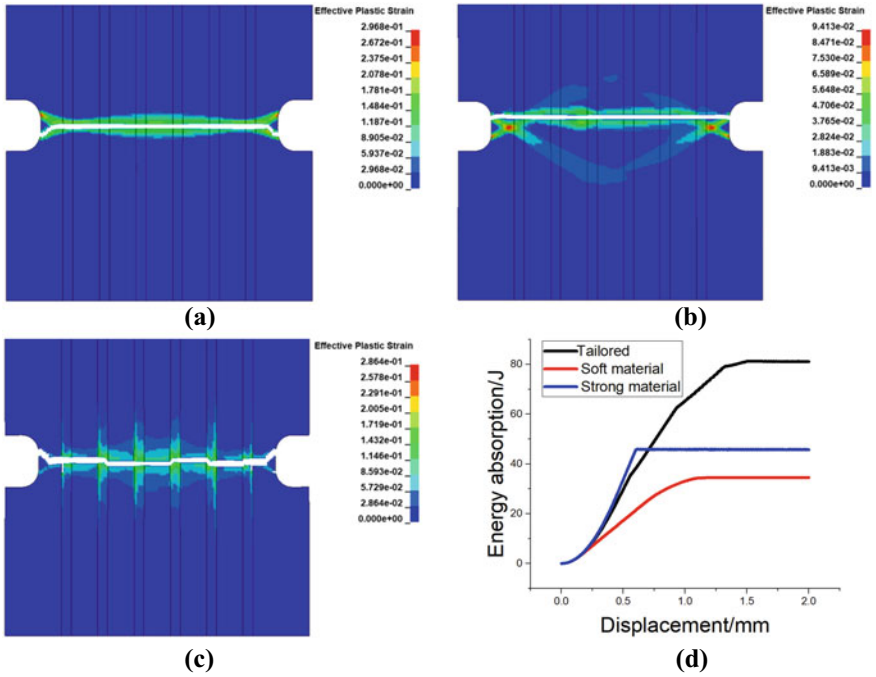

Fig. 8 The fracture morphology and effective plastic strain contour of (**a**) soft material sheet, (**b**) strong material sheet, (**c**) tailored sheet and (**d**) the curves of energy absorption versus displacement of different sheets. (Color figure online)

continuous energy absorption mode. Third, the crack shape of the tailored sheet is not a straight line but a z shape curve. This is also good for energy absorption as the crack length is prolonged.

According to the previous study and the fracture behavior of pure material sheets, two main reasons are provided for the promotion of the tailored sheet.

Firstly, the combination of heterogeneous materials can release the transverse constraint of the strong material from plane strain condition and fully utilize the elongation of the soft material by stretch the soft material in the transverse direction. If the constraints of the local structure were weakened, the far-field deformation is allowed to contribute to the energy absorption process. As the soft material cannot provide enough stress to resist the deformation of strong material, it has to deform transversely. Combining with the character of high failure plastic strain, the soft material can also provide a great deal of energy absorption.

Second, the local crack energy liberation will be absorbed by the soft material. As the failure of elements will cause a local energy liberation (elastic energy stored in local structure), and this energy liberation will cause a shack loading to the elements nearby and cause structure vibration for a short time. For soft material, this energy shock is not high enough to destroy the near crack field elements during this short

moment. Thus, a ductile fracture mode is observed. For strong material, the elastic energy stored in the element is high enough to destroy those near field elements and cause a continuous fracture mode. Thus, a brittle fracture mode is observed. For the tailored sheet, the local energy shock of the crack tip is not high enough to break the layer of soft material. Thus, crack propagation is inhibited.

To summarize, the designed tailored plane strain sheet performs much better than pure material sheets for energy absorption and provides a better ability to crack inhibition. FE results show great potential for the further application of this tailored structure. What is more, the laser quenching technology makes the manufacture of tailored sheets possible.

4 Conclusions

This study focuses on the energy absorption of tailored plane strain sheets before fracture initiation and after fracture initiation. Here shows the main conclusions of this study:

An analytical model is established to analyze the characters of the tailored plane strain sheet before the fracture initiation, and the extreme conditions were discussed. According to the material performance under extreme conditions, the soft material is under a biaxial tension loading condition and the constraints of the strong material are released.

For a certain material combination, an optimized geometry configuration is obtained before the fracture initiation. The width ratio of soft material vs strong material equal to 1:9 is suggested for the maximization of the energy absorption of the tailored sheet. But the optimized tailored sheet has similar energy absorption ability with the pure material ones.

The FE analysis is conducted based on a certain sheet geometry. Under this arrangement, the tailored sheet performs a promotion at the ability of energy absorption compared with the pure material sheets, the promotions are approximate to 135% for soft material sheet and 77% for strong material sheet, and a good form of crack inhibition is obtained according to this design.

Cyclic Hardening/Softening of a TRIP Duplex Stainless Steel

Miao Jin, Lei Chen, Zongyuan Zou, Shuo Hao, Qun Li, and Shiyan Zhao

Abstract Recently, a series of duplex stainless steels (DSSs) have been developed by replacing Ni–Mo with Mn–N, which makes DSS more economical and produces TRIP effect with higher strength and plasticity. In this work, the mechanical properties of a TRIP-assisted DSS under monotonic and cyclic loading conditions were studied and the micro-structure under cyclic loading was analyzed by transmission electron microscopy (TEM). The test steel exhibits enhanced mechanical properties and a typical "three-stages" hardening characteristic due to TRIP effect under monotonic loading conditions. Cyclic hardening/softening characteristics of the test steel are affected by strain amplitude and the number of cycles. With smaller strain amplitude, cyclic hardening occurs first, and then shifts to cyclic softening and gradually trends to stabilization. With larger strain amplitude, after initial rapidly cyclic hardening, the test steel still changes to cyclic softening, however, no stabilization occurs until failure. The dislocation walls in ferrite during cyclic deformation are responsible for the overall cyclic softening of the test steel; While austenite produces ε martensite transformation at larger strain amplitude, which suppresses the cyclic softening, so that with an increase in strain amplitude the cyclic softening rate increases rapidly, followed by a slow increase and a final decrease.

1 Introduction

Duplex stainless steels have a ferrite–austenite duplex structure. In recent years, in order to further reduce the cost of raw materials, researchers developed high-performance, economical duplex stainless steel with transformation induced plasticity (TRIP) effect [1, 2] through Mn–N alloying instead of expensive Ni, to replace the traditional Ni–Mo duplex stainless steel and Cr–Ni austenitic stainless steel to manufacture structural parts in petrochemical, marine, and other engineering fields. The mechanical properties of material under cyclic loading are different from that under monotonic loading. Existing research [3–5] shows that in duplex stainless steel the mechanical properties of the two phases are different, so that the deformation is not harmonious, which causes the cyclic deformation of the mechanical response to be in multiple stages, and the dominant deformation mechanism is obviously different in different stages; however, the study object is traditional Ni–Mo type duplex stainless steel. For duplex steel with metastable austenite, most studies focused on its mechanical properties under monotonic loading [6, 7], and corresponding TRIP microscopic mechanism [8, 9]. However, deformation-induced martensite transformation also occurs during cyclic loading in metastable austenite [10, 11], thus may affect cyclic hardening and softening. However, the cyclic deformation behavior of this TRIP duplex stainless steel has been reported rarely, and its mechanical response characteristics under cyclic loading conditions are still unclear. Therefore, this work takes a kind of duplex stainless steel with metastable austenite as the research object and focuses on analyzing and discussing its mechanical properties and microscopic mechanism during cyclic loading.

2 Materials and Experimental Methods

In this paper, the test duplex stainless steel was smelted by 20 kg vacuum induction furnace. After vacuum extraction, nitrogen with high purity was added to refine the ingot. The main chemical components are shown in Table 1. After casting, the ingot was then heated at 1150 °C and kept warm before forging, then was forged into a square billet of 20 mm × 20 mm. The forged billet was heated at 1050 °C and kept warm for 30 min, then cooled with oil. The original microstructure of the test steel is shown in Fig. 1, it can be seen that the two phases along the forging direction show a strip uniform distribution(the light color is austenitic γ, the dark color is ferritic α), and the ratio of the two phases is V_γ:$V_\alpha \approx 47$:53. The austenite is the hard phase

Table 1 Chemical composition of test steel (mass fraction wt%)

C	Si	Mn	Cr	Ni	N	Mo	Fe
0.04	1.6	2.9	19.6	2.0	0.2	0.1	bal

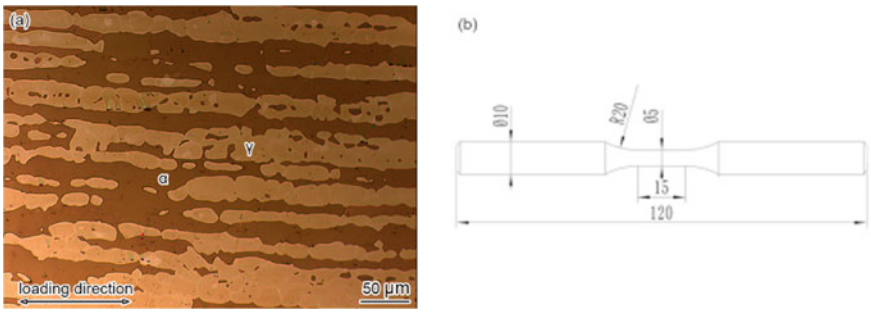

Fig. 1 Metallographic microscopic image (**a**) and sample schematic (**b**). (Color figure online)

with a hardness of about 272Hv, and the ferrite is the soft phase with a hardness of about 260Hv.

The tensile test and cyclic loading test were conducted on Instron 8801 hydraulic servo fatigue test machine at room temperature, with a strain rate of 0.002 S^{-1}, and the loading direction is parallel to forging direction. The samples meet the requirements of ISO 26077-2010 international standard, and the sample size is shown in Fig. 1b. The strain amplitudes of cyclic loading tests are 0.3%, 0.7%, 0.8%, and 1.0%, respectively.

Transmission electron microscopy (TEM) was used to observe the microscopic characteristics of the samples after cyclic loading. The samples were cut along the axis of the round rod in the gage section, polished to 30 um, and then be thinned with the TenuPol-5 electro polisher at room temperature. The electrolyte is perchlorate alcohol solution with 7% volume fraction and the voltage was 20 V. TEM analysis was performed on JEM-2010 transmission electron microscopy, and the operating voltage was 20 kV.

3 Results and Discussion

3.1 Mechanical Properties of Monotonic Loading

Figure 2 shows the engineering stress–strain curve (Fig. 2a) and the true stress–true strain and work-hardening curve (Fig. 2b) for the monotonic loading of the test steel. As can be seen from Fig. 2a, the steel has good mechanical properties, with yield strength of 517 MPa, tensile strength of 883 MPa, fracture elongation rate of 87.2%, and the product of strength and ductility of 77GPa%. When the engineering strain exceeds 20% (the true strain is about 0.18), the engineering stress increases rapidly again, and the engineering stress–strain curve is rough "S" shape. With the progress of deformation, work hardening rate first decreases, then increases to the peak, and finally decreases until fracture, showing the "three-stages" hardening characteristic,

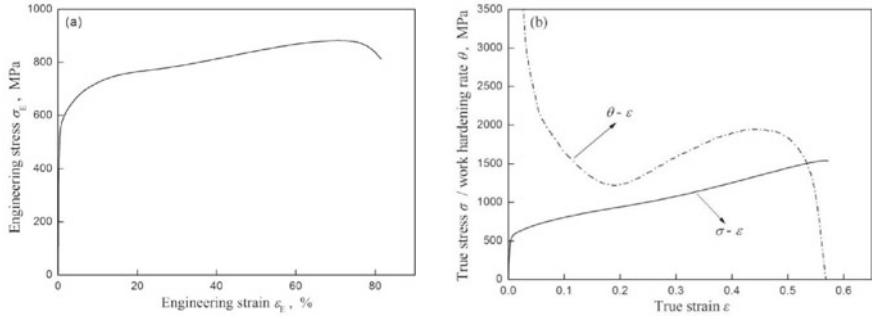

Fig. 2 Engineering stress–strain curve (**a**) and true stress–true strain and work hardening curve (**b**) of the test steel during monotonic loading

as shown in Fig. 2b. Therefore, it can be inferred that the austenitic phase in the duplex stainless steel produces deformation-induced martensitic phase transformation during the deformation process, resulting in the TRIP effect, which significantly improved the strength and plasticity [6].

3.2 Hysteresis Loops Under Cyclic Loading

Figure 3 shows the variation of hysteresis loop with cycles (N) of the cyclic loading tests. As can be seen, at the initial stage of cycles ($N < 5$) under different strain amplitudes, the loop becomes sharper from flat, meanwhile, the peak stress $\sigma_{\max}$ and the valley stress $\sigma_{\min}$ both increase rapidly with the increase of cycles, which shows the characteristics of initial cyclic hardening, however, with the continued increase of cycles, the loop flattens again from sharp, and the $\sigma_{\max}$ and $\sigma_{\min}$ begin to decrease slowly, the test steel shows the characteristics of subsequent cyclic softening. For the cyclic softening, with a smaller strain amplitude ($\varepsilon_a = 0.3\%$), the softening characteristic gradually slows down with cycles until stabilization and $\sigma_{\max}$ and $\sigma_{\min}$ remain unchanged, and the loop shape does not change significantly. However, when the strain amplitude is larger ($\varepsilon_a = 1.0\%$), the peak stress and the valley stress continue to decrease until failure.

3.3 Cyclic Hardening/softening

The cyclic stress response curve can show the variation of the stress amplitude with cycles under certain strain amplitudes, which is commonly used to describe the cyclic deformation of the material, the cyclic stress response curve of the tested steel is shown in Fig. 4. The cyclic hardening/softening characteristics of the test steel are affected by the amplitudes and cycles. With smaller strain amplitudes, the test steel

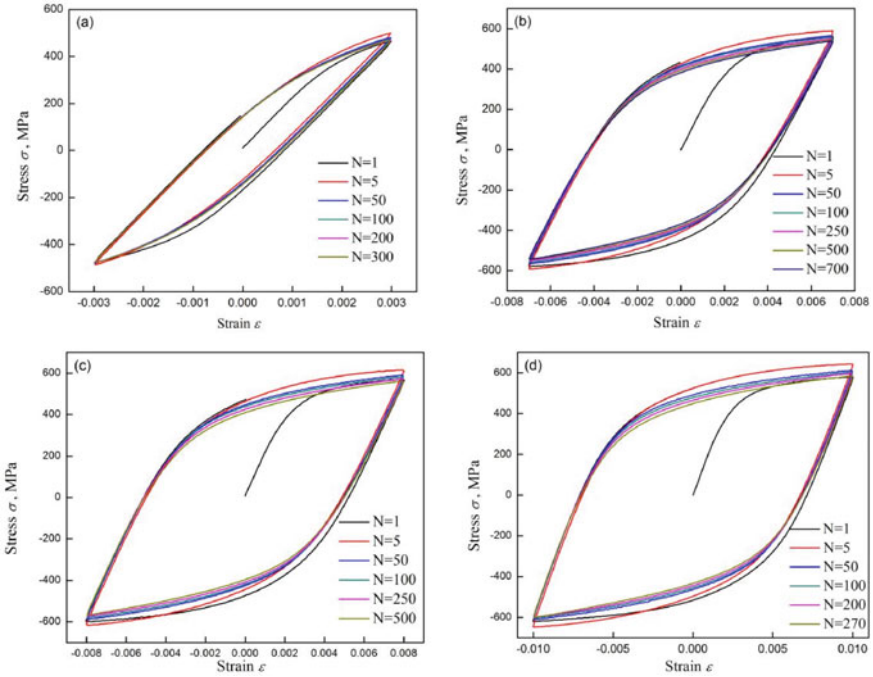

Fig. 3 Hysteresis loops with the number of cycles (**a**) $\varepsilon_a = 0.3\%$ (**b**) $\varepsilon_a = 0.7\%$ (**c**) $\varepsilon_a = 0.8\%$ (**d**) $\varepsilon_a = 1.0\%$. (Color figure online)

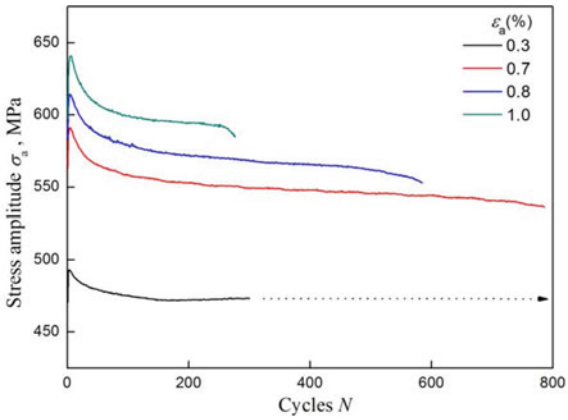

Fig. 4 Cyclic stress response curves. (Color figure online)

is cyclic hardening with initial cycles ($N < 5$), then turns to be cyclic softening and gradually stabilization, however, under larger strain amplitudes, after rapid initial cyclic hardening ($N < 5$), the test steel turns to be cyclic softening, and fails to reach cyclic stabilization until failure.

In order to further evaluate the influence of strain amplitude on the cyclic softening of the test steel, the cyclic softening rate parameter is introduced, and its expression is:

$$\delta = \frac{\sigma_{\max} - \sigma_s}{\sigma_{\max}}. \tag{1}$$

In the formula, δ is the cyclic softening rate, $\sigma_{\max}$ and σ_s are the maximum stress amplitude and stable stress amplitude (or half-life stress amplitude) in the cyclic loadings respectively.

The cyclic softening rate of the test steel under different plastic strain amplitudes is shown in Fig. 5, the corresponding relationship between strain amplitudes and plastic strain amplitudes is shown in Table 2. As can be seen from Fig. 5, the cyclic softening rate of the test steel increases rapidly with the increase in the plastic strain amplitude under smaller strain amplitude ($\varepsilon_{ap} < 0.42\%$), then within a certain range of plastic strain amplitude ($\varepsilon_{ap} = 0.42$–0.51%), the softening rate increases at a slower rate, and after exceeding a certain strain amplitude ($\varepsilon_{ap} > 0.51\%$), the softening rate decreases. The comparative analysis shows that the plastic strain amplitude is within the range of 0–0.6%, with an increase in plastic strain amplitude, the cyclic softening rate of duplex stainless steel increases first and then decreases. Figure 6 is the TEM image of the test steel after more than 700 cycles with strain amplitude

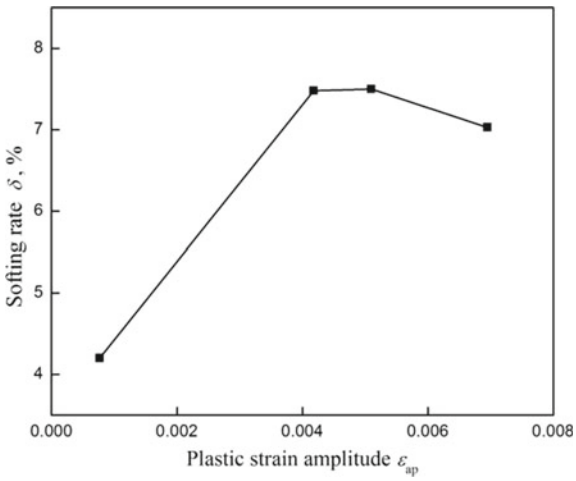

Fig. 5 Cyclic softening parameter δ as a function of the plastic strain amplitude

Note ε_a—strain amplitude, ε_{ap}—plastic strain amplitude

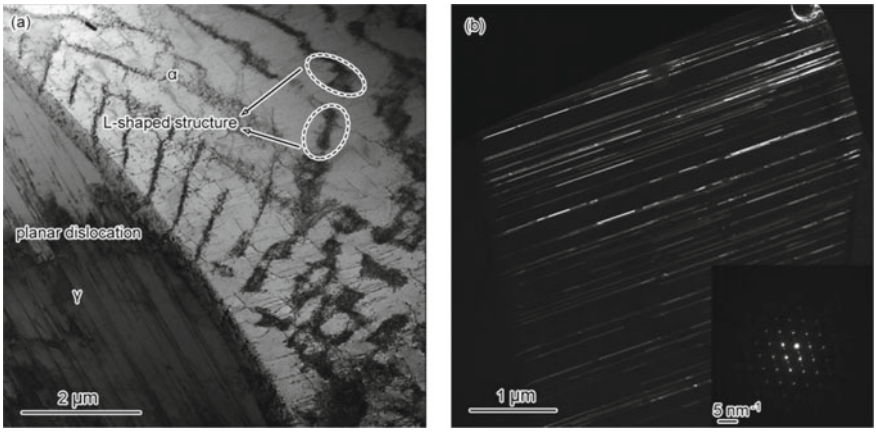

Fig. 6 Typical microstructure observed by transmission electron microscopy after more than 700 cycles ($\varepsilon_a = 0.7\%$). **a** Spatial dislocation structure in ferrite phase and planar dislocation structure in austenite phase (bright field), **b** ε martensite phase in austenite phase (dark field)

$\varepsilon_a = 0.7\%(\varepsilon_{ap} = 0.42\%)$. According to Fig. 6a, the ferrite phase is a spatial dislocation structure with high dislocation density. There are not only long dislocation walls that are nearly parallel to each other but also short dislocation walls that are perpendicular to each other, locally formed "L" structure or maze structure. The microscopic characteristics indicate the ferrite slips along two slip systems during cyclic deformation, which is the embodiment of cyclic plastic strain localization. The formation of such low energy dislocation structures as dislocation wall and dislocation cell in ferrite phase is the main reason for cyclic softening of duplex stainless steel [4]. Compared with ferrite, the cyclic deformation mechanism of austenitic phase is mainly planar dislocation structure [12]. It is worth noting that in the austenitic phase, the deformation band structure across the whole austenitic grain is distributed in parallel. Combined with the dark field image of Fig. 6b, it can be seen that the deformation bandwidth is between 30 and 60 nm, and the diffraction pattern indicates that it is an ε martensite with dense hexagonal structure, which indicates that the austenite in the test steel has cyclic deformation inducing martensite transformation under this deformation condition. Research has shown that the ε martensite during the deformation of metastable austenite could hinder the dislocation movement and strengthen it [11]. Therefore, although the deformation mechanism of austenitic phase is still dominated by plane dislocation slip, the occurrence of ε martensite would result in hardening of austenitic phase in some extent, although it is not enough to cause the overall cyclic hardening, it inhibits the cyclic softening, then slows down and even reduce the cyclic softening rate with an increase in strain amplitude (as shown in Fig. 5).

4 Conclusion

Under monotonic loading, the test steel shows the characteristics of three-stages hardening with obvious TRIP effect, which makes its mechanical properties excellent, the fracture elongation rate is up to 87.2%, the tensile strength is up to 883 MPa, and the product of strength and ductility is up to 77GPa%.

The cyclic hardening/softening characteristics of the test steel are sensitive to strain amplitude and cycles. Under the smaller strain amplitude, it shows cyclic hardening by initial circles ($N < 5$), then severely cyclic softening and gradually stabilization. However, in the case of larger strain amplitude, after the initial rapid cyclic hardening ($N < 5$), continuous cyclic softening is followed, and cyclic stabilization is not reached until failure.

Different forms of dislocation wall forming in ferrite phase during cyclic deformation are the main reasons for the overall cyclic softening. The austenite undergoes deformation-induced martensite transformation, which inhibits the macroscopic cyclic softening rate of the material, so that the cyclic softening rate of the test steel increased first and then gradually decreased with an increase in plastic strain amplitude.

The Local Strain Evolution for Structured Sheet Metals During Uniaxial Deformation

Evgenia Ermilova, Alexander Nikitin, and Sabine Weiß

Abstract Structured materials can be progressive alternatives to commonly used flat sheets because of their higher bending stiffness and stability compared to flat sheet metals, made of the same alloy. The application of sheet metals requires accurate information regarding their strength and deformation behavior. Such data are not commonly available and have to be measured by specific test setups and implementation of tests. The aim of this work is to obtain new knowledge about deformation mechanisms of structured sheet metals. Structured sheet metals (SSM) made of conventional deep-drawing steel DC04 were investigated by means of tensile tests. The influence of the structure type arrangement on the deformation behavior was analyzed. The evolution of local strains was analyzed by means of strain gauge measurements as well as 3D-displacement measurements with an ARAMIS high-resolution camera system. Local orientation changes in different structural elements were measured using the electron backscatter diffraction technique.

https://doi.org/10.1007/978-3-030-75381-8_143

thus the weight of the entire construction. Structured materials could be a progressive option for construction compared to widely used non-structured sheet metals, where the price depends directly on the amount of material used [1–5].

In the present work, the material characteristics were determined using a modified tensile test. Usually, sheet metals are tested according to DIN 6892-1 (N), which describes the test procedure as well as the specimen dimensions. However, this standard is deficient for the structural sheet investigation as the width of a single structured element is larger than the recommended specimen width. In addition, it is necessary to reduce the stress during placing of the sample into the test machine and the construction of special clamping systems, adapted to the structure of the respective sheet. The geometric dimensions of the test specimens have to be determined to evaluate the structured sheet metals (SSM) with regard to the single structured elements size.

The main interest of this study is to obtain new knowledge about deformation mechanisms of SSMs by means of an optical system ARAMIS [6], strain gauge measurements, and microstructure analysis of the material.

2 Materials and Methods

In the present work, structured steel sheets made of cold-rolled low carbon steel DC04 (EN steel number 1.0338) [7] were tested in tensile tests. The chemical composition of steel is according to EN 10130: 2006 (N) (Cold rolled low carbon steel flat products for cold forming. Technical delivery conditions) is presented in the Table 1. The sheet metals were structured by means of a hydraulic press. The thickness of the structured sheet metals was 0.5 mm. The depth of the honeycomb structure elements was $s = 3.1$ mm. The microstructure of the base material was fully recrystallized and isotropic. The rolling direction was not noticeable and the tensile strength in longitudinal and transverse direction was similar.

The structure consists of three elements: honeycomb, bridge, and triple point (Fig. 1). Wrench size and other important geometric parameters of each honeycomb are given in Fig. 1 as well.

Since the force is applied in one direction, the direction of the structural elements can have an influence on the mechanical behavior. Thus, sheets with the main structure directions will be investigated in this work with respect to their mechanical properties.

The direction of the structure is determined by the position of the structural element in the center of the specimen. There are three different types of specimen configuration (Fig. 2).

Table 1 Chemical composition of DC04 Steel

Grade	Number	Classification	C (%)	Mn (%)	P (%)	S (%)
DC04	1.0338	Non-alloy quality steel	≥0.08	≥0.40	≥0.03	≥0.03

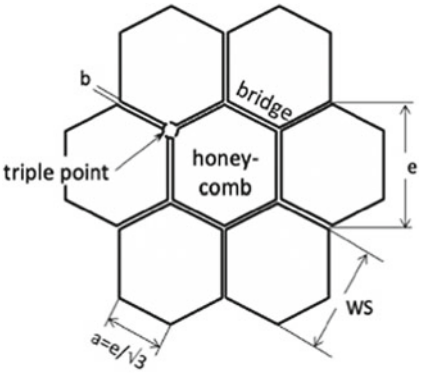

Fig. 1 Structured sheet metal (detail) with three structural elements: honeycomb, bridge, and triple point. Geometric parameters of a honeycomb—wrench size WS = 33 mm, across corners dimension e = 38 mm, edge length a = e/$\sqrt{3} \approx 22$ mm, width of the bridge b = 2 mm, diameter of the triple point = 3.8 mm

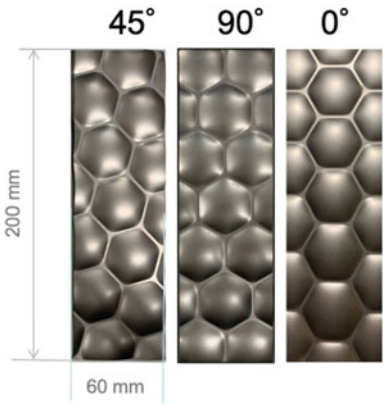

Fig. 2 Tensile test specimens: arrangement of the honeycomb structure. (Color figure online)

In order to study the influence of the structure arrangement on the mechanical properties of the sheet, it is necessary to have at least one entire structural element in the center of the specimen.

Rectangular specimens with a width of 60 mm were tested. The total length of the specimens was 200 mm. All specimens were laser-beam cut.

3 Test Setup Measuring System

The tensile tests were carried out using a universal material testing machine of the company "Walter + Bai ag". Five measurements were performed for each type to ensure reproducibility. By installing the test samples into the tensile test machine, the ends of the samples may be smoothened by the clamps, which can cause unwanted effects on the deformation. To eliminate this influence, existing methods can be adapted by developing special clamping jaws that perfectly fit to each variant of

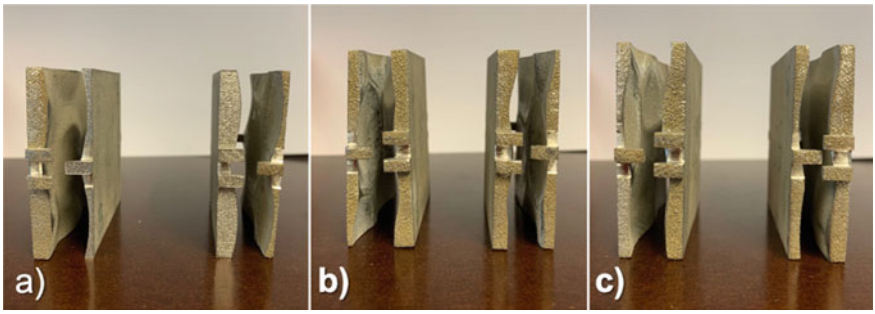

Fig. 3 Clamping jaws: structure directions: **a** 0°, **b** 45°, **c** 90°. (Color figure online)

the structure orientation. These clamping jaws were produced using the 3D Print Technology Selective Laser melting. In Fig. 3, photos of these clamping jaws for different structure directions are presented.

The inner surfaces of the clamping jaws perfectly fit the surfaces of the respective structural elements in this area of the samples. Thus, the honeycomb structure is not smoothened during mounting and further impact on the strain distribution in the gauge length during the test is avoided.

Specimen deformation and elongation were recorded by three different methods: measurement of the global position of the test machine (traverse position) and measurement of the local displacement by the optical ARAMIS system as well as strain gauge measurement.

The ARAMIS system allows to fully define the material and component behavior and to track experiments with high temporal and local resolution. ARAMIS is a non-contact and material independent optical measuring system. A dot pattern is applied onto the previously prepared surface of the sample. Each point is recognized by the high-speed camera and tracked during the entire process. From the measurement data material parameters are calculated, numerical simulations are validated and component motion as well as information are analyzed using the digital image correlation and evaluation software GOM Correlate.

A Strain gauge (SG) is a sensor, whose resistance varies with the applied force. It converts force, pressure, tension, weight, etc., into differences in electrical resistance, which can be measured.

In Fig. 4, the structure of the SG is shown schematically.

Stress and strain are the results if external forces are applied to a stationary object. Stress is defined as the internal resisting forces of the object, and strain is defined as the occurrence of displacement and deformation. SGs are used for the measurement of strain. Strain is referred to as positive if a material is stretched and negative if it is compressed. When a SG is compressed, its electrical resistance decreases and increases when it is stretched, respectively [8].

Linear SGs were used because of the uniaxial load application. For each structure direction, local stress was estimated in three structural elements: honeycomb (HB), triple point (TP), and bridge (B). Regarding the investigated structural element, two

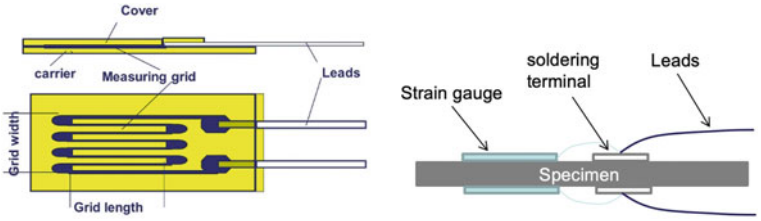

Fig. 4 Schematic illustration of the SG structure [8]. (Color figure online)

types of SGs of suitable length and width were selected. The SG type FLGB-1-11 with gauge length 1 mm and gauge width 1,1 mm was used for HB and SG type FLGB-2-11 with gauge length 2 mm and gauge width 1,5 mm for TP and Bridge element, respectively.

In total six strain gauges are installed on each structural element on both, the upper and the lower side of the structure sheet metals surface (Fig. 5).

For a better understanding of the development of stresses during deformation and the influence of the structure direction, the microstructure was investigated at different phases of the tensile test in different structural elements. The microstructure in the different processed conditions was characterized by ZEISS DSM962 scanning electron microscopy (SEM) using back-scattered electrons. For SEM, a Tescan Mira II XMH microscope and the above-mentioned Zeiss microscope were

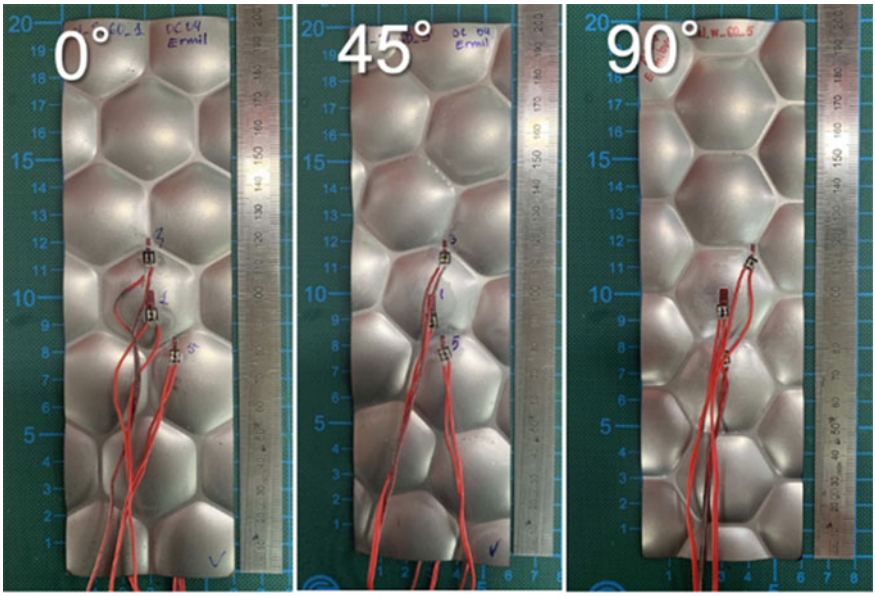

Fig. 5 Samples with strain gauges. (Color figure online)

used. Microstructural samples were taken with an image plane perpendicular to the long axis of the cast piece and parallel to the deformation axis of forged specimens, respectively.

4 Results and Discussion

All tested variations of samples show repeatable deformation behavior. The variance of the stress–strain curve is low. Figure 6 shows representative stress–strain curves for different structure directions: 0°, 45°, and 90°.

The tensile test data are presented in Table 2.

According to Table 2, structure 45° has the highest tensile strength.

Figure 6 shows that the structural direction 90° has significantly lower elongation values. Also as shown in Table 2, this structure has mean values. In structures structural direction 0° and 45° the uniaxial load is distributed more optimally for strength-elongation relationship.

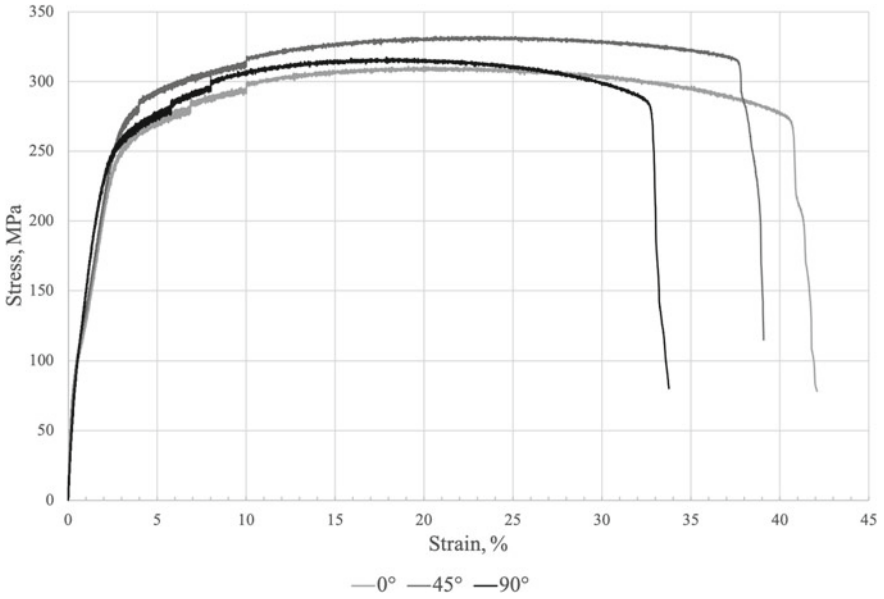

Fig. 6 Stress–strain curves for structure direction: 0°, 45°, and 90°

Table 2 Material properties of SSM

Structure direction	0°	45°	90°
Tensile strength (MPa)	310	332	316
Elongation (%)	38	35	30

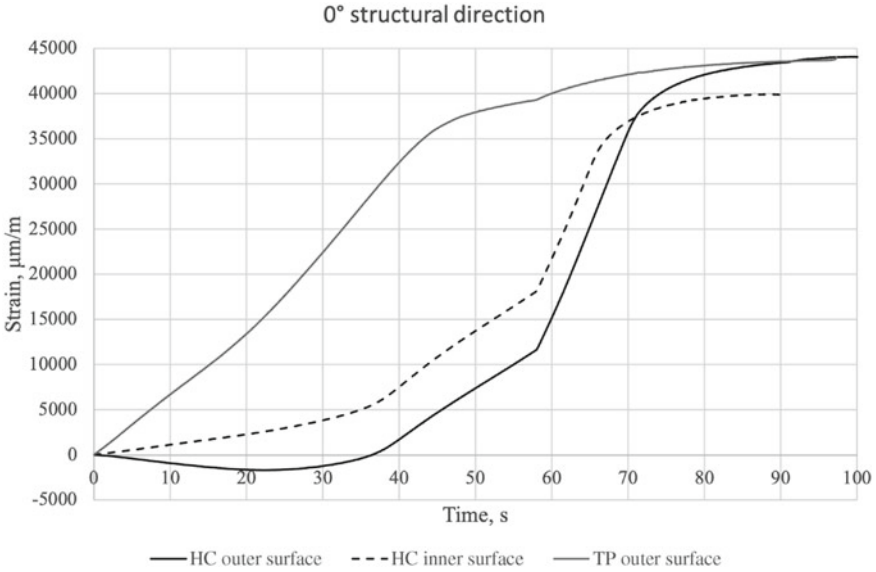

Fig. 7 Strain time histories for structural direction 0°

Strain gauges are very delicate to handle and can be damaged during the experiment, thus, measured values are not available for all structural elements in the following figures (Figs. 7, 8, and 9).

The curves of all three structure variants show that deformation starts in the structural element type bridge. Subsequently, strains arise in structural element type triple point and last, strains increase in the centers of the honeycombs. The differences between the stresses on the upper and lower surface are most pronounced in the centers of the honeycombs for all cases.

Similar results were obtained by the optical measuring system ARAMIS. Representative strain distributions are presented in Fig. 10.

At the beginning of the tensile tests, the deformation distributing over the sample is not evenly but localized in the structural element type bridge. Deformations in horizontal (or partially perpendicular to the direction of load application) bridges are higher than in vertical or inclined ones. Subsequently the structure begins to flatten and finally, maximum deformations are distributed over the entire honeycomb surface. Fracture is observed for all specimens to be parallel to the direction of maximum shear stress across the center of the HC.

The fractures of the samples with structure type 0 degree exclusively have zigzag form. Samples of structure type 45° always show a linear fracture line parallel to the direction of maximum shear stress. In samples with structure type 90° both types of fracture occur.

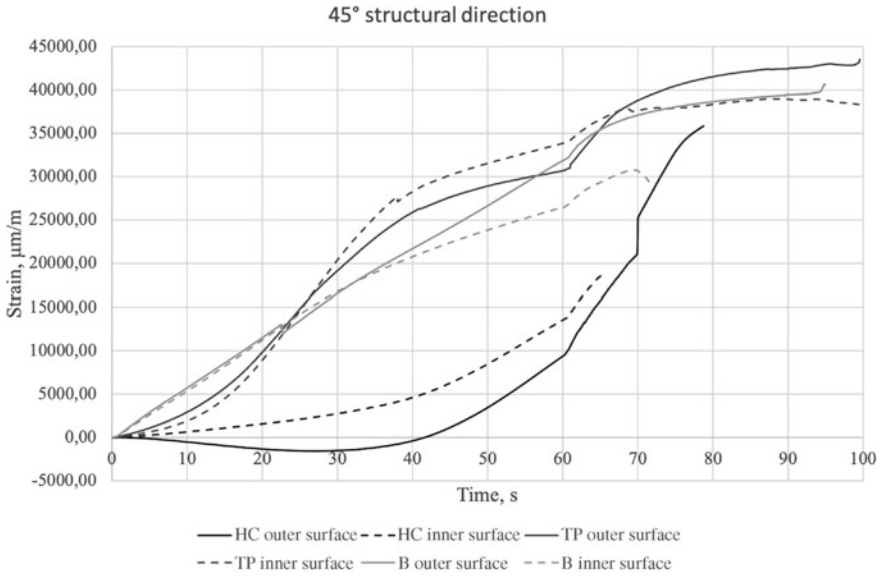

Fig. 8 Strain time histories for structural direction 45°

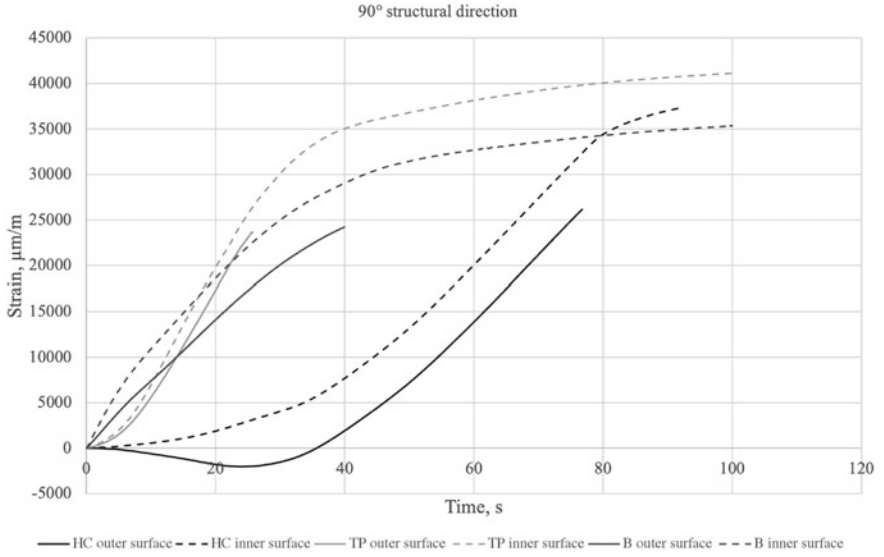

Fig. 9 Strain time histories for structural direction 90°

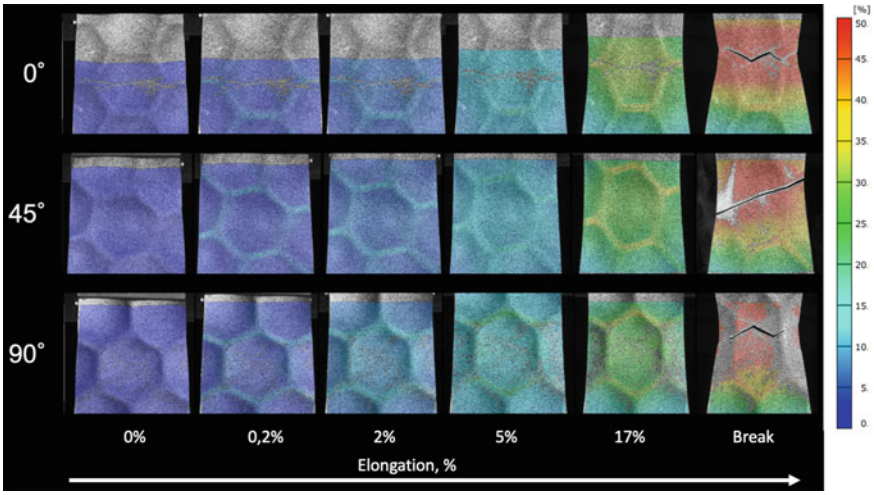

Fig. 10 ARAMIS data during tensile test. (Color figure online)

In order to fully understand the development of strains and the effect of the structure direction during deformation, the initial microstructure in different structural elements was analyzed.

Microstructure analysis in different phases of the tensile test for all three structural elements (honeycomb, triple point and bridge) and each structure direction is planned for future work.

Representative EBSD-mappings (Image Quality, Inverse Pole Figure, and Kernel Average Misorientation) of the respective structural elements are given in Fig. 11.

According to the Image quality mappings, the honeycomb structure seems to be fewest deformed, in the bridges the degree of deformation is slightly higher and the highest degree of deformation with obviously elongated grains was found for the triple points.

The inverse Pole Figure column shows the crystallographic orientation of each grain with respect to the rolling direction. In all cases, no preferred orientation is visible.

The local misorientation with regard to a central measuring point and a number of surrounding neighboring measuring points is determined for the Kernel Average Misorientation Mappings. Local misorientations, as indicators for local deformations, are colored according to the color code in Fig. 11. The blue color for the honeycomb documents very low deformation in this region. Green color coding in the surrounding of the grain boundaries in the structure element bridge indicates that the deformations are located close to the grain boundaries and inside some of the grains.

These grains are marked in pink, turquoise, white, and lilac colors in the IPF mapping corresponding to grains, oriented for single slip. For the structural element triple point highest misorientations become obvious, apparent by a large number

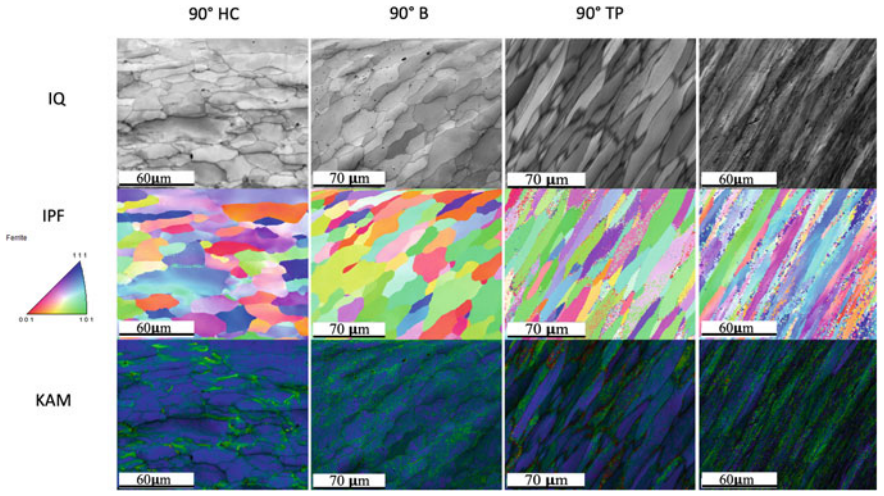

Fig. 11 EBSD-mappings (**I**mage **Q**uality, **I**nverse **P**ole **F**igure and **K**ernel **A**verage **M**isorientation) of honeycomb, bridge and triple point for 90° and triple point for 45° structural orientation. (Color figure online)

of light green colored grains. From these results it can be expected that the initial deformation, induced by the structuring of the samples, will influence the subsequent deformation during the tensile tests. It can be assumed that the earlier increase in strain in the bridges than in the triple points may be due to the lower strain hardening in the bridges during structuring. The deformation behavior of structured sheet metal can be identified as an interaction between local initial deformation and local subsequent deformation, depending on the structure direction.

5 Conclusion

In the present study, the influence of the structure direction on the deformation behavior of structured sheet metals was analyzed using tensile tests. Specimen deformation and elongation were recorded by three different methods: measurement of the global position of the test machine (traverse position) and measurement of the local displacement by the optical measurement system ARAMIS as well as by strain gauge measurements. The ARAMIS system enables visualization of the deformation distribution during the tensile test and numerical models of the deformation process. According to test data, the most optimal structure for strength/elongation relationships for uniaxial load is structural direction 45°. This estimation shows the localization of deformation in bridges perpendicular to the direction of load application. The fracture occurs nearly parallel to the direction of maximum shear and sometimes a zigzag shape of the fracture surface is obtained.

Electron microscopy results reveal initial deformation of the samples due to structuring, strongest within the structural element TP. An influence of this initial deformation on the further deformation behavior could be identified.

Acknowledgments The present work was carried out at the Brandenburg University of Technology (Cottbus). The authors are grateful to the German Federal Ministry of Education and Research (BMBF) for financial support of the project (Grant No. 03IP707).

Development and Implementation of Static Recrystallization Model of 6XXX Aluminum Alloy Using Industrial Experiments

Artem Alimov, Ivan Kniazkin, and Nikolay Biba

Abstract The paper focuses on the development of a static recrystallization model of 6XXX aluminum alloy based on industrial profiles extrusion analysis. 6XXX aluminum alloys are widely used for complex shapes with smooth surfaces suitable for visible architectural applications. Mechanical properties and surface defects, for example, streaking lines, are dependent on the microstructure. Static recrystallization occurs in alloys such as 6XXX due to high stacking fault energy. At the moment, there is no reliable static recrystallization model of 6XXX aluminum alloys found in the literature. In the presented paper, a new approach has been proposed to determine the parameters of Johnson–Mehl–Avrami–Kolmogorov equation. It is based on using strain and temperature history during extrusion of industrial profiles and examining the microstructure in their cross-sections and implementing the inverse analysis approach. The developed model has been verified and used for simulation of the microstructure evolution in industrial extrusion cases and has shown sufficient accuracy.

1 Introduction

Extrusion of aluminum alloys is widely used in the production of bars, tubes, wires as well as for the manufacture of profiles. The cross-section of profiles could be solid, semihollow or hollow and rather complex. Acceptable mechanical properties, low density, good corrosion resistance, and high processability are the reasons for the predominance of aluminum profiles in extrusion [1]. The moderate level of working temperatures of aluminum alloys that is lower than tempering temperature of tool steels allows producing the largely unrestricted shape of the cross-sectional geometry profiles with good precision and high surface quality.

Thermomechanical processing during extrusion and subsequent cooling led to the microstructure evolution of the material. It can involve static recrystallization, dynamic recrystallization (geometric or continuous), grain growth (normal or abnormal), and particle precipitation [2]. The occurrence of each metallurgical process depends on the mode of thermomechanical processing and the chemical composition of the alloy [3, 4]. In materials with high stacking fault energy, such as pure aluminum, low-alloyed aluminum alloys such as 6005, 6060, 6063, etc. dynamic recrystallization does not occur [5]. Static recrystallization occurs in such materials after deformation. In high-alloyed aluminum alloys, such as 7020, 7050, and 7075 that have a lower stacking fault energy, the dynamic recrystallization can occur [6, 7]. The division into two groups of alloys is conditional and a number of alloys are recrystallized both dynamically and statically. Simulation of microstructure evolution is essential for control of mechanical properties and to get high-quality extruded profiles.

The usual way to develop a model of microstructure evolution is to perform a series of laboratory experiments. The most widespread technique is to use a thermomechanical simulator. For example, Yi et al. [7] used Gleblee 1500 to develop a dynamic recrystallization model for 7050 aluminum alloy. Some researchers adopted real processes to perform them in the laboratory. For example, Donati et al. [8] used backward cup extrusion to study the microstructure evolution of 6060 and 6082 aluminum alloys. Segatori et al. [9], Bandini et al. [10], Güzel et al. [11] used laboratory forward extrusion setup to investigate the microstructure evolution during extrusion. Laboratory experiments have some restrictions because, for example, it is impossible to reach the same high strain and strain-rate levels as a real extrusion process. Moreover, it is necessary to make special samples use special testing equipment and so on. Another way is to use industrial experiments. For suppliers of aluminum profiles, it is much easier to use sections of the profiles for the study of microstructure evolution and development of the models. Different models were developed for the simulation of microstructure evolution in metals during thermomechanical processing [12–15].

The aim of the present research is to study a microstructure evolution in extrusion process and to develop a static recrystallization model for 6XXX aluminum alloys where the model parameters can be derived from industrial experients.

2 Materials and Methods

2.1 Materials

The study has been performed using the industrially extruded profile. The chemical composition of studied 6XXX aluminum alloy is presented in Table 1, and it corresponds to the alloy 6005.

The initial microstructure of the billet is presented in Fig. 1. The measured average grain size was 80.7 ± 9.2 µm. During the heating and extrusion grains were grown and the average grain size of non-deformed butt-end was 122.2 ± 24.9 µm.

2.2 Industrial Trials and Finite Element Simulation of the Extrusion Process

Studied profile was produced in industrial conditions. The extrusion trials were performed on 8 inch 20 MN direct single action horizontal hydraulic extrusion press. After extrusion, the profile was cooled by air. The parameters of the industrial extrusion trial are summarized in Table 2.

Extrusion process was simulated in QForm Extrusion FEM commercial code with the same parameters as in the industrial experiment. QForm Extrusion is the software

Table 2 The parameters of industrial extrusion trial

Parameter	Value
Velocity or ram, mm/s	4
Billet temperature, °C	480
Billet diameter, mm	185
Billet length, mm	650
Die set temperature, °C	450
Bolster and sub-bolster temperature, °C	25
Dummy block temperature, °C	450
Container temperature, °C	450

Fig. 2 Workpiece during extrusion simulation with strain field shown (the die set and container are not shown). (Color figure online)

which is able to simulate extrusion processes using the combined Lagrangian–Eulerian approach. Eulerian domain (Fig. 2) represents the stationary mesh created in a container and cavities of the die set including short part of the profile. Lagrangian domain is used to follow the profile flow. The combination of coupled mechanical task, namely the consideration of the influence of tool deformation on profile flow, and precise solve of the thermal task allows the software to achieve proper temperature, velocity and consequently strain distribution in the profile that finally defines the accuracy of the microstructural calculation. After simulation of the extrusion process, the profile geometry and calculated workpiece fields were then exported from QForm Extrusion to QForm General Forming finite element commercial code in.csv2d format for further simulation of cooling and static recrystallization that was carried out by means of the Heating–Cooling module.

Static recrystallized volume fraction was calculated by Johnson–Mehl–Avrami–Kolmogorov equation:

$$X_s = 1 - \exp\left[-0.693\left(\frac{t}{A_s \bullet \varepsilon^{N_s} \bullet \exp\left(\frac{Q_s}{RT}\right)}\right)^{k_s}\right], \quad (1)$$

where t is the time (s); ε is the retained strain; T is the temperature, °K; A_s, N_s, Q_s, k_s are the coefficients.

Average grain size in each node was calculated according to the mixture rule:

$$d_{\text{avg}} = d_s \bullet X_s + d_0(1 - X_s), \tag{2}$$

where d_s is the static recrystallized average grain size, μm; d_0 is the initial average grain size, μm.

2.3 Microstructure Characterization

The optical microscopy was used to characterize the microstructure. The samples were cut from the profile by a band saw and then were mounted in phenolic resin by mounting press Struers CitoPress-20. Samples were ground on abrasive clothes with successively finer grades of silicon carbide papers from 320 to 1200 grit and then polished with 0.1 μm diamond suspension. Olympus GX51 optical microscope was used to obtain images. Kellers etchant was used to reveal the microstructure. The average grain size has been evaluated by the planimetric procedure according to ASTM E1181-02 in certain areas of the samples followed by statistical processing with a significance level of 0.05. The software ImageJ (imagej.nih.gov/ij) was used for image analysis.

3 Results and Discussion

3.1 Static Recrystallization Model of 6XXX Aluminum Alloy Based on Industrial Experiments

Approach for development of static recrystallization model using industrial experiments is based on the inverse analysis. Profile section for investigation was cut out from the steady-state extrudate. To get an experimental average grain size distribution, it is necessary to choose a number of points on the profile and measure an average grain size in these points. QForm Extrusion simulation gives us such the process parameters in each point of the profile as strain, average deformation temperature, and strain-rate after extrusion. Using the assumption that static recrystallization is the only microstructure evolution process taking place according to Eqs. (1) and (2), it is possible to calculate an average grain size in every location after cooling. After that, the least square method could be used for obtaining the unknown coefficients A_s, N_s, Q_s, k_s. For this purpose, it is necessary to minimize the following target function:

Table 3 Parameters of 6XXX aluminum alloy static recrystallization model

A_s	N_s	Q_s	k_s
2.453E-5	−1.76	37,500	1.2

$$\Phi = \sum_{i=1}^{n} \left(d_{\exp_i} - d_{\mathrm{sim_i}}\right)^2, \tag{3}$$

where $d_{\exp}$ is the measured grain size, μm; d_{sim} is the simulated grain size, μm; n is the number of studied points.

Mathcad software was used for minimization of the target function by Levenberg–Marquardt algorithm. Obtained parameters of 6XXX aluminum alloy static recrystallization model are presented in Table 3.

3.2 Numerical and Experimental Study of Microstructure Evolution of 6XXX Aluminum Alloy

Obtained parameters of 6XXX aluminum alloy static recrystallization model were used to simulate average grain size distribution after cooling the profile.

The simulated average grain size in the profile cross-section is shown in Fig. 3. As we can see, grain size distribution is highly non-uniform and average grain size is within the range from 50 to 150 μm. Further study was focused on two regions of the profile cross-section, which are also shown in Fig. 3.

Grain size distribution in extruded profiles is highly dependent on the strain. Strain field in the profile is shown in Fig. 4.

We can see that strain values in the cross-section of the profile is in the range from 4.0 to 50.0. In general, the higher strain is in point, the lower average grain size. But there is a danger of secondary recrystallization occurrence, which may lead to abnormal grain growth. In the studied case, the profile has thin walls and cooling speed is sufficient to avoid the secondary recrystallization.

Fig. 3 Simulated average grain size distribution in the profile. (Color figure online)

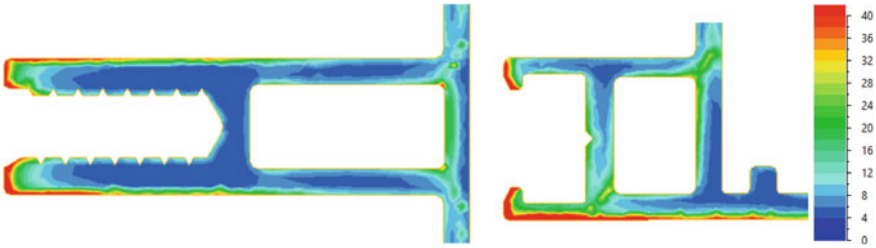

Fig. 4 The strain distribution in samples #1 and #2. (Color figure online)

Another feature of hollow profile aluminum extrusion technology is dividing the metal flow to a several streams and consequent welding due to high temperature and high pressure. Material streams in samples #1 and #2 are shown in Fig. 5.

Temperature in the studied part of the profile is highly uniform and equals 510 ± 10 °C (Fig. 6).

The simulated average grain size distribution and experimental microstructure in samples #1 and #2 are shown in Figs. 7 and 8, respectively.

As we can see, in most points correspondence is quite good, while in some points the difference is up to 1.5 times. Grain refinement in the welding seams can be seen on the simulated average grain size field. The correlation coefficient between experimental and simulated data is 0.89.

3.3 *Validation of the 6XXX Aluminum Alloy Static Recrystallization Model*

Experimental data for validation of the model is provided by ASAŞ Alüminyum Sanayi ve Ticaret A.Ş., Istanbul, Turkey (https://www.asastr.com/home).

The developed model of the static recrystallization was validated on another industrially extruded profile. This time the used aluminum alloy was 6063, which is in the same group of alloys as one used in the study.

The studied extruded profile has a complex shape and presented in Fig. 9. This is a solid profile with some detailed areas for assembling purposes.

The studied part of the extruded profile, macrograph, and microstructure is shown in Fig. 10. The zone for measurement of the average grain size is shown by the red square. The measured average grain size in this zone was 62.2 ± 4.8 μm.

Extrusion of the profile and consequent cooling was simulated. The simulated average grain size of the part of the extruded profile is shown in Fig. 11.

The studied area is shown by the red square on the profile. As we can see, the simulation predicts a high gradient of average grain size in the studied area. Average grain size varies approximately from 45 to 87 μm in the studied zone. Meanwhile, there is no such high gradient of the grain size in the extruded profile as can be seen in Fig. 10b. The simulated average grain size throughout the region was approximately 66 μm, which has good correspondence with experimental data.

Fig. 9 The studied extruded profile

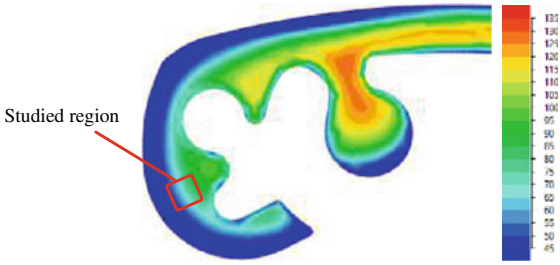

Fig. 11 The simulated average grain size of the part of the extruded profile. (Color figure online)

4 Conclusions

1. The microstructure of 6XXX aluminum the profiles after industrial extrusion process has been investigated and characterized.
2. The model of static recrystallization of 6XXX aluminum alloy based on industrial profiles extrusion analysis was developed and implemented in QForm finite element simulation code.
3. The new method of developing a microstructure evolution model using industrial experiments is quite simple and gives satisfactory results for preliminary analysis of profile microstructure.
4. The developed model was validated on 6063 aluminum alloy industrial extruded profile and shown satisfactory correspondence while further improvement is required.
5. Related processes of microstructure evolution should be taken into account to improve the accuracy of the average grain size calculation.

The Effect of T8 Heat Treatment on Wear Behaviour and Microstructure of 6063 Aluminium Alloy Deformed by Cryo and RT ECAP

Srinivasulu Arnuri and Swami Naidu Gurugubelli

Abstract The effect of T8 heat treatment on wear behaviour of AA6063 was studied and precipitation kinetics was evaluated by SEM and XRD studies. AA6063 square rods of 9.5 mm X 9.5 mm X 100 mm were solution treated at 520 °C for 2 h and quenched in water. One set of samples was processed by ECAP at room temperature and the other set was processed by Cryogenic ECAP after soaking in liquid nitrogen for 20 min. A die of 108° channel intersection angle and 36° outer curvature angle was used and each sample was given four passes in route A and aged at 180 °C for different timings and results compared. Hardness measurements were obtained at regular intervals and peak hardness was observed after 90 min of ageing for both Cryo-ECAPed and RT-ECAPed alloys. The solution treated alloy ECAPed at cryogenic temperature has shown maximum wear rate during the initial stages of ageing and reached the minimum after 90 min and nearly same wear rate was maintained until the overaged condition. The solution treated alloy ECAPed at room temperature has shown minimum wear rate during the initial stages of ageing and reached the maximum at about 50 min and it was not consistent during the later stages. SEM studies were performed on worn-out samples at different time intervals during ageing and the wear behaviour of the alloy was correlated with the microstructures. The wear results obtained were in good agreement with the microscopic analysis.

Keywords Ageing · 6063 aluminium alloy · Wear · Hardness · Cryo ECAP

1 Introduction

Equal Channel pressing of Aluminium 6063 was carried out by two different routes named RT ECAP and CRYO ECAP following by ageing treatment done. These two types of speciments were subjected to wear test to study wear beaviour difference.

Severe Plastic Deformation (SPD) has received enormous interest over the last two decades as a method capable of producing fully dense and bulk sub microcrystalline and nanocrystalline materials. It has shown a major impact on the field of material

https://doi.org/10.1007/978-3-030-75381-8_145

science [1, 2]. Equal Channel Angular Extrusion (ECAE) is one of the prominent procedures among the various severe plastic deformation techniques and has emerged as a widely known procedure for the fabrication of ultrafine-grained metals and alloys. Significant progress has been taking place in the development of ECAP in recent years, thereby suggesting there are excellent prospects for the future successful incorporation of the ECAP process into commercial manufacturing operations [3]. This technique allows obtaining ultra-fine grain in larger volumes; moreover, without change of its original cross-sectional area. The materials thus obtained can be used in automotive, military, and aerospace industries.

The 6063 aluminium alloy is a medium strength alloy commonly referred to as an architectural alloy. Its wide applicability is due to its good surface finish; high corrosion resistance, good weldability, and anodizing ability. Most commonly available as T6 temper and in the T4 condition, it exhibits good formability. The 6063 aluminium alloy is age-hardnable and it contains Mg and Si, which forms Mg_2Si during artificial or natural ageing. Several researchers worked on ageing and forming processes of these alloys and observed significant increase in hardness, strength, and other mechanical properties [4–12].

Post-ECAP ageing gives good strength along with ultrafine-grain size. Emanuela Cerri. Et al studied the influence of severe plastic deformation induced by post-ECAP ageing on the microstructure hardness and electrical conductivity [13]. Pre-ECAP solid solution treatment combined with post-ECAP ageing treatment has been found to be more effective than pre-ECAP peak-ageing treatment in enhancing the strength of a 6061 Al alloy [14]. Nicolae Serban et al. studied the die angle influence on ultimate compressive strength, yield strength, compression modulus, and microhardness and reported their observations [15]. Kameswari Bolem and Anandababu Varadala et al. said that microstructure and mechanical properties were highly improved after the third pass when the billets were pressed in route B_C through the dies having channel angle of 105° when Aluminium 5083 subjected to different passes and different die angle ECAP processes. [16]. Martin Fujda et al. studied the application of the optimal artificial-ageing regimes and observed that ageing after severe plastic deformation improved only the tensile ductility of the alloys. While their strength was slightly decreased because the softening effect caused by the solid solution recovery and the relaxation of the internal stress dominated over the hardening effect caused by the expected metastable β”- and β’-Mg_2Si phase precipitation during artificial ageing treatment [17].

Sushanta Kumar Panigrahi et al. worked with cryorolled and room temperature-rolled Al 6063 alloys and compared their mechanical properties. The ageing treatment of the severely deformed Al 6063 alloy has improved its strength and ductility significantly due to the precipitation hardening and grain coarsening mechanisms, respectively [18]. The work on the effect of cryogenic temperature on ECAP states that cryogenic temperature is supposed to suppress grain dynamic recovery in the cryogenic ECAP process, which provides gain in strength, tensile ductility, as well as a particularly uniform strain [19–21], This suppression of dynamic recovery is likely to preserve the high-density of defects, which could act as potential recrystallisation sites for the production of fine grain structures. Hence, ECAP at cryogenic

temperature has a promising role in the achievement of enhanced mechanical properties. However, literature on precipitation-hardenable alloys, especially on 6000 series alloys, is scarce. The improvement in the mechanical behaviour of AA2219, and AA6061, subjected to cryorolling followed by annealing and ageing treatment has been reported in literature [22, 23]. One of the known ways to improve the wear resistance of the heat treatable aluminium alloys is by using the artificial ageing [24]. YanboChen et al. studied and observed that high density dislocations can be observed inside some grains after eight cryoECAP passes, which obviously differs from the microstructure produced by ECAP at room temperature (RT-ECAP) for commercial pure Aluminium 1050.[25].

K. Sivaprasada et al. investigated the wear characteristics of the composite in the as-cast conditions by conducting abrasive wear test and slurry erosive test. Studies on abrasive wear behaviour of the metal matrix composites (MMCs) were also performed by varying parameters like wt% of TiB2 particles and load [26]. V. Daniel Jebin et al. studied the wear behaviour of Al6063 and observed that the wear rate decreased with weight percent of aluminium oxide [27]. S. Natarajan et al. worked on the sliding wear behaviour of Al 6063/TiB2 in situ composites at elevated temperatures [28]. The effect of humidity on the erosive wear of 6063 Al alloy was studied, by C. K. Fang and T. H. Chuang. They found that the humidity had a minor effect on the peak attack angle for target volume 7 loss, while its effects on the amount of volume loss and worn depth were significant and complex in most of the environmental conditions [29]. A. Karthikeyan and S. Nallusamy studied experimental analysis on Sliding Wear Behaviour of Aluminium-6063 with SiC Particulate Composites. They found from the experimental results that the sliding velocity greatly affects the wear rate, and on increasing the sliding velocity, the wear loss increases. It was also found that the wear loss decreases by increasing the amount of reinforcement element [30]. The effect of artificial ageing on wear properties of AA 6063 alloy was studied by M. Gavgali, Y. Totik, and R. Sadeler [31]. Wear studies on nano red mud particle aluminium matrix composites were performed by Satyanarayana G et al. and reported that the wear resistance significantly increases with reinforcement fraction up to some extent and then decreases [32].

The effect of T8 heat treatment on wear behaviour and microstructure of Cryogenic and room temperature Equi Chanel Angular Processed (ECAPed) 6063 aluminium alloy is studied in the present investigations. The wear behaviour of the alloy is correlated with the microstructures.

2 Materials and Method

Commercial Aluminium 6063 T6 graded with the chemical composition of 0.63 Mg, 0.43 Si, 0.15 Fe, 0.049 Cu, 0.03 Zn, 0.054 Mn, 0.005 P, and 98.6 Al considered as work material in this study. The square cross-sectional samples with the dimensions 9.5 mm X 9.5 mm size and 100 mm length were solution treated at 520 °C for 120 min and then water quenched for attaining a supersaturated solid solution. The treated

samples were divided into two sets. The first set of samples were processed for Cryo-ECAP after soaking for 20 min in liquid nitrogen(-196 °C) and another set of samples were processed for ECAP at room temperature directly after water quenching. All the samples were then severely deformed by pressing through a die having channel intersection angle of 108^0 and outer curvature angle of 36° for four passes in route A (no rotation of billet). The Molybdenum disulfide (MoS_2) lubricant was applied to all the faces of the billets and the square channels of the die before pressing. The computer-assisted universal testing machine (UTM) is used to perform the ECAP, as shown in Fig. 1a. The deformed billet in the exit channel of ECAP die is shown in Fig. 1b. Solution treated and CRYO treated after solution treatment samples shown in Fig. 1c and ECAPed samples were shown in Fig. 1d.

The billets deformed after dipping in liquid nitrogen required more pressing force than the other case and shiny surfaces were observed on the Cryo-ECAPed samples. Samples of 1:1 aspect ratio were obtained from the ECAPed alloys and aged at 180 °C for 500 min. Hardness measurements were obtained at the intervals of 15 min using Vickers hardness tester at an applied load of 300 gm and the average of three readings was noted after every 15 min. Wear tests were conducted using Pin-on-disc wear testing machine over a few samples of under aged, peak aged, and over aged. The specimens remain fixed and disc rotates during wear tests and the load was applied through a deadweight loading system to press the pin against the disc. The speed of the disc or motor rpm can be varied through the controller. The pin and the disc surfaces were polished with emery papers before conducting the test and tests were conducted as per ASTM G-99 standard under the unlubricated condition in a normal laboratory atmosphere at 50–60% relative humidity and a temperature of 28–32 °C.

3 Results and Discussion

The strength of the material increases tremendously due to the grain refinement and strain hardening the occurred by severe plastic deformation during ECAP. In addition, the increase in dislocation density during severe plastic deformation forms dislocation tangles, which, results in further strengthening of the alloy. The age hardening and wear behaviour of the alloy after four passes of ECAP at Cryogenic and RT are evaluated. SEM structures were obtained and the wear behaviour of the alloy is correlated with the microstructures.

3.1 *Age Hardening Behaviour of Cryo-ECAPed and RT-ECAPed Alloys*

The T6 hardness curves of undeformed, room temperature ECAPed, and Cryogenic ECAPed alloys are shown in Fig. 2. The solution-treated alloy directly aged without ECAP at 180 °C has shown the peak hardness of 75 VHN after 400 min. The solution treated alloys ECAPed at cryogenic and room temperature have shown peak hardness at 90 min of ageing. Two microstructural phenomena including precipitation and restoration take place by performing ageing after ECAP. The precipitates formed during ageing will pin dislocations and obstruct the glide motion of dislocations. The restoration processes are a direct result of the loss via recovery and recrystallization, of the dislocations introduced by ECAP. Nucleation and growth of dislocation-free grains occur during recrystallization within the deformed structure. Thus, the T8 hardness of the ECAPed alloy is more compared to that of the undeformed alloy. The increase in dislocation density due to severe plastic deformation enhances the diffusion rate of Mg and Si through dislocation pipes and hence the peak hardness point was reached much earlier during ageing of ECAPed alloy than that of the alloy aged without ECAP. Further, the dislocations, act as nucleation sites and promotes the precipitation of β″ and β′ finely dispersed phases in the microstructure. The T8 hardness of cryogenic ECAPed alloy was observed as 120 VHN and that of the alloy ECAPed at room temperature was 112 VHN. ECAP at subzero temperatures, leads to the formation of ultrafine-grain structures and dislocation pinning by precipitates formed during ageing will be higher and hence, higher T8 hardness was observed for the cryogenic ECAPed alloy.

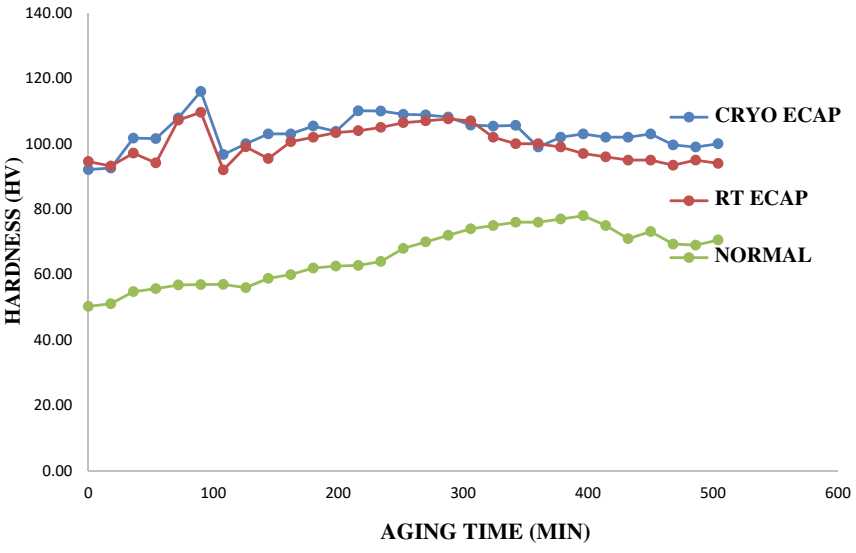

Fig. 2 Ageing curves for Cryo-ECAP and RT-ECAP conditions. (Color figure online)

3.1.1 SEM and EDX Analysis of the Alloy During Age Hardening

The scanning electron microscope (SEM) with Energy-Dispersive X-ray (EDX) spectroscopy attachment is used to perform the structural and elemental analysis on the precipitates formed in Cryo and RT-ECAPed Al6063 billets during ageing at 180 °C. The SEM images were obtained at 0 min, 90 min, 360 min of ageing and are shown in Fig. 3. At 0 min of ageing, ultrafine-grain structure is observed in the cryo-ECAPed alloy. With ageing, precipitates are formed and the coherency of precipitates is more for the cro-ECAPed alloy than RT-ECAPed alloy at 90 min of ageing. This is in agreement with the higher hardness obtained for the cryo-ECAPed alloy than the other(Fig. 4). Due to over ageing, the precipitates were grown and their coherency was also deviated in both the cases and the deviation is more for the

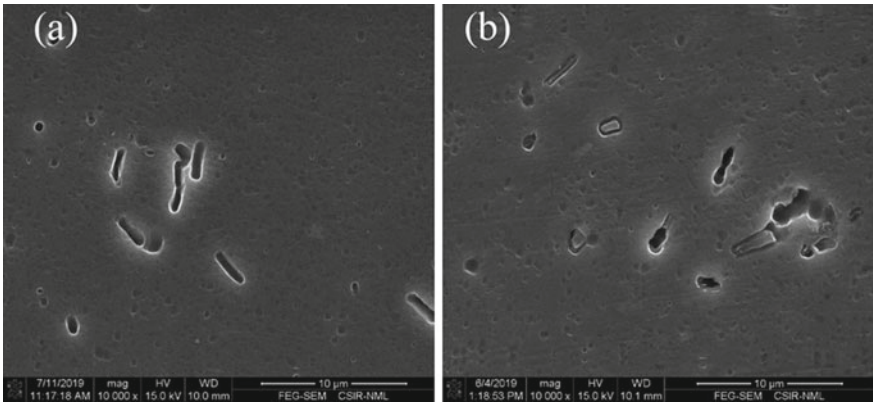

Fig. 3 SEM images of Al6063 at ageing time T = 0 min **a** Cryo ECAP **b** RT-ECAP

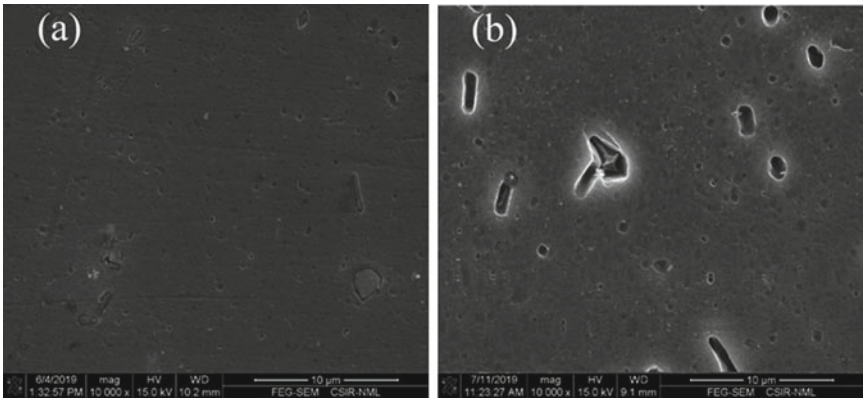

Fig. 4 SEM images of Al6063 at ageing time T = 90 min after **a** Cryo ECAP **b** RT-ECAP

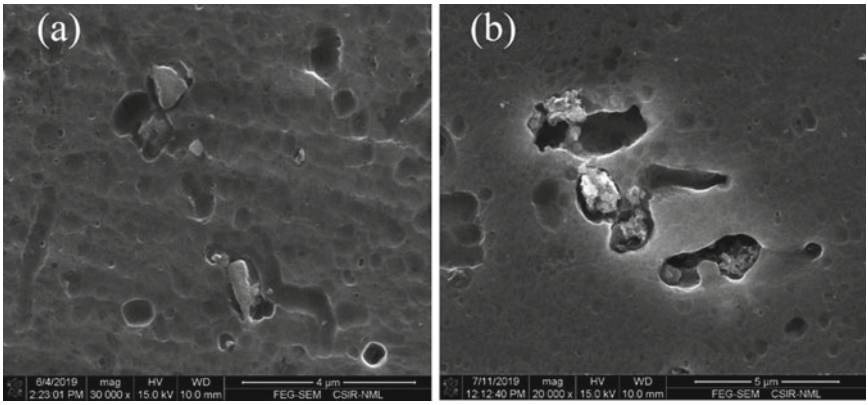

Fig. 5 SEM analysis of Al6063 at ageing time T = 360 min after **a** Cryo ECAP **b** RT-ECAP

RT-ECAPed alloy. Further, after 360 min of ageing, it has been observed tremendous growth of the precipitates in RT-ECAPed alloy and hence the hardness is not maintained consistently (Fig. 5).

The SEM and EDX analysis obtained for cryo-ECAPed and RT-ECAPed alloy at 90 min of ageing is depicted in Fig. 6a, b. From Fig. 6c, d it can be observed that a fraction of nitrogen is shown in the EDX of cryo-ECAPed alloy, which is due to the immersion in liquid nitrogen. A fraction of Ti is also observed and the formation of nitrides might be the reason for the higher hardness of cryo-ECAPed alloy compared to the RT-ECAPed alloy.

3.2 Effect of Ageing on Wear Behaviour of Cryo-ECAPed and RT-ECAPed Alloys

Wear rate was estimated by measuring the mass loss in the specimen after each test. The wear rate which relates to the mass loss to sliding distance (L) is calculated using the expression $W_r = \Delta m/L$. The curves showing wear rate of cryogenic and room temperature processed alloys aged at 180^0 C are shown in Fig. 7. The solution treated alloy ECAPed at cryogenic temperature has shown maximum wear rate during the initial stages of ageing and reached the minimum after 90 min and nearly same wear rate was maintained until the overaged condition. The solution treated alloy ECAPed at room temperature has shown minimum wear rate during the initial stages of ageing and reached to the maximum within 50 min and it was not consistent during the later stages. The strength of both the alloys was increased due to grain refinement and strain hardening that occurred by severe plastic deformation by ECAP. On the other hand, the deformation at subzero temperatures increases the brittleness of the alloy. Further, the liquid nitrogen immersion may lead to the formation of delaminated

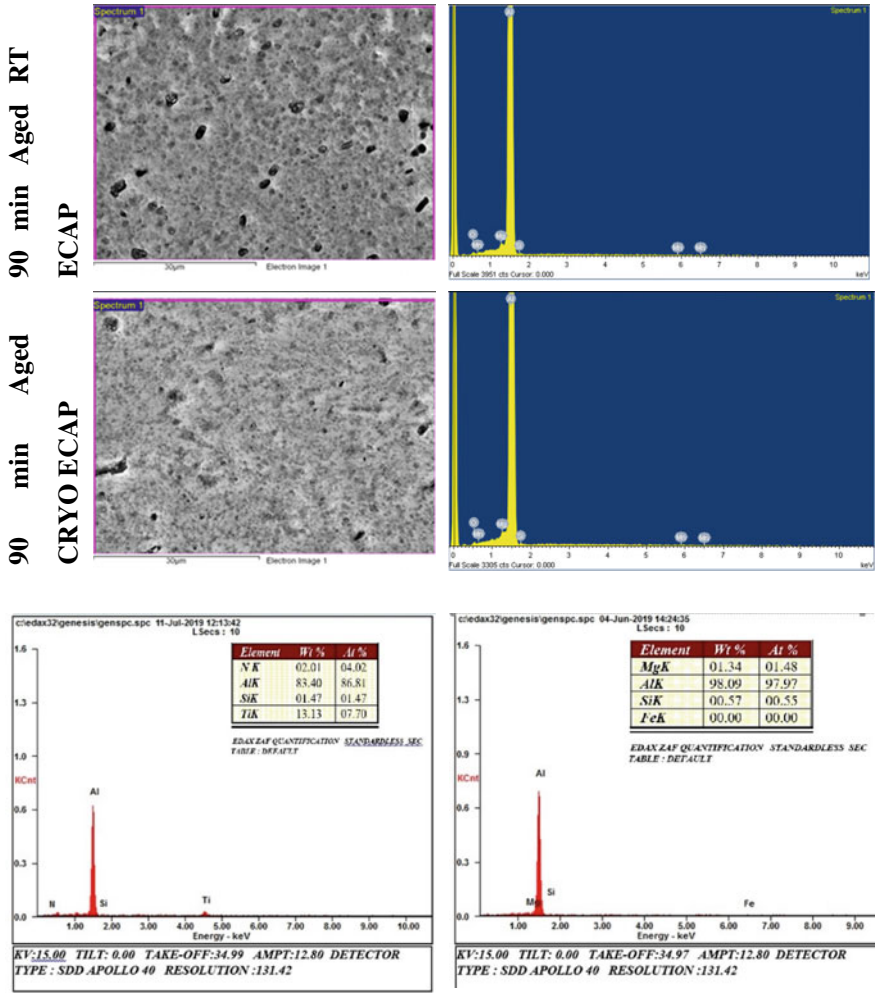

Fig. 6 **a** SEM and EDX images of 90 min hours aged RT ECAP. **b** CRYO ECAP. **c** EDX analysis of Al6063 at ageing time T = 90 min after Cryo ECAP. **d** EDX analysis of Al6063 at ageing time T = 90 min after RT-ECAP. (Color figure online)

layers and pits in case of cryo-ECAPed alloy. Hence, the alloy ECAPed at cryogenic temperatures has shown maximum wear rate during the initial stages of ageing.

3.2.1 SEM Analysis and Correlation with Hardness Behaviour

The wear test samples were observed under Scanning Electron Microscope and the SEM images of the cryogenic and room temperature ECAPed worn-out samples at 0 min of ageing are shown in Figs. 8 and 9 respectively. The Cryo-ECAPed fractograh

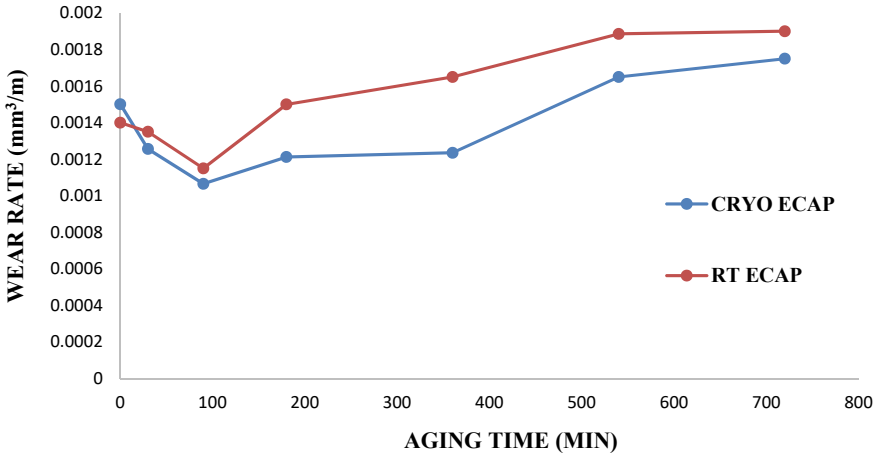

Fig. 7 Variation of wear rate with respect to the ageing time of Cryo and RT ECAPed specimens. (Color figure online)

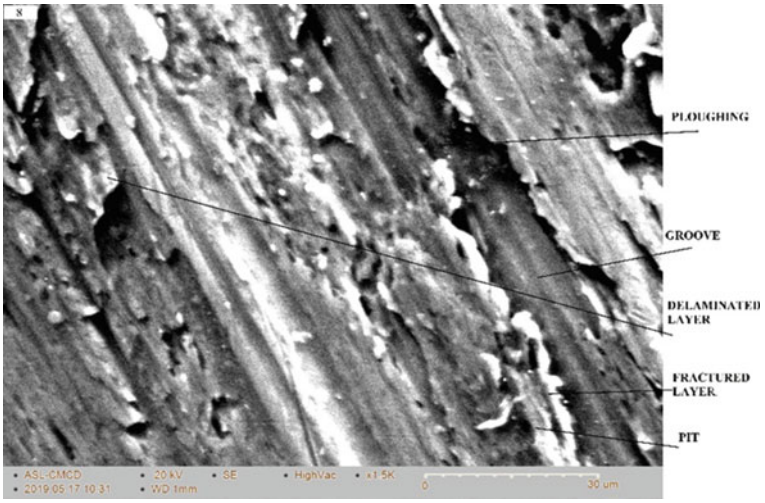

Fig. 8 Wear SEM analysis of Al6063 at ageing time T = 0 min after Cryo ECAP. (Color figure online)

shows groves, delaminated layers, ploughing places, and pits. This is due to the liquid nitrogen immersion effect. Grooves and small delaminated layers were also observed in the fractograph of room temperature ECAPed alloy but to a lesser extent as it is free from liquid nitrogen immersion. Therefore, the cryo-ECAPed alloy has shown a significantly higher wear rate at 0 min of ageing than that of room temperature

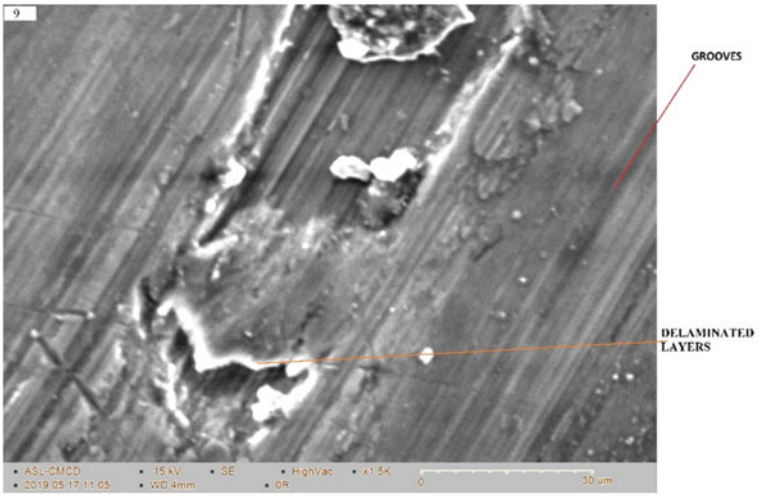

Fig. 9 Wear SEM analysis of Al6063 at ageing time T = 0 min after RT- ECAP. (Color figure online)

ECAPed alloy. Therefore, the SEM images are in consistent with the wear behaviour of the alloy.

The SEM images of the cryogenic and room temperature ECAPed worn-out samples at 90 min of ageing are shown in Figs. 10 and 11, respectively. The groves, delaminated layers, ploughing places, and pits are minimized in the Cryo-ECAPed

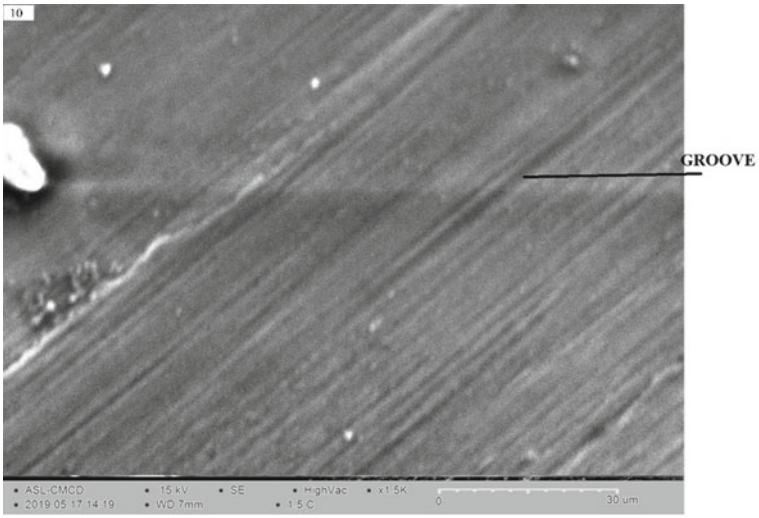

Fig. 10 Wear SEM analysis of Al6063 at ageing time T = 90 min after Cryo ECAP

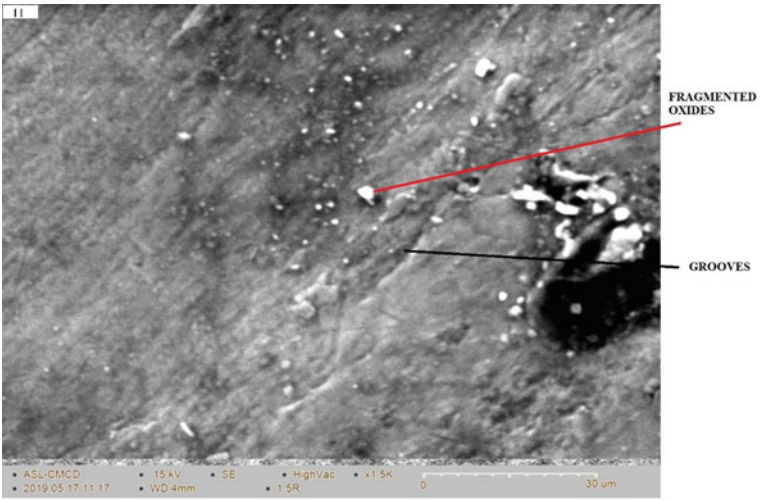

Fig. 11 Wear SEM analysis of Al6063 at ageing time T = 90 min after RT-ECAP. (Color figure online)

alloy after 90 min of ageing and are lowered even below that observed in the RT-ECAPed alloy. This might be the reason for the significantly decreased wear rate of Cryo-ECAPed alloy aged for 90 min. The SEM images are well in agreement with the wear behaviour of the alloys.

The SEM images of the cryogenic and room temperature ECAPed worn out samples at 360 min of ageing are shown in Figs. 12 and 13 respectively. Ageing

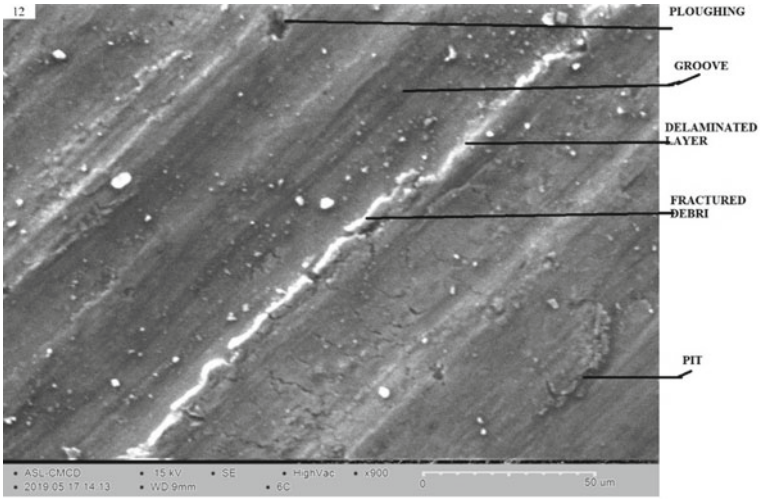

Fig. 12 Wear SEM analysis of Al6063 at ageing time T = 360 min after Cryo ECAP

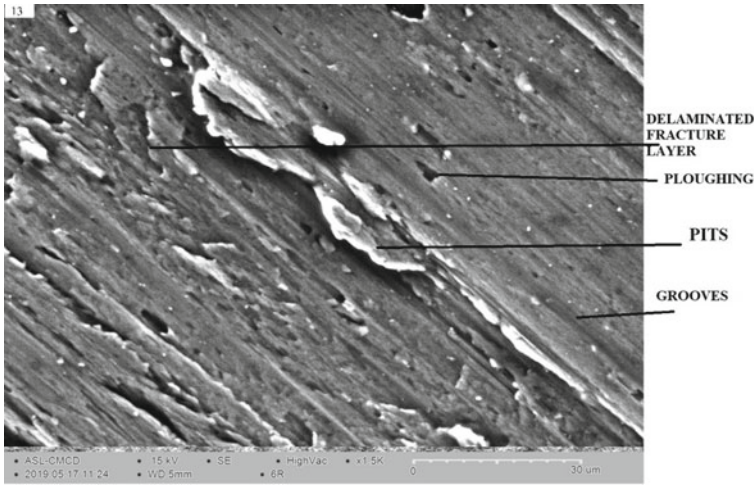

Fig. 13 Wear SEM analysis of Al6063 at ageing time T = 360 min after RT- ECAP

beyond 90 min, has caused a further increase in the formation of grooves, pits, and delaminated layers in the RT-ECAPed alloy and no such development was observed in Cryo-ECAPed alloy. Therefore, the wear rate was almost consistent at the minimum level for the Cryo-ECAPed alloy even during over ageing conditions. The observed SEM images are well correlated with the wear behaviour of the alloys.

4 Conclusions

The effect of T8 heat treatment on wear behaviour and microstructure of 6063 aluminium alloy is studied and the results are correlated. The following conclusions are drawn from the present experimental investigations.

1. The increase in dislocation density due to severe plastic deformation enhances the diffusion rate of Mg and Si through dislocation pipes and hence the peak hardness point was reached much earlier, i.e. at 90 min of ageing in case of ECAPed alloy, rather than that occurred at 480 min for the undeformed alloy.
2. The T8 hardness of cryogenic ECAPed alloy was observed as 120 VHN and that of the alloy ECAPed at room temperature was 112 VHN. ECAP at subzero temperatures, leads to the formation of ultrafine-grain structures and dislocation pinning by precipitates formed during ageing will be higher and hence, higher T8 hardness was observed for the cryogenic ECAPed alloy compared to the RT-ECAPed alloy.
3. The solution treated alloy ECAPed at cryogenic temperature has shown maximum wear rate during the initial stages of ageing and reached to the minimum after 90 min and nearly same wear rate was maintained until the

overaged condition. The liquid nitrogen immersion has led to the formation of delaminated layers and pits which was observed from the SEM images. This might be the reason for the higher wear rate.

4. The solution treated alloy ECAPed at room temperature has shown minimum wear rate during the initial stages of ageing and reached the maximum within 50 min and it was not consistent during the later stages.
5. Excellent agreement between the wear behaviour and microstructures is observed from the present investigations.

Metal Foils for Bipolar Plates—Correlation of Initial Grain Size and Forming Behavior of 316L

Alexander Bauer, Thomas Mehner, Birgit Awiszus, and Thomas Lampke

Abstract As the forming of metallic bipolar plates is mostly still in the state of research, the underlying forming mechanisms are not fully understood. This study deals with the topic of different grain sizes in the initial metal sheets and their influence on the forming results. Therefore, a work-hardened 316L-foil (0.1 mm) was processed with different heat treatment strategies resulting in three different grain sizes with average grain diameters of 47.4, 19.3, and 7.9 μm. Afterward, all heat-treated blanks were cut and deep-drawn between two rigid dies to form a bipolar plate flow field. Besides force and geometrical factors like thinning and springback, the microstructure was analyzed by XRD and EBSD. Using these characterization methods, the mechanisms of twinning and preferred deformation of specific grain orientations during the forming process can be identified. Therefore, the impact of size effects on the forming behavior of metallic bipolar plates is shown. It can be concluded that a fine-grained initial state is preferable.

1 Introduction

Metallic bipolar plates for Proton-Exchange Membrane (PEM) fuel cells are a promising component in the context of relevant topics like resource efficiency and the reduction of emissions in the mobility sector. An application of metallic bipolar plates can significantly reduce manufacturing costs and therefore help the PEM fuel cell to achieve a widespread market penetration in general. Nevertheless, the mass

production of metallic bipolar plates is still being researched. One reason for that is the underlying forming mechanisms of metal foils, which are not easily scaled down from conventional thicknesses to thicknesses of of 0.5 mm. The related size effects, which cause these kinds of differences, were analyzed in several publications. *Tiesler* et al. provide a good overview about the size effects that occur in deep-drawing processes, for instance, the increasing influence of single grains [1]. For a comparison of metal sheets (thicknesses > 1 mm) with the corresponding metal foils (<25 µm) of aluminum and unalloyed steel, it was found that the friction values increased during the forming of the metal foils, while the limited drawing ratio decreased [2]. Other scientists found out that the anisotropy values decreased and the yield strength as well as the tensile strength increased with a rising number of grains over the sheet thickness of 0.1 mm in 1.4301 stainless steel foils [3, 4]. Several other publications also dealt with the appearance of size effects during the forming of copper foils [5, 6] or aluminum [7, 8]. In general, it can be seen that the particular forming mechanisms of metal foils are mostly analyzed separately and without a special focus such as the use as a bipolar plate. In this article, the relevant effects are analyzed concerning the requirements for bipolar plates. Therefore, three different grain sizes, which were generated from the initial metal foils and which were subsequently formed to bipolar plate-shaped test samples, were analyzed. Besides general methods for the analysis of the macro- and microscopical geometry development, X-ray diffraction (XRD), and electron backscatter diffraction (EBSD) were used to achieve an in-depth understanding of the microstructural phenomena, which appear during the forming process. On the one hand, this leads to better insights into the forming process and the parameters that affect it. On the other hand, the knowledge gained from this research results in a recommendation of an initial state of the metal foils which differs from those currently used for the majority of semi-finished products for metallic bipolar plates.

2 Materials and Methods

The initial material was a conventional 316L (1.4404) stainless steel foil with a thickness of 0.1 mm in a work-hardened state. The chemical composition (mass fraction) is specified as follows: C: 0.02%; Si: 0.41%; Mn: 1.34%; P: 0.03%; S: 0.004%; Cr: 16.64%; Ni: 10.01%; Mo: 2.00%. The tensile strength was 1274 MPa, which is an increase of about 85% compared to the annealed material state. In preparation for the heat treatments, the samples were cut from the coil with a stationary precision cutting machine to a size of 80 mm × 50 mm. Afterward, the cut samples were heat-treated in a *Torvac 12 Mark IV* vacuum furnace. The required temperatures in order to achieve three significantly different grain sizes were obtained from preliminary investigations (Table 1).

Subsequent to the holding times from Table 1, the samples were slowly cooled down to room temperature within the furnace, under vacuum condition, and without additional coolants.

Table 1 Different grain sizes with associated heat treatment parameters

Requested grain size	Nomenclature	Temperature (°C)	Duration (h)
Coarse (≈50 µm)	316L-CG	1100	0.5
Medium (≈25 µm)	316L-MG	970	1
Fine (≈7.5 µm)	316L-FG	850	1

After the heat treatment, four specimens of each material state (316L-CG, -MG, -FG) were formed within a four-column servo press (*Hegewald & Peschke Meß- und Prüftechnik GmbH*) (Fig. 1a). This forming machine, which is specialized in performing microforming operations with high accuracy, enabled a precise forming process with an identical start at a pre-force of 150 N, a velocity of 1 mm/s, and a defined stop at a drawing gap of 0.12 mm. This gap was combined from the sheet thickness (0.1 mm) and an additional offset (0.02 mm). No additional lubrication was used. The geometry was defined by a rigid punch and a rigid die with the shape of relevant bipolar plate channel geometries and a circumferential outer structure (Fig. 1b, c). Figure 1c shows the relevant channel dimensions: RE: entry radius, RG: ground radius, BW: bottom width, FA: flank angle, and h: channel height.

Subsequent to the forming operation, a variety of evaluation methods was used to examine the results. First of all, the geometry evolution was analyzed on the macro- and microscale. The macroscale investigations were carried out with a photogrammetric *GOM ATOS Core* system, which digitized the formed 3D geometry and enabled a separate evaluation with a direct comparison of the CAD or FEM geometry in the software tool *GOM* Inspect (Fig. 2 left, middle). For this comparison, four spots on the edge of the flow field were defined at first. In the second step, the perpendicular distance between the experimental GOM geometry and the CAD or FEM result was measured to determine the differences in the geometrical development.

The channel thinning was analyzed with micrographs from the channel cross sections under an optical microscope. Therefore, the samples were prepared with a

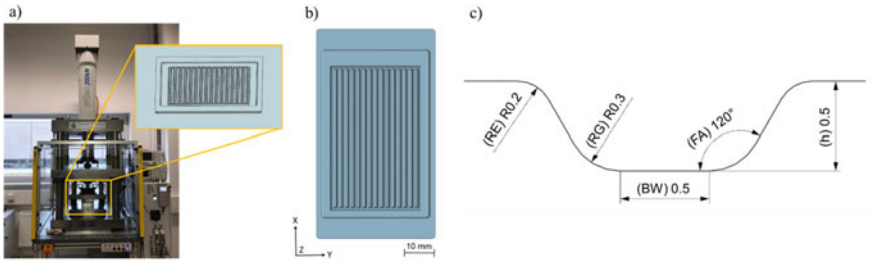

Fig. 1 Left: Servo press with enlarged CAD-surface of die [9]; middle: top view of a test sample [9]; right: channel cross section of a test sample [according to 10]. (Color figure online)

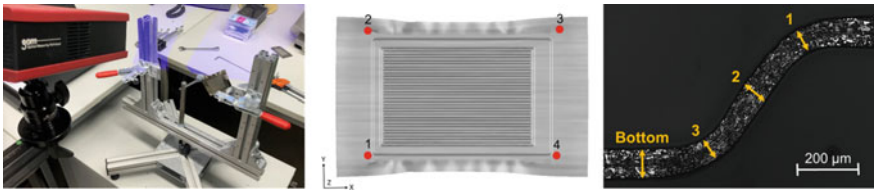

Fig. 2 Left: GOM measurement; middle: arrangement of measurement positions for comparison of the macroscopic geometry; right: arrangement of measurement positions for thinning. (Color figure online)

Discotom cutting machine transversal to the channels, embedded in epoxy resin, and subsequently polished and etched to show microstructural features. Afterward, the specimens were analyzed and measured under an *Axiovert 200* microscope with the corresponding software *AxioVison*, both from the *Carl Zeiss AG*. The results were averaged from three different channels in the middle of the flow fields. Furthermore, four different spots were measured for each channel: upper radius, flank, lower radius, and bottom (Fig. 2 right).

Furthermore, the roughness was evaluated with a *VK-X1000* confocal microscope from the *Keyence Corporation*. The measurements by focus variation were implemented at an area of 5.5 mm × 4.5 mm and consecutively examined within the *Keyence Multi-File-Analyzer* software. Therefore, multiple measuring sections were defined at the channel top, the flank, and the channel bottom and afterwards combined to a mean value.

To achieve a deeper understanding of the microstructural phenomena like twinning and grain orientation dependent deformation, EBSD was used. The experiments were conducted in a *Neon 40EsB* scanning electron microscope of the *Carl Zeiss AG* using a voltage of 15 kV and a sample tilt of 70°. The step size was 0.1 µm. For the evaluation, the software *TEAM EBSD Analysis System* (*EDAX Inc.*) was used. A cleanup has been performed using Grain Confidence Index Standardization (tolerance angle 15°) and Neighbor Confidence Index Correlation (minimum confidence index of 0.2). All of the EBSD images were taken from the upper radius area as one of the spots, which is affected the most by the forming process (Fig. 3).

Further investigations of the microstructure were done by XRD using a diffractometer *D8 Discover* (*Bruker AXS*) with Co Kα radiation (tube parameters: 40 kV,

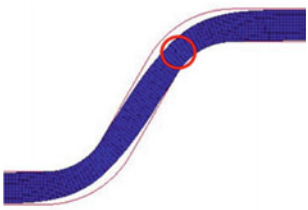

Fig. 3 Position of the EBSD measurements (red mark). (Color figure online)

40 mA), polycap optics for beam focusing, a pinhole aperture with a diameter of 0.5 mm, and an energy-filtered 1D detector Lynxexe XE. A step size of 0.02° with a measurement time of 7.2 s/step. Microstrains (peak broadening caused by lattice defects) and crystallite sizes were evaluated using the program *TOPAS* (*Bruker AXS*).

3 Results and Discussion

3.1 Heat Treatments of the Metal Foils

The 316L stainless steel foil was used in a work-hardened state to enable recrystallization with a broad spectrum of possible grain sizes (Fig. 4). Besides the average grain diameter (316L-CG: 47.4 µm; 316L-MG: 19.3 µm; 316L-FG: 7.9 µm), the micro-sections of all different grain sizes show the presence of crystal twins. One reason for the occurrence of the crystal twins in face-centered cubic materials is the tendency to develop twins during annealing processes [11]. On the one hand, a higher amount of annealing twins can be seen in the fine-grained specimen (316L-FG) due to its smaller grain sizes. On the other hand, the ratio of the total length of the boundaries of crystal twins to the total length of grain boundaries in general is lower in the fine-grained specimen (316L-FG) than in the coarse-grained specimen (316L-CG). This implies that the impact of the twins on the forming behavior, as a possible boundary for the accumulation of dislocations, has to be analyzed based on forming experiments. All forming-relevant mechanical properties, like flow and forming limit curves, were affected by the heat treatments. This has previously been discussed by the authors [9].

For comparison, a work-hardened and an annealed state of 316L foil were measured by XRD to analyze the amount of dislocations (i.e., microstrains, which are directly connected to the presence of dislocations). The measured microstrain of the work-hardened state was 0.47, in contrast to the annealed state, for which the microstrain is below the detection limit. According to the measured values, the investigated samples showed a complete recrystallization after the heat treatments with the temperatures given in Table 1.

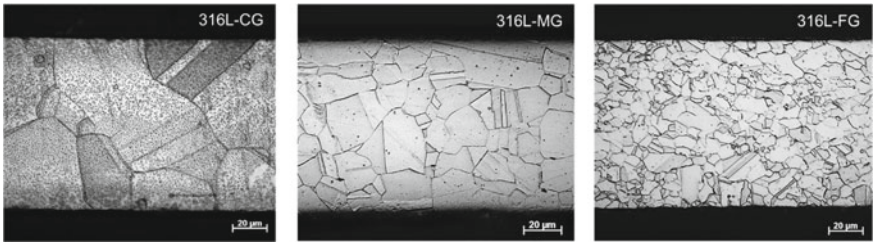

Fig. 4 Microsections of 316L with different heat treatment temperatures

3.2 Forming Experiments

All specimens were intentionally formed without a binder (blank holder) to show the impact on the forming results more clearly and unaffected by additional material flow controlling technologies (Fig. 5). A comparison of the required forming forces between the samples of different grain sizes showed no significant differences. Therefore, it is not discussed in more detail within this publication. In general, the sheets of all grain sizes reached the final shape at approximately 90 kN.

At first sight, it can be directly seen that the three grain sizes show different values for the distortion caused by the springback of the samples. The springback of the coarse-grained specimens (316L-CG) is the lowest, whereas for 316L-MG and 316L-FG, it is almost identical. This classification can be confirmed in the photogrammetric analyses. The coarse-grained specimens show the lowest perpendicular deviation between the experimental geometry and the CAD construction (Fig. 6). The wrinkles in all specimens appear as the reason for the stresses connected with the material flow into the die.

The corresponding values of all samples can be found in Table 2.

Regarding the detected springback effect and the related accuracy of the forming result, the coarse-grained specimens show the best values for a forming process without binder. As the macrostructural development of the geometry is just one factor which has to be considered for a comparison of initial material states. Further aspects have to be examined for a reliable statement.

The thinning behavior of the three grain sizes is shown in Table 3. The fine-grained and the middle-grained specimens look almost identical in regards to the thinning.

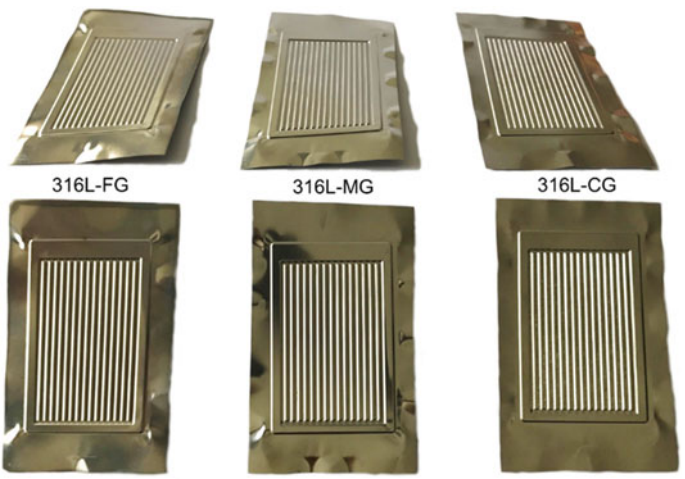

Fig. 5 Forming results for different heat-treatment temperatures and without binder. (Color figure online)

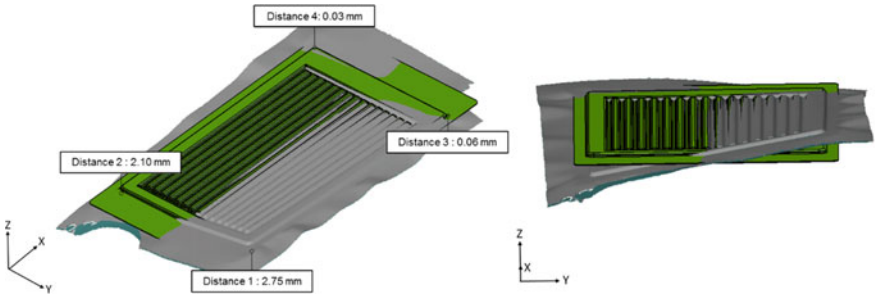

Fig. 6 Differences of 316L-MG between CAD geometry (green) and experimental forming results (gray). (Color figure online)

Table 2 Comparison of the distances between experiments and CAD construction

	Deviations forming versus CAD (mm)		
Measuring point	316L-CG	316L-MG	316L-FG
Distance 1	+1.75	+2.75	+3.20
Distance 2	−1.32	−2.10	−2.10
Distance 3	−0.02	−0.06	−0.04
Distance 4	+0.06	+0.03	+0.07

Table 3 Comparison of the thinning in the formed specimens with different gain sizes

Measuring point	316L-CG	316L-MG	316L-FG
Bottom, reference value (μm)	98.9	96.1	98.2
	Thinning (%)		
1. Channel top radius	23.5	23.0	25.4
2. Flank	20.0	13.4	14.6
3. Channel bottom radius	23.1	19.0	21.8

The greatest difference can be seen in the coarse-grained specimen, which shows a more uniform thinning, even in the channel flanks.

The coarse-grained specimens show excess thinning effects in a few channel flanks over the whole specimen, which is not considered in the mean values of Table 3. An example is shown in Fig. 7.

For comparability, these exceptional cases were not considered for the values in Table 3 as only just a few channels were affected by this exaggerated thinning, but in terms of the microstructural effects, these cases are of special interest. The otherwise similar values of the thinning require an in-depth investigation in order to understand the additional effects caused by the forming and their influence on the future application in fuel cells. Thus, the measurements of the thinning were directly correlated to the results from the EBSD. The differences in the material-flow behavior

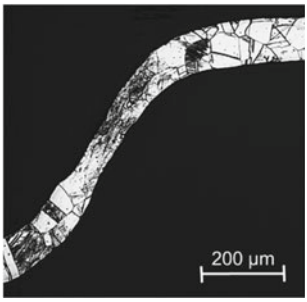

Fig. 7 Example for excess thinning in the channel flanks of 316L-CG

and the grain structure result from the specific microstructure of the specimens with different grain sizes.

During the analysis of the medium grain sizes, the annealing twins, which were caused by the heat treatment, were still clearly visible (Fig. 8, left). Most of them can be seen for orientations close to {111} (blue, violet) or {001} (red, orange). The right image of Fig. 8 shows the forming twins as well as the annealing twins with red lines. The formation of forming twins is related to energetic reasons. While crystallographic slipping is the main forming mechanism, which appears in ductile materials, plastic deformation can also be enabled by twinning [12]. In the length measurements of the grain and twin boundaries in all measured grains, almost identical values can be measured for both boundary types (total length grain boundaries: 4.40 mm; total length twin boundaries: 4.47 mm). However, not all of the twin boundaries could be

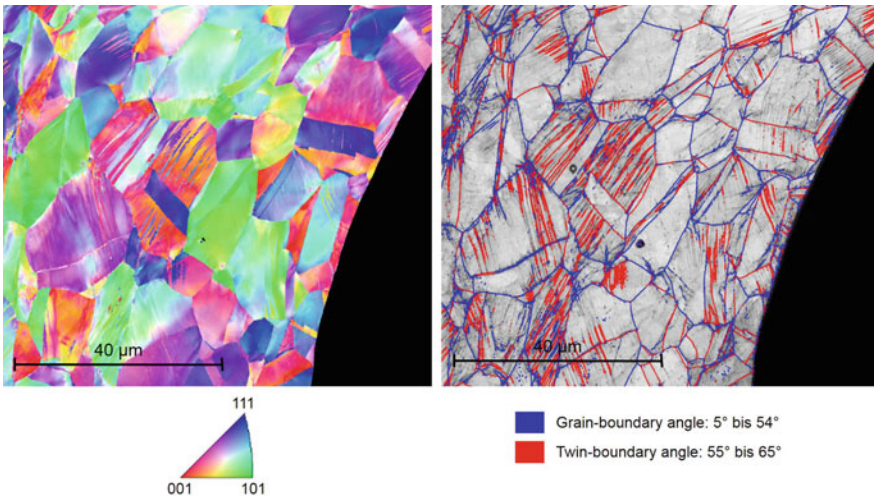

Fig. 8 EBSD micrographs of formed 316L-MG, left: grain orientation (inverse pole figure), right: grain (blue), and twin (red) boundaries. (Color figure online)

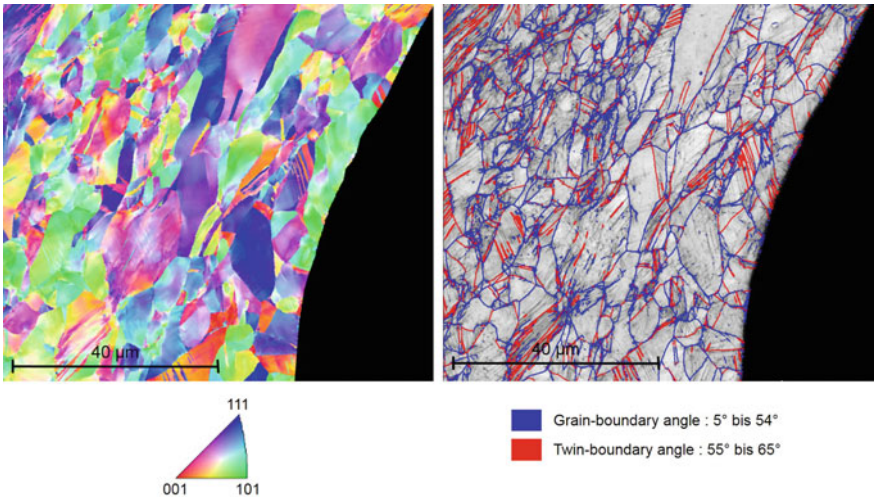

Fig. 9 EBSD micrographs of formed 316L-FG, left: grain orientation (inverse pole figure), right: grain (blue), and twin (red) boundaries. (Color figure online)

analyzed due to their small width and the limited resolution of EBSD. With a closer analysis of Fig. 8, the annealing twins can still be observed by their characteristic straight boundaries. In the left image, the forming twins can be identified as sharp, wide bands within the grains.

The evaluation of the EBSD image of a 316L-FG specimen showed a similar deformation as seen in 316L-MG, as there exists a variety of grain boundaries (Fig. 9). Therefore, a homogenous deformation is possible for the medium as well as for the fine-grained sizes (Table 3). Further refinement of the grain size would not change the thinning significantly.

In a direct comparison between 316L-FG and 316L-MG, it can be seen that the fine-grained specimen developed less forming twins. The total length of all grain boundaries comes to 6.55 mm, whereas the twin-boundary length just reached a total of 3.85 mm. This means that the summed-up length of grain boundaries is nearly twice as large as for the twin boundaries, while the ratio within the medium grain sizes was almost equivalent. The reason is the higher number of possible slip planes in the fine-grained specimen, which is more favorable for the forming mechanisms from the energetic point of view. This means that the size effects have a higher impact on the forming mechanisms with a decreasing amount of grains over the thickness of the specimen. In particular, this can be seen most clearly for the coarse-grained specimen 316L-CG (Fig. 10).

The microsections in Fig. 7 already showed that some of the flanks within the 316L-CG samples underwent an excess thinning. One reason for this material behavior is that some areas of the 316L-CG samples are only one or two grains thick. This means that in parts of the sample there is no possibility for crystallographic slipping, which results in a significant stretching of single grains and thus

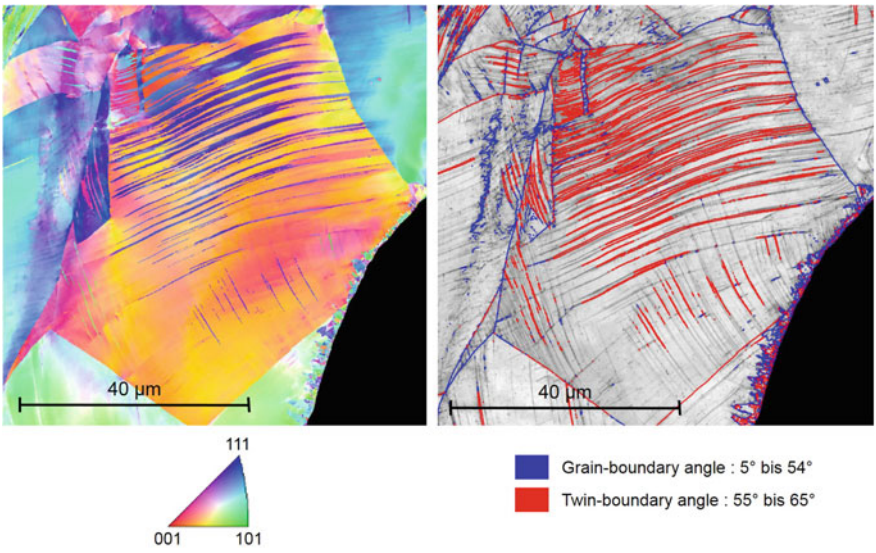

Fig. 10 EBSD micrographs of formed 316L-CG, left: grain orientation (inverse pole figure), right: grain (blue), and twin (red) boundaries. (Color figure online)

unwanted thinning in formed areas. Such a material behavior can also be referred to as a size effect, which means that there are changes in the plasticity between highly fine-grained materials and local areas with fewer grains over the specimen's thickness. This can also be concluded from the EBSD analysis in Fig. 10. The total amount of crystal twins, which occur during the forming process, are more than double the length as the grain boundaries (total length of grain boundaries: 2.34 mm; total length of twin boundaries: 5.07 mm; some very thin twin boundaries are not included). This implies that the samples lack slipping planes and therefore crystal twinning became the major forming mechanism. In combination with the presence of only one or two single grains across the thickness, this leads to increased thinning effects.

Concluding the analyses of the thinning behavior and the crystallographic effects, the fine-grained specimens show the best attributes for the use as a bipolar plate. A clearly polycrystalline microstructure enables good forming behavior and the highest forming capacity without unpredictable thinning or damage. The total length of 10.40 mm for grain and twin boundaries is the highest value of the investigated specimens, which indicates that 316L-FG contains the longest boundaries to accumulate dislocations. This means that the fine-grained structures have a higher stability against external deformation.

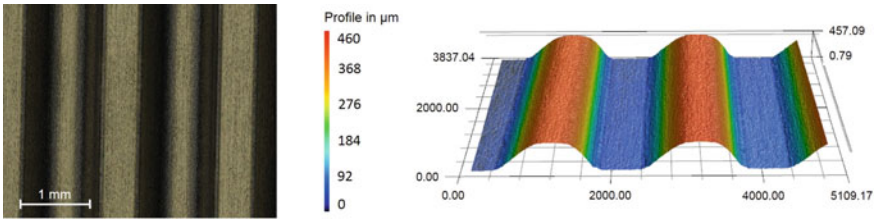

Fig. 11 Confocal measurements of a formed specimen (316L-FG), left: scanned area, right: sample profile. (Color figure online)

Table 4 Arithmetical mean deviation (R_a) values of formed samples with different initial grain sizes

Measuring position	Arithmetical mean deviation R_a (µm)		
	316L-CG	316L-MG	316L-FG
Channel top	3.69	3.25	3.21
Flank	6.25	4.10	3.68
Channel bottom	3.64	2.89	2.03

3.3 Roughness

For metallic bipolar plates, roughness is an important factor during the operational cycles with a flowing medium and the corrosive environment. Therefore, the evolution of the roughness that results from the forming processes with different initial grain sizes is important. The roughness of the initial metal foils prior to the heat treatments was measured with $R_a = 3.2$ µm. With a focus on the roughness, of the heat-treated and formed specimen, at the channel top, the flank, and the channel bottom, distinct differences can be observed between the three sample types. Figure 11 shows the measured area from the fine-grained formed specimen and the corresponding profile.

All measured values are summarized in Table 4.

From the measured values in Table 4, different conclusions can be drawn. Firstly, it is visible that all specimens reached the highest roughness values in the flank areas, which also include the radii. From the forming point of view, this is an expected behavior because in areas with free strain, the surface is enlarged, which in turn causes an increase in roughness [13]. The highest loads for the forming of these bipolar plate channel structures can be found in the radii and flank areas. Additionally, the different initial grain sizes can be seen to have an effect. The highest roughness values can clearly be observed in the coarse-grained material and the lowest ones were measured in the fine-grained samples. For that reason, it can be concluded that the initial grain size has a major impact on the development of the surface roughness after the forming process. This is of special interest for future use as a bipolar plate. A higher roughness provides a bigger surface for corrosion while the accumulation of produced water in pits or gaps is supported by bigger grains. This can lead to the formation of local elements where the corrosive attack starts. With respect to the

durability of the bipolar plates, fine-grained specimens would be preferable due to the lower roughness after forming.

4 Conclusions

In summary, it can be clearly seen that different grain sizes in the semi-finished products lead to considerable differences in the forming results, which occur due to size effects. For the definition of an ideal initial material state, the results are contrary. The coarse-grained specimens showed the lowest springback for a forming without binder, which would be preferable. However, the fine-grained specimens showed the best microstructural properties with regard to the application as a bipolar plate in PEM fuel cells. With a view on the roughness evolution, the best results were achieved by the fine-grained material, which could reduce corrosion during the operation of the fuel cell.

Another argument, which supports the use of fine-grained specimens, can be found in the production technology. In the specific case of deep drawing of metallic bipolar plates, a binder can be added to the tool design. An optimization of this process, which was used in the experiments presented, showed that the springback effect, which occurred in different intensities depending on the grain size, was almost eliminated (Fig. 12).

Within Fig. 12, it is clearly visible that, when compared to Fig. 5, no springback and no differences between the different grain sizes can be observed. This means

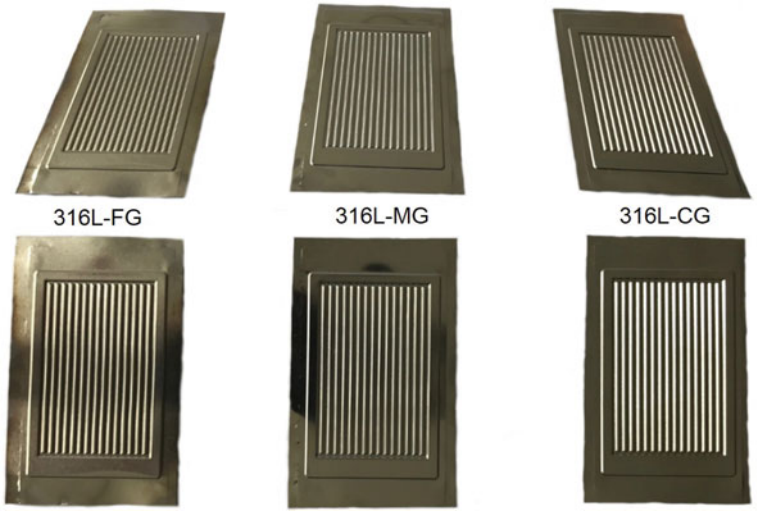

Fig. 12 Optimized forming results for different heat treatment temperatures and with binder. (Color figure online)

that the fine-grained specimen, which led to the highest springback effect without a binder, also gave flat results without wrinkles. Thus, it can be seen that even the worst springback effect of the fine-grained specimen was successfully compensated by technological adaption.

Furthermore, considering the production costs, a fine-grained microstructure could be produced with a low annealing temperature after the last rolling pass. In the present case, the fine-grained specimens were annealed at a temperature of 850 °C, whereas conventional heat treatments were done at around 1000 °C for medium grain sizes. The production of coils of fine-grained material is more resource- and cost-efficient. Overall, based on the results of this investigation, the fine-grained initial state (grain diameter < 10 μm) can be recommended for the production of metallic bipolar plates.

Within modern engineering product or process developments, the use of numerical simulations like FEM is a conventional strategy to predict requested results. The FEM simulation of metal foil forming processes is challenging because of the appearance of size effects like mentioned in this paper. Nevertheless, numerical simulations were done to predict the forming results even with different initial material states and grain sizes. The results with the specific material data like flow curve, anisotropy values, and forming limit curve showed a very good agreement with the experiments, especially compared with conventional 316-L database materials. An associated research project will be described in more detail in upcoming publications.

Study of the Influence of the Mixed-Grain Structure on the Microscopic Deformation Behavior of 316LN Steel

Y. Q. Li, H. M. Zhang, M. X. Liu, and Z. S. Cui

Abstract Mixed grains are often encountered in heavy forgings. Taking 316LN austenitic stainless steel as an investigated material, two kinds of grain structures were tested for observation of microscopic deformation heterogeneity: uniform fine grains and mixed structures with millimeter-grade coarse grains (MCGs). Tensile tests, optical microscope (OM) observations, EBSD tests as well as crystal plasticity (CP) simulations were performed. Results showed that obvious slip bands were observed in the MCGs. During the deformation, the MCGs exhibited single slip bands if they were with soft orientation, and cross slip bands if they were with hard orientation. The fine grains were seen easily rotated in the deformation, forming distinguished bumpy grain boundaries, while the MCGs displayed smooth and collapsed grain morphology. The interior MCGs undertook severer deformation than the fine grains, which showed the strain partitioning ability of MCGs was limited. This deformation behavior is possible to lead the crack initiation in the interface among MCGs and surrounding fine grains.

Keywords 316LN austenitic stainless steel · Millimeter-Grade Coarse Grains (MCGs)

1 Introduction

ASTM-TP316LN (316LN) austenitic stainless steel, which contains extra low carbon grade and strictly controlled nitrogen content, is widely used in the nuclear power station equipment (NPSE) for its excellent combination of high strength, good corrosion resistance, and adequate weldability [1]. Owing to the inhomogeneous distributions of the temperature and deformation during the forging, the coarse and fine grains, i.e., the mixed-grain structures, usually coexist in the forged pipes, resulting in the heterogeneous microstructure and anisotropic performance. Figure 1a presents the relationships between ductility and grain size of this steel. Figure 1b shows the

typical feature of MCGs. One can see that the elongation of the sample with the mixed-grain structure is about 20% which is much smaller than that with uniform grains. Since the testing material does not show phase transformation and multi-phase-induced heterogeneous deformation, the phenomenon above is mainly due to grain structure. In general, it is significant to refine the austenitic grains for its better material property. Recrystallization is an effective way to refine the grains, and there are many studies about recrystallization [2, 3]. In the research of recrystallization, two key factors that are most concerned about are the temperature and the corresponding deformation. This study takes the sample with the mixed-grain structure as the main research object and investigates the influence of the MCGs on the deformation by ex-situ tensile tests, scanning electron microscope (SEM), and other test methods in order to provide the guidance for the future refinement process.

2 Material Preparation and CP Modeling

2.1 Experiment

The material selected for this study is an as-forged 316LN stainless steel with major element compositions shown in Table 1. Two as-received samples were prepared to probe the influence of the mixed-grain structure on the deformation behavior.

Table 1 Major element composition of studied material in wt%

Element	Cr	Ni	Mo	Mn	Si	Fe	Others
wt%	17.46	11.33	2.11	1.62	0.47	66.82	0.19

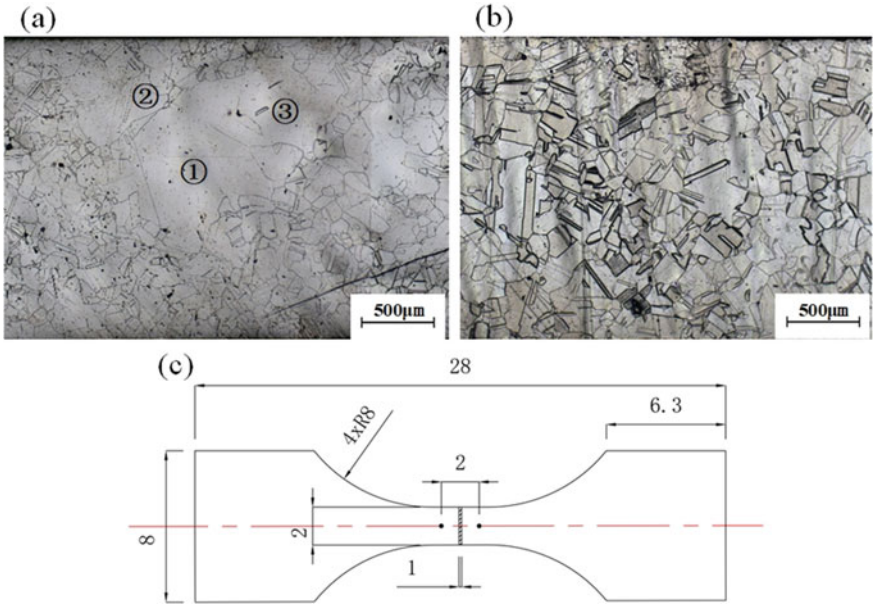

Fig. 2 The microstructures and dimensions of the tensile testing samples. **a** With mixed-grain structure, **b** with uniform grain structure, and **c** the dimensions of the micro tensile testing sample. (Color figure online)

One possesses the mixture of MCGs and fine grains, and as a contrast, the grain of the other is uniform. After standard grinding and polishing, two samples were still prepared by electrochemical polishing for the convenience of optical observation and EBSD observation. The electrolyte for electrochemical polishing is 4% oxalic acid solution. Figure 2 shows the dimension of the non-standard tensile testing sample and the optical micrographs of the gauge part. The grains (marked as 1, 2, and 3) in the center of the sample are the typical microstructure of MCGs.

The ex-situ micro uniaxial tensile tests were carried out at room temperature in a microtester machine (MTest5000, China Mechanical Testing Equipment Co., Ltd) with a load cell of 5000 N (CHcontech) at a strain rate of 0.001 s^{-1}. The tensile specimen was deformed to different strain levels by interrupted tensile testing. After every interruption, the microstructure was observed under an optical microscope (OM; Zeiss Axio Imager M2m), and the specimen was analyzed using a scanning electron microscope NanoSEM 230 equipped with an EBSD detector.

Table 2 Material parameters of the studied 316LN steel for the CP simulations

C_{11}	C_{12}	C_{44}	g_0	g_s
262.5 GPa	112.5 GPa	75.0 GPa	95.0 MPa	395.0 MPa
h_0	$\dot{\gamma}_0$	m	a	
1050.0 MPa	0.001 s^{-1}	0.02	2.95	

2.2 Modeling Methodology and Simulation Setup

The CP using a spectral numerical solver [5] was adopted based on DAMASK [6]. The CP model of the representative volume element (RVE), as well as the corresponding parameter and the boundary conditions setup, is introduced as follows.

2.2.1 Crystal Plasticity-Based Constitutive Model

A phenomenological rate-dependent flow law is adopted to describe the slip rate of the α-th slip system.

$$\dot{\gamma}^{\alpha} = \dot{\gamma}_0 \left(\frac{|\tau^{\alpha}|}{\mathrm{g}^{\alpha}} \right)^{1/m} \mathrm{sign}(\tau^{\alpha}) \tag{1}$$

With $\dot{\gamma}_0$ the reference strain rate, τ^{α} the resolved shear stress, g^{α} the resistance to shear, and m the strain rate sensitivity exponent. g^{α} is generally given by

$$\dot{\mathrm{g}}^{\alpha} = \sum_{\beta} h_{\alpha\beta} \dot{\gamma}^{\beta} \tag{2}$$

where $h_{\alpha\beta}$ is the matrix of slip hardening moduli, and can be expressed as

$$h_{\alpha\beta} = h_0 \left[q + (1-q)\delta^{\alpha\beta} \right] \left| 1 - \frac{\mathrm{g}^{\beta}}{\mathrm{g}_s} \right|^{a} \mathrm{sign}\left(1 - \frac{\mathrm{g}^{\beta}}{\mathrm{g}_s} \right) \tag{3}$$

In which h_0, g_s, and a are the reference self-hardening moduli, saturation shear resistance, and hardening exponent, respectively. q is the ratio of self-hardening to latent hardening, and here q is set to 1 for self-hardening and 1.4 for latent hardening as proposed by Pierce et al. [7]. The determined parameters for the studied material are listed in Table 2 [4].

2.2.2 RVEs and Representative Microstructures

In this research, considering the computational cost, the 2D RVEs were generated through the EBSD data for the CP simulation. The periodic boundary was imposed

in the length and thickness direction. The surfaces along the width direction were defined as free surface by adding an air layer to the surface. During the uniaxial tensile simulation, each RVE underwent the prescribed total deformation gradient $\bar{\mathbf{F}}$ and the first P–K stress $\bar{\mathbf{P}}$ along the length direction under a strain rate of 0.001 s^{-1}. Two tensors are expressed as Eq. (4):

$$\bar{\mathbf{F}} = \begin{bmatrix} 1.349 & 0 & 0 \\ 0 & * & 0 \\ 0 & 0 & * \end{bmatrix} \text{ and } \bar{\mathbf{P}} = \begin{bmatrix} * & * & * \\ * & 0 & * \\ * & * & 0 \end{bmatrix} \tag{4}$$

where the asterisk "*" denotes the undefined component. 1.349 means a maximum nominal strain of 0.349, which is equivalent to a true strain of about 0.3.

Fig. 3a1, b1 presents the representative microstructures used in simulation, and the distribution of the Taylor factor is shown in Fig. 3a2, b2. Owing to the characteristic of single phase, the Taylor factor of the studied material can be used to represent the ability of initial slip or initial deformation. The smaller the value of the Taylor factor, the easier the initial slip. From Fig. 3a2, it was clear that one of the MCGs in the center of the gauge showed soft orientation.

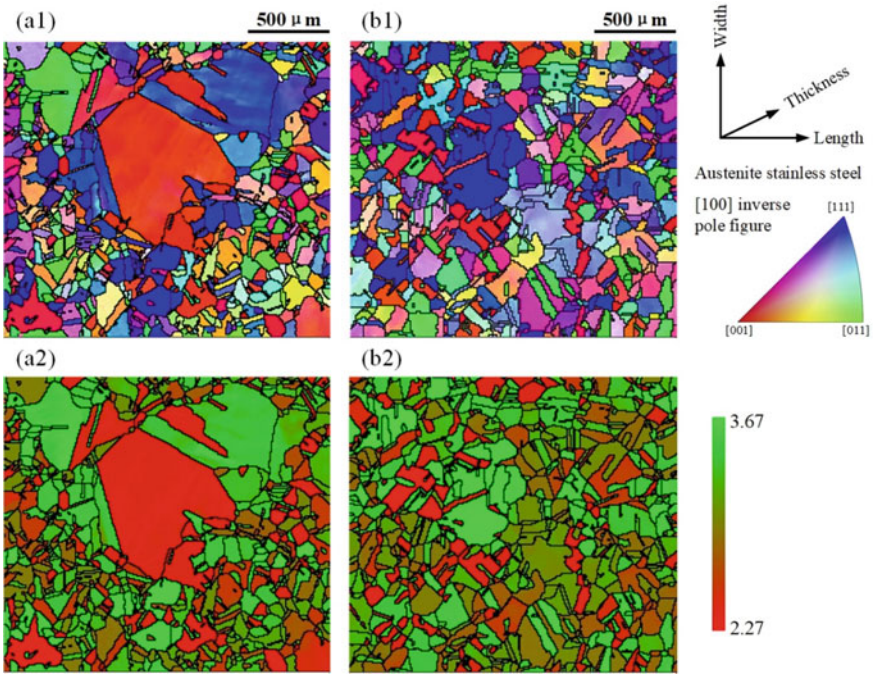

Fig. 3 OIM images obtained from EBSD used for CP simulation of micro-tensile tests and the initial distribution of Taylor factor. **a** With mixed-grain structure, and **b** with uniform grain structure. (Color figure online)

3 Results and Discussion

Figure 4 presents the change of the microstructure for two samples in each interruption. The levels of the true strain were 0.5%, 3%, and 10%, respectively. The selections of the interruptions of true strain have different meanings. The strain level of 0.5% represents the stage that the yielding of the material starts and the strain level of 3% means a stable deformation state. The strain level of 10% signifies a relatively large deformation state. One can see in Fig. 4a1–a3 that the microstructural change of the sample with uniform fine grains is consistent in every strain level. It implies that the deformation or the strain distribution is homogeneous. The typical characteristics contain slip bands and uniform bumpy surfaces which indicates the occurrence of both crystal slip and rotation. By contrast, when the specimen is initially strained to 0.5%, distinct slip bands appear in the MCGs (marked as 1 and 2) as shown in Fig. 4b1. However, this phenomenon is not obvious in other grains containing the coarse grain (marked as 3) and fine grains. It indicates that, in the beginning of the deformation, the deformation takes place mainly in the grains (marked as 1 and 2) because of their soft orientation and large grain size. It is also concluded that for the same phase of similar orientations, the larger the grain size, the smaller the yield strength. The aforementioned conclusions agree well with the Hall–Patch relationship [8, 9]. The result of 3% true strain is shown in Fig. 4b2. One can see that the single slip bands of MCGs (marked as 1 and 2) deepen and inconspicuous cross slip bands appear in the MCG (marked as 3). The surface of MCGs is smooth while the surface of the region of fine grains is bumpy. It elucidates that the MCGs in soft orientations undertake the primary deformation in the form of the single slip.

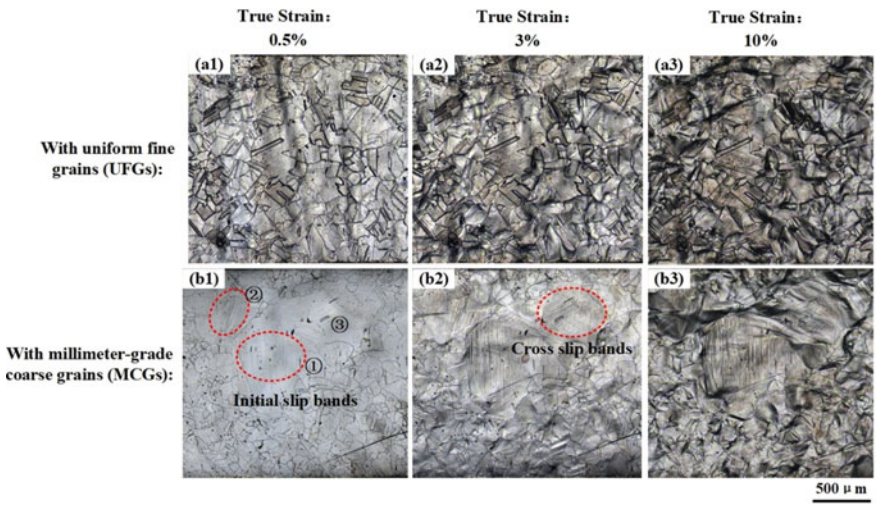

Fig. 4 The microstructure of two samples after deformation is characterized by optical microscopy. **a** The sample with uniform fine grains and **b** the sample with MCGs. (Color figure online)

However, although the MCG in hard orientations bears no much plastic deformation at the beginning of the tensile test, it has no choice but to undertake some plastic deformation in the subsequent deformation process because the crystal rotation is not easy to happen due to its large grain size. It is noted that the plastic deformation of hard-oriented grains is achieved in a way of multi-slip system. As shown in Fig. 4b3, the surface of MCGs collapses when the true strain reaches 10%. But the surrounding fine grains also show a bumpy surface as the sample with uniform fine grains. It once again verifies the conclusion that the crystal rotation is hard to occur for MCGs and the plastic deformation is performed in the form of crystal slip which is reflected in the tensile sample as the smooth and collapsed surface caused by the material flow of MCGs. It can be deduced that the stress in the collapsed MCGs is bigger and the interface among the MCGs and the surrounding fine grains is the region of stress concentration.

The simulation results are shown in Fig. 5. One can see that in Fig. 5b1, the strain distribution of the sample with MCGs agrees well with the experimental results that: (i) the MCGs with soft orientations undertake the main plastic deformation and (ii) even though the hard-oriented MCG is difficult to undertake plastic deformation at the initial stage of tensile tests, it has to bear some plastic deformation to make the overall deformation coordinate due to its large grain size and difficult crystal rotation. The results of the stress distribution shown in the Fig. 5b2 indicates that the stress of the MCG in hard orientation is bigger than other grains, and the stress concentration (marked by the dashed ellipse) is also observed in the interface among the MCGs

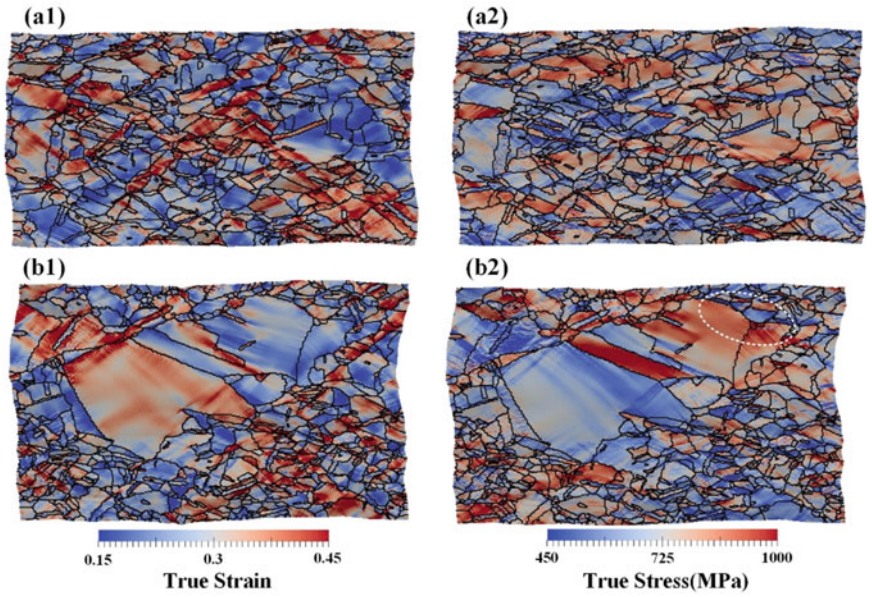

Fig. 5 The simulated von Mises stress and von Mises strain to 30% true strain. **a** The sample with uniform fine grains and **b** the sample with MCGs. (Color figure online)

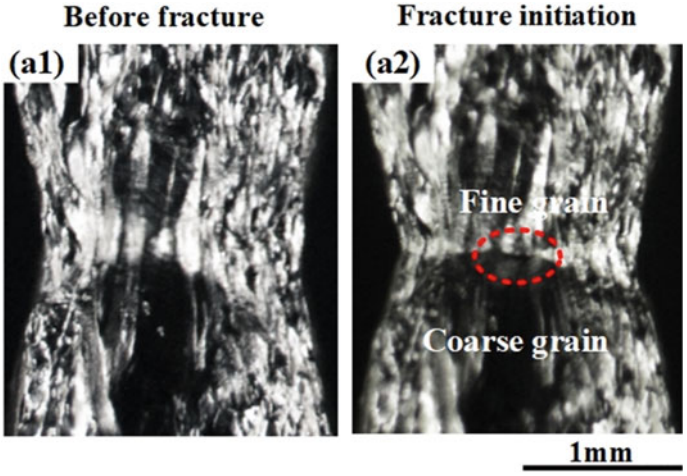

Fig. 6 The fracture initiation of the sample with MCGs obtained by the optical microscopy. (Color figure online)

and the surrounding fine grains. But the stress in the region of soft-oriented MCGs is small. It is noted that the stress concentration is not distinct in the interface among the soft-oriented MCGs and the surrounding fine grains. The reason is that soft-oriented grains bear main plastic deformation, which leads to less deformation of fine grains around them. Therefore, the stress in these fine grains is low and the stress concentration is not obvious. As for the sample with uniform fine grains, the stress distribution is more uniform. The fracture initiation of the sample with MCGs was captured by the optical microscope, and the results are given by Fig. 6. The collapsed area at the bottom of the figure is the region containing the MCGs. One can see that the crack initiated in the interface among the MCGs and fine grains. Thus, the results of the macroscopic mechanical curves shown in Fig. 1 can be explained as follows that the deformation of the MCGs is mainly conducted by the crystal slip due to their coarse grain size. As the deformation continues, the surface of the MCGs collapses because of the sharp flow of the material which reducing the thickness of this part, thus leading to the increase of stress. More importantly, the stress concentration existing in the interface among the MCGs and the surrounding fine grains accelerates the nucleation of the crack. That is why the elongation is greatly reduced.

Figure 7 shows the SEM results of the fracture morphologies for both samples. One can see that the fracture of the sample with uniform fine grains shows the typical microstructure of the dimples as well as the big holes caused by the initial hole of the material and the inclusion. By contrast, for the sample with MCGs, the region corresponding to the fracture initiation shown in Fig. 7b3 is characterized by the mixture of shear and dimples. The differences also exist in fracture propagation. As shown in Fig. 7b1, in the region of the MCGs, the fracture propagation is in the form of transgranular fracture, and the surface shows smooth morphology caused by shear deformation. It indicates that the crystal slip in the MCGs and their big grain size

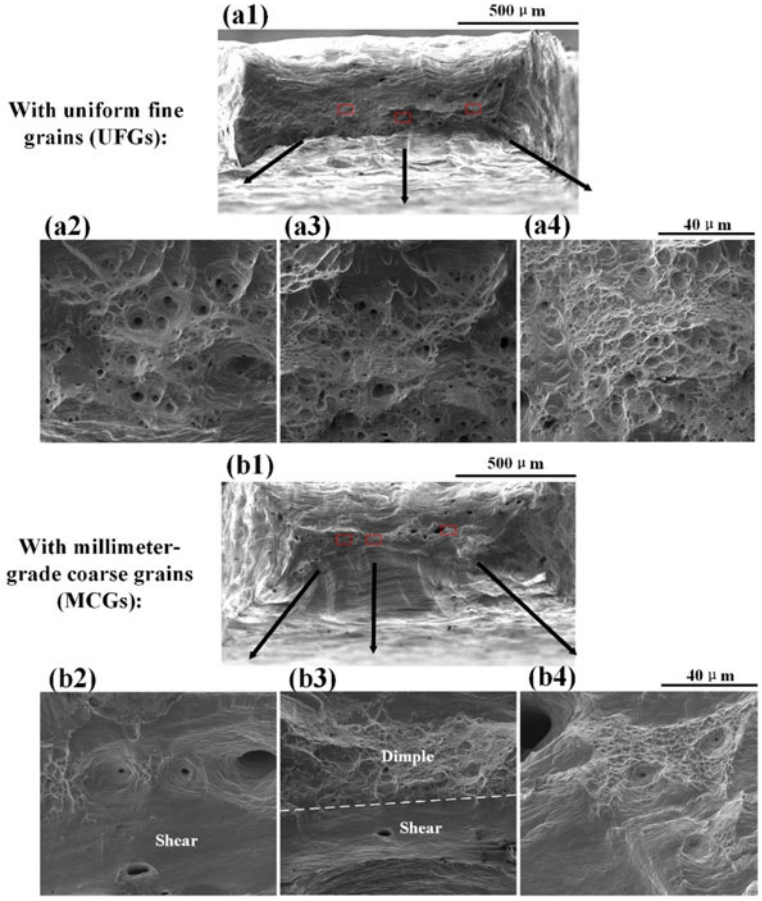

Fig. 7 The SEM results of the fracture morphologies. **a** The sample with uniform fine grains, and **b** the sample with MCGs. (Color figure online)

have a great influence on fracture propagation. While in the region of the fine grains, the ductile fracture with typical dimple morphologies is the main mode for fracture propagation.

4 Conclusion

This study applied the ex-situ tensile tests as well as SEM and other methods to probe the effect of the mixed-grain structure existing in 316LN stainless steel on the deformation. It can be concluded as follows:

1. The yielding strength of the MCGs is smaller than fine grains which is manifested by the occurrence of the initial slip band on their surface. As the deformation continues, the plastic deformation of the MCGs in soft orientation is mainly achieved in the way of single slip, while the MCGs in hard orientation bear the deformation in the mode of multi slip system.
2. When the deformation reaches some degree, the surface of the MCGs collapses seriously which increases the stress of this part and the stress concentration in the interface among the MCGs and surrounding fine grains. The severe stress concentration leads to the early crack initiation. In addition, the fracture propagation is also affected by the MCGs which is characterized by the morphology of shear.

Dependence of Mesoscale Structure of Drawn High-Carbon Steel Wire on Wire Diameter

Shiori Gondo, Rena Tanemura, Ryuki Mitsui, Satoshi Kajino, Motoo Asakawa, Kosuke Takemoto, Kenichi Tashima, and Shinsuke Suzuki

Abstract This study aims to clarify the transition of mesoscale structure of a drawn wire versus drawing strain. High-carbon steel wires 0.276, 0.444, and 0.936 mm in diameter were drawn until wires could be drawn without rupture. Two results were obtained from a crystal orientation analysis of the electron backscatter diffraction pattern. First, the mesoscale structure in the wire consisted only of a subprimary fiber texture {100}<110>-{111}<110> at the drawing limit, that is the largest drawing strain when the wire could be drawn without rupture. Second, it is predicted that the transition of the mesoscale structure versus the drawing strain will occur as follows

regardless of the initial wire diameter: In the beginning of wire drawing, the wire will have only a primary fiber texture {100}<110>-{111}<110>. After a slight increase in the drawing strain, the wire will have the primary fiber texture at its outer side and a secondary fiber texture {111}<110>-{110}<110> at the inner side. After a further increase in the drawing strain, the wire will have a subprimary fiber texture at the outer side and a secondary fiber texture at the inner side. Moreover, increase in the drawing strain, the wire will have only a subprimary fiber texture.

Keywords High-carbon steel wire · Wire drawing · Crystal orientation · Fiber texture · EBSD analysis

1 Introduction

An increase in the strength of metallic materials through the wire drawing process is required for reduction of the load on the environment. Recently, high-carbon steel wire with a tensile strength of 7000 MPa was fabricated by a wire drawing process at the laboratory scale [1]. However, in general, the ductility of the wire significantly decreases with increasing its strength which follows on an increase in drawing strain. Thus, the clarification of an effective microstructure is necessary in order to maintain the balance between strength and ductility.

Some existing literatures have focused on vacancies [2], dislocations [2], the lamellar angle in the longitudinal direction of the wire [3, 4], lamellar spacing [5], and the fragmentation and decomposition of cementite [6–9]. However, no previous report has mentioned the relationship between microstructures and a decrease in ductility of the drawn wire.

On the contrary, we established the tensile testing method and the measurement method for ductility of the fine metal wire [10], and clarify the effect of back stress which applied to the wire at entrance side of the die during wire drawing on mechanical properties of drawn fine high-carbon steel wire [11]. Although the ductility of the wire significantly decreased on 1st pass, after that, the ductility of the wire slightly decreased and then increased with increasing drawing strain. Furthermore, a decrease in back stress improved the ductility of the drawn wire. To clarify the mechanism, we have focused on crystal orientation distribution in the radial direction of the wire as one of the microstructures that had not yet been analyzed detailly [12]. For a high-carbon steel wire with an initial diameter of 0.444 mm, the transition of the crystal orientation distribution, “mesoscale structure” characterized by the fiber textures, versus the drawing strain was clarified as follows. In the beginning of wire drawing, the wire had only a primary fiber texture {100}<110>-{111}<110>. After a slight increase in the drawing strain, the wire had a primary fiber texture at the outer side and secondary fiber texture {111}<110>-{110}<110> at the inner side. After a further increase in drawing strain, the wire had a subprimary fiber texture {100}<110>-{111}<110> at the outer side and secondary fiber texture at the inner side. Although the tendency that a decrease in thickness of subprimary fiber texture

via decreasing back stress improves ductility has been obtained, it is not clarified whether this tendency is universal or not. Because the mesoscale structure at the drawing limit, i.e., the largest drawing strain at which the wire can be drawn without rupture, and the dependence of mesoscale structure on wire diameter are not clarified well. Two approaches are adopted for obtaining a more beneficial understanding of the relationship between mesoscale structure and the mechanical properties. The first is clarifying the mesoscale structure at the wire drawing limit. The second is clarifying the effect of the initial diameter of the wire on the mesoscale structure, because it is expected that crystal orientation distribution in the radial direction of the wires with a small diameter would be uniformized following a decrease in the stress gradient. The theoretical analysis has reported that the strain gradient in the radial direction of the wire decreases with decreasing wire diameter [13]. Therefore, the objective of this study is to clarify the transition of the mesoscale structure of the wires with different initial diameters with respect to the drawing strain up to the wire drawing limits.

2 Experimental Procedures

The starting materials were patented pearlitic steel wires 0.276, 0.444, and 0.936 mm in diameter. They were provided by Nippon Steel SG Wire Co., Ltd. Table 1 shows the chemical composition of the wires. The composition was measured according to the Japanese Industrial Standards (JIS) G1211 [14], G1212 [15] and G1258 [16] for C, Si, and other relevant elements, respectively.

The wires were drawn under areal reduction for one pass of 7% and a back stress ratio less than 5% using non-slip type drawing machines (Factory-Automation Electronics Inc., D3UlTM-5D/D3UlTM-10D). The definitions of the areal reduction for one pass, the back stress ratio and the drawing strain ε_n were the same as definitions in our previous works [10–12, 17]. The subscript n indicates the pass number. Figure 1 shows the relationship between the drawing direction and direction of back stress. The wire with an initial diameter of 0.444 mm, which had already been drawn

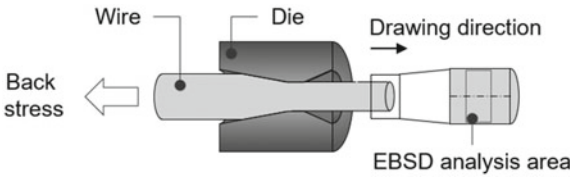

Fig. 1 Schematic figure of the wire drawing process and electron backscatter diffraction analysis area

to 0.063 mm in our previous work [12], was drawn in this study. After the wires were drawn, the diameters of the wires were measured using a laser interferometer (Zumbach Electronics AG, DU600-RO-OL). The surface of the wires was observed through a field emission scanning electron microscope (FE-SEM) (Carl Zeiss AG, Ultra Plus).

The preparation methods for the samples of transmission electron microscope (TEM) observation and crystal orientation analysis were similar to that of our previous work [12]. The sample for TEM was prepared by focused ion beam (FIB) (JEOL Ltd., JIB-4000). The lamellar structure of starting materials was observed through TEM (JEOL Ltd., JEM-2100F). The samples for electron backscatter diffraction (EBSD) analysis were polished by Ites Co., Ltd. The width of the polished plane was larger than 90% of the diameter of the wire. Kikuchi patterns of the drawn wires were obtained by FE-SEM with EBSD (Bruker Co., XFlash 6130) at the magnification the observation field was full with the polished plane. Then, pole figures of divided analysis areas in several were drawn by using software (Bruker Co., Esprit 2.1). The width of the separated areas was approximately one tenth of the width of the polished plane. After analysis, the mesoscale structure was decided based on the fiber textures: primary, secondary, and subprimary fiber textures [12].

3 Results

Figure 2 shows TEM image of lamellar structure in a starting wire with an initial diameter of 0.444 mm [12]. The obvious difference of lamellar spacing was not observed because the average of lamellar spacings of the starting wires with diameters of 0.276, 0.444, and 0.396 mm were approximately 58 nm, 58 nm, and 61 nm, respectively.

Figure 3 shows the relationship among the initial diameter of wires, the smallest diameter of drawn wires, and drawing strain, and the SEM images of the drawn wires with the smallest diameter. The wires with the initial diameters of 0.276 and 0.936 mm were able to be drawn to 0.021 mm ($\varepsilon = 5.12$) and 0.093 mm ($\varepsilon = 4.62$) without rupture, respectively. The wire with an initial diameter of 0.063 mm ($d_0 = 0.\ 444$ mm) could be drawn to 0.029 mm ($\varepsilon = 5.42$) without rupture. The wire with a diameter of 0.093 mm ($d_0 = 0.936$ mm) fractured as soon as the drawing

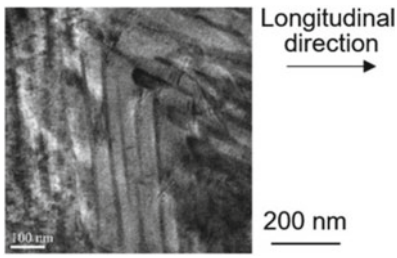

Fig. 2 Transmission electron microscope image of lamellar structure in starting wire with an initial diameter of 0.444 mm [12]

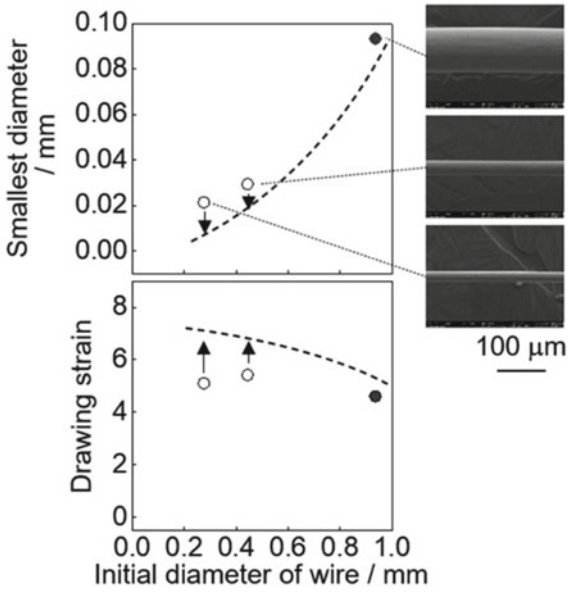

Fig. 3 Relationships among the initial diameter of wires, the smallest diameter of drawn wires and their drawing strain, and the scanning electron microscope images of the most finely drawn wires. The wires with the initial diameters of 0.276, 0.444, and 0.936 mm could be drawn to 0.021 mm ($\varepsilon = 5.12$), 0.029 mm ($\varepsilon = 5.42$), and 0.093 mm ($\varepsilon = 4.62$) without rupture, respectively. At the next drawing step, the wire with a diameter of 0.936 mm (indicated by gray-colored plot) could be put through the die hole but was fractured as soon as the drawing commenced. The wires indicated by white-colored plots could not be put through the die hole. The dashed curves are rough estimation of the wire drawing limit, i.e., the largest drawing strain at which the wire can be drawn without rupture

commenced. The wires with diameters of 0.021 mm ($d_0 = 0.276$ mm) and 0.029 mm ($d_0 = 0.444$ mm) were too fine to be put through the die hole.

Figure 4 shows the mesoscale structure of the drawn wires with initial diameters of 0.276, 0.444, and 0.936 mm. Regardless of the initial diameter, the wires with a drawing strain of approximately 1.5 had a primary fiber texture and secondary fiber texture at outer and inner sides of the wire, respectively. The wires with diameters of 0.029 mm ($d_0 = 0.276$ mm, $\varepsilon = 4.48$), 0.029 mm ($d_0 = 0.444$ mm, $\varepsilon = 5.42$) and 0.093 mm ($d_0 = 0.936$ mm, $\varepsilon = 4.62$) had only a subprimary fiber texture throughout the entire wire.

4 Discussion

Although the wires with initial diameters of 0.276 and 0.444 mm were too fine to be put through the die hole after drawing to 0.029 and 0.021 mm, respectively and could

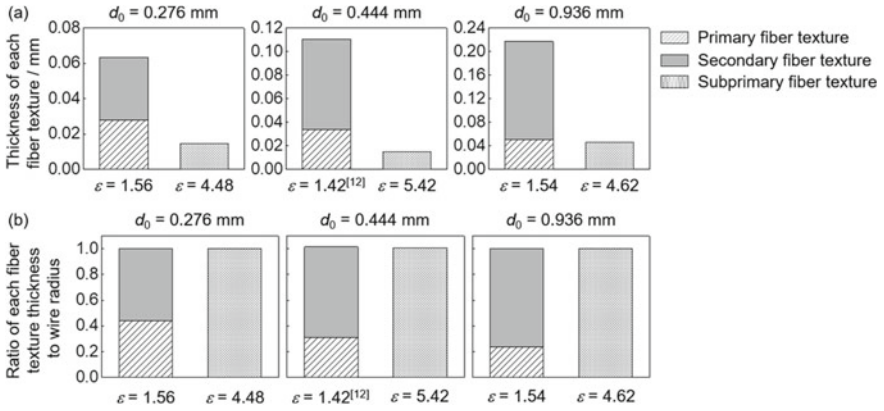

Fig. 4 Mesoscale structure of the wires with $d_0 = 0.276$ mm ($\varepsilon = 1.56$, $\varepsilon = 4.48$), $d_0 = 0.444$ mm ($\varepsilon = 1.42$ [12] and $\varepsilon = 5.42$), and $d_0 = 0.936$ mm ($\varepsilon = 1.54$, $\varepsilon = 4.62$): **a** the thickness of each fiber texture and **b** its ratio to the wire radius

not be drawn to their drawing limits by using the drawing machine, it was implied that wires with a smaller diameter can be drawn to a higher drawing strain.

The drawn wire with a diameter of 0.093 mm ($d_0 = 0.936$ mm, $\varepsilon = 4.62$) had only a subprimary fiber texture. For the wires with initial diameters of 0.276 and 0.444 mm, the wire with the drawing strain less than the limit strain had only subprimary fiber texture. Thus, the wire with the greatest drawing strain had mesoscale structure that consisted only of a subprimary fiber texture

In wires with a drawing strain of approximately 1.5, the mesoscale structure consisted of a primary fiber texture and secondary fiber texture regardless of the initial diameter, as shown in Fig. 5. In contrast, wires with a drawing strain around approximately 5 had a mesoscale structure that consisted only of a subprimary fiber

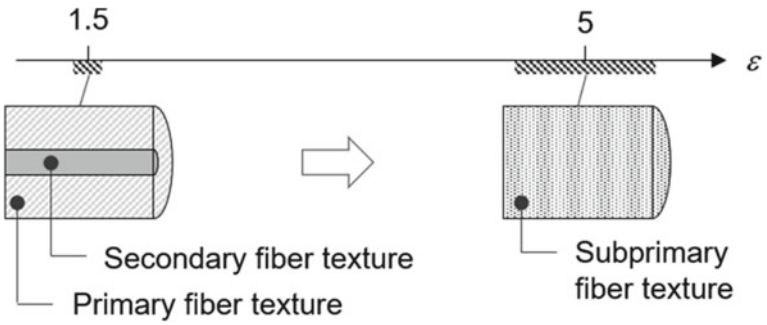

Fig. 5 Schematic figure of mesoscale structure transition versus the drawing strain of the wires with initial diameters of 0.276, 0.444, and 0.936 mm. Regardless of the initial diameter, the wires with drawing strains of approximately 1.5 had primary and secondary fiber textures. The wires with drawing strains around 5 had only a subprimary fiber texture

texture. Therefore, it is predicted that the transition order of mesoscale structure versus drawing strain is not dependent on the initial diameter as follows: In the beginning of wire drawing, the wire has only a primary fiber texture. After a slight increase in the drawing strain, the wire has the primary fiber texture at its the outer side and a secondary fiber texture at the inner side. After a further increase in the drawing strain, the wire has a subprimary fiber texture at the outer side and a secondary fiber texture at the inner side. Moreover at a large the drawing strain, the wire has only a subprimary fiber texture.

At a drawing strain of approximately 1.5, the ratio of the thickness of the secondary fiber texture to the radius of the wire increased when the initial diameter decreased. In addition, our previous work indicated that the transition of the ratio of the secondary fiber texture thickness to wire radius could be fit with a quadratic function [12]. The study also clarified the tendency that an increase in the back stress ratio shifted the transition to a lower drawing strain. Assuming that the transition can be accurately fitted by the quadratic function regardless of the initial diameter of the wires, it is predicted that one of the following patterns occurs when the initial diameter decreases. First, the drawing strain at the formation of fiber textures decreases and disappearance of secondary fiber texture increases; furthermore, the maximum value of the fitting curve increases. Second, the transition of mesoscale structure versus drawing strain shifts to a higher drawing strain. Third, both patterns happen at the same time. These guesses differ from the prediction based on the strain gradient mentioned in the introduction; this would be due to the small variation in strain gradients for the different initial diameter wires used in this study. The authors predict that obtaining a large variation of strain gradients required comparing the mesoscale structure of the wire on a scale of several micrometers to that on a scale of several millimeters.

5 Conclusion

The following conclusions were obtained by clarifying the mesoscale structure, which is characterized by the fiber textures of the drawn high-carbon steel wire, versus the drawing strain for the wires with initial diameters of 0.276, 0.444, and 0.936 mm.

(1) The mesoscale structure of the drawn wire consists only of subprimary fiber texture at the largest drawing strain when the wire can be drawn without rupture.
(2) It is predicted that the transition order of the mesoscale structure versus the drawing strain is independent of the initial wire diameter.

Thermomechanical Analysis and Experimental Validation of ECAP for Aluminum Sheet Metal

Maximilian Gruber, Yiheng Yang, Christian Illgen, Philipp Frint, Martin F.-X. Wagner, and Wolfram Volk

Abstract Equal-channel angular pressing (ECAP) is an established method for the improvement of mechanical properties by grain refinement through shear strains. While there is a profound knowledge about ECAP of bulk materials, there is only a little information on the effect of ECAP on sheet metals. Therefore, a tool was developed that is able to perform ECAP tests for metals with a thickness of 1.8 mm. In this contribution, a thermomechanical simulation model is used to examine the novel process. The simulation is performed to investigate the dissipated forming heat and the heat due to friction. To validate the numerical results, experiments with the ECAP tool for sheet metal are performed. By drilling holes in the sheet material, the forming temperature can be measured with thermocouples and friction parameters used in the simulation can be calibrated inversely. Since a detailed material model is essential for the inverse determination of individual parameters, a special focus of this article is on the determination of the thermomechanical parameters. For example, the plastic flow behavior or thermomechanical conversion, expressed as the Taylor–Quinney coefficient, is examined under a stress state similar to ECAP by means of a Miyauchi test. In this way, fundamental correlations between the heat development in the ECAP process for aluminum sheet metal and the shear strain introduced into the material can be obtained.

1 Introduction

In recent years, Equal-channel Angular Pressing (ECAP) , which was already introduced in the 1980s by Segal [1], has been attracting increasing scientific and technological interest [2]. In particular, ECAP offers the possibility of introducing high shear deformations into semi-finished products, which makes it possible to produce (ultra-)fine-grained microstructures. During ECAP, a typically square or circular cross-sectioned billet is pressed through a rigid and angled channel. Both channels (entrance and exit channels) are intersected by a shear plane, where shear deformation is introduced into the material. To impose higher strains, processing by ECAP can be performed repeatedly in several consecutive passes and also in different processing routes.

While there are already scientifically valuable, fundamental parameter studies on the effects of channel geometry, processing temperature and processing route on the resulting microstructure and mechanical properties [3, 4], an important and still unresolved problem is the viability of ECAP processing for use in industrial environment. Different approaches were already pursued to solve industrial suitability: On the one hand, the ECAP process has been modified. This has resulted in processes such as *Conshearing* or the *ECAP-Conform* process [5–7]. Another approach, on the other hand, deals with adapting the geometry of the semi-finished product to conventional ECAP. Some studies already investigated the influence of up-scaling on the refinement of the grains, since conventional ECAP processing is typically performed on a laboratory scale [7]. In addition, investigations on plate samples with a thickness of 5 mm have already been conducted successfully [8].

The tool used in the present study was developed by Suh et al. [9]. Its unconventional design allows processing of sheet materials with sheet thicknesses of 1.8 mm. Initial numerical investigations have already shown the influence of different channel geometries (r, R, w, h, and Φ) on the processes for sheet metal [10], see Fig. 1. In addition, it has already been shown that this ECAP-tool can be used to carry out various process routes. Using these process routes, different deformations and thus textures can be generated in the material [11]. Initial successes with regard to an industrial use of ECAP have already been achieved. However, especially with regard to the homogeneity of the microstructure over the sheet thickness, the process still needs to be further improved. This inhomogeneity is mainly influenced by the friction in the channel [12]. Figure 1b exemplarily shows a small region at the upper surface of the sheet where the material is severely sheared in a direction opposite to the ECAP direction, followed by a second region with a large number of grains showing a distinct orientation toward the direction of induced shear strain.

Temperature-related effects also have a major influence on the characteristics of the microstructure and the design of the process. The energy terms investigated in this study include plastic strain energy, frictional sliding energy, and heat transfer energy. Especially the thermomechanical conversion, well known as the Taylor–Quinney coefficient (TQC), has a strong influence on the heat development in the process [13]. Nonetheless, the TQC is often generally assumed to be equal to 0.9 in numerical

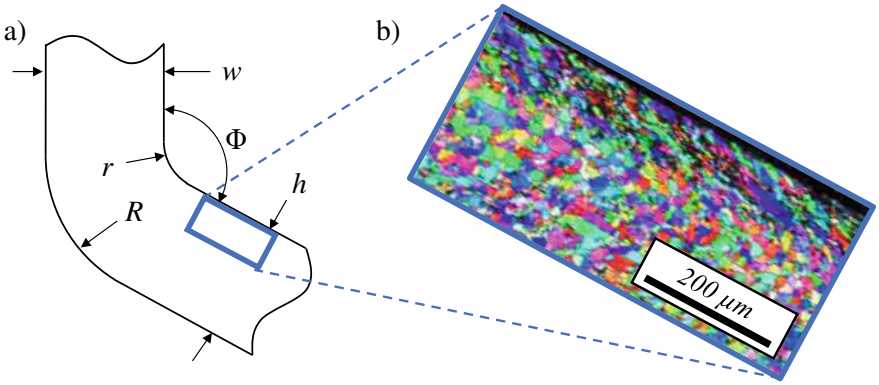

Fig. 1 **a** Schematic sketch of the channel parameters; **b** orientation maps determined by electron backscatter diffraction of the severely deformed microstructure, indicating inhomogeneity especially at the sheet metal surface (top of the box). (Color figure online)

investigations. However, several studies already show that the TQC depends on the material or alloy, the stress mode, and the strain rate [14]. For aluminum, one can find some literature values for the TQC, but they vary greatly between 0.25 and 1.0 [14, 15]. In addition, when determining the TQC, it should be noted that temperature losses must be taken into account at slow forming speeds. For example, Behrens et al. show that heat losses and thermal conduction depend on the forming time for the determination of the TQC of high-strength steels [16]. Thus, an increasing forming speed leads to a temperature increase.

In order to get a detailed basic understanding of the ECAP process for aluminum sheets, numerical investigations are carried out within the scope of this work. A particular focus is placed on the consideration of frictional and thermomechanical effects with the aim of reducing the inhomogeneity of the microstructure. The material parameters for the numerical model are determined for this purpose. Friction, which is essential for the understanding and optimization of the process, can then be inversely determined by experimental validation and calibration. Using this simulation, the introduced strains that cause the desired grain refinement during ECAP can be examined. This provides the basis for a subsequent optimization of process parameters.

2 Experimental Investigations

This section explains the experimental investigations and the temperature measurement during the ECAP test. Conventionally cold-rolled AA5083 sheets with a thickness of 1.8 mm were used in this work. To provide a homogenous microstructure, a recrystallization annealing heat treatment was performed at 500 °C for 1 h. In the initial position of the ECAP test tool (see Fig. 2a), a sheet with a dimension of 200 ×

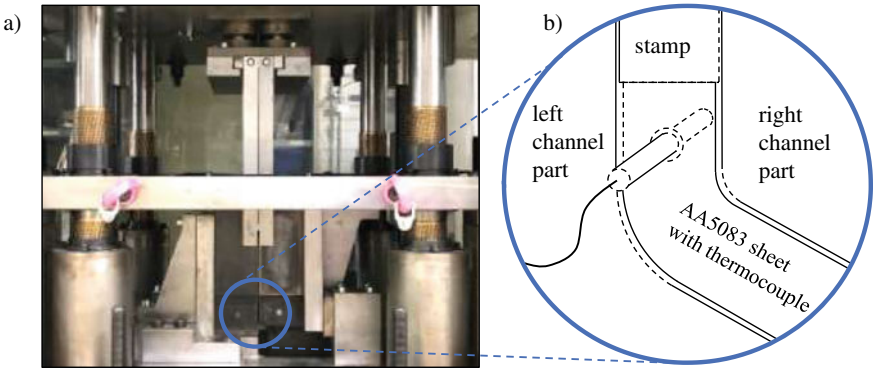

Fig. 2 **a** ECAP tool for sheet metals with 1.8 mm thickness; **b** schematic sketch of the temperature measurement in the experiment. Holes with a diameter of 0.55 mm were drilled 10-mm-deep in the middle of the sheet metal thickness to place thermocouples inside the sheet metal. (Color figure online)

$200 \times 1.8\ \text{mm}^3$ is laterally inserted between the channel parts. The sheet was pressed through the channel, consisting of the left and the right channel parts (see Fig. 2b), with a constant stamp speed of 5 mm/s with a channel angle of $\Phi = 120°$. The inner radius r is 0.5 mm and the outer radius R is 2.5 mm. For the present study, a width w of 2.22 mm and a height h of 1.8 mm were used. The pressing direction during ECAP was parallel to the rolling direction of the AA5083 sheet. The experiments were performed at room temperature.

In order to measure the temperature in the sheet metal during the ECAP process, 10 mm deep holes with a diameter of 0.55 mm for thermocouples were placed in the middle of the sides of the tested sheets, see Fig. 2b. The holes were positioned in the middle of the length of the specimens (100 mm from the edge of the sheet). Type K thermocouples with a thickness of 0.5 mm were used to measure the temperature. Thermal copper paste was used to fill the holes with the thermocouples to ensure a good heat transfer between the thermocouple and the aluminum sheet. The experiments were conducted with (f_{low}) and without (f_{high}) lubrication, to investigate the temperature development due to frictional effects. To reduce friction, the lubricant Bechem Beruforge 150D was used for the f_{low} tests [17].

Figure 3a shows the results of the temperature measurements during ECAP. The maximum temperatures develop when the position of the thermocouple (position = 100 mm) is in the shear zone of the ECAP channel. A maximum temperature increase of 15.2 K was observed in the lubricated tests (f_{low}). An increase of 18.6 K was measured without lubrication (f_{high}). Even before the maximum one can determine an increased temperature in the f_{high} sample compared to f_{low}. Due to the high thermal conductivity of the aluminum material, it is assumed that the increased friction in the channel causes higher temperatures even after passing through the shear zone. This also affects the following sheet metal sections. In addition, frictional effects at the channel walls already occur with the non-lubricated sample before it enters the

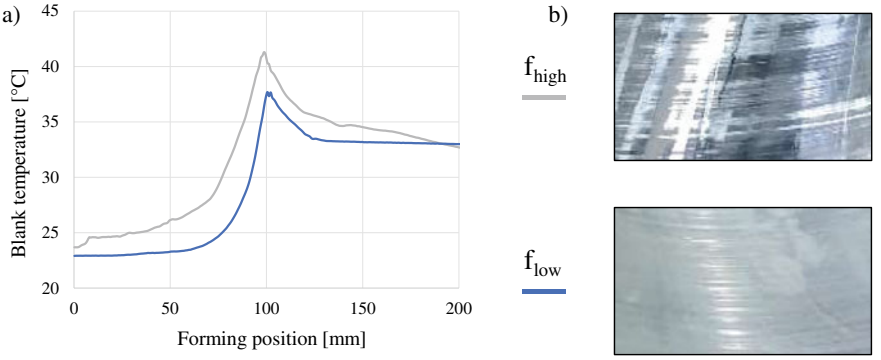

Fig. 3 **a** Absolute temperatures measured in the middle of the sheet in the experiment with (f_{low}) and without (f_{high}) lubrication; **b** surfaces of the ECAP processed sheets with high and low friction. (Color figure online)

shear zone. After the temperature maximum, localized in the shear zone at position 100 mm, the ECAP-processed material is still in contact with the tool surfaces. This produces heat conduction into the channel parts of the tool and thus leads to faster cooling for a distance of 20 mm (100–120 mm), which corresponds to the length of the channel exit after the shear zone. After the sheet metal leaves the tool, heat radiation and convection to the environment occur. Compared to the heat transfer into the active elements, the temperature therefore sinks more slowly. In the area without tool contact, it is noticeable that the temperature of the sample drops faster with increased friction. This can be attributed to damage to the sheet metal surface and the associated changes in radiation and convection behavior. Figure 3b shows the surfaces of the tested samples. The damage caused by low lubrication (f_{high}) can be seen clearly. These assumptions will be examined in more detail in the numerical part. In the area of the thermocouples, cracks form more easily in the aluminum. After the thermocouple has passed through the ECAP channel, however, the process stabilizes again immediately and proceeds as before the thermocouple passed through. The thermocouple cannot be pulled out of the sheet after the test, the shear deformation of the aluminum thus clamps the thermocouple and there is still continuous contact between the thermocouple and the material.

To determine the strains in the experiment, the approach according to Iwahashi is followed [18]. In the following formula, other symbols are used than in the original reference, since the symbols are necessary for the description of the thermomechanical characteristics. The formula describes the analytical calculation of the true plastic strain φ. The angle Φ' describes the angle of the specimen at the channel inner radius, ψ describes the angle at the channel outer radius. The angles are shown in Fig. 4.

$$\varphi = \frac{2\cot\left(\frac{\Phi'}{2} + \frac{\psi}{2}\right) + \psi cosec\left(\frac{\Phi'}{2} + \frac{\psi}{2}\right)}{\sqrt{3}} \tag{1}$$

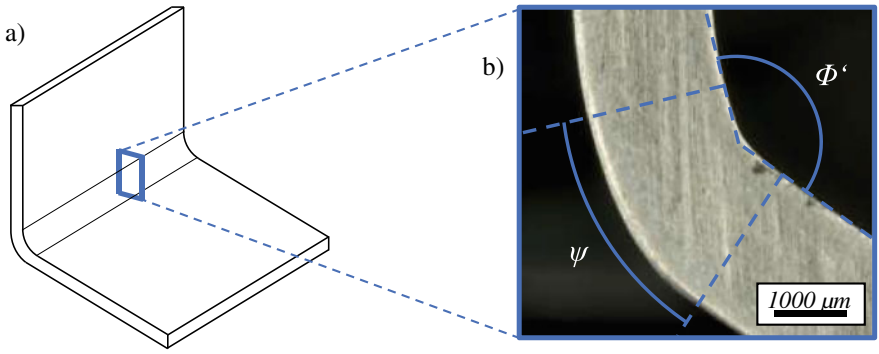

Fig. 4 **a** schematic sketch of the ECAP-deformed sheet metal. The specimen is cut out in the middle of the channel section; **b** Cross section of the specimen for determining the deformation angles Φ’ and ψ. (Color figure online)

To determine the geometric parameters for this approach, a sample is taken parallel to the ECAP direction in the center of the sheet. The specimen cross section is shown in Fig. 4b. Due to the fact that the sheet thickness is smaller than the channel width, the angle Φ' increases compared to the channel angle Φ. For the inner angle Φ', the value is 139°. The outer angle is 45°. Thus, according to Iwahashi's formula, a plastic strain φ of 0.413 is obtained.

3 Material Modeling

As a basis for the numerical investigations, first the used material model is described. To describe quasi-static hardening and elastic behavior, tensile tests according to ISO 6892 [19] were carried out at 0° with respect to the rolling direction (RD). Hydraulic bulge tests according to ISO 16808 [20] were performed to determine the equi-biaxial flow curve and to extrapolate the uniaxial flow curve. Since shear stress predominates in the ECAP process, quasi-static Miyauchi tests as described in Yin et al. were also performed [21]. These were used as a second extrapolation approach to investigate the influence of hardening behavior on the thermomechanical conversion. For the Miyauchi test a tool (Fig. 5a) was implemented in a ZwickRoell 150 kN machine. The specimen geometry is shown in Fig. 5b). To keep the shear strain homogeneous within a certain area, grooves were milled into the shear deformation area of the samples, see Fig. 5c). The load direction (LD) was parallel to the rolling direction (0°). 3D strain measurements were performed with the Aramis system (GOM GmbH) on the left shear zone of the symmetric specimen, see Fig. 5b). A constant crosshead speed of 0.0025 mm/s was used to obtain a quasi-static strain rate. The hardening curve with the bulge extrapolation approach was modeled using a combined Gosh and Hockett–Sherby approximation with a combination factor $\alpha = 0.265$ for the strains up to a value of 2 [22, 23]. The hardening curve of the

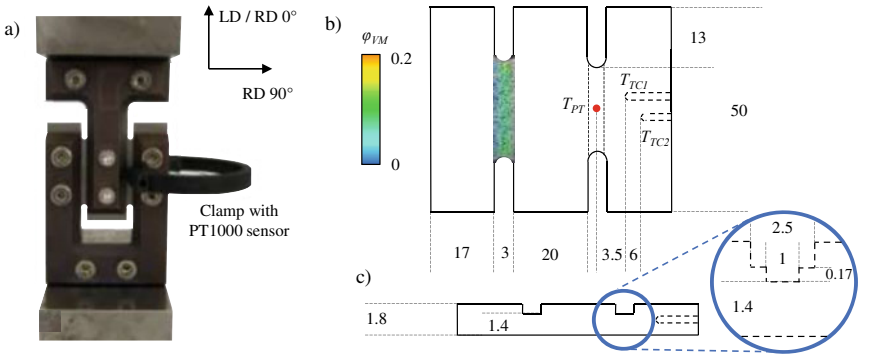

Fig. 5 **a** Miyauchi test tool with a clamp for the PT1000 sensor; **b** geometry [mm] of the Miyauchi specimen (top view). On the left side, the strains are detected; on the right side, temperature is measured with a PT1000 sensor (T_{PT}) and two thermocouples Typ K (T_{TC1}, T_{TC2}); **c** geometry [mm] of the Miyauchi specimen (side view). (Color figure online)

Miyauchi approach was modeled with an approximation according to Voce [24]. All experiments were mainly evaluated by the freely available Material Modeler tool [25]. The parameters defining the mechanical characteristics are summarized in Table 1 and the underlying mechanical data as well as the extrapolated curves are shown in Fig. 6.

In addition, intensive studies were carried out on the thermomechanical parameters, with a particular focus on an exact determination of the TQC. In order to generate a stress state comparable to the ECAP test, Miyauchi tests with LD oriented at 90° to RD were performed for the measurements. The temperature T_{PT} was detected

Table 1 Mechanical properties used for numerical investigations

Parameter	Value	References

Poisson's ratio ν	0.33	[26]
Density ρ	2,670 kg/m^3	[26]

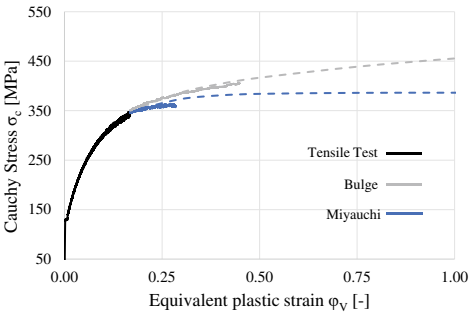

Fig. 6 Flow curve with the extrapolation strategies for bulge und Miyauchi tests. (Color figure online)

inline by a method based on a PT1000 sensor [27]. The sensor was applied to the sample with a clamp, see Fig. 5a, measuring the absolute temperature on the right shear zone of the specimen, see Fig. 5b. In order to draw conclusions about the heat conduction in the material, holes were also drilled into the side of the sample, see Fig. 5b). In these holes, the temperatures were measured with type K thermocouples (T_{TC1}, T_{TC2}). The distances between measuring points T_{PT} and T_{TC1} and between T_{PT} and T_{TC2} were 3.5 mm and 9.5 mm, respectively. The symmetry of the specimen allows the measured strain and temperature to be correlated. A crosshead speed of 2.5 mm/s was used in order to achieve a strain rate of 1/s, which approximately corresponds to the test conditions in the ECAP process. To validate the Miyauchi method, measurements were also carried out at a strain rate of 4/s with a crosshead speed of 10 mm/s.

In the Miyauchi test, no adiabatic condition can be assumed to evaluate the TQC since the tool is located very close to the forming zone and the forming motion of the testing machine is too slow for an adiabatic process. The following formulas therefore describe the individual terms that are assumed for the calculation of the TQC under consideration of the dissipated heat. In forming processes, heat is generated by energy dissipation. The sources of this are plastic deformation and friction:

$$\dot{W}_{Dissipation} = \dot{W}_{p,diss} + \dot{W}_{f,diss} \tag{2}$$

In the Miyauchi tests, the specimen is screwed on the test tool. This avoids relative movement between specimen and tool and the test is frictionless. Therefore, $\dot{W}_{f,diss}$ can be assumed to be 0. The TQC $\beta(t)$ is then introduced as the ratio of dissipated heat $\int_0^t \dot{W}_{p,diss} \cdot dt$ to plastic work $\int_0^t \dot{W}_p \cdot dt$.

$$\beta(t) = \frac{\int_0^t \dot{W}_{p,diss} \cdot dt}{\int_0^t \dot{W}_p \cdot dt} \tag{3}$$

The plastic power $\dot{W}_p$ is then calculated based on the plastic flow curve as follows:

$$\dot{W}_p = V \cdot \sigma_s \cdot \dot{\varphi} \tag{4}$$

where σ_s is the shear stress and $\dot{\varphi}$ is the plastic strain rate. For volume V, a homogenously deformed area in the milled section is assumed ($2.5 \times 24 \times 1.57$ mm^3). For the calculation of the dissipated heat rate $\dot{W}_{diss}$ several terms have to be considered:

$$\dot{W}_{p,diss} = \dot{W}_{heat} + \dot{W}_{cond} + \dot{W}_{conv} + \dot{W}_{rad} \tag{5}$$

where $\dot{W}_{heat}$ is the rate of thermal energy that is stored in the deformation area, $\dot{W}_{cond}$ represents the heat conduction from the deformation area into another part of the sample, $\dot{W}_{conv}$ is the heat loss rate across the surface into air, and $\dot{W}_{rad}$ is the heat loss rate related to radiation into the environment:

$$\dot{W}_{heat} = \rho \cdot c_p \cdot \dot{T}_{PT} \tag{6}$$

$$\dot{W}_{cond} = k \cdot A_{ref} \cdot \frac{T_{PT} - T_{ref}}{l_{ref}} \tag{7}$$

$$\dot{W}_{conv} = h \cdot A_{surf} \cdot (T_{PT} - T_{\infty}) \tag{8}$$

$$\dot{W}_{rad} = \varepsilon \cdot \sigma \cdot A_{surf} \cdot \left(T_{PT}^4 - T_{\infty}^4\right) \tag{9}$$

where T_{PT} is the temperature in the middle of the plastic deformation area and T_{∞} is the room temperature. The heat conduction $\dot{W}_{cond}$ plays an important role due to the non-adiabatic state. The term l_{ref} is calculated as follows:

$$l_{ref} = l_{12} \cdot \frac{A_{ref}}{A_{12}} \cdot \frac{T_{PT} - T_{ref}}{T_{TC1} - T_{TC2}} \tag{10}$$

where l_{ref} is a virtual quantity used to describe the length required in the observed metal from the measured temperature T_{PT} to the reference temperature T_{ref}, which is selected as the room temperature. l_{12} is the distance between T_{TC1} and T_{TC2}. A_{ref} is the area connecting the deformation area and the reference area ($2 \times (24 \times 1.57$ mm^2)). A_{12} is the cross section between the measuring points T_{TC1} and T_{TC2} (50×1.8 mm^2)). A_{surf} is the radiation surface of the homogenous deformed area ($2 \times (24 \times 1.57) \times 2.5$ mm^2). The associated values and references can be found in Table 2. The thermal conductance h_c 40,000 W/(m^2 K) depending on the clearance to the tool surface is based on the results of Cooper et al. and varied in the numerical investigations, see Table 3 [28].

The flow curve of the Miyauchi test and the measured temperature ΔT_{PT} are shown in Fig. 7a. The curves are representative of four tests with the strain rate 1/s (SR1). The tests showed a mean value for the ultimate strength of 192.75 MPa (standard deviation ± 0.9). In addition, two tests were carried out at a strain rate of 4/s (SR4), resulting in an average ultimate strength of 185.2 MPa (standard deviation ± 0.1). The evolution of the calculated TQC values (Eqs. (2)–(10)) with increasing true plastic strain is shown in Fig. 7b). The calculation with Iwahashi's formula (1) has shown that an averaged equivalent plastic strain of ~0.41 is achieved with the

present ECAP-setup. Therefore, the TQC value was also determined at this strain (average of SR1 and SR4) as 0.47 and used for further simulations.

4 Numerical Investigations and Discussion

The ECAP test is about introducing high shear strains as homogeneously as possible into the material. Therefore, 2D plane strain simulations were conducted using the explicit FE code Abaqus (Version 2020). The channel and the stamp were modeled as discrete rigid. The sheet was meshed with rhomboid-shaped CPE4R-elements. An element size of $e = 0.12$ mm and a minimum mass-scale time increment of 1e−005 s were used. These values were adapted from the numerical setup of [10]. Since it is a continuous process without large accelerated masses, no dynamic effects or erroneous mesh distortions could be detected and an acceptable simulation time could be achieved. The material parameters as described above were used for the model. The friction was modeled as isotropic penalty. For the contact, the "hard contact" implemented in Abaqus was selected. The temperature was analyzed at the same position as in the experiment on an element in the center of the sheet. Simulations with a low friction $f = 0.02$ were first performed to investigate the influence of a variation in material parameters. These variations were carried out in order to investigate the influences on the temperature profiles. The effect of a change of the thermal conductivity h_c value is shown in Fig. 8a. When the literature value of 40,000 W/(m^2 K) is reduced to 4,000 W/(m^2 K), the temperature in the sheet metal is increased by ~4 K. Less heat, therefore, is transferred to the tool. Since this value has a great effect on the result of the simulation, it should not be referred to literature values but to experimental investigations for further studies, based on the ECAP setup and materials. A variation of the heat transfer coefficient h, which represents the convection of the process, is considered in Fig. 8b. For the heat transfer coefficient $h = 10$ W/(m^2 K), the temperature curve behaves like in the experiment with good lubrication and good workpiece surface (f_{low}). If the value of h is decreased, no difference is obtained. If the value of h is increased, the temperature of the sheet decreases more strongly after leaving the channel. This behavior corresponds to the experiment with increased friction and poor surface (f_{high}). The assumption that the poor surface effectively causes a higher amount of convective heat transfer is thus confirmed. Moreover, since there are no differences in the temperature maximum

for the two relevant values 10 and 100 W/(m^2 K), the value 10 W/(m^2 K) was used in all further numerical investigations discussed below. Radiation has a negligible influence at the relatively low temperatures observed during sheet metal ECAP and was therefore not examined in more detail.

In the next step, the difference in the extrapolation strategies (bulge and Miyauchi) and the influence of the TQC are discussed, see Fig. 9. The maximum temperature difference of the bulge extrapolation is 14.1 K, whereas the maximum temperature difference of the Miyauchi extrapolation is 13.6 K (Fig. 9a). This shows that the experimental determination of flow behavior has an influence on the accuracy of the simulation of SPD processes, but does not play an important role in the consideration of thermomechanical effects. In order to map the stress state in the ECAP process as precisely as possible, even for high deformations, extrapolation using the Miyauchi test is used for the following numerical testing. Figure 9b shows the considerable influence of the TQC. The measured value of 0.47 is compared with the frequently used default value of 0.9. A difference of 11.4 K can be seen between the maxima

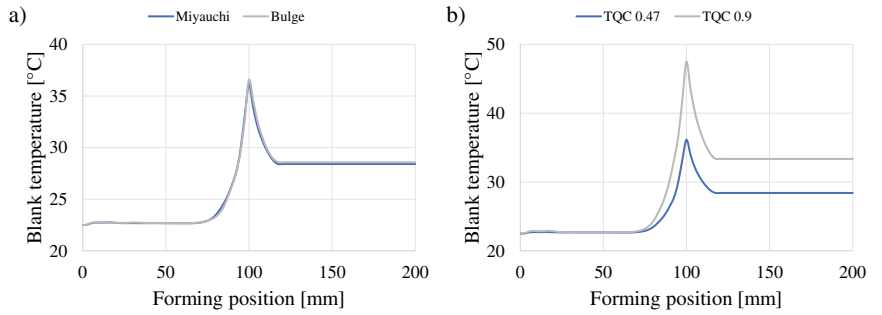

Fig. 9 **a** temperature depending on the position of the ECAP sheet for different flow curve extrapolations (Miyauchi and Bulge); **b** blank temperature depending on the position of the ECAP sheet for different TQC values. (Color figure online)

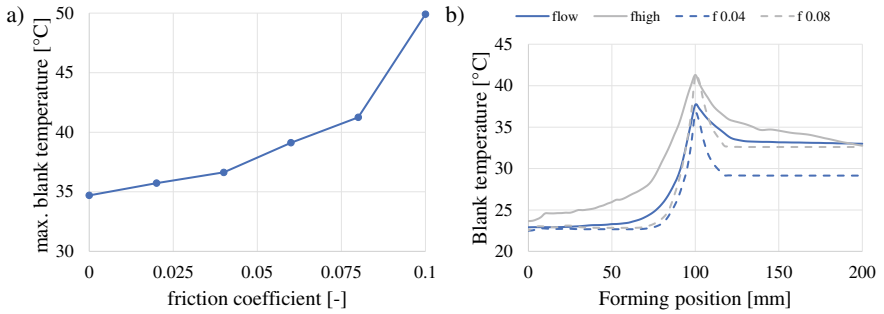

Fig. 10 **a** maximum blank temperature depending on different friction coefficients determined in the numerical investigation; **b** Comparison between simulation and experiment. A friction coefficient of 0.04 fits well for the lubricated experiment (f_{low}) whereas a friction coefficient of 0.08 matches the unlubricated experiment (f_{high}). (Color figure online)

of the curves. This demonstrates that the material parameters must be considered in detail and adapted carefully for numerical investigations, especially if they concern friction. Since the strain rate and also the stress state also have an influence on the TQC, the determination of this parameter should also be adapted to the present process, as in this study.

In the following, the influence of friction on the process is examined. For this purpose, the simulation was conducted with different coefficients of friction in a range from 0.0 to 0.1. Figure 10a shows the temperature maxima with the associated friction coefficients. An almost linear rise in temperature can be seen between 0.0 and 0.04 with increasing friction. The temperature increases more strongly after this initial linear region. Figure 10b shows the curves for the coefficients 0.04 and 0.08 (dashed lines) and, for comparison, the two experimental curves. For the selected parameter setup, the friction values can therefore be determined for a lubricated and not lubricated surface. These findings agree well with the results of Frint et al., who determined a friction coefficient of 0.06 for the (bulk) ECAP process also using the lubricant Bechem Beruforge 150D [17].

5 Conclusion and Outlook

In the present study, ECAP experiments were carried out with two different friction states (f_{high} = not lubricated and f_{low} = lubricated). In order to determine this friction, Miyauchi tests were carried out and three temperatures were measured at several positions in order to determine the TQC during the shear deformation. With this parameter setup, numerical investigations were carried out in order to predict the friction inversely. Temperatures were measured in the experiments and used for the

validation of the numerical model. By comparing the temperatures between simulation and experiment, it was possible to determine coefficients of friction for the ECAP process. The following findings were obtained in this way:

- An increase in temperature of 18.6 K can be measured in the ECAP process for sheet metals. With lubrication, the temperate is lower by 3.4 K.
- In the numerical investigations, the hardening curve, and thus the selected extrapolation approach, have an influence on thermal conversion in the process. Nevertheless, this difference is comparatively small and it is not necessary to resort to extrapolation using shear tests (Miyauchi) for an accurate ECAP simulation.
- It turns out that, in addition to the TQC, the thermal conductance h_c also has an influence on the simulation. For further studies, this parameter should also be determined experimentally.
- It was shown that a default TQC of 0.9 is clearly too high for the present material and process. A TQC of 0.47 was determined for the AA5083 material using the Miyauchi test. The testing parameters (strain, strain rate, stress state) were adapted to the ECAP process. The tests also showed that fluctuations occur primarily in the temperature measurement. In order to estimate the TQC even more accurately, further strain rates should be tested. In addition, a validation by means of a Miyauchi simulation can produce a more detailed result of the parameter l_{ref}. In further studies it can be investigated whether this method can also be used for other materials.
- A second validation method for the ECAP-simulation could be the determination of the process forces. In further studies, this approach could provide additional confirmation of the TQC value
- A friction coefficient of 0.04 was determined by the new method within the lubricated process. Without the use of the lubricant, the component surface was poor and the coefficient increased to 0.08.

Transformation of α→β During Hot Deformation in the Two-Phase Region of Ti–6Al–2Zr–1Mo–1V Alloy

Lei Chen, Qifei Zhang, Qun Li, Miao Jin, Shiyan Zhao, and Baofeng Guo

Abstract Isothermal compressive tests were performed on a Ti–6Al–2Zr–1Mo–1V alloy below the beta-transus. The results showed that straining caused a decrease in the primary α phase, indicating that a strain-induced phase transformation of α→β occurred, whereby an additional dynamic softening was shown. This transformation was sensitive to temperature and strain rate. The higher the temperature was, the more the primary α phase transformed. The extent of α→β increased as the strain rate decreased. The α phase even transformed to β phase completely so long as the deformation duration was enough. Besides deformation, the overall heat duration which included the reheating before deformation and the absolute duration during deformation caused the additional dissolution of primary α phase. In this work, a quantitative model for dissolution kinetics of the primary α phase was established considering the strain-induced phase transformation and the overall heat duration.

Keywords Ti–6Al–2Zr–1Mo–1V alloy · Isothermal compressive tests · Dynamic transformation

1 Introduction

Dynamic transformation of steels was first reported by Yada in the 1980s. When conventional steels had been compressed or/and rolled at a temperature above the Ae3, transformation of austenite into ferrite occurred in the samples [1]. Similarly, this phenomenon was found in titanium alloys. However, the dynamic transformation of titanium alloy is different from that in steels. Generally, the dynamic transformation of titanium alloy was thermally deformed below the β-transus temperature, and the phenomenon of α phase transforming into β phase occurred [2–9]. The superplastic deformation of Ti–5.5Al–1Fe titanium alloy in the two-phase region was tested by Koike and co-workers [2]. Their results showed the stress of the α phase increased during the superplastic deformation and caused the stress-induced

phase transformation of α→β that further resulted in a large superplastic elongation. Although Koike showed that the primary α phase changed with strain, they didn't report changes in β phase caused by dynamic transformation. Similar results were reported by Matsumoto [3], Zhang [4], Sun [5], etc. But they also ignored the effects of changes in β phase on the mechanical behavior. Recently, Guo et al. [6] reported the dynamic transformation of Ti–6Al–4V alloy during hot torsion tests and proposed that the critical stress required to initiate dynamic transformation was less than the peak stress [7]. They expressed the change of β phase produced by dynamic transformation, but they did not propose a systematic model to describe the special microstructural change and, meanwhile, the effect of static heat duration before deformation on the β phase was not considered. Aranas [8] and Foul et al. [9] showed that the dynamic transformation took place during hot compression of pure titanium depended on the total energy obstacle and driving force. Similarly, the heat duration effect during reheating was not be involved.

In the current work, the static heat treatment of Ti–6Al–2Zr–1Mo–1V titanium alloy was carried out at the temperature from 940 to 970 °C. It was found that the primary α phase fraction is sensitive to holding time. Dynamic transformation was observed during hot compression under various conditions. On this basis, the predicted model of the primary α phase fraction was proposed in order to understand the dynamic transformation better.

2 Experimental Procedure

2.1 Experimental Material

The studied material, commercial Ti–6Al–2Zr–1Mo–1V titanium alloy, was forged into a bar with a diameter of 300 mm. The β-transus temperature of the alloy was 995 °C by means of metallographic method. Figure 1 shows the initial microstructure of the test alloy. It can be seen that the initial microstructure is mainly composed of primary equiaxed α phase with a fraction of 55%, β-transformed structure consists of lamellar α and residual β. The average size of primary α phase is about 18 μm and the thickness of lamellar α phase is about 2.2 μm.

2.2 Compression Deformation Tests

Cylindrical specimens with 10 mm in diameter and 15 mm in length were machined along the forging direction. Hot compression tests were carried out on the Gleeble-3800 thermal–mechanical simulator. Samples were carried out to deformation of 50% at a strain rate 0.01 s^{-1} and at the temperatures of 940, 950, 960, and 970 °C, respectively. The deformation of 5–70% was carried out at a strain rate of 0.001 s^{-1}

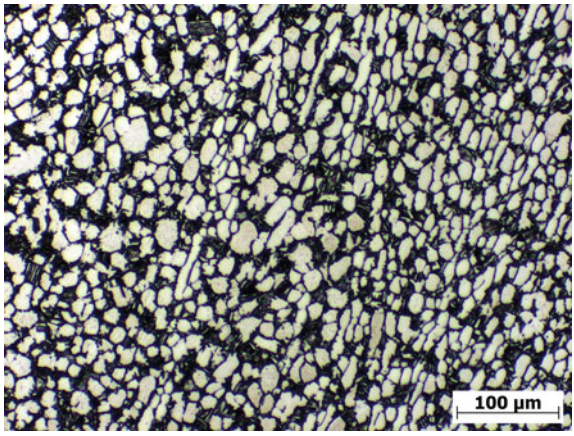

Fig. 1 Initial microstructure of Ti–6Al–2Zr–1Mo–1V titanium alloy. (Color figure online)

and at 960 °C in order to determine the effect of strain on the transformation. Strain rates of 1, 0.1, 0.01, and 0.001 s^{-1} were applied for analyzing the effect of strain rate on the transformation when the deformation is 30% and the temperature is 960 °C. Heating rate for all compression is 10 °C/s. Specimens were held at deformation temperature for 10 min and then deformed. Subsequently, deformed samples were cooled to room temperature in air.

2.3 Heat Treatment

In order to compare the microstructural differences during hot compression and heat treatment, the quantitatively microstructural analysis was done. The size of specimens for heat treatment tests was the same as that for heat compression to eliminated the size effect. The specimens were heated at 960 °C for 0, 3, 5, 10, 30, and 60 min, respectively. Then, reheated specimens also were cooled to room temperature in air.

2.4 Microstructural Characterization

Deformed microstructures were investigated using optical microscopy (OM). They were sectioned along their symmetry axes and ground on silicon carbide papers with particle sizes from 120 to 2500 mesh by an automatic polishing machine. Subsequently, the mechanochemical method was carried out to polish samples. Final polishing was carried out by using the 80–100 nm alkaline colloidal silica solution with mash fraction and followed by etching with a mixed etchant solution of 2 ml HF+12 ml HNO_3+14 ml H_2O for 5–15 s. The metallographic analysis was performed the Image-Pro Plus software to quantify the fraction of equiaxed primary α grains.

The average α and β phase fractions were evaluated on the basis of five graphs for each sample.

3 Experimental Results

3.1 Flow Curves

The flow curves for Ti–6Al–2Zr–1Mo–1V alloy, at a strain rate of 0.01 s^{-1} are displayed in Fig. 2. As can be seen in the figure, the stress decreases with the increasing temperature. At each temperature, the stress rapidly increases to the peak stress with increasing strain at the deformed temperature, and gradually decreases and then reaches the steady-state stress when the work hardening and the flow softening tend to a balance. Here, the stress at the strain of 0.2% is taken as the initial yield stress. It is worth mentioning that the steady-state stress is lower than the initial yield stress at each deformation temperature. Generally, the flow softening occurs during hot deformation of most metal materials due to the DRX, because the dislocation density decreases rapidly once the DRX starts [10, 11]. However, it is well known that work hardening cannot be completely eliminated by dynamic recrystallization whereby a part of deformed microstructure (unrecrystallized microstructure) remains, so the steady-state stress is always higher than the initial yield stress [12, 13]. Obviously, an additional flow softening mechanism exists during hot deformation of the test alloy.

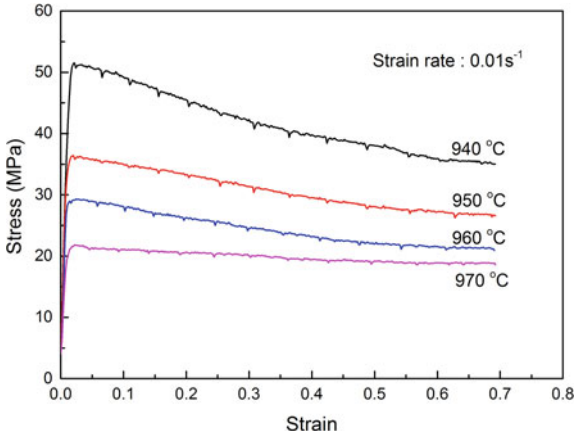

Fig. 2 Stress–strain curves at a strain rate of 0.01 s^{-1}. (Color figure online)

3.2 Microstructure Analysis

Figure 3 shows the microstructures of undeformed and deformed specimens tested at different temperatures in the two-phase region. Obviously, the primary α phase fraction decreases with increasing temperature. The relationship between deformation temperature and primary α phase fraction is displayed in Fig. 6a. The α phase fraction changes from 0.371 to 0.293 during the deformation of 940 °C. Particularly, the α phase almost disappears after deformation of 50% at 960 °C and 970 °C. The primary α phase in the undeformed samples decreases is due to the gradual dissolution of primary α phase into β during static reheating [6, 14, 15]. However, the decrease of the primary α phase during deformation indicates that the dynamic phase transformation of α→β occurs. The decreasing of harder α phase during deformation is the important cause for the aforementioned additional flow softening.

The effects of strain and strain rate on the microstructures are depicted in Figs. 4 and 5, respectively. Meanwhile, the changes of the primary α phase fraction after deformation at 960 °C and 0.001 s^{-1} are displayed in Fig. 6b. It can be seen that the α phase fraction and grain size decrease as the strain increases. Compared with the undeformed sample, when the strain is 0.051, the primary α phase fraction reduces to 0.133. When the strain was increased to 0.693, the α fraction was close to zero (0.0003). With further increase in the strain to 1.204, the primary α phase completely disappeared.

The effect of strain rate on such dynamic transformation of α→β is depicted in Fig. 6c. It is evident that the primary α phase fraction and grain size decrease with the decreasing strain rate. At the same strain, the primary α fraction is 0.157 at the strain rate of 1 s^{-1} while it was reduced to 0.006 at the strain rate of 0.001 s^{-1}.

3.3 Static Transformation During Heat Treatment

The microstructures during static heat treatment at 960 °C display in Fig. 7. And the change in the α phase fraction is illustrated in Fig. 8. It can be seen that the α phase fraction decreases with increasing holding time. It gradually trends to the equilibrium state where the α phase fraction does not change with holding time. For the test alloy, the α volume fraction changes from 0.317 to 0.161 when the holding time is from 3 to 30 min. With further increase in the holding time to 60 min, the α phase fraction still remains 0.159 indicating the α volume fraction is stable after a heat duration of 30 min.

4 Discussion

4.1 The Effect of Deformation Heat

The effect of the deformation heat on the alloy cannot be ignored during hot deformation [16, 17] because the material properties will change due to this increasing temperature, especially for the titanium alloy that has poor thermal conductivity [18, 19]. The change in temperature attributable to deformation is given by

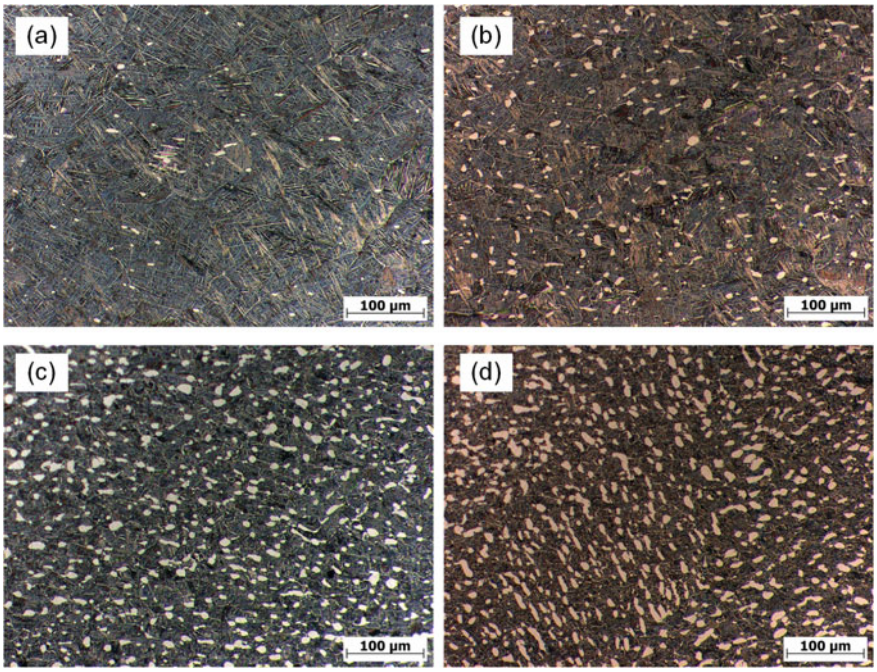

Fig. 5 Microstructures of samples deformed to a strain of 0.357 with different strain rates at 960 °C: **a** 0.001 s^{-1}, **b** 0.01 s^{-1}, **c** 0.1 s^{-1} and **d** 1 s^{-1}. (Color figure online)

$$\Delta T = \frac{0.95\eta \int_0^{\varepsilon} \sigma d\varepsilon}{\rho C_{\mathrm{p}}} \tag{1}$$

where ΔT refers to the temperature increase, η is the adiabatic correction factor, σ is the stress, ε is the strain, ρ is the density of test alloy, C_{p} is the specific heat [20]. The adiabatic correction factor employed here is 0.25 when the strain rate is 0.01 s^{-1} [20]. At the same strain (0.693) and strain rate (0.01 s^{-1}), the temperature increase caused by deformation heating at different conditions is listed in Table 1. The temperature increase decreases slightly as the deformation temperature increases. Compared with the deformation temperature, the deformation heating at the condition of 0.01 s^{-1} is too small to be neglected [6].

4.2 Model of Dynamic Transformation of α→β

The primary α phase fraction changes during heat treatment when the holding time is not enough to reach equilibrium state [21]. In present compression tests, samples reheated for 10 min have no nonequilibrium α phase fraction. Therefore, during deformation, especially at a lower strain rate, the transformed α phase fraction includes

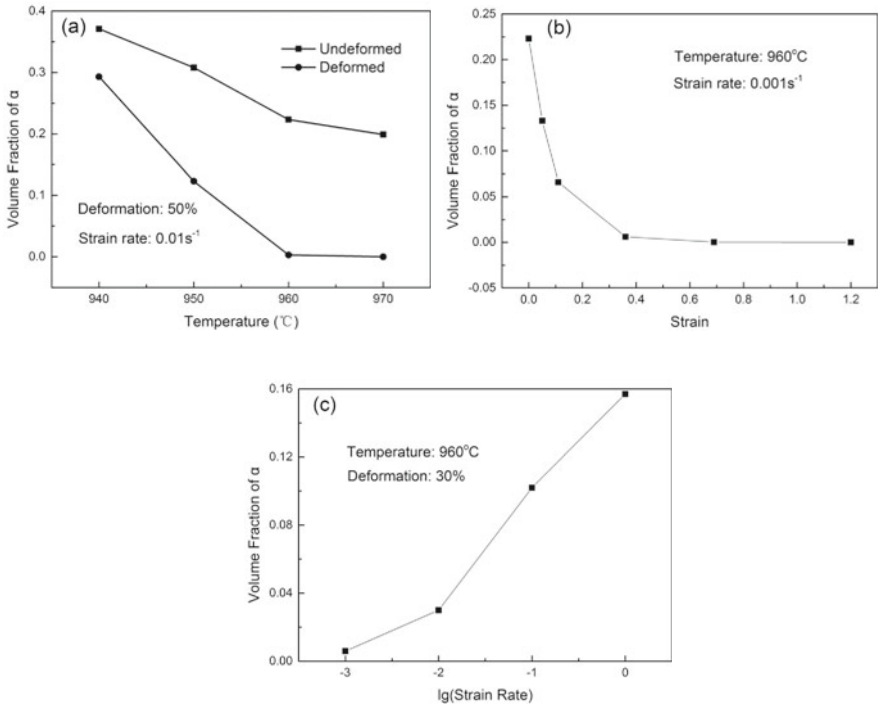

Fig. 6 The primary α phase fraction at different conditions. **a** temperature effect; **b** strain effect; **c** strain rate effect

two parts. The first part is due to dynamic transformation induced by deformation and the second part comes from static transformation due to longer heat duration during deformation with lower strain rate. So the true change in the primary α phase fraction caused by dynamic deformation can be expressed:

$$\omega_{\mathrm{DT}}(\alpha) = \omega_{\mathrm{HT}}(\alpha) - \omega_{\mathrm{D}}(\alpha) \tag{2}$$

where $\omega_{\mathrm{DT}}(\alpha)$ is the transformed fraction of the α phase caused by dynamic transformation, $\omega_{\mathrm{HT}}(\alpha)$ is the primary α phase fraction after the overall heat duration (including the holding time before deformation and deformation time), and $\omega_{\mathrm{D}}(\alpha)$ is the remaining primary α phase fraction after deformation.

Based on the results in Figs. 6b and 8, the variation of the primary α phase during overall deformation at 960 °C is obtained, as shown in Fig. 9. The shadow region represents the true change in primary α phase fraction caused by dynamic deformation. It can be seen that the values of aforementioned $\omega_{\mathrm{HT}}(\alpha)$ at a certain strain actually correspond to the spot on the black line, but always not to the spot at 600 s (10 min) which represents the value before the deformation.

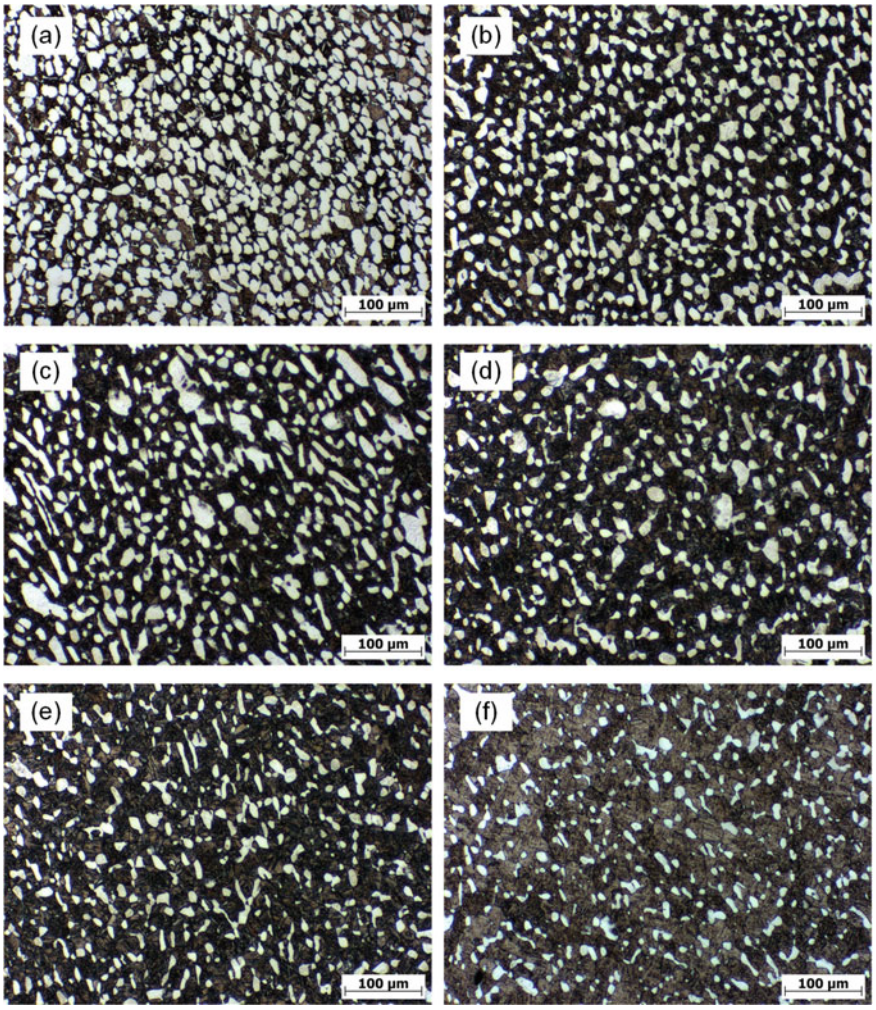

Fig. 7 Microstructures after reheating at 960 °C for different holding time. **a** 0 min, **b** 3 min, **c** 5 min, **d** 10 min, **e** 30 min and **f** 60 min. (Color figure online)

The model of classical Johnson–Mehl–Avrami (JMA) is widely used to describe the models of phase transformation in titanium alloy [22, 23]. In this paper, the model for dissolution kinetics of the primary α phase at 960 °C can be represented:

$$\omega_{\alpha}(t) = 1 - \exp\left[-(kt)^{n}\right] \tag{3}$$

where $\omega_{\alpha}(t)$ is the extent of the transformation at a given time t, n is the JMA exponent, k is a rate constant which depends on the temperature.

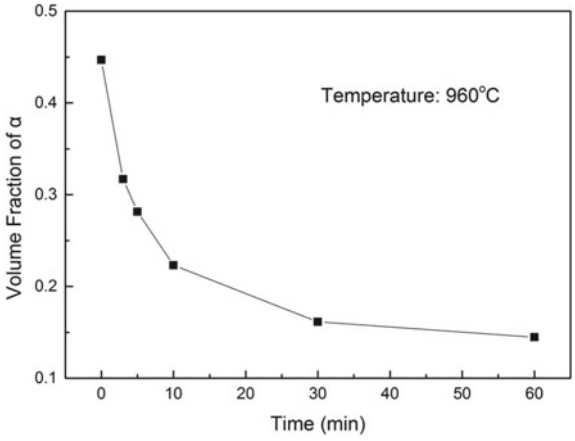

Fig. 8 Volume fraction of primary α phase at different holding time and the same holding temperature

Table 1 The deformation heating at different conditions

Deformation temperature (°C)	940	950	960	970
Temperature increase (°C)	1.72	1.27	1.0	0.82

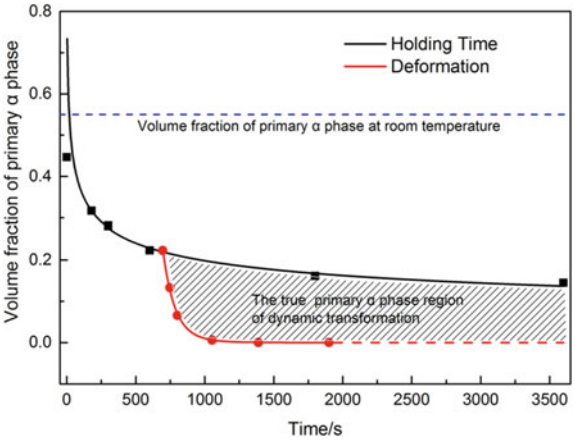

Fig. 9 The variation of primary α phase during overall deformation at 960 °C. (Color figure online)

The parameters k and n are calculated by regression analysis based on Fig. 9, and then the transformed kinetic of the primary α phase during the overall heat duration at 960 °C is given by Eq. (4) and the transformed model for the remaining primary α phase after deformation is expressed as Eq. (5), respectively, as follows:

$$\omega_{HT-\alpha}(t) = 1 - \exp\left[-(0.116t)^{-0.318}\right] \tag{4}$$

$$\omega_{D-\alpha}(t) = 1 - \exp\left[-(0.002t)^{-8.815}\right] \tag{5}$$

Therefore, the model of dissolution kinetics for the primary α phase during dynamic transformation is given by

$$\omega_{DT-\alpha}(t) = \exp\left[-(0.002t)^{-8.815}\right] - \exp\left[-(0.116t)^{-0.318}\right] \quad (6)$$

On basis of these models, the primary α phase fraction can be accurately predicted for overall hot working process in order to tailor the microstructure and mechanical properties.

5 Conclusion

The dynamic transformation behavior of Ti–6Al–2Zr–1Mo–1V titanium alloy was studied by means of hot compression deformation tests. The current results can be summarized as follows:

1. Dynamic transformation of α→β took place during hot forging which caused an additional dynamic softening.
2. Dynamic transformation depended on the deformed temperature and strain rate. It can be facilitated by increasing temperature and/or decreasing strain rate. The primary α phase even completely disappeared at some conditions.
3. A predicted model of the primary α phase during overall hot working was proposed.

Formability Improvements of AA5754-H32 at Room Temperature via Continuous Bending Under Tension (CBT) and Pre-forming Heat Treatment

Jinjin Ha, Antonio Piccininni, Yannis P. Korkolis, Gianfranco Palumbo, Marko Knezevic, and Brad L. Kinsey

Abstract Aluminum (Al) alloys play a critical role for the transportation applications where weight reduction is a key aspect; however, the poor formability at room temperature limits their application for complex components. An innovative methodology to overcome this limitation is based on subjecting the material to a local, short-term heat treatment before stamping, to obtain a tailored distribution of properties. In addition, Continuous-Bending-under-Tension uses the action of three rollers to remarkably increase the total elongation to failure. In the present work, the combination of the two approaches is investigated to improve the formability at room temperature of a strain-hardenable 5xxx Al alloy, AA5754-H32. Specimens were subjected to both CBT and pre-forming heat treatments, and force-displacement curves were compared to evaluate the formability improvements.

Keywords Al alloys · Formability · Continuous-bending-under-tension · Heat treatment · Material characterization

1 Introduction

As an interest in stronger and lighter automotive materials continuously increases, so does the need to discover new forming processes to improve limited ductility of these materials. One such process is continuous-bending-under-tension (CBT) [1–4], in which, as explicitly described in the name, bending is superimposed on tension by several rollers throughout loading. The beneficial effect of bending with tension is enhancing elongation-to-fracture (ETF), as a result, a higher strain than the conventional forming limit can be achieved. Zecevic et al. [4] reported that large plastic

strain in the CBT processed specimen resulted in formation of a strong <111> fiber texture throughout the material. This observation indicates that an adequate amount of CBT processing prior to forming can be promising to enhance a certain texture like <111> fiber which improves formability in the subsequent forming operation. On the other hand, the manipulation of microstructure by an appropriate heat treatment [5–7] is also an important aspect on formability, especially for aluminum alloys. Moreover, it has been reported that the local modification of the material properties prior to the forming operations is considered a promising approach to improve the formability of Al alloys at room temperature: in the case of the deep drawing of a 6xxx age-hardenable Al alloys, it has been demonstrated that if the peripheral region of the circular specimen is locally brought from an initial T6 state to a fully solutioned one, a remarkable improvement of the limit drawing ratio (LDR) can be achieved [8]. This suggests a possibility that the CBT processing integrated with local heat treatment can further improve LDR in the cup drawing arose from both <111> texture and strength variation in the material. In this paper, a preliminary study of local heat treatment (LHT) effect on the CBT process is performed for AA5754-H32. Bending depth and crosshead velocity which changes strain rate of tension are controlled to maximize ETF. The experimental procedure and results are presented in the following sections.

2 Continuous-Bending-Under-Tension (CBT) and Local Heat Treatment (LHT)

The custom CBT machine built at the University of New Hampshire [9–11], which includes three rollers, is used for the experiments. The schematic and details are described in Fig. 1. The machine consists of a moving carriage, two stationary stands assembled with three rollers, a base, and control systems. The bending depth, δ, can be varied by adjusting the top roller in the vertical direction. The machine is equipped with two load cells, which are located at the actuator and the carriage, respectively. The signal used for this work is from the load cell on the carriage. The bending depth

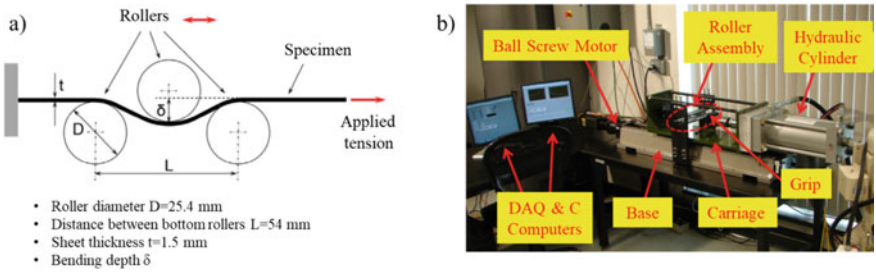

Fig. 1 **a** Schematic of the CBT process and **b** a photograph of the machine at the University of New Hampshire [8]. (Color figure online)

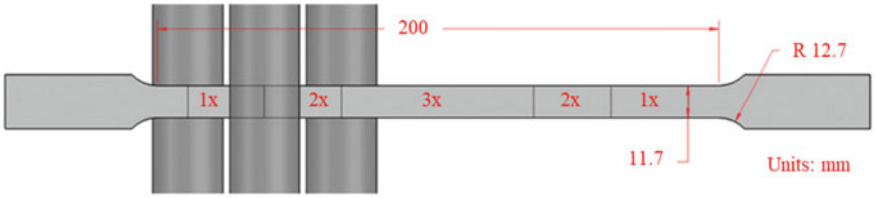

Fig. 2 Initial CBT specimen with three rollers and the 1x, 2x, and 3x deformation regions [8]. (Color figure online)

and crosshead velocity, which is calculated by a cylinder position, are test variables, while the carriage moving velocity is kept constant at 66 mm/s. Figure 2 represents a sample deformed specimen for the CBT with different bending cycles, i.e., x1, x2, and x3, in the gage section: the material at both ends is subjected to only one bending-unbending cycle per stroke, while three cycles per stroke in the center. A stroke is defined as the carriage moving from one end of the machine to the other and back again.

In order to investigate the heat treatment effect on the formability, the experiments are performed using two different types of specimens, as shown in Fig. 3a and b. One is the as-received condition (AA5754-H32 of 1.5 mm thickness) and the other is the locally heat treated. Laser treatment is designed by means of preliminary thermal FE simulations (Abaqus CAE 6.17) with the aim of locally bringing the material to the annealed state: the heating strategy is based on five consecutive linear tracks (length equal to the specimen width) setting the spot dimension at 10 mm and considering a top-hat energy distribution (the sequence of the laser track is also reported in Fig. 3b).

One of the key aspects in the laser treatment design is the evaluation of its effectiveness, i.e., properly calculating the distribution of the material properties at the end of the heat treatment. To accomplish such an ambitious goal, an experimental study is carried out exploiting the potentialities of the Gleeble 3180 system (shown in Fig. 4a): striped specimens in wrought conditions (AA5754-H32) are heated up by Joule effect modulating the current flow according to the acquisition of the "pilot" thermocouple, indicated as TC2 in Fig. 4b. Being the two ends of the specimen

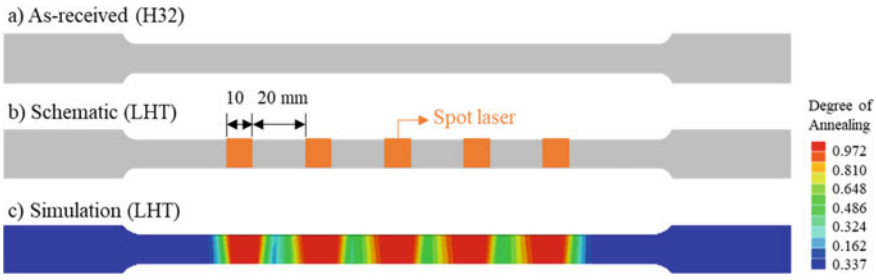

Fig. 3 Specimen preparation for the CBT test: **a** as-received (AA5754-H32), **b** locally heat treated (AA5754-LHT), and **c** simulation result of degree of annealing. (Color figure online)

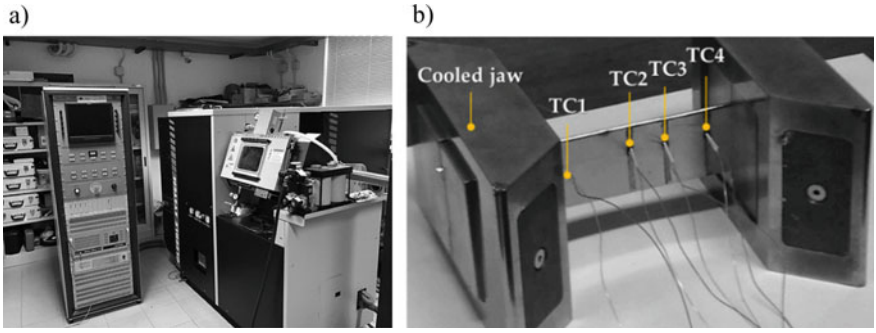

Fig. 4 Experimental setup for the annealing tests: **a** Gleeble 3180 physical simulator, **b** thermocouples arrangement for the temperature monitoring. (Color figure online)

clamped between cooled jaws, a parabolic distribution of temperature is obtained thus subjecting the material simultaneously to several heating treatments within the same test.

At the end of each test, the treated specimens are subjected to hardness tests at room temperature (Qness micro hardness tester Q10 A+, setting a load of 200 g and a dwell time of 15 s) thus relating the hardness value with a specific combination of heating temperature and holding time. Results from the annealing tests are expressed in terms of an output variable—the Degree of Annealing (DoA)—defined according to Eq. (1).

$$\mathrm{DoA} = \frac{\mathrm{HV}_{\mathrm{H32}} - \mathrm{HV}_{\mathrm{meas}}}{\mathrm{HV}_{\mathrm{H32}} - \mathrm{HV}_{\mathrm{H111}}} \tag{1}$$

where $\mathrm{HV}_{\mathrm{H32}}$, $\mathrm{HV}_{\mathrm{H111}}$, and $\mathrm{HV}_{\mathrm{meas}}$ are, respectively, the reference hardness of the material in the as-received conditions, the hardness in the annealed state, and the one measured at the end of each physically simulated annealing test; in such a way, a value of the DoA variable equal to 1 means a fully annealed material, whereas small value of the DoA means the material maintaining the purchasing conditions. All the results from the annealing tests are arranged and implemented within a Python-based post-processing script able to associate a single DoA value to each node of the specimen according to its thermal history: the final DoA distribution (thus providing also a distribution of the material properties at the end of the laser heating) relative to the heating at a temperature of 500 °C and setting a material/radiation interaction time equal to 2 s is reported in Fig. 3c. The laser heat treatment, according to what is defined by the FE numerical runs, is then experimentally replicated on a 1 kW diode laser (specimens are previously painted with graphite spray to increase the radiation absorption during the heating).

3 Results and Discussion

Figures 5 and 6 present the force–displacement curve with different bending depths and crosshead velocities for AA5754-H32 and -LHT. In general, the CBT force–displacement curve includes repetitive peaks during the process, which indicates the moment when the rollers are locating at each end of the gage section and the overall deformation is approaching to the simple tension without the bending effect. It is not noise or anything like that, but directly tied to the kinematics of the CBT process, as detailed in one of our earlier works [11]. The tested bending depths are $\delta = 1.5$, 2.5, and 3.5 mm with a constant crosshead velocity at $v = 0.8$ mm/s (Fig. 5a), and crosshead velocities are $v = 0.18$, 0.8, and 1.6 mm/s with a constant bending depth at $\delta = 2.5$ mm (Fig. 5b). Monotonic tension without bending (-H32, gray line in figures) is plotted as a reference. As the bending depth increases, the overall force level decreases, and can be even lower than the initial yield stress of the monotonic

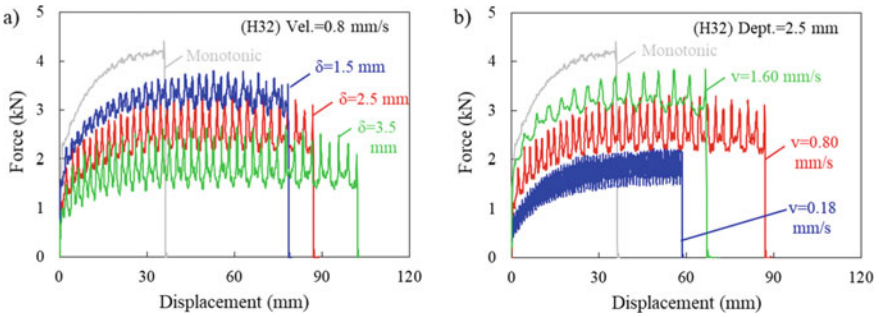

Fig. 5 Sensitivity test on AA5754-H32 (as-received) for **a** the bending depth with a constant crosshead velocity $v = 0.8$ mm/s and **b** the crosshead velocity with a constant bending depth $\delta = 2.5$ mm. (Color figure online)

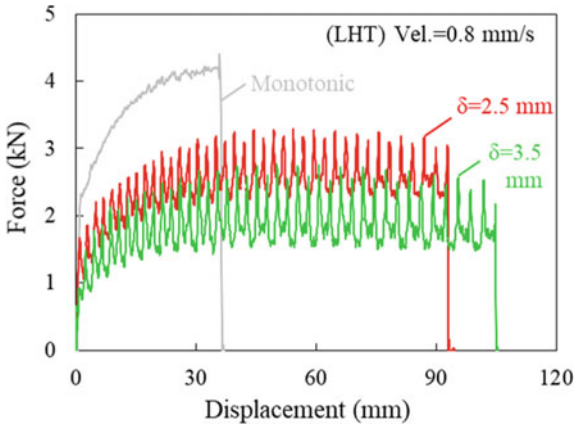

Fig. 6 Sensitivity test on AA5754-LHT for the bending depth (locally heat treated) with crosshead velocity $v = 0.8$ mm/s. (Color figure online)

curve when the bending depth is δ = 3.5 mm (Figs. 5a and 6). This indicates that the plastic flow produced by the bending–unbending cycles becomes dominant over the one by the tension force. In contrast, the higher crosshead velocity increases the force level and reduces the number of cycles at the same displacement level (Fig. 5b). This represents that the plastic flow produced by the tension force is more significant than the bending–unbending effect at the higher crosshead velocity. As is evident from Figs. 5 and 6, the optimal condition is the bending depth δ = 3.5 mm with the crosshead velocity v = 0.8 mm/s for both AA5754-H32 and -LHT samples.

Figure 7 shows the comparison of AA5754-H32 and -LHT at the bending depth δ = 2.5 (Fig. 7a) and 3.5 mm (Fig. 7b) with the crosshead velocity v = 0.8 mm/s. At both bending depths, ETF, represented by the total displacement to failure, is slightly improved in AA5754-LHT. This may result from the microstructural change related to the heat treatment, which is the objective of the authors' ongoing study. Tested specimens are compared in Fig. 8, along with an undeformed and a deformed ones under uniaxial tension without bending. It is seen that the CBT process enhances

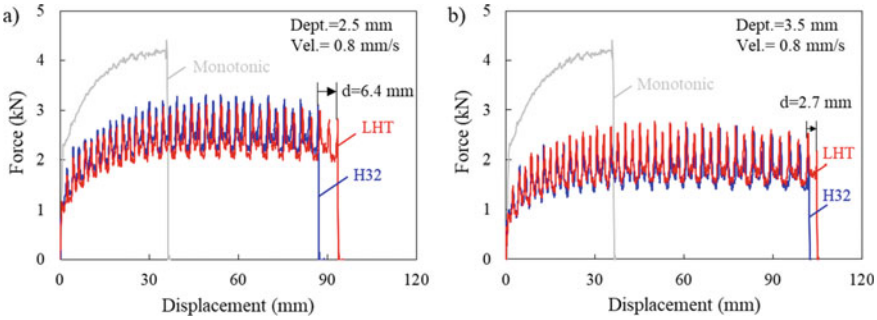

Fig. 7 Comparison of force–displacement for AA5754-H32 and -LHT: **a** bending depth δ = 2.5 mm and **b** bending depth δ = 3.5 mm with crosshead velocity v = 0.8 mm/s. (Color figure online)

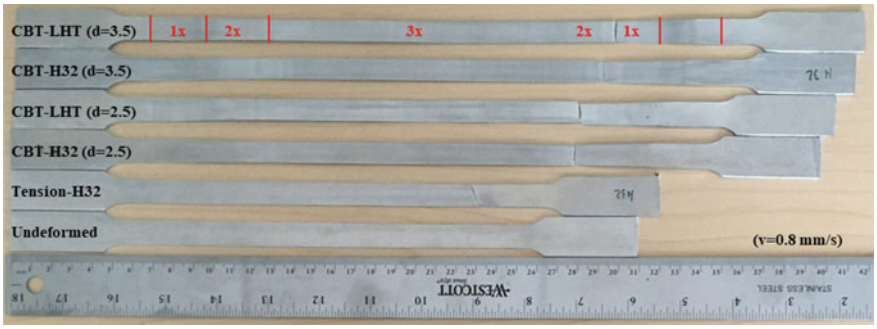

Fig. 8 Comparison of the failed specimens with bending depths δ = 2.5 and δ = 3.5 mm with a crosshead velocity v = 0.8 mm/s along RD. Undeformed and deformed specimens under uniaxial tension are included as references. (Color figure online)

the formability more than twice compared to uniaxial tension. The orientation of the fracture is also changed from an angle to the loading direction for localized necking (uniaxial tension specimen) to perpendicular to the tensile loading direction (CBT specimen).

4 Conclusion

In this work, CBT processing of AA5754-H32 and -LHT conditions is investigated through a parametric study on the bending depth and crosshead velocity. The force–displacement curves show a high sensitivity on these process parameters, from which the optimal condition is found as the bending depth $\delta = 3.5$ mm and crosshead velocity $v = 0.8$ mm/s. Under this condition, the formability of the material is improved more than twice compared to the uniaxial tension. The ductility is further improved by the local heat treatment (LHT) compared to the as-received condition (H32), even though not as drastically as in comparison to uniaxial tension.

Microstructure Evolution During Isothermal Forging of 7A85 Aluminum Aviation Component

Jian-Liang Hu, You-Ping Yi, Miao Jin, and Hong Bo

Abstract A 7A85 aluminum aviation component with high ribs and thin webs was successfully formed by the isothermal forging process, and its microstructure was investigated by optical microscope (OM), transmission electron microscope (TEM), and cellular automaton simulation. Metallographic images show the recrystallization phenomenon takes place all over the aviation forging, and a uniform grain size is obtained. The cellular automaton model of 7A85 aluminum alloy, including dislocation density model, nucleation rate equation as well as grain growth model was established, and the parameters of the cellular automaton models were determined by the hot compression experiment on the thermal-mechanical simulator Gleeble-1500. The cellular automaton simulation results agree well with the optical micrographs of the aviation forging, showing good homogeneity in both the size and the distribution of grain structure. The TEM images show that a homogeneous distributed dislocations and precipitates of the forging formed by the isothermal forging process can be attained, which can inhibit the migration of the grain boundaries, resulting in the small and uniform grains of the aviation forging.

1 Introduction

The weight reduction of the aviation component plays a very important role in the aerospace field [1–3]. Thus, aviation components are usually designed into thin webs and high ribs to reduce the weight. However, this causes some problems, which are the forming difficulty and non-uniform properties of complex aviation component. In fact, the temperature of dies and the billet are the same during the isothermal forging process, thus the deformation resistance of material significantly reduced. Therefore, it is a suitable way for the deformation of complex aviation components.

In order to obtain an appropriate forming process for aviation components with irregular shape, massive works have been done on isothermal forging process in the past few years [4–7]. In the work by Shan et al. [8], a bracket of magnesium alloy with irregular shapes was forged by isothermal forging process, and the dimensional precision of the forging met the requirement well. An aluminum alloy component with complex shape was obtained by isothermal forging process, and the optimum conditions of the forging process were determined [9]. The simulation of AZ31B magnesium alloy was carried out by Rao et al. to optimize the parameters of forging process [10].

Dynamic recrystallization, which affects the microstructure and mechanical properties of forging, is a common phenomenon during the isothermal forging process. Therefore, in order to numerically simulate the dynamic recrystallization processes by cellular automaton method, numerous attempts have been made in the past decade. A multi-scale model of 1050 aluminum alloy was proposed to analyze the softening kinetics and microstructure revolution during the isothermal annealing process by Shabaniverki et al. [11], and the predicted results agree well with the experimental data. A three-dimensional cellular automaton model of Al–Si-Mg alloy was established to investigate the grain growth of different crystallographic orientations during the polycrystalline solidification by Chen et al. [12]. Li et al. [13] and Huang et al. [14] both developed a cellular automaton program of 7050 aluminum alloy to simulate the influence of the forging process on the dynamic recrystallization phenomenon and the size of grains. Whereas little work was reported to predict the dynamic recrystallization phenomenon of aviation components in the isothermal forging process using the cellular automaton method. In this work, the isothermal forging process of complex aviation component with thin webs and high ribs is carried out, and the microstructure evolution of the aviation forging is studied by optical microscope, transmission electron microscope, and cellular automaton simulation.

2 Experimental

2.1 The Hot Compression Experiments of 7A85 Aluminum Alloy

The hot compression experiments of 7A85 aluminum alloy were performed on the thermal-mechanical simulator Gleeble-1500. The chemical composition of 7A85 aluminum alloy is given in Table 1. The deformation temperature of the hot compression experiments ranges from 300 to 450 °C in the strain rate interval 0.001–1 s^{-1}. The total strain of the samples is 0.9. Before compression, the samples were heated to set temperature at a rate of 10 °C/s and heat preservation time was 5 min. After compression, the samples were quenched immediately. A graphite lubricant was applied to reduce the friction of specimens during the hot compression experiments.

2.2 The Isothermal Forging Experiment of Aviation Component

The isothermal forging experiment of the aviation forging was conducted on the 40 MN hydraulic machine. The deformation temperature of the forging was 450°, and the dies along with billet were holding at the set temperature for 4 h. In order to reduce the friction of the billet during deformation, a water-based lubricant was used. Figure 1 shows the load and velocity curve of the isothermal forging experiment, the maximum load is up to 32.7 MN. To shorten the process time, the loading velocity was set into four levels of 1, 0.1, 0.01, and 0.002 mm/s.

The aviation forging with a maximum web thickness of 42 mm and maximum lib height of 125 mm is successfully obtained in this work, shown in Fig. 2. It can be seen that during the isothermal forging process, the metal flows smoothly and thus it is very likely to cause underfill, crack, and other defects. The aviation forging was cut along the cross section, which is shown in Fig. 2. And the specimens of microstructure analysis were taken from the cross section. Microstructures of the aviation forging were studied by means of optical microscope.

3 Results and Discussion

3.1 Flow Behavior of 7A85 Aluminum Alloy

The stress-strain curves were obtained by hot compression experiments under different deformation conditions as shown in Fig. 3. The flow behavior of 7A85 aluminum alloy is significantly influenced by deformation conditions. While the deformation temperature grows, the flow stress decreases. And with the decrease of strain rate, the flow stress decreases as well. In general, work hardening, dynamic

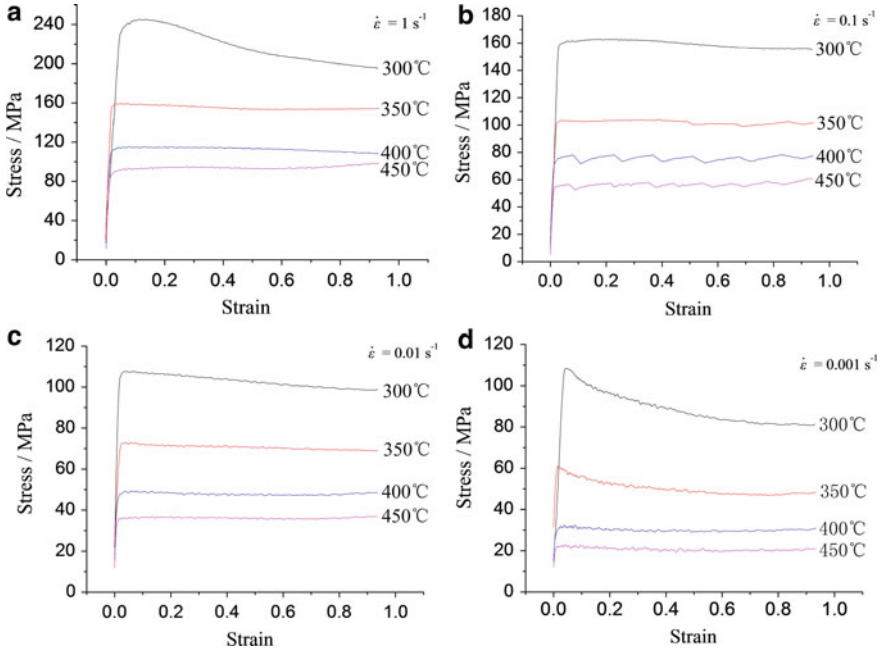

Fig. 3 The stress-strain curves of 7A85 aluminum alloy at different strain rates. (Color figure online)

recovery as well as dynamic recrystallization are metallurgical phenomena during the hot deformation process of 7A85 aluminum alloy [15, 16].

3.2 Microstructure Simulation

In general, the dislocation density is influenced by work hardening, dynamic recovery, and dynamic recrystallization. Both the dynamic recovery and dynamic recrystallization have softening effects on the dislocation density. The dislocation density equation can be established as [17].

$$\frac{d\rho}{d\varepsilon} = k_1\sqrt{\rho} - k_2\rho \tag{1}$$

where ρ stands for the dislocation density. ε is the strain. k_1 and k_2 are the work hardening parameter and the softening parameter, respectively, which can be expressed as the following formulas:

$$k_1 = 2\theta_0/(\alpha\mu b) \tag{2}$$

$$k_2 = 2\theta_0/(\sigma_s) \tag{3}$$

where α stands for the dislocation interaction term. For 7A85 aluminum alloy, $\alpha = 0.5$. μ stands for the shear modulus. b is the Burgers vector. σ_s is the peak stress. $\theta_0 = \mathrm{d}\sigma/\mathrm{d}\varepsilon$ is the work hardening rate. The relationship of work hardening rate and deformation temperature, strain rate is as follows:

$$\theta_0 = A_1 \dot{\varepsilon}^{B_1} \exp(C_1/T) \tag{4}$$

where A_1, B_1, C_1 are constants.

The natural logarithm of both sides of the formula (4) is obtained.

$$\mathrm{In}\,\theta_0 = \mathrm{In}\,A_1 + B_1\,\mathrm{In}\,\dot{\varepsilon} + C_1/T \tag{5}$$

According to the results of hot compression experiments, the relationships of ln θ_0 and In $\dot{\varepsilon}$, T^{-1} are obtained, shown in Figs. 4 and 5, the linear regression fitting analysis of the data is carried out to obtain the value of A_1, B_1, and C_1. And the work hardening rate is formed.

$$\theta_0 = 583.013\dot{\varepsilon}^{0.182725} \exp(1539.608/T) \tag{6}$$

Thus, the dislocation density model of 7A85 aluminum alloy during hot forming can be generated as follows:

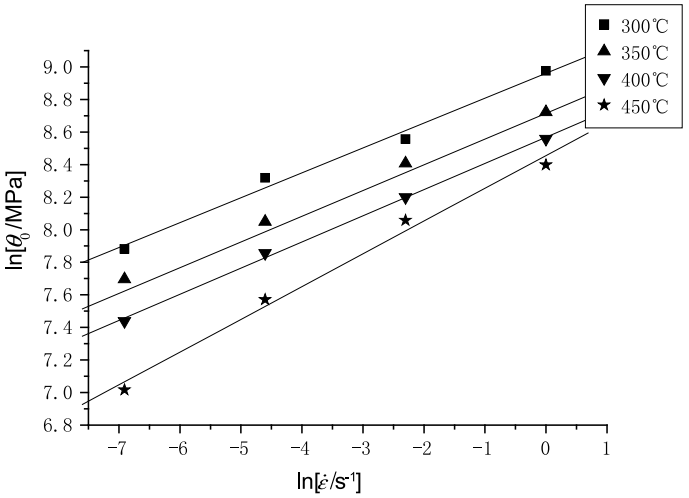

Fig. 4 The relationship of ln θ_0 to In $\dot{\varepsilon}$

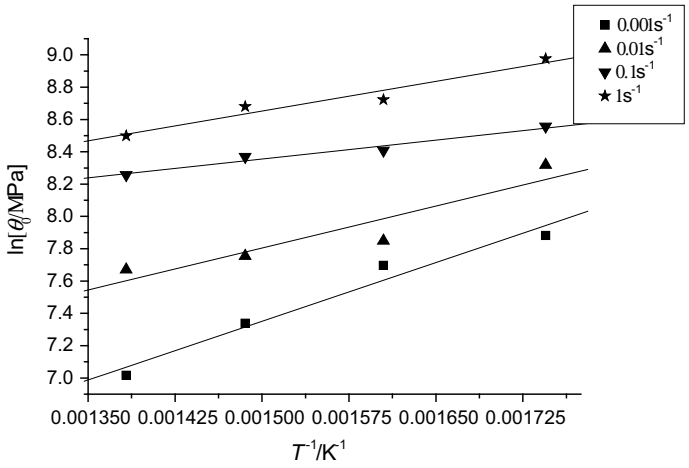

Fig. 5 The relationship of ln θ_0 to T^{-1}

$$\frac{\mathrm{d}\rho}{\mathrm{d}\varepsilon} = \frac{1166.026\dot{\varepsilon}^{0.182725}\exp(1539.608/T)}{\alpha u b}\sqrt{\rho} - \frac{1166.026\dot{\varepsilon}^{0.182725}\exp(1539.608/T)}{\sigma_s}\rho \tag{7}$$

Nucleation is assumed to occur when the dislocation density reached up to the critical value ρ_c. The nucleation rate ($\dot{n}$) can be considered as a function of the deformation temperature and the strain rate [18].

$$\dot{n} = C \cdot \dot{\varepsilon} \cdot \exp\left(-\frac{Q_{act}}{RT}\right) \tag{8}$$

where C is nucleation coefficient. For 7A85 aluminum alloy, $C = 200$. Q_{act} is activation energy. R is the universal gas constant.

Grain boundary migrates from low dislocation density area to high dislocation density area [19]. The migrating velocity mainly depends on the mobility of grain boundary, and the difference in dislocation densities inside and outside of grain boundaries. So the growth velocity of grain can be expressed as the following formula:

$$v_i = Mp_i \tag{9}$$

where v_i is the migrating velocity of grain boundary. M stands for the grain boundary mobility. p_i is the driving force of dynamic recrystallization grain.

$$M = \frac{b^2}{kT} D_0 \exp\left(-\frac{Q_b}{RT}\right) \tag{10}$$

$$p_i = \tau \Delta\rho - \frac{2\gamma_i}{r_i} \tag{11}$$

where b is the Burgers vector. k stands for the Boltzmann constant. D_0 is the self-diffusion coefficient of grain boundary. R is the universal gas constant. Q_b is the activation energy of grain boundary self-diffusion. $\Delta\rho$ is the difference of dislocation density between the growing and the non-growing grains. r is the radius of the growing grain. $\tau = 0.5\mu b^2$ is the dislocation line energy. γ_i stands for the grain boundary energy which can be calculated by

$$\gamma_i = \begin{cases} \gamma_m \frac{\theta_i}{\theta_m}\left(1 - \mathrm{In}\frac{\theta_i}{\theta_m}\right) & \theta_i \le \theta_i \\ \gamma_m & \theta_i > \theta_m \end{cases} \tag{12}$$

where θ_i is the misorientation between grains. And θ_m, γ_m stand for critical misorientation and critical grain boundary energy, respectively.

The cellular automaton model is employed to investigate the dynamic recrystallization phenomenon of the aviation forging by isothermal forging process. The material parameters of 7A85 aluminum alloy in the simulation are as shown in Table 2. The area of aviation forging for the simulation is 1 mm × 1 mm, which can be divided into 500 × 500 simulation meshes. The primary grain orientation was randomly set at the range of 0º–180º.

Figure 6 is the cross section of aviation forging for metallographic observation and the metallographic images of the isothermal forging are shown in Fig. 7. Large deformation takes place at Point 2 of the intersecting surface of the forging. Thus, the line shape distribution of grains is obvious. On the contrary, the metal flew gently

Table 2 Material parameters of 7A85 aluminum alloy

Material parameter	Value
b (m)	2.0×10^{-10}
μ (MPa)	2.69×10^{4}
Q_act (KJ/mol)	313.386
Q_b (KJ/mol)	117.2
D_0 ($\mathrm{m^2/s}$)	3.8×10^{-4}
γ_m ($\mathrm{J/m^2}$)	0.76

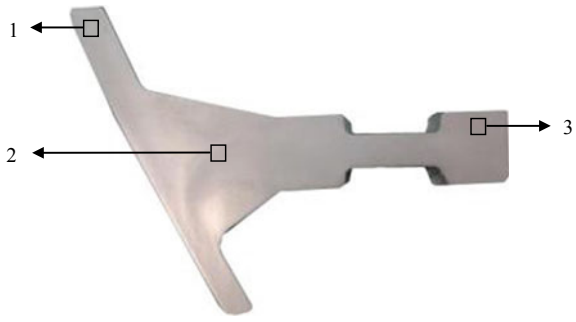

Fig. 6 The cross section of aviation forging for metallographic observation. (Color figure online)

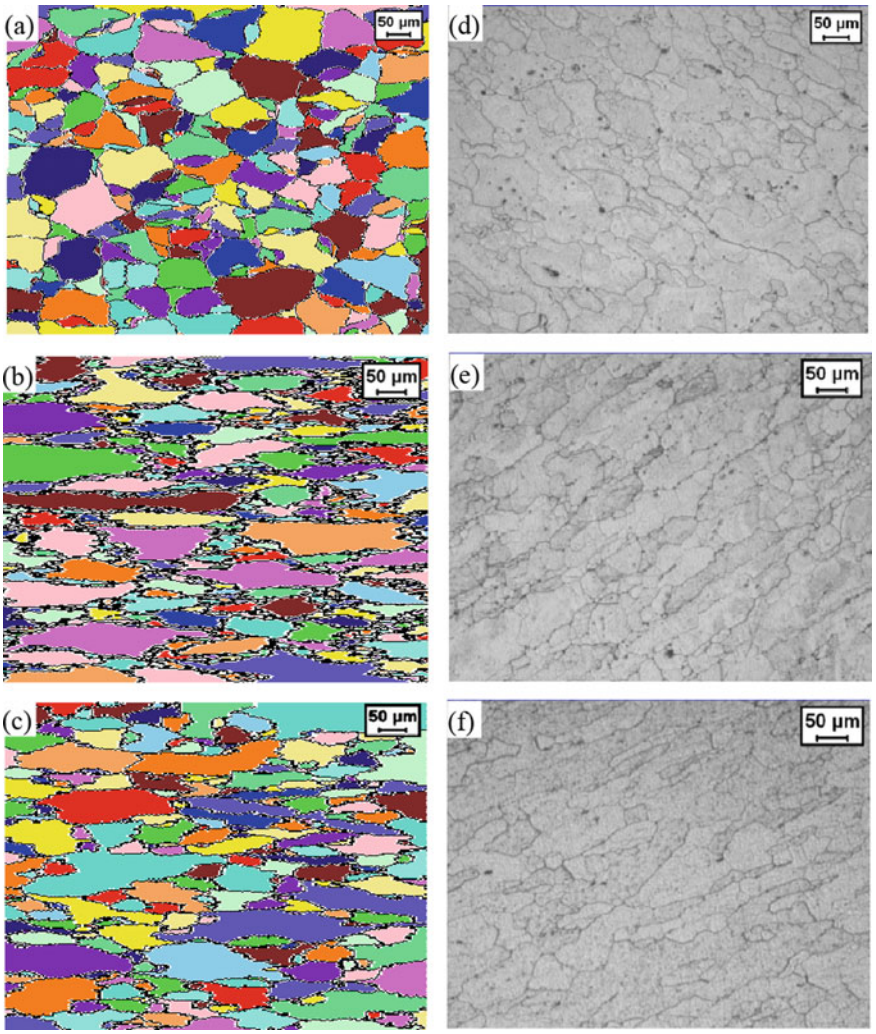

Fig. 7 Grain structure of simulation and experimental results **a**, **d** Point 1; **b**, **e** Point 2; **c**, **f** Point 3. (Color figure online)

at Point 1 and Point 3 of the forging. So the line shape distribution of grains is inconspicuous. What is more, uniform recrystallization grains can be seen all over the intersecting surface of the joint forging. The average grain sizes of Point 1 to Point 3 are 62 μm, 48 μm, and 73 μm, respectively. Besides, the average grain sizes of the cellular automaton simulation are 72, 45, and 62 μm, which agree well with the optical micrographs of the aviation forging, showing good homogeneity in both the size and the distribution of grain structure.

3.3 Microstructure Evolution Analysis

In order to seek the reason why the aviation forging has a uniform microstructure, the dislocation and precipitate of the forging were studied as shown in Fig. 8. During the isothermal forging process, the dynamic recrystallization occurs all over the aviation forging, leading to the reduction of dislocation density. As the deformation continued, due to different grain orientation, some grains with favorable orientation are likely to slip along the grain boundary as shown in Fig. 8a. While the movement of those grains with unfavorable orientation is restrained, resulting in the increase of dislocation density, as shown in Fig. 8b. Under extremely slow speed and isothermal conditions, dislocations slide and climb around the grain boundary, and the sliding fraction

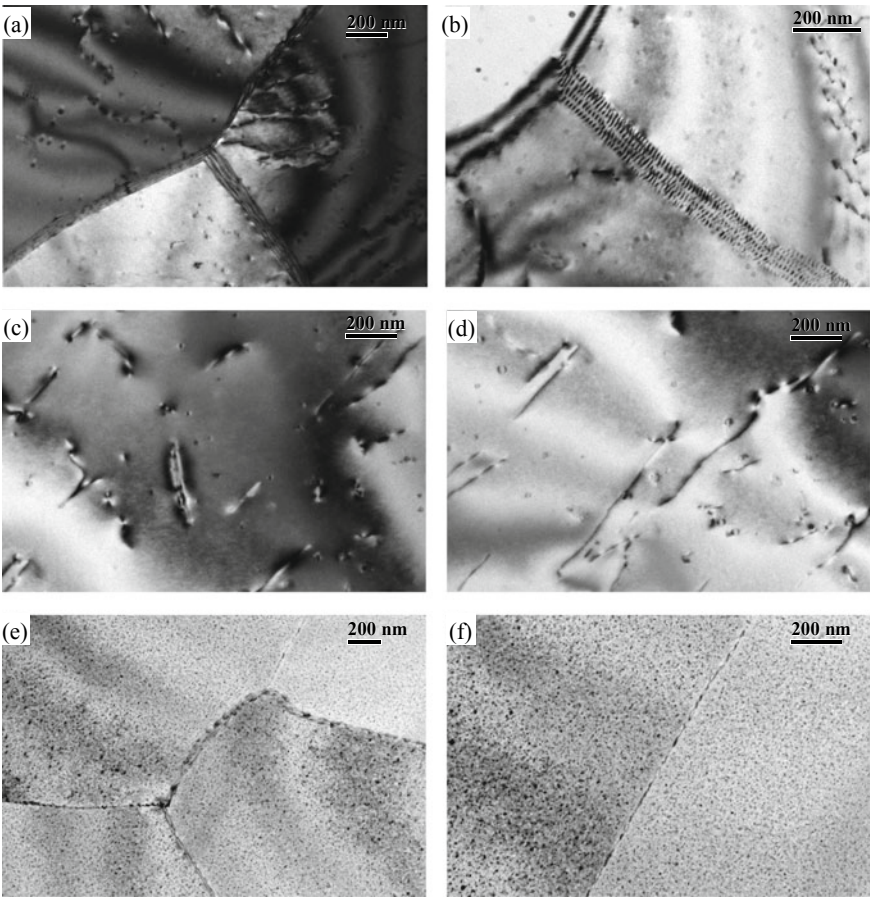

Fig. 8 TEM images of aviation forging: **a** grain boundary sliding; **b** dislocation wall; **c** dislocations at the surface; **d** dislocations at the core; **e** precipitates at the surface; **f** precipitates at the core. (Color figure online)

causes the grain boundary sliding, while the climbing fraction causes diffusion creep [20]. So, during the isothermal forging process, the grain boundary sliding is the main mechanism of deformation, and the diffusion creep is the principal factor of improving grain boundary sliding.

As can be seen from Fig. 8c, d, there is a relatively homogeneous distribution of dislocations at both the surface and the core of the forging. And the precipitates are more prone to form around dislocations of high strain energy and interface energy [16, 21, 22]. As a consequence, the morphology of the precipitates is homogeneous both in the matrix and at the grain boundary of the aviation forging formed by the isothermal forging process as shown in Fig. 8e, f.

From what has been mentioned above, it can be known that the reasons why such a homogenous microstructure was obtained by isothermal forging process are as shown below. Firstly, the billet during the isothermal forging process is at a nearly constant temperature, and the loading speed is extremely slow, so grain boundary sliding is the main mechanism of deformation, and the diffusion creep is the principal factor of improving grain boundary sliding. Thus, the dislocations have enough time to move into the grain boundary or annihilate each other, resulting in the homogeneous distribution of dislocations. Secondly, the precipitates are more prone to form around the homogeneous distributed dislocations, so that uniform precipitates can be attained. Eventually, the grain boundaries can be pinned by the dispersed precipitates so that the small and uniform grain is obtained by the isothermal forging process.

4 Conclusions

(1) The 7A85 aluminum aviation component with high ribs and thin webs was successfully forged by the isothermal forging process. And there are little defects such as underfill or crack of the aviation forging.

(2) The cellular automaton models of 7A85 aluminum alloy, including dislocation density model, nucleation rate equation as well as grain growth model, were established to investigate the dynamic recrystallization phenomenon of the aviation forging by isothermal forging process. The cellular automaton simulation results agree well with the optical micrographs of the aviation forging, showing good homogeneity in both the size and the distribution of grain structure.

(3) During the isothermal forging process, the grain boundary sliding is the main mechanism of deformation, and the diffusion creep is the principal factor of improving grain boundary sliding. Because of the homogeneous distributed dislocations and precipitates, which inhibit the migration of the grain boundaries, the grains of the aviation forging are small and uniform.

The Deformation and Microstructure Analysis of Medium Carbon Steel During Die Forging Process and the Effect of Microalloying Elements

Bo Jiang, Guoning He, Chengcheng Zhang, Xiaolei Ma, Chaolei Zhang, and Yazheng Liu

Abstract The deformation and microstructure of medium carbon steel during die forging process was analyzed by using thermo-simulation test in this paper. The effect of microalloying elements V, Ti, and Nb on the microstructures after deformation was also analyzed. The results showed that there are a critical deformation amount of 6% which increases the grain size of steel in die forging process. The deformation amount during die forging process should reach 20% in order to refine the microstructures. The addition of Ti can largely reduce the grain size of the final product while the further addition of Nb doesn't have significant effect on the grain size. The addition of Ti can significantly increase the ferrite and intra-granular ferrite in the steel by refining the microstructure and offering the precipitates (V, Ti)(C, N) as the nuclei of intra-granular ferrite. The further addition of Nb in the V-Ti-N steel can further increase the size of the precipitates (V, Ti, Nb)(C, N) but suppress the formation of ferrite by improving the hardenability of steel. Thus, there are few ferrite and intra-granular ferrite in the V-Ti-Nb-N steel than that in the V-Ti-N steel.

1 Introduction

Low toughness of medium carbon steel products produced by die forging process has been continuously limiting its application in the high-performance automobile engine. Previous results showed that coarser grain in some parts of the products had resulted in the deterioration of toughness. However, the reason why the coarser grain was formed in the forged steel was not clear and there is no theory basis for the optimization of the manufacturing process. Up to now, microalloying elements have been widely used for the refinement of microstructures by preventing the grain growth in the reheating process [1–3]. However, the microalloying precipitates are very complex in different steels and the effect of microalloying elements on the grain size of different steels is different.

In recent years, many people have focused on the intra-granular ferrite in the forged steel because the pearlite can be divided and thus the microstructures can be refined [4–6]. The intra-granular ferrite often nucleates at microalloying nitrides which precipitated at manganese sulfide particles because the intra-granular ferrite had the Baker–Nutting orientation relationship with the precipitates [7, 8]. Thus, there is an important influence of the microalloying elements on the formation of intra-granular ferrite because the composition, size, and distribution of the precipitates can vary a lot with the microalloying elements. Reports showed that the addition of Ti into V-N steel could increase the size of the precipitates (Ti, V)(C, N) and promote the formation of intra-granular ferrite [9, 10]. For the given medium carbon steel, the effect of microalloying elements was only focused on the rolled billet by my previous work [11]. No reports about the effect of microalloying elements on the microstructures after die forging process have been found.

In this paper, the effect of deformation amount on the microstructure during die forging process was investigated. Based on the results, the reason of the formation of coarser grain was analyzed and the optimization of process parameters was suggested. In addition, the effects of microalloying elements on the grain size, the ferrite, and the intra-granular ferrite were analyzed.

2 Experimental Section

2.1 Materials and Processes

The investigated steel was produced as a 39 kg ingot in a vacuum melting furnace. The diameter of the ingot was around 100 mm. It was then reheated at 1200 °C and soaked for nearly 3 h. After that, the experimental ingot was forged into a round billet with

Table 1 Chemical compositions of steels (wt%)

Steel	C	Si	Mn	S	Cr	N	V	Ti	Nb
No. 1	0.37	0.53	1.34	0.056	0.27	0.019	–	–	–
No. 2, V-N steel	0.36	0.55	1.35	0.061	0.26	0.018	0.10	–	–
No. 3, V-Ti-N steel	0.35	0.54	1.37	0.058	0.27	0.019	0.10	0.018	–
No. 4, V-Ti-Nb-N steel	0.37	0.55	1.37	0.057	0.26	0.017	0.10	0.017	0.025

the diameter of 60 mm in a steel mill. The starting and finish forging temperatures were 1150 and 900 °C, separately. The cooling process was conducted in a furnace with the starting furnace temperature of 700 °C. The chemical compositions of the investigated steels were listed in Table 1. The difference of the chemical composition was designed in order to analyze the effect of microalloying elements V, Ti, and Nb. The reference steel is the medium carbon steel No. 1 which was determined as 0.37C-0.53Si-1.34Mn-0.056S-0.27Cr and was Fe balanced. This steel has been mostly used in the market until now. The microstructures of different steels have been analyzed in the previous study [11]. The grain sizes of steels No. 3 and No. 4 were the finest while that of steel No. 1 was the largest. Although there exists an effect of the starting microstructure on the grain size of the steel after thermo-simulation experiment. However, there was no difference of the grain size for a given steel while the reheating temperature was 1200 °C and the soaking time was 3 min.

A Gleeble thermo-simulation machine was employed to analyze the deformation behavior and microstructure of the experimental steel during die forging process. Figure 1a schematically shows the process routes in the experiments on the Gleeble thermo-simulation machine. The parameters were set based on the manufacturing process in the factory. The specimens for the experiments were all cut from 1/2 diameter of the billets and then were machined into cylinders of 8 mm in diameter and 20 mm in length. Then the specimens were firstly heated up at the heating rate of 15 ℃/s to a peak temperature of 1200 ℃, held for 3 min and then cooled to the deformation temperature of 1100 ℃ with the cooling rate of 15 ℃/s. After that, the specimens were soaked for 10 s for temperature homogenization and then were

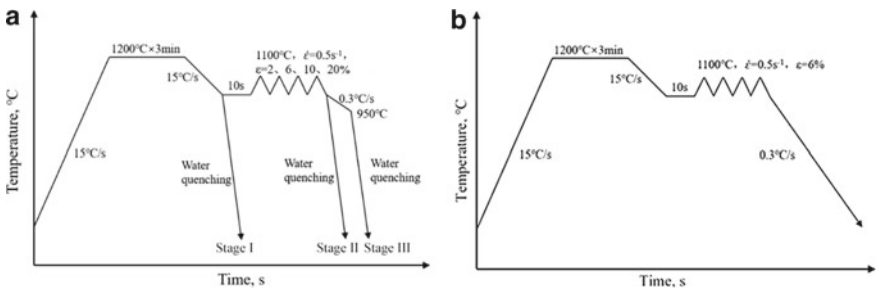

Fig. 1 The schematic process route of the thermo-simulation experiment: **a** water quenching; **b** slow cooling

deformed at the rate of 0.5 s^{-1} with different deformation amounts 2, 6, 10, and 20%. After deformation, the specimens were cooled to 950 ºC with the cooling rate of 0.3 ºC/s and then water quenched. The cooling rate was set based on the real condition. Argon is used in this experiment for protection in order to prevent the surface of the sample from oxidation. Three specimens were prepared for the experiments because the quenched microstructures at different stages I, II, and III as shown in Fig. 1a were all needed to analyze the microstructure evolution. In addition, another thermo-simulation experiment was also conducted to analyze the microstructure cooled with the rate of 0.3 ºC/s to room temperature after deformation. The schematic route can be seen in Fig. 1b.

2.2 Microstructural Investigation

Quenched specimens were polished by conventional metallographic techniques and then etched in a saturated picric acid buffer aqueous solution at 50–60 °C to reveal the prior austenite grain boundary. Metallographic examination was observed by means of optical microscope (OM, model: Zeiss Scope A1). The average grain sizes were measured by a quantitative image analyzer. The samples after the experiment with the route shown in Fig. 1b were mechanically ground, polished, and then etched in 4% nital. Micrographs were obtained by OM and field emission scanning electron microscopy (FESEM, model: FEI quanta FEG 450). Transmission electron microscopy (TEM, model: JEM-2100(HR)) analysis was also performed to investigate the microalloying precipitates on carbon extraction replicas. The energy dispersive X-ray spectrum (EDS) in the FESEM and TEM was used to identify the chemical composition of the precipitates. The extraction replicas were prepared by evaporating carbon film on the samples which were pre-polished and pre-etched in 4% nital. Then the specimens were immersed in 4% nital to strip the carbon film from the surface.

3 Results and Discussion

3.1 Quenched Microstructure Investigation

3.1.1 Effect of Deformation Amount on the Grain Size

Firstly, the prior austenite grains of steel at the final stage III with different deformation amounts were observed in order to analyze the effect of deformation amount. The optical microstructures and the grain size distribution can be seen in Fig. 2. The grain size firstly increased with the deformation amount from 2 to 6% and then decreased with the deformation amount from 6 to 20%. When the deformation amount reached

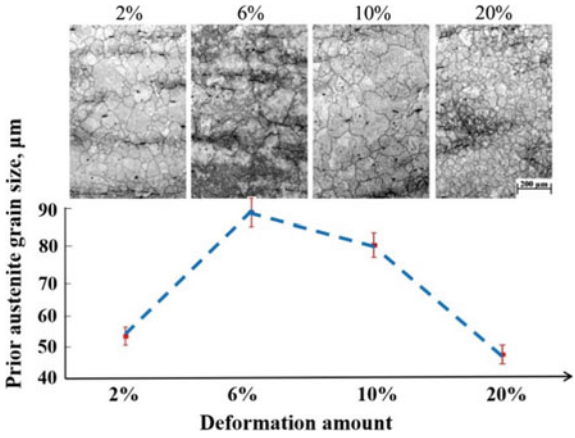

Fig. 2 The optical microstructures of prior austenite grain of steel No. 4 at stage III with different deformation amounts. (Color figure online)

20%, the grain size was almost the same as the size of the microstructure at the stage I without deformation which can be seen in Fig. 4d. Thus, there existed a critical deformation amount zone at which the grain size increased dramatically. In this steel, the critical deformation amount at which the grain size was the largest was 6%. A question is arisen now here whether this big increase in grain size should be attributed to the small deformation amount or the following slow cooling process. Another experiment can be used for verification. The process parameters were totally the same as the route as shown in Fig. 1a except that no deformation was conducted in this route. The prior austenite grain was shown in Fig. 3. The grain size was 52.3 μm which meant that there was no big increase in the process without deformation. It has been known to us that the recrystallization after deformation is an energy-driven process and can promote the nucleation of new grain and thus refine the grain [12, 13]. However, nucleation of grain cannot proceed if the deformation amount is small

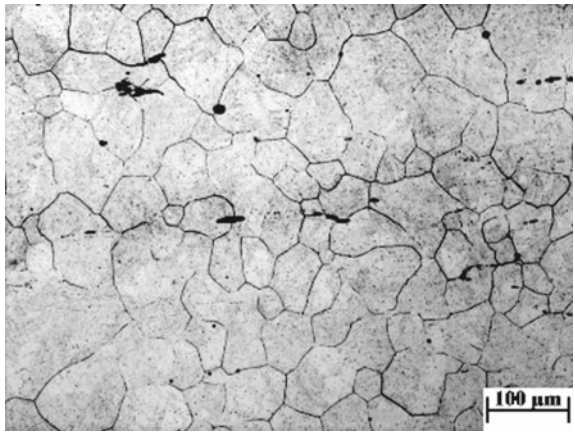

Fig. 3 The optical microstructures of prior austenite grain of steel No. 4 after the thermo-simulation experiment without deformation

[14]. In this case, only recovery can occur and then the grain grows in the following slow cooling process with the energy driving.

According to our previous research, the microstructures in die forging products were very inhomogeneous and the toughness of the steel was very low because there always existed coarser grains in the microstructures [15]. Besides the deformation amounts across the section of forged products varied a lot thus there were some places with deformation amount which should be as low as less than 10%. In that sense, the appearance of coarser microstructure should be attributed to the low deformation amount during die forging. Also, the deformation amount should be higher than 20% in order to avoid the coarsening of grain according to the results in this work.

3.1.2 Effect of Microalloying Elements on the Grain Size

The quenched microstructures of different steels at different thermo-simulation stages with the deformation amount 6% were shown in Fig. 4. The prior austenite grain sizes were also measured and the results were shown in Fig. 5. It can be seen in the figure that the prior austenite grain sizes of steel No. 1 and No. 2 are very close and much larger than that of steel No. 3 and steel No. 4 at stage I. These results are unanimous to the previous study which showed that the existence of precipitates Ti (C,N) and (Nb, Ti)(C,N) in steel No. 3 and steel No. 4 had reduced the austenite grain size [16]. The precipitates V(C, N) were dissolved at 1200 °C and thus the grain size in steel No. 2 was nearly the same as in steel No. 1. In Figs. 2 and 3, the prior austenite grains of different steels at the stages II and III were also shown. As can be seen, there are only small increase in grain size from stage I to stage II. However,

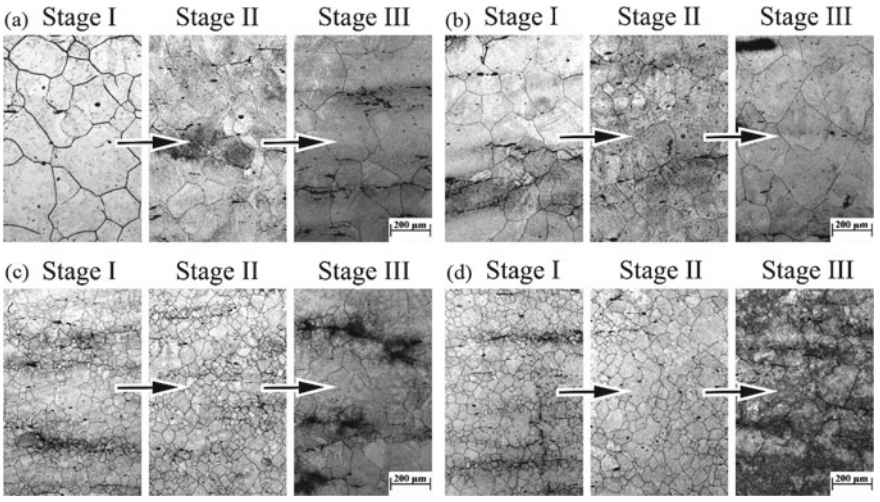

Fig. 4 The optical microstructures of prior austenite grain of different steels at different thermo-simulation stages: **a** steel No. 1; **b** steel No. 2; **c** steel No. 3; **d** steel No. 4

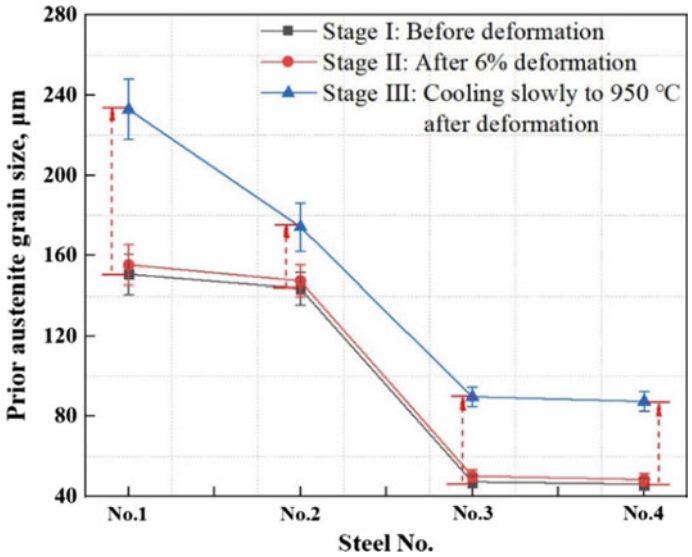

Fig. 5 The prior austenite grain size of different steels at different thermo-simulation stages. (Color figure online)

a big increase in grain size occurred from stage II to stage III when the deformed specimen was cooled to 950 °C. This result was also unanimous to part 3.1.1 which showed that the grain growth occurred in the slow cooling process while was driven by the energy offered by deformation with small amount.

For different steels, effects of the microalloying elements on the grain size at different stages were almost the same. The grain size of steel No. 1 was almost the same as that of steel No. 2 at all stages. The grain sizes of steel No. 3 and steel No. 4 were also nearly the same. However, the grain sizes of steel No. 3 and steel No. 4 were much smaller than that of steel No. 1 and steel No. 2. In addition, there was no much difference in grain size of steel No. 3 and steel No. 4. The addition of Nb cannot obviously prevent the growth of grain in the steel with the given chemical composition.

3.2 Slow Cooled Microstructure Investigation

3.2.1 OM Analysis

The optical microstructures of different steels after the experiment with the route in Fig. 1b can be seen in Fig. 6. As seen in the figure, the microstructures in different steels mainly consisted of pearlite, grain boundary ferrite, and intra-granular ferrite.

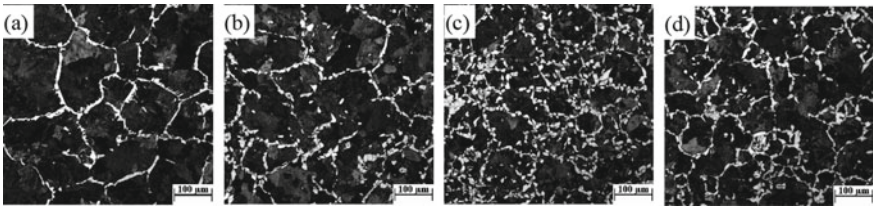

Fig. 6 The optical microstructures of different steels after the experiment with the route in Fig. 1b: **a** steel No. 1; **b** steel No. 2; **c** steel No. 3; **d** steel No. 4

Table 2 The grain size and the volume fractions of ferrite and intra-granular ferrite in different steels

Steel	Size of grain boundary ferrite network (μm)	Volume fraction of ferrite (%)	Volume fraction of intra-granular ferrite (%)
No. 1	159.3	6.9	0.07
No. 2	142.8	8.8	0.84
No. 3	62.3	14.4	1.38
No. 4	61.9	12.4	0.86

The effect of microalloying elements on the grain size in the slow cooled microstructure as shown in Table 2 was almost the same as that in the quenched microstructure. The grain sizes in steel No. 3 and steel No. 4 were the smallest while that of steel No. 1 and steel No. 2 were relatively larger. However, the difference in microstructures of different steels was also obvious. As can be seen, there existed more intra-granular ferrite in steel No. 2, steel No. 3, and steel No. 4. The volume fractions of ferrite and intra-granular ferrite were shown in Table 2. The volume fractions of ferrite and intra-granular ferrite in steel No. 1 were the smallest while that in steel No. 3 were the highest. As we know, the refinement of austenite can promote the formation of ferrite by offering more boundaries for nucleation. Thus, steel No. 1 had the lowest volume fraction of ferrite because of its larger grain size. However, the grain size of steel No. 4 was nearly the same as that of steel No. 3 but had the smaller volume fractions of ferrite and intra-granular ferrite. The volume fraction of intra-granular ferrite in steel No. 4 was even approximately half that of steel No. 3.

3.2.2 FESEM and TEM Analysis

The FESEM microstructures of different steels were shown in Fig. 7 to analyze the intra-granular ferrite and the microalloying precipitates. It can be seen in the figure that most intra-granular ferrites were formed on the particles. To further analyze the particles, the EDS results showed that the nuclei of the intra-granular ferrite were microalloying particle on MnS inclusions. The nuclei of the intra-granular ferrites in steel No. 2, steel No. 3, and steel No. 3 were V(C, N), (V, Ti)(C, N), and (V, Ti,

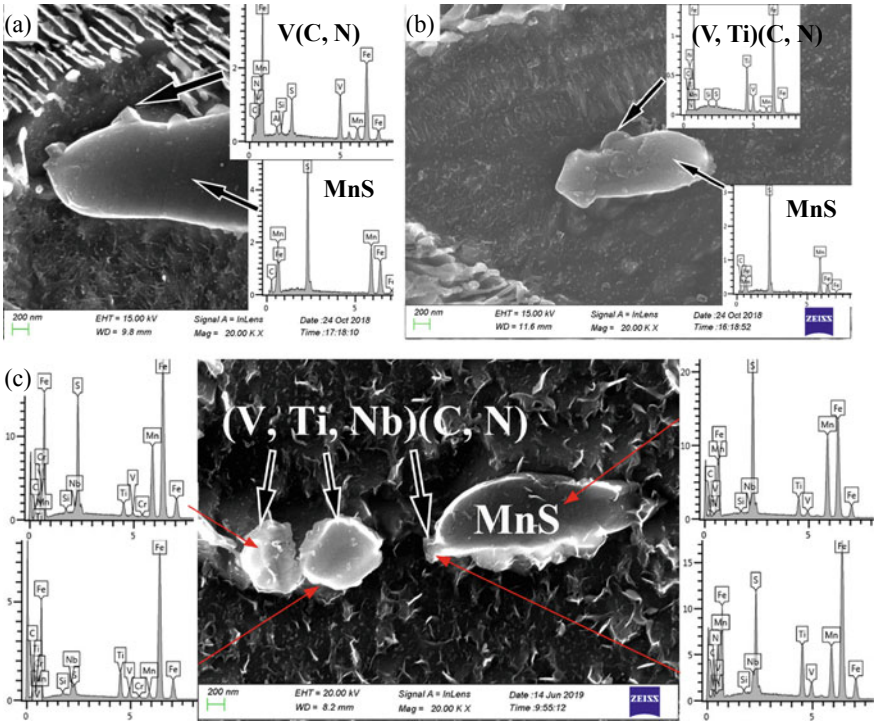

Fig. 7 The FESEM microstructures of different steels after the experiment with the route in Fig. 1b: **a** steel No. 2; **b** steel No. 3; **c** steel No. 4. (Color figure online)

Nb)(C, N) particles, respectively. The results were unanimous to the many previous studies which showed that the intra-granular ferrite had the Baker–Nutting orientation relationship with microalloying nitride [7, 8]. Thus, the microalloying nitrides in the steel played an important in the formation of intra-granular ferrite.

TEM morphologies of the precipitates in steel No. 3 and steel No. 4 are shown in Figs. 8 and 9 by means of observing the carbon extraction replicas evaporated on the samples. Results showed that there existed three kinds of precipitates in steel No. 3: clustered precipitates V(C, N) with the diameter less than 50 nm, ellipsoidal precipitates (V, Ti)(C, N) with the diameter nearly 50 nm in Fig. 8b, and quadrate precipitates (V, Ti)(C, N) with the diameter larger than 100 nm in Fig. 8c. In Fig. 9, the distribution of precipitates in steel No .4 was nearly the same as in steel No. 3. However, the precipitates in steel No. 4 were (V, Ti, Nb)(C, N) and there were Nb-rich and Ti-rich precipitates as shown in Fig. 9b, c. The Nb-rich precipitate could be formed on the Ti-rich precipitate and thus increase the size of the composite precipitate. Further quantitative analysis on the number and size of the precipitates showed that the average sizes of the precipitates in steel No. 3 and steel No. 4 were 55 nm and 72 nm, respectively. The numbers of the precipitates per μm^2 in steel No.

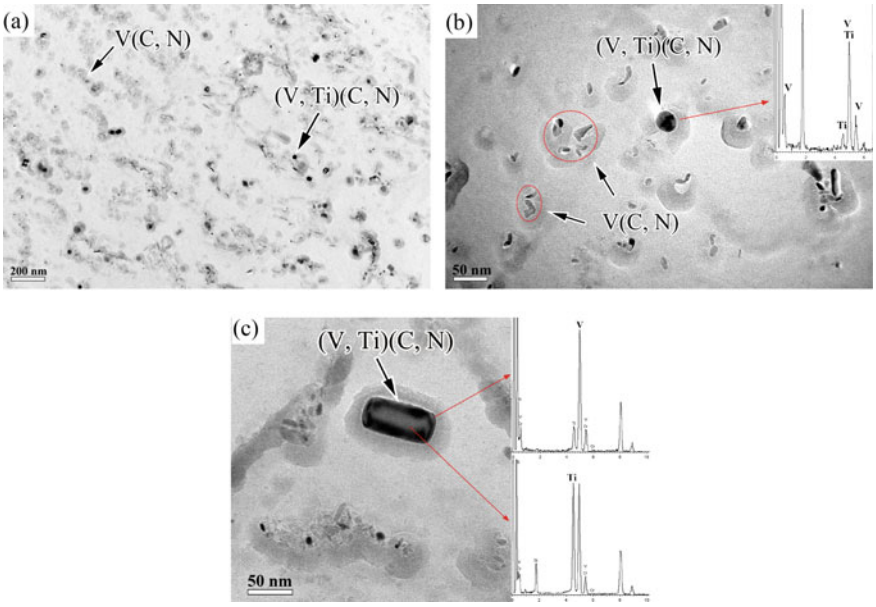

Fig. 8 TEM morphology and EDS results of the precipitates in steel No. 3: **a** low magnification; **b** elliptical precipitates (V, Ti)(C, N) with high magnification; **c** quadrate precipitates (V, Ti)(C, N) with high magnification. (Color figure online)

3 and steel No. 4 were approximately 9.1 and 8.3, respectively. The addition of Nb in the investigated steel can obviously increase the size of the precipitates.

3.2.3 Effect of Microalloying Elements on the Formation of Intra-granular Ferrite

Many researches showed that the size of the precipitates should reach a critical size which may be a few hundred nanometers in order to induce the nuclei of intra-granular ferrite [9, 10, 17–19]. Based on the results in part 3.2.2, the addition of Nb can increase the size of the precipitates and thus should promote the formation of intra-granular ferrite. However, the volume fraction of intra-granular ferrite in steel No. 4 was much lower than that in steel No. 3. Also, the addition of Nb reduced the volume fraction of ferrite. To further analyze the effect of Nb on the formation of ferrite, the linear expansion amount versus temperature in the cooling process is shown in Fig. 10. The phase transformation temperatures can be obtained as shown in the figure according to the curve slope changes. The transformation temperature range of ferrite and pearlite in steel No. 4 was obviously delayed to lower range compared with that in steel No. 3. Previous studies showed that Nb can improve the hardenability of steel and thus promote the pearlite formation and suppress the ferrite formation [20, 21]. It can be concluded the effect of Nb on the hardenability of steel

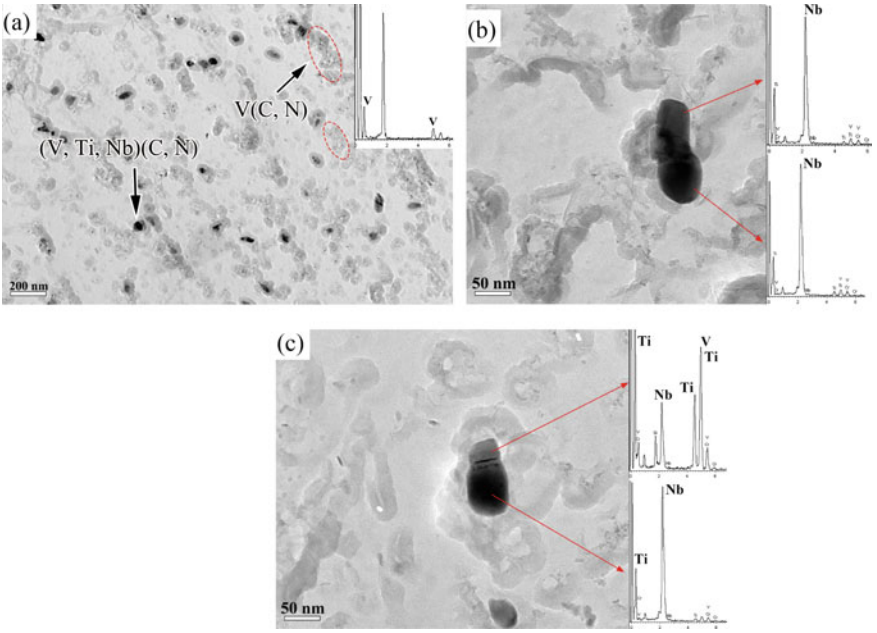

Fig. 9 TEM morphology and EDS results of the precipitates in steel No. 4: **a** low magnification; **b** Nb-rich precipitates (V, Ti, Nb)(C, N) with high magnification; **c** Nb and Ti composite precipitates (V, Ti, Nb)(C, N) with high magnification. (Color figure online)

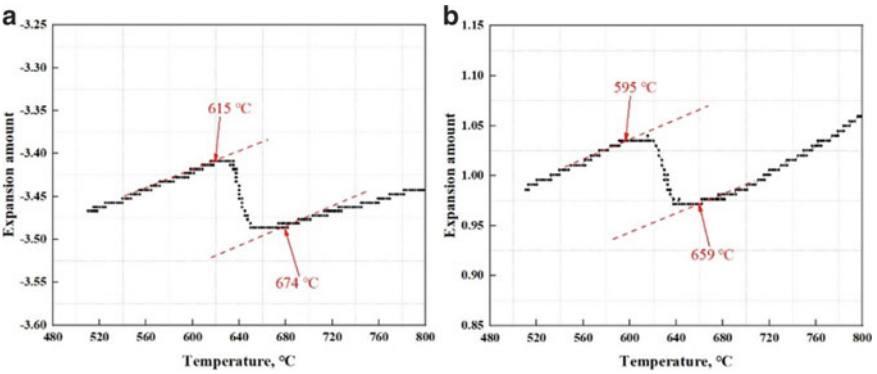

Fig. 10 The linear expansion amount versus temperature in cooling process: **a** steel No. 3; **b** steel No. 4. (Color figure online)

was higher than that on the formation of intra-granular ferrite. Thus, there were few ferrite and intra-granular ferrite in steel No. 4 than that in steel No. 3 in the process with the cooling rate of 0.3 °C/s.

4 Conclusions

(1) There is a critical deformation amount 6% which increases the grain size of steel in die forging process. The grain growth occurred at the cooling process after deformation and was driven by the energy offered by the deformation with small amount. The deformation amount during die forging process should reach 20% in order to refine the microstructures.
(2) The addition of V in the investigated steel can only reduce the grain size of the final product by 16.5 μm. The addition of Ti can largely reduce the grain size from 142.8 to 62.3 μm while the further addition of Nb doesn't have significant effect on the grain size.
(3) The addition of Ti can significantly increase the ferrite and intra-granular ferrite in the steel by refining the microstructure and offering the precipitates (V, Ti)(C, N) as the nuclei of intra-granular ferrite. The further addition of Nb in the V-Ti-N steel can further increase the size of the precipitates but suppress the formation of ferrite by improving the hardenability of steel. Thus, there are few ferrite and intra-granular ferrite in the V-Ti-Nb-N steel than that in the V-Ti-N steel.

Effect of Ferrite Rolling Temperature on the Microstructure and Properties of an Ultra-Low Carbon Steel Produced by CSP Process

Guoning He, Xuewen Hu, Bo Jiang, Chaolei Zhang, Haibo Wang, and Yazheng Liu

Abstract The higher strength of hot rolled steel sheet by compact strip production (CSP) process has been restricting its application in higher formability and thinner steel sheet because of higher cold rolling load. Ferrite rolling process has been widely researched since it has successfully reduced the strength of cold rolling feeds. In this paper, the microstructures and properties of a hot rolled ultra-low carbon steel SPHE by CSP process with different rolling temperatures were investigated. Strengthening mechanism was discussed by EBSD and TEM analysis. Results showed the mechanisms why the strength of the steel deformed with the finishing rolling temperature at single ferrite zone was increased while the elongation was decreased. The deformation resistance and microstructure versus temperature and the transformation behavior were analyzed. It was found that deformation at dual phase zone near to Ac1 can further increase the grain size and thus decrease the strength and meantime keep the elongation.

1 Introduction

Compact strip production (CSP) process is one of the main thin slab continuous casting and rolling production lines, which produces hot strips using a brief production line combining science, technology, and engineering [1, 2]. CSP appeared in 1989 and has developed rapidly because of its low cost and high efficiency. China has the largest thin slab continuous casting and rolling production line and output. By the end of 2018, China has built 17 thin slab continuous casting and rolling production lines, 15 of which are still in operation, with a total capacity of more than 35 million tons/year. Compared with traditional technology, CSP products have finer microstructure and higher strength with the same composition [3, 4]. Therefore, it has obvious advantages to develop high-strength steel by CSP process. CSP manufacturers all over the world are developing to fine grain ultra-high-strength steel, including multi-phase steel, pipeline steel, and other high value-added products [5–7].

The sheet thickness can be reduced while adopting high-strength steel, which is an important way to realize a vehicle is lightweight [8, 9]. This requires sheets that should not only maintain higher mechanical properties, but also should be thinner and lighter. For the CSP process, the unique funnel-shaped crystallizer and high casting speed can easily result in slag entrapment. In addition, after continuous casting, soaking and rolling are carried out directly, and surface defects cannot be removed. It is difficult to produce ultrathin hot rolled sheet by CSP process because of its poor surface quality [10].

Due to the poor quality of hot rolled sheet, CSP process often provides base material of cold rolling. However, when taking the CSP hot rolled sheet as base material to produce the cold rolling sheet, it has higher yield strength, lower elongation ratio, and poorer stamping performance. The high yield strength has adverse effects on cold rolling. Several studies suggest that boron added in low carbon steel can make grain coarsening, leading to reduction of yield strength but brings little effect. Recent years, study on hot rolled in ferrite region based on CSP line achieved good results in reduction of yield strength [11].

In this paper, the microstructures and properties of a hot rolled ultra-low carbon steel SPHE by CSP process with different ferrite region rolling temperatures were investigated. The results can provide a reference for study and application of ferrite region rolling on CSP line.

2 Experimental Procedure

2.1 Materials

The chemical composition of the experimental ultra-low carbon steel sheet SPHE by CSP process is shown in Table 1. The phase transition point Ar1 and Ar3 at this composition are 881 °C and 915 °C. The production process flow diagram of the

Table 1 The chemical composition of SPHE sheet

Elements	C	Si	Mn	P	S	Als	Ti
Mass fraction (%)	0.002	0.012	0.11	0.014	0.004	0.053	0.060

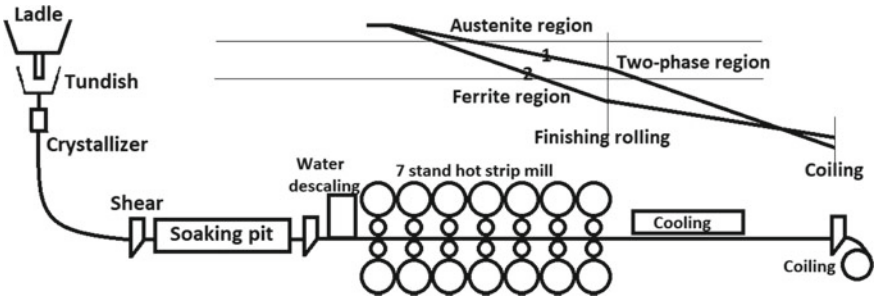

Fig. 1 The production process flow diagram of CSP process

experimental sheet is shown in Fig. 1. Hot rolled sheets of 3 mm thickness were produced by two different rolling processes named 1 and 2, one with the finishing rolling temperature about 890 °C and the other with about 807 °C. Process 1 represents a kind of two-phase region rolling or high-temperature ferrite rolling, and process 2 represents a kind of low-temperature ferrite rolling. Both sheets were coiled at the temperature of 660 ± 30 °C after rolling.

2.2 Microstructural Characterization

The optical microscope (OM) microstructures were observed in normal direction (ND), rolling direction (RD), and transverse direction (TD) at the 1/2 width of the hot rolled sheet, and the surface of sample was etched by 4% nitric acid in alcohol. Electron backscatter diffraction (EBSD) measurements were made in TD of the sample in a scanning electron microscope (SEM), operated at 20 kV. The surface of sample was electropolished in 15% perchloric acid in alcohol. The precipitates and dislocation were observed by transmission electron microscope (TEM) analysis and energy dispersive spectrometer (EDS).

2.3 Mechanical Properties

The standard samples were cut to test the mechanical properties at the 1/2 width of the hot rolled sheet. The transversal, longitudinal, and diagonal of sheets were all analyzed, and the sampling method is shown in Fig. 2. The average plastic strain

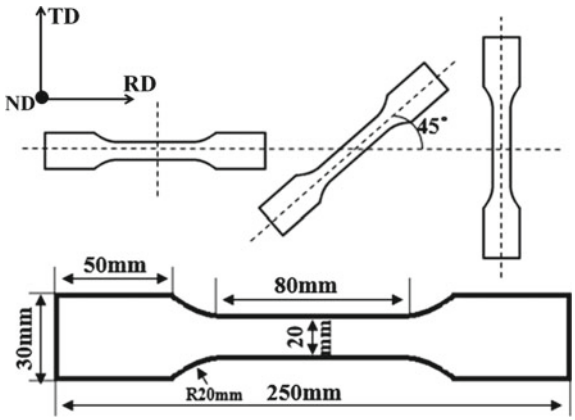

Fig. 2 The sampling method of mechanical properties

ratio r value and the anisotropic coefficient Δr value were also calculated. Mechanical properties tests were carried out according to the Chinese national standard GB/T228-2010 and GB/T5028-2008.

The deformation resistances and microstructures under different deformation temperatures were investigated by Gleeble 3800 thermal–mechanical simulation. The deformation temperature was set as 930, 900, 885, 870, 835, 800, and 700 °C after austenitizing at 1000 °C for 1 min. The deformation true strain was 0.92 and deformation rate was 40 s^{-1}.

3 Results and Discussion

3.1 OM Microstructure

The OM microstructures of two hot rolled sheets in different observation directions were shown in Fig. 3. The microstructure of the sheet in process 1 was equiaxed ferrite and the grain boundary of ferrite was clear. There is no significant difference among the ferrite morphology in ND, RD, and TD. Because of the low finishing temperature in process 2, more work hardening exists at the strip. And yet the grain boundary was not etched by nitric acid in process 2, only ferrite grains with different etching degrees could be seen indistinctly. It can be surmised that the energy in grains was higher than that in grain boundaries.

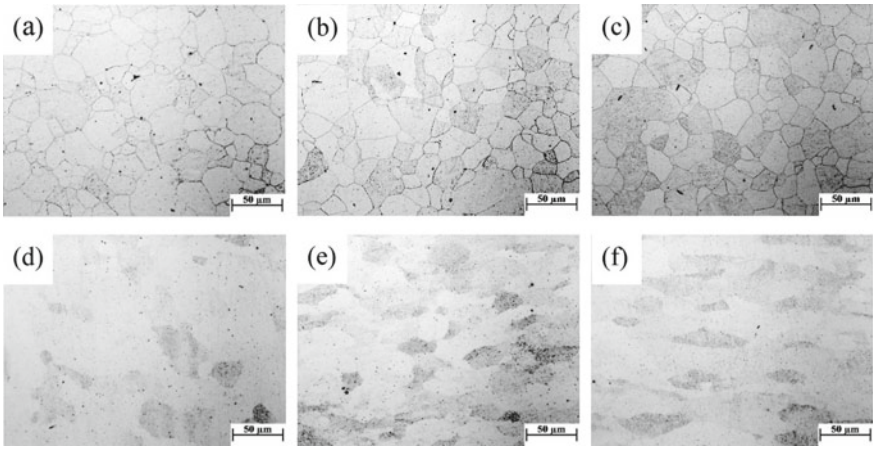

Fig. 3 OM microstructure of two sheets in different observation directions: **a**, **b**, **c** process 1, **d**, **e**, **f** process 2, **a**, **d** ND, **b**, **e** RD, **c, f** TD

3.2 EBSD Analysis

The grain boundaries analyzed by EBSD of two hot rolled sheets were shown in Fig. 4. The grain boundaries of ferrite in process 1 were mainly high-angle grain boundaries (>15°), the average grain size was 25.3 μm. But there were many low-angle grain boundaries (<15°) in process 2, the ferrite was deformed and irregular.

The grain orientations referenced to the sheet plane (the rolling surface) and rolling direction were obtained by EBSD, as shown in Fig. 5. EBSD result showed that there was a good agreement with the grain orientations of the two hot rolled sheets. The grains referenced to the sheet plane were mainly in blue and red, and the grains referenced to the rolling direction were mainly in green. This represented

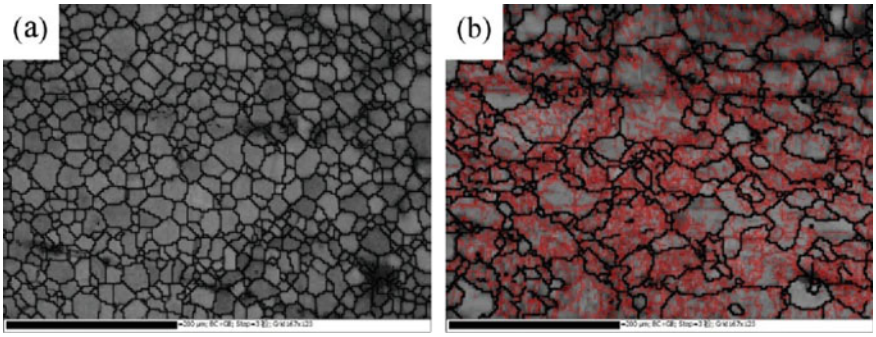

Fig. 4 Grain boundaries morphology in TD observed by EBSD: **a** process 1, **b** process 2. (Color figure online)

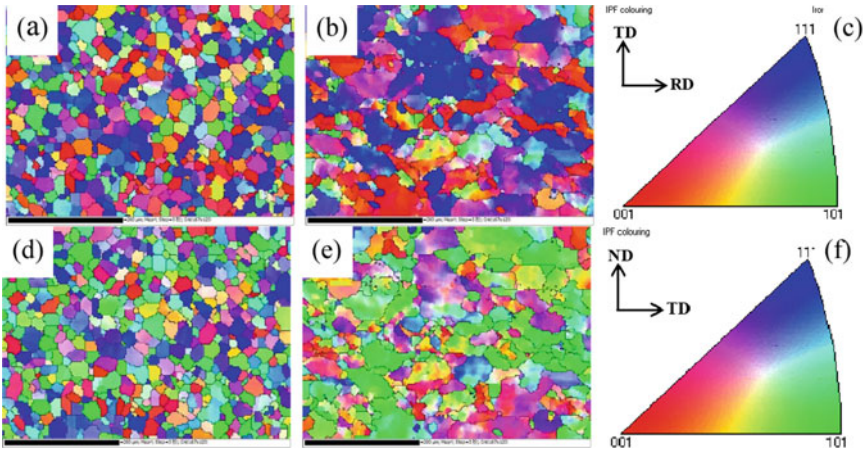

Fig. 5 The grain orientations referenced to the sheet plane and rolling direction: **a**, **c** process 1, **b**, **d** process 2, **a**, **b**, **c** the sheet plane, **d**, **e**, **f** rolling direction. (Color figure online)

that both of the grain orientations in process 1 and process 2 were {111}<110> and {001}<110>. The grain orientation in process 1 was more disordered.

3.3 TEM Analysis

The dislocation morphologies of two hot rolled sheets were observed by TEM, and the results were shown in Fig. 6. The number of dislocation lines observed in process 1 were quite lower than that in process 2. There were no or little single dislocation line observed in most field of view in process 1, and dislocation tangle existed in the rare case. But the observation in process 2 showed a lot of dislocation pile up and nets, as well as subgrain boundaries.

The precipitates in two hot rolled sheets were investigated by carbon extraction replica method, as shown in Fig. 7. A large number of small round-shaped precipitates were found in process 1, with size of 20–30 nm, which could be identified as $Ti_4C_2S_2$ by EDS [12]. The number of $Ti_4C_2S_2$ precipitates increased in process 2, while the size and shape have almost no change. It was speculated that the low finishing temperature deformation induced the $Ti_4C_2S_2$ precipitation.

3.4 Mechanical Property

The mechanical properties in different sampling directions of the two hot rolled sheets were shown in Table 2. The mechanical properties of process 1 in different

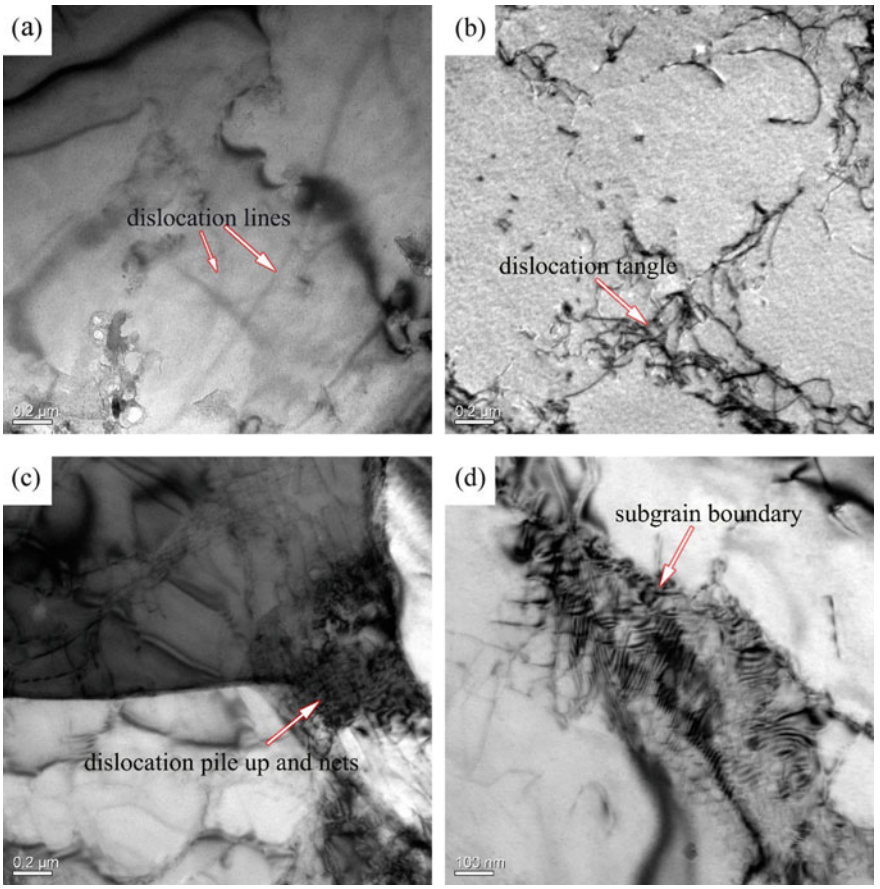

Fig. 6 The dislocation morphologies observed by TEM: **a**, **b** process 1, **c**, **d** process 2. (Color figure online)

directions had no obvious difference, whereas the mechanical properties of process 2 in longitudinal direction were relatively low. Comparing the mechanical properties of the two hot rolled sheets, the average yield strength and tensile strength of process 2 were increased by 61 MPa and 45 MPa, respectively, while the average elongation was decreased by 22%. The average n value of process 2 was also decreased 0.11, but the Δr and $\bar{r}$ changed little.

The average deformation resistances and microstructures of experimental SPHE steel under different deformation temperatures were shown in Fig. 8 and Fig. 9, respectively. With the increase of deformation temperature, the average deformation resistance of SPHE steel decreased firstly, then increased, and reached a minimum value in the vicinity of 870 °C. Moreover, the decrease of deformation temperature from 930 to 870 °C led to an obvious increase of grain size. But with the deformation temperature continuing to decrease, the grains were elongated along the direction of deformation and the amount of crystal defects increased.

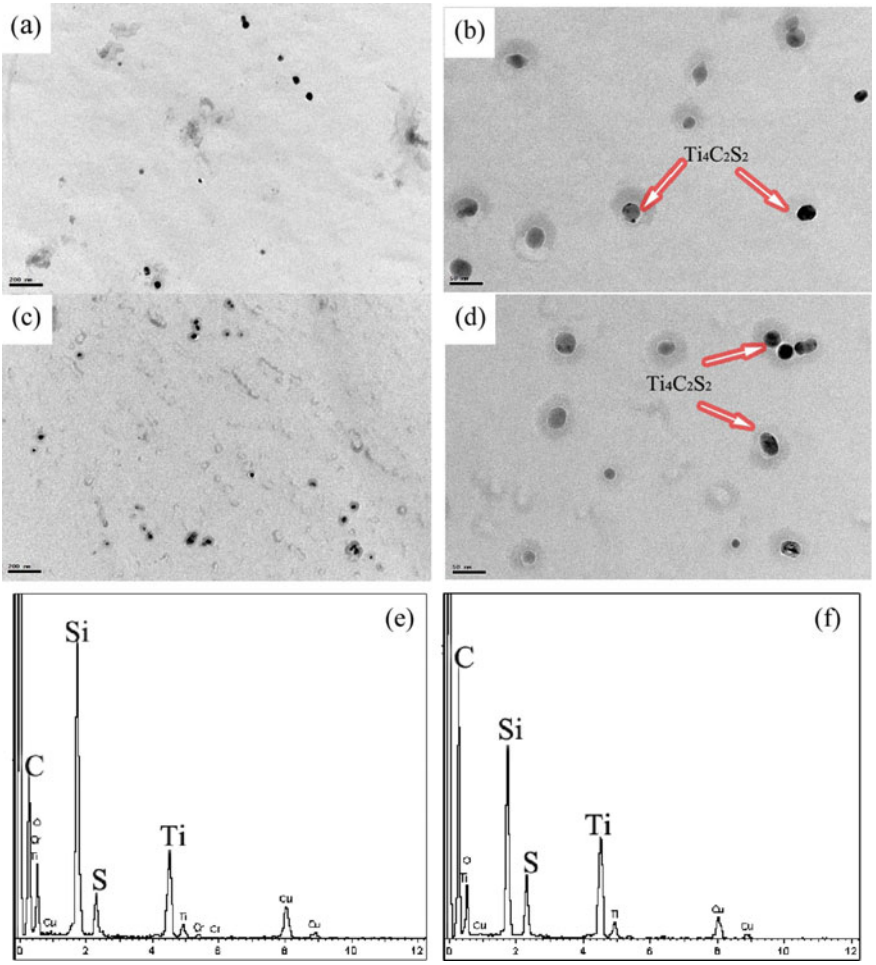

Fig. 7 $Ti_4C_2S_2$ precipitate observed by TEM with corresponding EDS analysis: **a**, **b**, **e** process 1, **c**, **d**, **f** process 2. (Color figure online)

At the same temperature, the yield strength of ferrite was lower than that of austenite, while the slip systems of ferrite with BCC structure were less than austenite with FCC structure, so the plasticity of austenite is better than ferrite [13]. When the deformation temperature got into the two-phase region, the appearance of low strength ferrite led to the significant reduction of deformation resistance. Meanwhile, austenite dynamic recrystallization and phase transformation consumed the deformation energy, and large size grains with little crystal defects were formed. With the deformation temperature continued to decline, single phase ferrite with BCC structure was hard to dynamic recrystallize and recover, a large number of deformation

Table 2 Mechanical properties in different sampling directions of hot rolled sheets

Process	Direction	Yield strength (MPa)	Tensile strength (MPa)	Elongation (%)	n	r	Δr	$\bar{r}$
Process 1	Transversal	205	289	44.8	0.24	1.07	−0.05	1.08

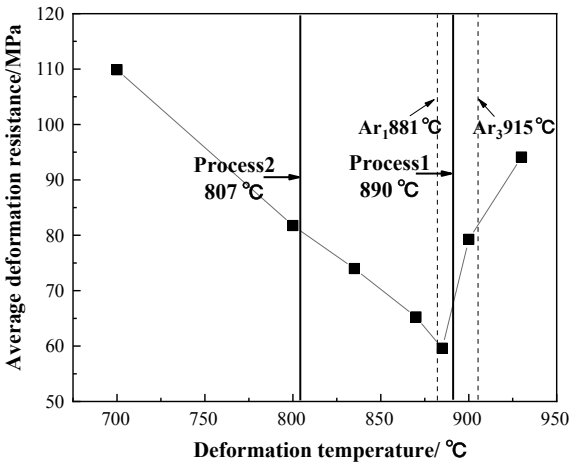

Fig. 8 The average deformation resistances of experimental SPHE steel under different deformation temperatures

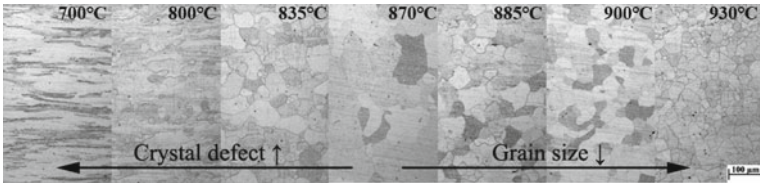

Fig. 9 The microstructures of experimental SPHE steel under different deformation temperatures

energy and crystal defects will be introduced, and the deformation resistance will substantially increase.

Table 3 The comparison of influence parameters of each strengthening factor of hot rolled sheets

Strengthening factor	Influence parameter	Process 1	Process 2
σFe	Microstructure	Ferrite	
σss	Chemical composition	The same SPHE sheet	
σd	Dislocation	Lower density	Higher density
σsg	Substructure	Less	More
σt	Texture	Negligible	
σp	Precipitation	Less	More
σg	Grain size	Bigger	Smaller
σs	All	Lower	Higher

3.5 Strengthening Mechanism

The yield strength of ferrite steel can be regarded as a combination of several strengthening factors, such as the strength of ferrite matrix σFe, the solid solution strengthening σss, the dislocation strengthening σd, the substructure strengthening σsg, the texture strengthening σt, the precipitation strengthening σp, and the fine grain strengthening σg. Therefore, the yield strength can be factorized as follows in Eq. (1) [14].

$$\sigma s = \sigma Fe + \sigma ss + \sigma d + \sigma sg + \sigma t + \sigma p + \sigma g \quad (1)$$

The influence parameters of each strengthening factor were compared and analyzed for the two sheets. Each influence parameter was shown in Table 3. For the two hot rolled SPHE sheets in process 1 and 2, σFe and σss were the same because of the same ferrite single phase and chemical composition. The dislocation density in process 2 was much higher than that in process 1, so the dislocation strengthening σd was also higher. In addition, the subgrain boundaries and larger number of $Ti_4C_2S_2$ precipitates meant that σsg and σp in process 2 will be higher than that in process 1. The variation of grain orientation of the two sheets was relatively small, thus σt was negligible. Due to the bigger grain size in process 1, the σg was quite smaller than that in process 2. Superposition of all factors resulted in the difference of yield strength in the two processes.

4 Conclusions

(1) Ultra-low carbon steel SPHE hot rolled sheet with the finishing rolling temperature about 890 °C mainly had high-angle grain boundaries, and the average

grain size of ferrite was 25.3 μm. But there were many low-angle grain boundaries in the steel sheet with the finishing rolling temperature about 807 °C, and the ferrite was deformed and irregular.

(2) Compared with low finishing rolling temperature sheet, the steel sheet with the finishing rolling temperature about 890 °C had lower dislocation density, less number of subgrain boundaries and $Ti_4C_2S_2$ precipitates, and larger grain size, the comprehensive action of these effects brought the obvious decrease of yield strength and increase of elongation.

(3) With the increase of deformation temperature, the average deformation resistance of SPHE steel decreased firstly and then increased. The decrease of deformation temperature from 930 to 870 °C led to an obvious increase of grain size and with the deformation temperature continuing to decrease, the grains were elongated along the direction of deformation and the amount of crystal defects increased.

The Effect of Temperature on the Strain-Induced Austenite to Martensite Transformation in SS 316L During Uniaxial Tension

Elizabeth M. Mamros, M. Bram Kuijer, Mohammad Ali Davarpanah, Ian Baker, and Brad L. Kinsey

Abstract Controlling the microstructure of components is of interest to achieve optimal final part properties, i.e., materials by design. The manufacturing process itself can affect a material's characteristics by changing the microstructure. For example, past research has shown that austenite to martensite phase transformation in stainless steel occurs during deformation. Temperature is known to have a significant influence on this phenomenon. In this paper, the effect of temperature on the austenitic to martensite phase transformation in SS 316L under uniaxial tension is investigated. Both a cooling system and a heat exchanger were employed in a uniaxial tension experimental setup to control the temperature. Tensile specimens were strained to fracture at four temperatures of −15, 0, 10, and 20 °C. Digital imaging correlation (DIC) and a thermal imaging camera were used for tests at 0 °C and above to capture strain and temperature data, respectively. Strain and temperature data could not be obtained at −15 °C due to the DIC paint flaking during testing. X-ray diffraction was used to measure the volume fraction of martensite in both the as-received and the tensile-tested materials.

Keywords Forming · Uniaxial tension · Martensitic transformation · Stainless steel

1 Introduction

One means to achieve optimal final part properties during forming is by controlling the microstructure of materials. However, this objective is extremely complex due to the number of variables involved, including temperature, strain rate, stress–strain state, and deformation path, and their interdependence [1].

A microstructural phase transformation to martensite occurs during forming in austenitic stainless steels (SS) at room temperature. This effect is increased at temperatures below zero Centigrade and at high strains [2]. Hecker et al. found that at strains <0.25, high strain rates produced more martensite, while the converse occurred at larger strains [1]. Thus, for uniaxial tensile tests of ductile materials, low strain rates and low temperatures are preferred to obtain a larger volume fraction of martensite.

As is typical for all metals and alloys, austenitic SS exhibits plasticity-induced heating. Nonhomogeneous deformation along the gauge length and heat conduction from the center toward the ends of the specimen lead to temperature gradients which affect the amount of martensitic transformation. The volume fraction of martensite increases from the end of the gauge length toward the center in deformed specimens [3]. Huang et al. [4] found that at temperatures >50 °C, martensite is not present. At −70 °C, the martensitic transformation rate reaches a maximum at approximately 0.15 strain. As the temperature increases toward room temperature, the maximum martensitic transformation rate decreases and occurs at higher strains.

At low temperatures between approximately −80 and −50 °C, the strength increases rapidly due to the high rate of martensitic transformation at low strains. Due to the large amount of martensite near the beginning of the forming process, the strain hardening rate suddenly decreases at higher strains. If the temperature is approximately 25 °C, then the rate of martensitic transformation is lower at low strains but occurs over a larger range of strains. This leads to a lower rate of increase in flow stress due to martensitic transformation and a more gradual decrease in the strain hardening rate at high strains. Consequently, maximum uniform elongation occurs around 0 °C [4].

Moser et al. [5] conducted isothermal uniaxial tension tests for SS 304 specimens at temperatures ranging from 0 to 100 °C and found the largest weight percent of martensite in the 0 °C specimens. Therefore, additional experiments are required at subzero temperatures to verify that the volume fraction of martensite continues to increase with decreasing temperature.

In this paper, results from “isothermal” uniaxial tensile tests on SS 316L specimens are presented for temperatures ranging from −15 to 20 °C (room temperature). (Note that a temperature gradient exists just prior to fracture, so the test is not truly isothermal.) To investigate the temperature effect on martensitic phase transformation, X-ray diffraction (XRD) was used, and the resulting volume fractions in the gauge section were compared for the formed specimens. Digital image correlation (DIC) and thermal imaging were used to measure strain and temperature, respectively, for tests with a temperature above 0 °C. The required speckle pattern was not able to withstand the subzero temperature conditions due to paint flaking. Based on previous work, the hypothesis is that the volume fraction of martensite will increase with decreasing temperature.

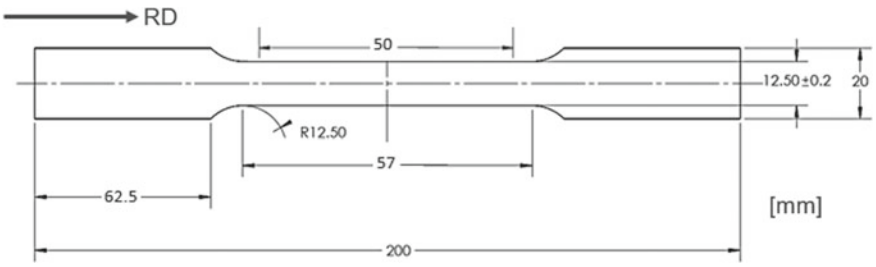

Fig. 1 ASTM E8 specimens obtained from 1.2 mm thick SS 316L

2 Experimental Setup and Methods

2.1 Material and Specimen Preparation

Dogbone specimens, dimensioned according to the ASTM E8 standard, were waterjet cut from SS 316L, 1.2 mm thick sheets with the 57 mm gauge length oriented along the rolling direction (Fig. 1). Due to the rough surfaces created by waterjet cutting, the edges were sanded, and the initial width and thickness were measured with a caliper and micrometer, respectively, prior to testing.

2.2 Cooling System

A cooling system, which consisted of a compressor (Thermo Fisher), pump (Thermo Fisher), and cold plate (AAVID), was used with a 60% ethylene glycol/40% water mixture to create "isothermal" testing conditions. The cooling system temperature range is −50 to 200 °C, but the lower threshold for the ethylene glycol/water coolant is −30 °C. The temperature range of the cold plate is −65 to 155 °C. To account for heat transfer, the temperature setting for the cooling system was adjusted accordingly to ensure that the specimen reached the desired steady-state temperature prior to each experiment. The specimen temperature was verified with a thermocouple.

2.3 Experimental Setup

A MTS Landmark machine with a 250 kN load cell was utilized to perform the uniaxial tension tests. A pulling speed of 0.1 mm/s was used, which produced an initial strain rate of ~1×10^{-3} s^{-1}. The cold plate was clamped to the bottom half of each specimen in the grip area and remained stationary during the experiment (Fig. 2). A small force was applied out-of-plane behind the cold plate to create

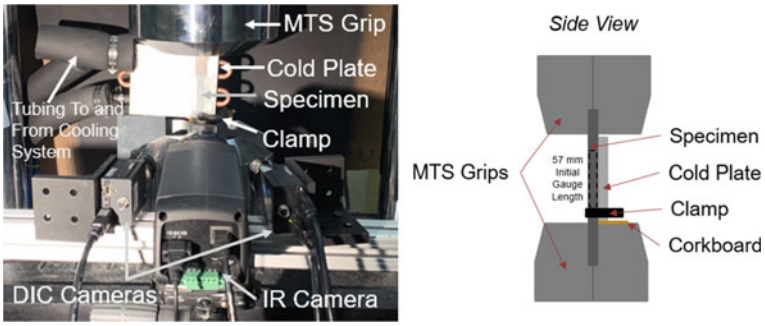

Fig. 2 Experimental setup with DIC, IR camera, cooling system, and MTS grips. (Color figure online)

uniform contact across the entire specimen gauge area for the duration of the test. A piece of corkboard was used to ensure that no contact occurred between the MTS grips and the cold plate.

2.4 Digital Image Correlation and Thermal Camera

To capture local strains *in situ*, two FLIR 5.0-megapixel cameras with 17 mm Schneider Xenoplan compact lenses were set up for three-dimensional DIC (Fig. 2). To create the contrast required for this technique, white background with a black speckle pattern in the foreground was created with spray paint.

Coupled with the DIC cameras in VIC Snap, the image capturing software (Correlated Solutions Inc.), a FLIR SC-645 infrared (IR) camera was used to measure the temperature during the tests. The infrared camera has a temperature range of −20 to 650 °C with a temperature resolution of 0.05 °C. The spatial resolution is 640 × 480 pixels. The emissivity was set to 0.98 based on the specimen speckle pattern. This value was determined by calibrating the infrared camera to thermocouple readings on painted specimens. All images, i.e., strain and thermal, were captured synchronously every 500 ms.

All images were post-processed with subset and step sizes of 17 and 4, respectively, in VIC-3D (Correlated Solutions Inc.). An area slightly larger than the 57 mm gauge length was selected for the analyses along with an inspect rectangle surrounding the fracture location and an inspect point at the fracture location to extract strain and temperature data.

2.5 Martensitic Transformation Measurements

A Bruker GADDS AXS XRD with a cobalt X-ray source was utilized to measure the volume fraction of the BCC phase or martensite. Two scans were performed, centered at 55 and 85° two-theta, using a voltage and current of 40 kV and 20 mA, respectively. The goniometer radius was set to 123.3 mm. DIFFRAC.EVA was used to convert the captured Debye rings into peak data. Additional post-processing was completed in MAUD [6] to determine the volume fraction of the FCC (austenite) and the BCC (martensite) phases in each specimen. Each specimen was ground using a polishing wheel with 600-grit SiC paper to create a flat surface as required for the XRD. A large water flow was used to eliminate a heat-induced phase change and damage during polishing.

3 Results and Discussion

3.1 Temperature

Figure 3 shows the strain and temperature distributions from the last image captured by the DIC and IR camera prior to fracture for the 0, 10, and 20 °C specimens. Table 1 shows the corresponding true strain and temperature values at a point located in the center of the fracture location. Neither DIC nor IR data could be captured from the −15 °C specimens as the paint used to provide the speckle pattern lost adhesion at subzero temperatures.

From Fig. 3, it is evident that the cold plate is able to maintain nearly isothermal conditions near the ends of the specimen throughout the duration of the test. However, the gauge section still undergoes plasticity-induced heating and reaches gradients up to approximately 35 °C across the 57 mm gauge length for the room temperature experiments. This heating occurs rapidly as the specimen approaches fracture (Fig. 4) because the cold plate is no longer sufficient to maintain an isothermal temperature. The sequential frame numbers and strain values are provided in Fig. 4 to show that the temperature increase is primarily at the end of the test as the strain localization occurs.

As is evident in Table 1, the 10 and 20 °C specimens experienced a maximum increase in temperature of approximately 35 °C, but the 0 °C specimen's temperature increased nearly 43 °C. The 0 and 20 °C specimens showed nearly the same true strain just before fracture, but the 10 °C specimen exhibited a slightly higher true strain around 80% just before fracture. This difference in strain is due to specimen to specimen variations in material and the sampling rate of the DIC.

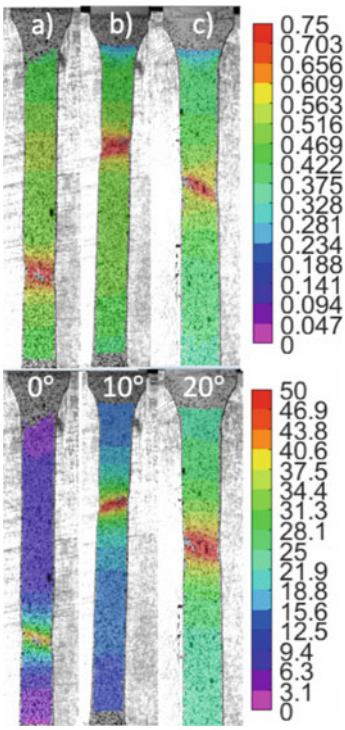

Fig. 3 True strain (top) and temperature (bottom) distributions prior to fracture for **a** 0 °C, **b** 10 °C, and **c** 20 °C specimens. (Color figure online)

Table 1 DIC and IR results from uniaxial tests

Specimen (°C)	True strain just before fracture	Temperature just before fracture (°C)
0	0.721	42.74
10	0.805	45.90
20	0.733	56.05

3.2 Stress–Strain Curves

Since DIC data is not available for −15 °C experiments, engineering stress versus plastic strain curves were created using the MTS cylinder location data for the strain calculation (Fig. 5). A general trend of increased engineering flow stress as the temperature decreases occurs from 20 to −15 °C, which is consistent with results in Huang et al. [4]. This strain data represents the deformation over the entire gauge area with the engineering stress calculated from the initial specimen cross-section. As shown in Fig. 3 though, the strain localizes in the necked region of the specimen during the tests.

DIC allows the strain in the fracture region to be assessed and the stress to be calculated based on the instantaneous gauge area, i.e., the true stress, up to localized

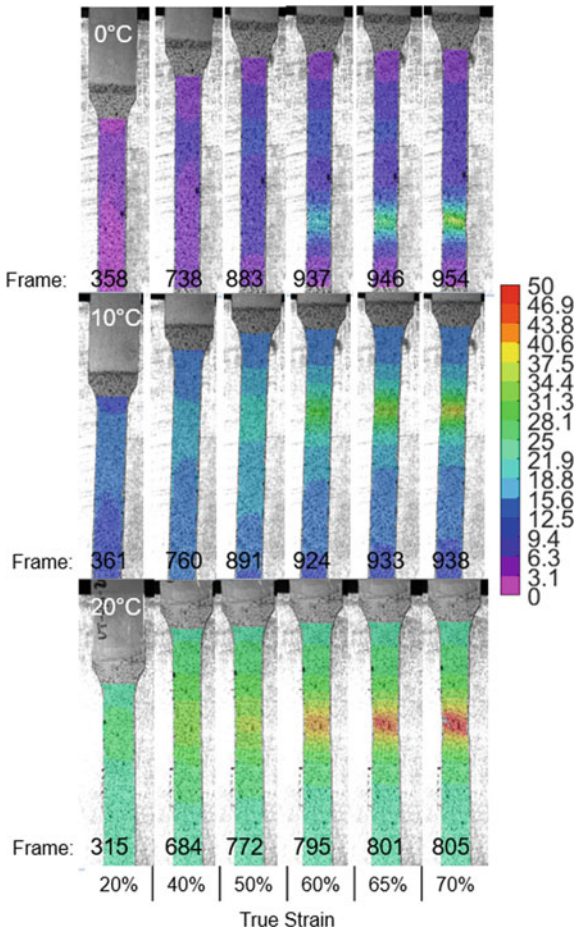

Fig. 4 Temperature distribution (°C) over time (represented by frame number) for 0 °C (top), 10 °C (middle), and 20 °C (bottom) specimens. (Color figure online)

necking. Figure 6 shows the true stress–true strain curves for specimens tested at 0, 10, and 20 °C. As is evident, the temperature effect of Fig. 5 is also present when probing data in the fracture location. While at least three specimens have already been tested at each temperature, additional trials will be conducted to assure the consistency of this data.

3.3 Martensitic Transformations

An additional set of experiments were conducted, stopping at 60% engineering strain for consistency, to obtain samples for XRD measurements. Table 2 shows the volume fractions of martensite for these specimens measured in the gauge area 15 mm above

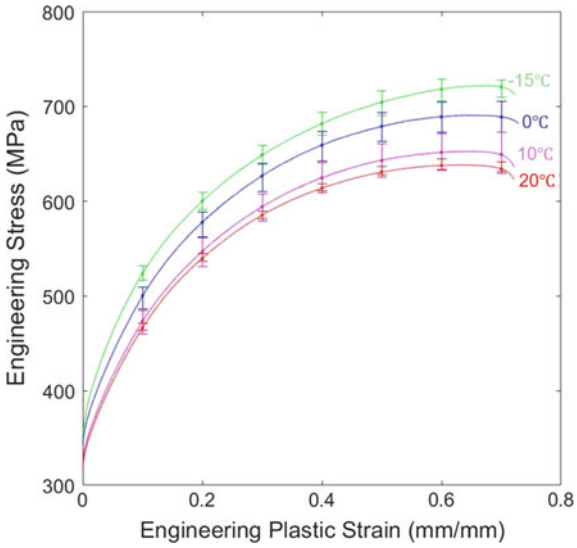

Fig. 5 Engineering stress–engineering plastic strain for −15, 0, 10, and 20 °C tests. (Color figure online)

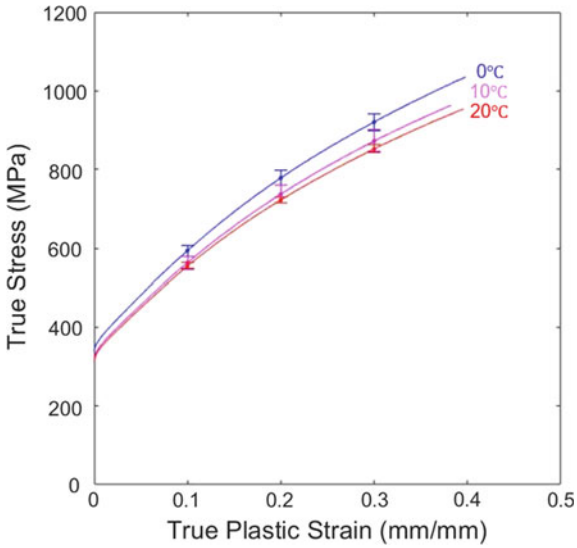

Fig. 6 True stress–true plastic strain curves for 0, 10, and 20 °C tests. (Color figure online)

Table 2 Martensite volume fractions from XRD in the gauge section

Temperature (°C)	Volume fraction
−15	0.135
0	0.115
10	0.089
20	0.100

the bottom grip section. This nearly follows the expected trend that the volume fraction of martensite increases with decreasing temperature. The increased martensite causes the higher stress values as seen in Fig. 5. As anticipated, the as-received material shows no martensite present so the plasticity-induced austenite to martensite transformation occurs at all temperatures investigated. Note that higher values of martensite that followed the expected trend were measured in the failure location of the specimen, but the localized deformation in this region was not uniaxial tension. Therefore, only martensite measurements in the gauge section away from the failure location are reported.

4 Conclusion and Future Work

SS 316L specimens were loaded in uniaxial tension until fracture under nearly isothermal conditions at −15, 0, 10, and 20 °C. XRD measurements showed that reducing the temperature generally increases the volume fraction of martensite in the tested specimens at the fracture location and in the gauge section. Future experiments could include a different method of creating isothermal conditions, e.g., an enclosed cooling system, to further reduce the observed plasticity-induced heating effects. Alternatively, a different coolant could be used with the current cooling system to perform additional experiments at even lower temperatures. Electron backscatter diffraction (EBSD) will be used to verify the martensite volume fractions. In the future, crystal plasticity modeling will be implemented to provide a fundamental understanding of the phase transformation mechanisms and determine optimal deformation paths to intentionally manipulate final material properties.

Acknowledgments Support for the NH BioMade Project is provided by the National Science Foundation through the EPSCoR Research Infrastructure Improvement Award #1757371. Special appreciation to Marguerite Kennish for her assistance with uniaxial tension testing and processing the data.

Energy-Dependent Surface Integrity of Stainless Steel AISI 304 After Robot-Based Machine Hammer Peening

Robby Mannens, Lars Uhlmann, Andreas Feuerhack, and Thomas Bergs

Abstract Machine hammer peening (MHP) is a high-frequency, incremental surface treatment with a spherical plunger which enables reproducible local plastic forming of metallic surface layers. The elasto-plastic deformation leads to a targeted smoothing or structuring of the surface as well as to the induction of compressive residual stresses and strain hardening. However, since MHP is still a relatively new process, there are still considerably knowledge deficits with regard to the cause–effect relationships of the energy inputs set by the MHP process parameters and the resulting surface integrity of technically relevant alloys. Therefore, the objective of this work is to investigate the influence of the peening strategies and the resulting contact energies on the surface roughness, the surface hardness, the residual stresses, and the microstructure of AISI 304. The results show that MHP leads to smoother and harder surfaces resulting from deformation-induced martensite formation accompanied by high compressive residual stresses and subgrain refinement resulting from higher dislocation densities.

Keywords Machine hammer peening · Stainless steel · Surface integrity

1 Introduction and State of the Art

1.1 Initial Situation and Motivation

In the course of current efforts such as lightweight construction and resource efficiency, forming technology plays a key role [1]. By means of forming, components with outstanding mechanical properties can be manufactured while retaining the initial volume. Since the component or tool surface layer is often the most heavily loaded area, even a targeted local forming of the surface layer leads to a significant improvement in fatigue strength and wear resistance [2]. In addition to established

manufacturing processes such as shot peening [3], deep rolling [4], and laser shock peening [5], machine hammer peening (MHP) has been used and researched for several years.

In MHP, a plunger with a mostly spherical hammer head is accelerated at high frequency toward a workpiece surface to be machined [6]. The periodic oscillation movement can be realized according to the pneumatic, mechanical, piezoelectric, or electrodynamic active principle. The hammer tools are mainly guided by machining centers, in some cases also by industrial robots with high rigidity [7]. The contact conditions for highly dynamic MHP are described using energy-based approaches [8]. Due to the impact velocities of the hammer head and the resulting contact energies, the MHP smoothes or structures metallic surfaces, introduces compressive residual stresses and strain hardening [9]. Recent investigations on the influence of MHP on the microstructure [7] as well as the MHP of hard material particles into the surface layer [10] were also carried out.

Due to its technology-related kinematics, MHP enables defined local machining of the workpiece surface layer [6] in contrast to shot peening, which usually leads to lower roughness. By using the MHP in machining centers, the workpiece can be machined in one clamping to the preceding machining process, which allows high reproducibility and short secondary processing times. The surface smoothing, compressive residual stress maxima, and work hardening achievable with MHP are comparable to deep rolling [11]. On the other hand, surface cracks can form during deep rolling if unsuitable process parameters are selected [12].

However, since electrodynamic MHP is still a relatively new manufacturing technology, there are still considerable knowledge deficits with regard to the contact energy applied and the resulting surface integrity, especially in the area of subgrain size and dislocation density modification of technically relevant alloys. Due to the interesting hardening properties of austenitic stainless steels during mechanical forming at room temperature [13], the surface integrity of an AISI 304 stainless steel influenced by the electrodynamic MHP is investigated in this paper.

1.2 Objective

The aim of this work is the experimental analysis of the cause–effect relationships between the energy input resulting from different process settings during electrodynamic machine hammer peening (MHP) and the surface integrity of an AISI 304 stainless steel. Based on this knowledge, an energy-based design of the electrodynamic MHP as a consequence of process parameters can be carried out to achieve advantageous surface integrities of AISI 304 stainless steel.

1.3 Approach

In the first step, the existing electrodynamic MHP system will be extended by implementing a fiber-optic distance sensor for in-process measurement of the plunger stroke. In the second step, point hammer tests will be performed to determine the hammer kinematics and impact energy. By knowing the impact velocities and thus contact energies, further cause–effect relationships to the resulting surface integrity are to be determined in comparison to earlier work on MHP of stainless steels [14]. In the third step, experimental MHP tests will be performed on flat AISI 304 stainless steel samples and the surface layer will then be characterized with respect to roughness, surface hardness, residual stresses, and subgrain size. The experimental results will be synthesized and an energy–based recommendation for the adjustment of the MHP process parameters to achieve defined AISI 304 surface layer states will be formulated.

2 Experimental Work

2.1 Further Development of an Electrodynamic MHP System

Before the experimental MHP tests were carried out, the hammer tool of the used electrodynamic hammer system type 2002 from accurapuls was upgraded, see Fig. 1a. For this purpose, a fiber-optic distance sensor RC20 from PHILTEC was integrated into the hammer tool. This sensor works according to the principle of reflected intensity. Since the oscillating mass in the hammer tool can be regarded as a coherent unit, the stroke exerted on the workpiece can be determined by means of a back-sided sensor placement, see Fig. 1b.

For the best possible reflection conditions, a thin stainless steel plate polished to $Sa = 0.3$ µm was cast into an epoxy resin matrix at the upper end of the oscillating body, see Fig. 1c. The additional mass added is $m_{er} = 4$ g and, compared to the mass of the oscillating body $m_{ob} = 363$ g together with the plunger mass $m_{p12} = 67.1$ g (hammer head diameter $d = 12$ mm) or $m_{p6} = 77.2$ g ($d = 6$ mm), has a negligible influence on the MHP process kinematics. The sensor was calibrated by means of programmed vertical movement of an ABB IRB6660-205/1.9 robot with the aid of a compensation curve and a high-speed camera Phantom v7.3 with the lens AF NIKKOR 24-85 MM 1:2, 8-4D. After calibration, the stroke h could be determined with an accuracy $\Delta h = \pm$ 10 µm in the operational range $h = 0.25 \ldots 1.7$ mm. Furthermore, based on the results of HABERSOHN, the influence of axial elastic strains in the hammer tool during MHP processing and thus a distortion of the stroke measurement could be excluded [15]. The software LABVIEW and DIADEM from National Instruments were used for data acquisition, visualization, and evaluation.

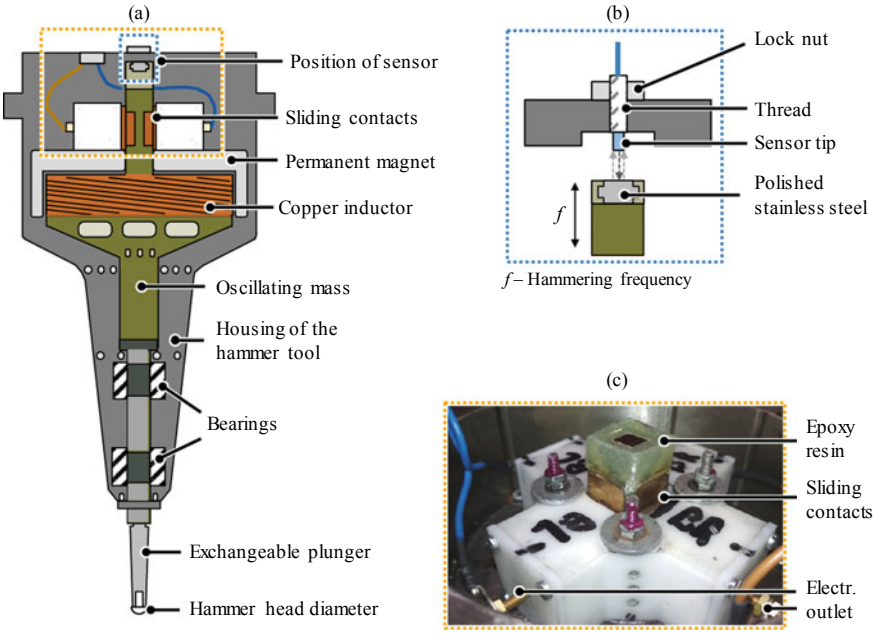

Fig. 1 **a** Structure of the electrodynamic accurapuls hammer tool, **b** scheme of sensor implementation, and **c** stainless steel plate embedded in epoxy resin. (Color figure online)

2.2 MHP Setup for Determination of Process Kinematics

To determine the kinematics of the electrodynamic MHP system, hammering tests were carried out on a pre-strengthened point on a AISI 4140 specimen, varying the process parameters hammering frequency $f = 20 \ldots 400$ Hz in 20 Hz steps, electrical power stage $P_{el} = 40 \ldots 80\%$ in 10% steps, stroke $h = 0.1 \ldots 1.0$ mm in 0.1 mm steps, and hammer head diameter $d = 6$, 12 mm. The corresponding electrical power P in the specified range was calculated from the voltage and current values measured with a multimeter at $P = 22 \ldots 713$ W. A parallelepiped specimen with the dimensions $40 \times 40 \times 100$ mm (W × H × L) was clamped centrally on a machine table using a vice and hammered in the center of the specimen. Using the LABVIEW software, the stroke measurement data recorded with a sampling frequency of $f_s = 50$ kHz were visualized and then evaluated using the DIADEM software. By means of the first test series, the general process kinematics of the accurapuls hammer system type 2002 used at the WZL were determined.

Table 1 Chemical composition of the used AISI 304 stainless steel

Elements	C	Si	Mn	P	S	Cr	Ni	N
Weight (%)	0.014	0.357	1.943	0.024	0.002	18.32	8.607	0.058

2.3 Materials and Sample Preparation

For the MHP tests, milled AISI 304 specimens (1.4301) with the dimensions 100 × 40 × 30 mm (L × W × H) were used. The specimens were ground plane-parallel on a surface grinding machine Blohm Planomat HP 620 CNC using a ceramic bonded grinding wheel Elbe S2704, a cutting speed $v_{cu} = 30$ m/s, and an infeed $a_p = 0.01$ mm to achieve an average roughness $Sa < 1$ µm. The mean value of the chemical composition determined by spark spectroscopy out of three measurements meets the requirements of DIN EN 10088-3, see Table 1.

2.4 MHP Parameter Study

The MHP tests were carried out using an electrodynamic hammer system type 2002 from accurapuls on a robot ABB IRB6660-205/1.9, see Fig. 2a.

For the analysis of the effects of selected MHP process parameters on the surface integrity, a full factorial experimental design was chosen according to the rules of statistical experimental methodology with triple repetition. The hammering frequency $f = 120, 180$ Hz, the stroke $h = 0.3, 0.5$ mm, the hammer head diameter $d = 6, 12$ mm, and the indentation distance $a =$ path distance $b = 0.05, 0.2$ mm were varied in two steps, see Table 2. All tests were carried out with an impact angle

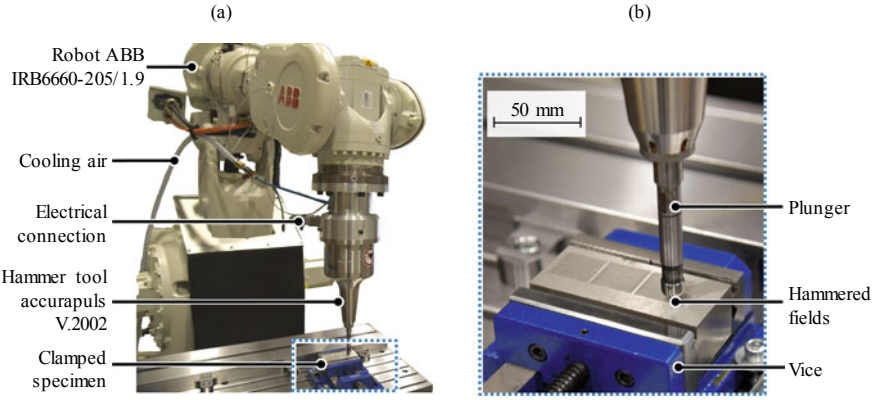

Fig. 2 **a** Hammer tool accurapuls type 2002 adapted to a robot ABB IRB 6660-205/1.9 and **b** specimen clamped in vice. (Color figure online)

Table 2 Parameter setups for MHP processing

No.	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16

$\beta_i = 0°$, which corresponds to an orthogonal alignment of the hammer tool to the specimen surface, and a meander-shaped machining strategy on a field size of 25 × 25 mm. The high-temperature lubricant Castrol Viscogen KL3 was used as lubricant because of industrial recommendations and one overrun was chosen. This second series of experiments investigated the cause–effect relationships between selected MHP parameters and the resulting surface integrity of AISI 304 stainless steel.

2.5 Analysis Methods

The roughness of the specimens was determined by means of a measuring system Hommel Etamic T8000 RC according to ISO 25178 on 1.6 × 1.6 mm measuring fields. The surface macrohardness according to Vickers was determined by five-fold repeated measurement and subsequent averaging using a Zwick Roell Indentec ZHU250 hardness tester according to DIN EN ISO 6507-1. The depth profiles of the residual stresses were measured with the PRISM hole drilling system from Stresstech according to the principle of electronic speckle pattern interferometry (ESPI) and calculated according to the SCHAJER integral method and TIKHONOV regularization [16]. The grain size distribution was determined by the Central Facility for Electron Microscopy (GFE) of RWTH Aachen University using the scanning electron microscope JEOL JSM7000F and an integrated EBSD/EDX system EDAX Pegasus.

3 Results

3.1 Process Kinematics and Impact Energies

Figure 3a shows selected stroke characteristics with a set power stage $P_{el} = 70\%$ and a hammer head diameter $d = 12$ mm as a function of frequency f with a defined stroke $h = 0.5$ mm. Figure 3b compares different stroke characteristics $h = 0.3, 0.5, 0.7$ mm for a set hammering frequency $f = 120$ Hz.

Figure 3a shows that the set stroke $h = 0.5$ mm is maintained very precisely. Before the actual stroke cycle is executed, the oscillating mass undergoes a first slight

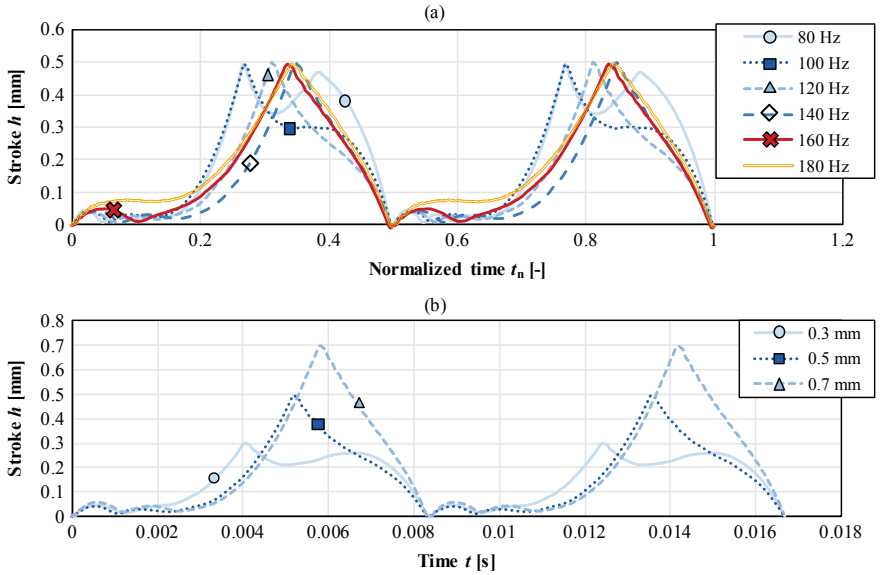

Fig. 3 Stroke characteristics of electrodynamic hammer system for **a** different hammering frequencies and **b** for different strokes. (Color figure online)

oscillation movement, with the exception of the hammer frequency $f = 180$ Hz. At a low frequency $f = 80$ Hz, a second contact occurs after the first contact of the hammer head with the workpiece surface. With increasing frequency, this effect decreases further and a symmetrical stroke before and after the workpiece contact occurs. As the frequency increases, the hammer head comes into contact with the workpiece with a delay. In addition, it can be seen that the acceleration of the hammer head between the frequencies $f = 80 \ldots 140$ Hz is similar (comparable gradient) and decreases for the frequencies $f = 160 \ldots 180$ Hz.

DIADEM was used to determine the impact velocity curve by deriving the stroke characteristics. Within these curves, three sections with 10 stroke cycles each were selected. From the thirty stroke cycles, the maximum impact velocity was determined each per stroke and the mean value was then calculated. Figure 4a shows the impact velocities for the hammer head diameter $d = 12$ mm at the electrical power stage $P_{el} = 70\%$ for various stroke–frequency combinations. It can be seen that as the stroke increases, the impact velocity increases along the hammer frequency band. A maximum impact velocity $v_{c,max} = 620$ mm/s is achieved with a stroke $h = 1.0$ mm and a frequency $f = 180$ Hz. As the stroke increases, the maximum impact velocity shifts toward lower hammering frequencies. The range of impact velocities relevant for the parameter setups selected for the MHP tests lies between $v_c = 300 \ldots 420$ mm/s. By knowing the weight of the oscillating mass and the masses of the plunger, the contact energy E_c was calculated using the following equation:

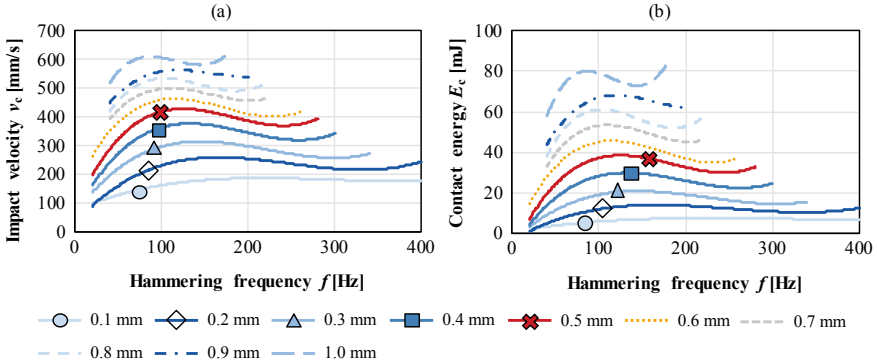

Fig. 4 **a** Experimentally determined impact velocities and **b** calculated contact energies. (Color figure online)

$$E_{\text{kin}} = E_{\text{c}} = \frac{1}{2} \cdot \left(m_{\text{ob}} + m_{\text{p}}\right) \cdot v_{\text{c}}^2 \tag{1}$$

with m_{ob}—mass of the oscillating body, m_{p}—mass of the plunger, and v_{c}—impact velocity. The calculated contact energies are shown in Fig. 4b. Similar to the impact velocities, the maximum contact energy shifts to lower hammer frequencies as the stroke increases. The maximum contact energy in the investigated parameter range and electrical power level $P_{\text{el}} = 70\%$ is $E_{\text{c,max}} = 84$ mJ. Due to the increasing stroke, the acceleration path of the plunger and thus also the contact energy increase. The deviations between the contact energies at $d = 6$ mm and $d = 12$ mm are in the range $\Delta E_{\text{c}} = \pm 5\%$.

3.2 Surface Roughness and Hardness

Figure 5a shows the roughness values *Sa* and *Sz* as a function of the MHP setups. It can be seen that the electrodynamic MHP can lead both to an increase and to a reduction of the roughness of the ground initial surface. However, the already very low roughness of the ground surface must be taken into account. The greatest influence in the parameter range considered is the indentation distance *a*. Contrary to expectations, an increased indentation distance tends to lead to a reduction of roughness parameters. Thus, it is assumed that an indentation distance $a = 0.05$ mm was selected too small. The increased energy density associated with a smaller indentation *a* and stepover distance *b* could therefore be too high for the strength of the AISI 304 stainless steel. This leads to the formation of pronounced surface structures with material build-up. The next largest effect on the roughness values results from the stroke *h* and the interaction of the hammer head diameter *d* with the stroke *h*, see Fig. 5b. The lowest

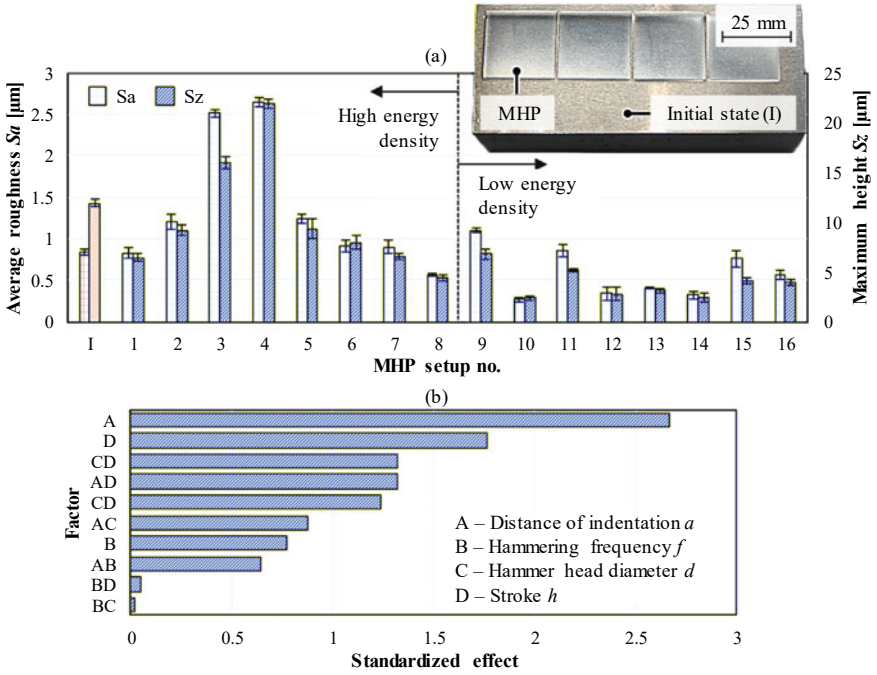

Fig. 5 **a** Surface roughness *Sa* and *Sz* as a function of the selected MHP setups compared to the initial state (I) and **b** DOE results of the analysis of significance in terms of average roughness *Sa* – Pareto chart of effects. (Color figure online)

roughness values $Sa = 0.264$ µm and $Sz = 2.35$ µm due to the MHP setup 10 are even higher than a polish quality.

The surface hardness is shown in Fig. 6. It can be seen that the surface hardness for all MHP setups could be increased significantly compared to the initial ground

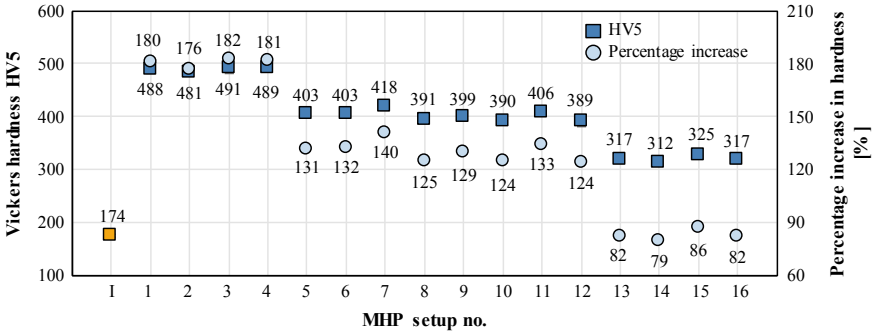

Fig. 6 Resulting surface hardness HV5 for the used MHP setups compared to the initial ground state (I). (Color figure online)

state (I). For the MHP setup 3, a maximum hardness of 491 HV5 could be achieved, which corresponds to a percentage increase in hardness of 182%. In addition to the indentation distance a, the stroke h and the hammer frequency f also have a significant influence on the surface hardness. A smaller indentation distance a and thus a higher energy density leads to higher surface hardness. A lower hammer frequency f also leads to an increase in surface hardness. Contrary to expectations that a higher stroke and thus a higher contact energy results in greater surface hardness, a higher stroke h tends to result in lower surface hardness.

3.3 Residual Stresses

For the sake of clarity, only two different MHP setups of the largest and lowest compressive residual stress maxima were compared to the ground sample initial state in Fig. 7a. The characteristic curve of the residual stresses introduced by the MHP could be determined for all MHP setups. All other residual stress curves of the other MHP setups lie between the curves shown here.

The residual stresses were measured in the middle of the hammered sample fields (white field, Fig. 7a). According to the stored coordinate system, the y-coordinate

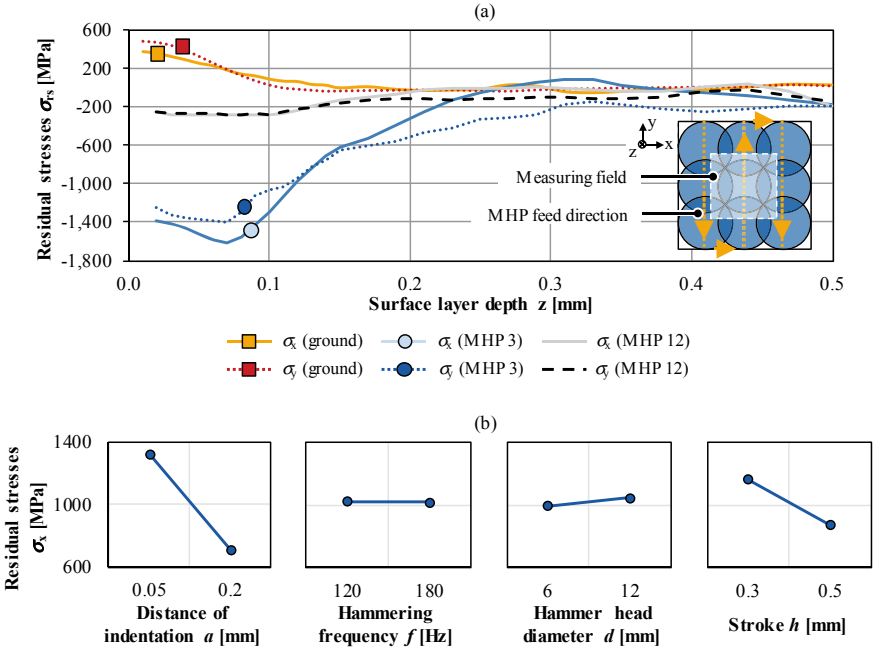

Fig. 7 **a** Comparison of residual stress depth distributions and **b** main effect diagrams. (Color figure online)

describes the path feed direction of the MHP tool and the x-coordinate the orthogonal direction. For all MHP setups, the maximum of the compressive residual stresses in the x-direction, i.e., orthogonal to the MHP feed direction, was applied directly below the sample surface in a surface layer depth $z = 0.04 \ldots 0.1$ mm. The generated compressive residual stress maxima were in a large range $\sigma_x = 330 \ldots 1700$ MPa. The indentation distance a and the stroke h had the greatest influence and by reducing them, the maximum residual stresses can be significantly increased, see Fig. 7b. In addition, it was found that the zero crossing of the residual stresses was already achieved at a surface layer depth $z = 0.25 \ldots 0.41$ mm.

3.4 Microstructure

In addition to IPF maps (Inverse Pole Figure Maps), see Fig. 8a, KAM maps (Kernel Average Misorientation), see Fig. 8b, of the hammered specimen no. 3 (highest contact energy) were also produced. KAM maps indicate the misorientations between adjacent measuring points and can provide a suitable quantitative estimate of the internal distortions since the total distortions are displayed independently of their dislocations or subgranular origin. In order to enable a direct comparison of the unhammered initial surface layer with the hammered surface layer, initial surfaces adjacent to a hammered area were analyzed. For the material AISI 304, a significant subgrain refinement of the surface layer to a depth $z = 200$ µm could be demonstrated. The initial grain size of $l_{g,i} = 22 \ldots 80$ µm could be reduced by MHP to

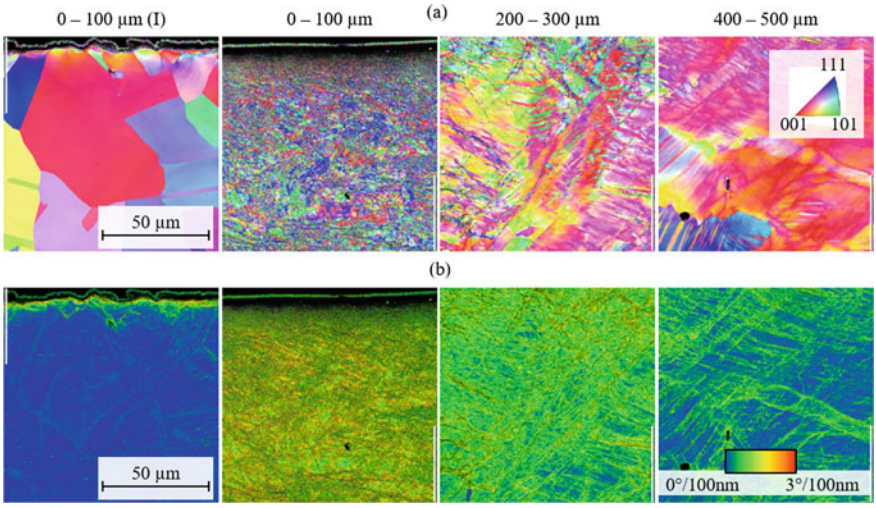

Fig. 8 **a** IPF maps of ground initial surface (A) compared with MHP treated specimen and **b** corresponding KAM maps. (Color figure online)

$l_{g,MHP} = 0.5 \ldots 5$ µm in the first 100 µm surface layer depth. In a surface layer depth of $z = 200 \ldots 500$ µm, pronounced cubic face-centered twin grain boundaries were generated. Based on the KAM maps, it is assumed that there has been a significant increase in dislocation density in the near-surface layers. Only at a depth $z \approx 1{,}000$ µm was a structure similar to the initial state detected.

4 Discussion

The presented results showed a significant impact of the electrodynamic MHP on the resulting surface integrity of AISI 304 stainless steel. The effects can be explained by means of the applied contact energy depending on the selected MHP process parameters. The implementation of a fiber-optic reflection-compensating distance sensor made it possible for the first time to permanently measure the stroke of the electrodynamic MHP inline and thus to calculate the contact energy. It could be shown that the hammering frequency f has a significant impact on the MHP process kinematics. If a low hammer frequency was selected, the phenomenon of multiple impacts of the hammer head on the workpiece surface was observed. The results correspond to the findings of [17]. The phenomenon of repeated workpiece contact during a peening cycle can be described in such a way that, due to the very short contact time resulting from the hard workpiece contact, the hammer head rebounds from the surface before the voltage pulse is over. At low frequencies, the intensity of the voltage pulse is still sufficient to accelerate the hammer head again in the direction of the workpiece. This assumption was confirmed by analysis of the hammer forces using a Kistler 9257B force measuring platform. The hammer system follows the excitation frequency with a small phase shift, which is due to induction.

Furthermore, it could be shown that by means of electrodynamic MHP, the surface roughness can nearly reach a polished quality. Nonetheless, the result that a higher indentation distance a leads to lower roughness values is new. Due to the characteristics of AISI 304 with a low yield strength $R_{p0.2} = 516 \ldots 560$ MPa determined in compression tests in the strain rate range relevant for electrodynamic MHP $\dot{\varphi} = 10 \ldots 100\ s^{-1}$, the selected indentation and path distance $a = b = 0.05$ mm and the associated high energy density w are possibly responsible for the increase in roughness. While the energy density for an indentation distance $a = 0.05$ mm lies between $w \approx 11{,}300 \ldots 26{,}200$ mJ/mm^2, for an indentation distance $a = 0.2$ mm, the energy density $w \approx 700 \ldots 1{,}600$ mJ/mm^2 is lower by a factor of 16. Since the diameter of an indentation is in the range $d_i = 1$ mm, a sufficient overlapping of the single indentations and thus complete machining of the workpiece surface with larger indentation distances can be achieved. Another positive side effect is the shorter machining time. Since the test series presented here was carried out with plungers with a high surface quality ($Sa < 0.1$ µm), the quality of the hammer head surface must also be taken into account in the machining result of the surface roughness, as described in [18].

The evaluation of the surface hardness shows a significant increase in hardness. By selecting a small test force, a deformation-induced martensite transformation could be avoided by the hardness impression. In preliminary tests, it was found that the hardness values determined hardly fluctuate between HV1 and HV5 and that the mean indentation depth of the hardness indentation is $z_i = 35$ µm. Regarding the observed effect of reduced hardness values using higher stroke values, one possible explanation is the exceeding of a critical energy value above which first annihilation processes of the dislocations occur in the surface layer due to a very high dislocation density. The dislocation density thus decreases again a little and the strength of the material thereby is lower compared to the machined surface layer with a lower stroke.

The residual stress characteristic typical for surface layer machining processes was obtained for all selected MHP parameter setups. Due to inhomogeneous elastic–plastic deformation, compressive residual stresses are induced in the near-surface area. The interaction between plastic elongation and Hertzian pressure leads to the development of the characteristic residual stress curves. Plastic elongation describes the deformation of surface layer areas near the surface by a superposition of normal and tangential forces. This results in the compressive residual stress maxima at the surface. For the comparatively soft stainless steel, this mechanism dominates, which is why the compressive residual stress maximum of the AISI 304 lies directly below the surface. Hertzian pressure due to orthogonal forces to the workpiece surface causes shear and residual stresses to develop below the surface. With harder materials, this mechanism is dominant and causes a displacement of the residual compressive stress maxima to greater surface layer depths.

According to SHAKOVA ET AL., it is possible to quantitatively determine the dislocation density using KAM-Maps with comparable values as in a TEM measurement for materials formed at low strains [19]. The AISI 304 with its low stacking fault energy favors the formation of planar lattice defects such as stacking faults, deformation twins, or martensite during forming with sufficient forming work. It is observed that the metastable austenitic initial structure (cubic face-centered, fcc, γ-austenite) is strongly crossed by cubic body-centered (bcc) α′-martensite after MHP at a surface layer depth z <100 µm due to the deformation-induced structural transformation. It has been shown that martensite formation has increased at intersection points of shear bands. This is consistent with the findings of [20].

5 Conclusion and Outlook

It could be shown that an inline stroke tracking of the electrodynamic MHP is possible by means of a fiber-optic distance sensor, which guarantees a high resolution of a few µm in the small stroke range. By deriving the stroke characteristics, impact velocity and contact energies can be calculated by knowing the oscillating mass and thus the deformation work used. Despite the low contact energies available for the electrodynamic MHP for forming the surface layer, significantly different properties can be set. Although a ground starting surface with already low roughness

values was available, the roughness could be improved to a level similar to that of a polished surface by selecting suitable MHP parameters. However, it is important to note the high energy density associated with a small indentation and path distance, which can lead to a deterioration of the roughness values and macroscopic waviness. The analysis of the surface hardness showed that the MHP can generally increase the surface hardness. However, the use of increased contact energies can limit this effect. Due to the low strength of the investigated ASIS 304, the maximum residual compressive stress was very close to the surface. Furthermore, the zero crossing of the residual stress was at low depths. For the first time, a subgrain refinement could be determined due to a significant increase of the dislocation density for the stainless steel ASIS 304 according to the electrodynamic MHP. In addition to this strengthening mechanism, further effects such as twin and shear band formation as well as deformation-induced martensite formation in different surface layer depths were observed.

In future work, the influence of individual MHP impacts on the resulting indentation volume and the influence of different contact energies on the deformation-induced martensite transformation in near-surface areas for the austenitic stainless steel AISI 304 can be investigated. In addition, analyses of the microhardness in the surface layer depth should be carried out in order to describe further cause–effect correlations, especially in connection with subgrain refinement. If necessary, the different mechanisms must be separated and their effects on friction wear and fatigue properties investigated.

Non-isothermal Modeling of Static Recrystallization in Hydroformed Steel Tube Using a Coupled Cellular Automata and Finite Element Model

Amir Asgharzadeh, Sobhan Alah Nazari Tiji, Taejoon Park, and Farhang Pourboghrat

Abstract A thermo-microstructural modeling setup was developed to model the progress of static recrystallization (SRX) during annealing of hydroformed steel tube under non-isothermal annealing condition. In this model, a coupled Cellular Automata and Finite Element thermal model was implemented to predict the kinetics of SRX, which accounts for the impact of multiaxial deformation and annealing temperature regime. First, an analytical solution was developed to calculate the flow behavior of the steel tube during hydroforming experiment based on the data extracted from digital image correlation (DIC) measurements. Second, the actual microstructure and texture of the as-deformed material was obtained with EBSD test. Third, the calculated deformation characteristics as well as the obtained crystallographic and microstructural data were imported to the developed Finite Element-Cellular Automata model to predict the progress of SRX and temperature changes during annealing. The results show a reasonable agreement between the experimental data and predictions, confirming the accuracy of the developed modeling setup in the prediction of the kinetics of SRX within hydroformed steel tubes.

Keywords Tube hydroforming · Finite element method · Cellular automata · Static recrystallization

1 Introduction

The final microstructure of heavily deformed metallic materials significantly depends on the behavior of static recrystallization (SRX) taking place during post-deformation annealing process [1]. The deformation and annealing parameters including the amount of imposed strain as well as the annealing temperature and duration are

the most influential parameters on the kinetics of SRX [2]. To obtain a desired final microstructure, several attempts have been performed to effectively predict the influence of the aforementioned parameters on the SRX behavior for different materials [3–7]. Among all the proposed empirical and numerical models, Cellular Automata (CA) model has been extensively utilized to model the SRX kinetics, since it is based on a powerful algorithm to predict the morphological features of annealing microstructure with high prediction accuracy and computational efficiency [8].

The basics of CA model for modeling of SRX kinetics were developed by Hesselbarth and Göbel [9], where the simultaneous operation of nucleation and grain growth phenomena was assumed to control the progress of SRX. Based on the proposed CA algorithm, different CA models have been developed to model the kinetics of SRX under complex deformation and annealing conditions. For instance, Lin et al. [10] have simulated the SRX kinetics within Ni-based superalloy during annealing after hot compression test using a 2D CA model. Using a similar model, Huang et al. [11] have predicted the SRX behavior of an aluminum alloy after double-pass hot compression tests. In other studies, a coupled Finite Element (FE) and CA model has been developed to model the SRX kinetics within single- and multi-pass cold-rolled Al alloys [6, 12].

Since the temperature regime during annealing process is greatly influential on the SRX behavior, a few researchers have incorporated the thermal model into the CA model to predict the SRX kinetics under non-isothermal annealing condition. In this regard, Salehi and Serajzadeh [13] have developed a coupled FE thermal model and CA model to predict the SRX features of cold-rolled steel. In another study, a FE-CA model has been utilized to model the SRX kinetics during non-isothermal annealing of cold-rolled carbon steels [14]. In addition, Schäfer et al. [15] have simulated the progress of SRX in a cold-rolled Al alloy using a non-isothermal CA model, in which the complex effects of recovery and precipitation on the kinetics of SRX have been considered.

In this study, a modeling setup based on the coupled FE-CA model has been developed to predict the kinetics of SRX in the bulged steel tube under non-isothermal annealing condition. The impact of process parameters including deformation characteristics as well as the subsequent annealing condition on the SRX features has been investigated. In many of earlier research, variety of assumptions have been made to model the kinetics of SRX, which significantly affected the modeling results. Examples of such assumptions are adopting constitutive models for deformation characterization, approximation of initial grain topology, considering a random orientation, and assuming isothermal annealing condition. To improve the accuracy of the predictions, all the mentioned assumptions have been removed from the modeling setup employed in the present study. To that end, first, an analytical solution based on membrane theory has been utilized to calculate the principal stress components during tube hydroforming (THF) process using the strain field data obtained experimentally from DIC measurements and the internal pressure and axial load applied during the bulging experiment. Second, the initial state of CA model including grain topology and crystallographic data has been defined based on the EBSD data, collected from the as-deformed tubes. Third, a thermal FE model has

been incorporated into the 2D CA model to predict the temperature variations, SRX kinetics, and final grain topology. Finally, the predicted features of the recrystallized microstructure have been compared with the experimental data.

2 Experimental Procedure

In the present study, a low carbon steel tube with outer diameter and thickness of 38 mm and 1.24 mm, respectively, and chemical composition of Fe—0.13 wt% C—0.3 wt% Mn—0.02 wt% P—0.15 wt% Si—0.3 wt% S was investigated. The as-received tubes were annealed at 900 °C for 75 min followed by air cooling to obtain a single phase ferritic initial microstructure. The mechanical properties of these tubes were assessed through tensile test based on E8-E8M-09 ASTM standard. For the tensile tests, the dog-bone specimens with the gauge length and width of 32 mm and 6 mm, respectively, were cut along the longitudinal direction of the tubes. Furthermore, the tube hydroforming tests were carried out with a combination of axial feed and internal pressure, which were applied by the actuators and intensifier, respectively. The prescribed boundary conditions (the pressure and axial feed profiles) were precisely followed by the THF machine by means of a controlling station. Note that the internal pressure was applied through a water pressurization medium. The deformation characteristics of the bulging tube was recorded using a Digital Image Correlation (DIC) machine throughout the hydroforming process. Finally, the crystallographic texture of the as-deformed tube was measured by means of a ThermoScientic^{TM}ApreoLoVacfield emission EBSD microscope equipped with EDAX Hikari XP camera.

Afterward, the as-deformed tubes were annealed in a furnace that was preheated to the temperature of 700 °C. The temperature change within the bulged specimen during the annealing process was recorded using a K-type thermocouple, which was attached to the specimen through a hole drilled in the thickness of the specimen. After the annealing process, each specimen was quenched in cold water to preserve the final microstructure. Then, the hardness measurements were performed on all specimens to assess the changes in mechanical properties of the specimen during annealing treatment. Because of the curvature of the bulged tube, the convex surface of the specimen was placed on a flat holder, and the concave side of the sample was penetrated by the spherical indenter of the Rockwell hardness machine [16]. Moreover, the annealed specimen was cut along the hoop and axial direction, followed by sample preparation to observe the annealed microstructure through optical microscopy. To that end, all the samples were mounted, polished up to 0.05 μm roughness, and etched by Nital detergent containing 100 ml ethanol and 5 ml nitric acid.

3 Modeling Methodology

3.1 Analytical Modeling of THF

The multiaxial flow behavior of the bulged tube can be determined using the displacement data obtained from DIC measurement and the internal pressure and axial load applied during the hydroforming test. In this regard, an analytical solution is employed to determine the principal strain and stress components at the pole of the bulged tube based on membrane theory. After calculation of the strain components along the hoop and axial directions based on the DIC measurement, and assuming plastic incompressibility and neglecting elastic strains, the instantaneous thickness (t) at the pole of the bulged tube can be calculated as below

$$t = t_0 \exp(-(\varepsilon_h + \varepsilon_A)) \tag{1}$$

where t_0 is the initial tube thickness, and ε_h and ε_A are the hoop and axial strain components at the pole of the bulging tube, respectively. Besides, the force applied to the tube in axial direction can be calculated as below

$$F_A = -F_R + \pi R_0^2 P_i \tag{2}$$

where F_A is the axial force applied to the mid-cross section of the tube, F_R is the measured reaction force at the end of the tube, P_i is the internal pressure, and R_0 is the initial inside radius of the tube. Then, the calculated tube thickness, axial force, and internal pressure are used to calculate the stress components in axial and hoop directions at the pole of the bulging tube, as follows

$$\sigma_A = \frac{F_A}{2\pi R_h t} \tag{3}$$

$$\sigma_h = \frac{\left(R_A - \frac{t}{2}\right)\left(R_h - \frac{t}{2}\right)P_i - \sigma_A R_h t}{R_A t} \tag{4}$$

where σ_A and σ_h are the axial and hoop stress components, respectively. In addition, R_A and R_h are the radius of the bulging tube in the axial and hoop directions at the pole of the bulging tube, respectively, which are determined based on the displacement data obtained from DIC measurement throughout the THF process. To do so, the equation of circle is fitted to the multiple points' coordinate using the least mean square fitting algorithm [17]. The detailed description of the utilized approach can be found in Ref. [17, 18]. The texture analysis performed on the EBSD images taken from the as-received tube (it will be discussed in the next section) confirmed that the investigated material is isotropic. Therefore, the equivalent stress ($\bar{\sigma}$) and equivalent strain ($\bar{\varepsilon}$) at the pole of the bulged tube can be determined based on the isotropic von-Mises function, as below

$$\bar{\sigma} = \sqrt{\sigma_A^2 - \sigma_A \sigma_h + \sigma_h^2} \tag{5}$$

$$\bar{\varepsilon} = \frac{2}{\sqrt{3}} \sqrt{\left(\varepsilon_A^2 + \varepsilon_A \varepsilon_h + \varepsilon_h^2\right)} \tag{6}$$

In order to connect the deformation characteristics of THF process to the microstructural events happening during subsequent annealing process, the equivalent stress at the last time increment of THF is used to estimate the amount of dislocation density generated during deformation. Therefore, the local dislocation density (ρ_d) is calculated through the following relationship [19]:

$$\rho_d = \left(\frac{\Delta\sigma}{\alpha M_\alpha G b}\right)^2 \tag{7}$$

where $\Delta\sigma$ is the difference between the yield stress of fully recrystallized specimen and the final equivalent stress at the pole of the bulged tube, M_α is the Taylor factor, α is a constant, b is the burgers vector, and G is the shear modulus.

3.2 Microstructural Model

The progress of static recrystallization is identified by two simultaneous phenomena: nucleation of defect free nuclei and growth of these grains toward the deformed context. Both mechanisms are controlled by the internal energy stored during deformation as well as the temperature regime during subsequent annealing process. In CA model, the growth mechanism can be interpreted by the term of local velocity of grain boundary (V), which can be defined as below based on the Turnbull's rate equation [20],

$$V = M \cdot P \tag{8}$$

where P is the local driving pressure, and M is the local mobility of grain boundary that can be calculated for low carbon steel as follows [21],

$$M = \frac{5.4 \times 10^{-8} b}{kT} \exp\left(-\frac{Q_m + Q_{gb}^\alpha}{RT}\right) \tag{9}$$

where k is the Boltzmann constant, T is temperature, Q_m is the activation energy of grain boundary motion, Q_{gb}^α is the activation energy for the grain boundary diffusion, and R is the universal gas constant. On the other hand, the local driving pressure (P) acting on the grain boundary can be calculated by

$$P = \alpha G b^2 \Delta\rho_d + \kappa\gamma \tag{10}$$

where $\Delta\rho_d$ is the difference between the dislocation density of two sides of the moving grain boundary, κ is the grain boundary curvature, which is calculated through the kink template method [22], and γ is the grain boundary energy. In the developed CA model, the total annealing time is discretized into multiple time steps, in which the growth phenomenon is assumed to occur in a stable manner. Therefore, the simulation time step (Δt) can be calculated using the following relationship:

$$\Delta t = \frac{\lambda}{V_{\max}} \tag{11}$$

where λ is the cell length, and $V_{\max}$ is the maximum velocity of the GB obtained from Eq. (8).

The kinetics of nucleation phenomenon during the progress of static recrystallization is a function of temperature and the change in system's energy due to the formation of defect free nuclei. Therefore, the nucleation rate ($\dot{n}$) can be defined through the following equation [23],

$$\dot{n} = c_0 \Delta E \exp\left(\frac{-Q_N}{RT}\right) \tag{12}$$

where c_0 is a positive fitting factor, Q_N is the nucleation activation energy, and ΔE is the energy change due to the change in dislocation density and surface energy of grain boundaries during nucleation. Therefore, based on the calculated time step for the time increment i, the local nucleation probability is calculated using the following equation:

$$P^i_{\text{nucleation}} = \dot{n}^i \lambda^3 \Delta t_i \tag{13}$$

where $\dot{n}$ is obtained from Eq. (12), and Δt is obtained from Eq. (11) for the time increment i. Then, the calculated nucleation probability is compared to a pseudorandom number, generated through Mersenne-Twister algorithm [24], as a probabilistic transformation rule to decide whether the transformation from deformed site into a fresh nucleus can occur. The detailed description of the developed CA model can be found in Ref. [18].

3.3 Thermal Model

As explained in the previous section, temperature is one of the most important parameters that controls the kinetics of static recrystallization and progress of softening mechanisms. In this regard, a thermal finite element model has been developed to precisely asses the temperature changes in the bulged specimen during annealing process. Accordingly, a 2D transient thermal model in Cartesian coordinate has been utilized to determine the temperature distribution within the anneal specimen as

below [13],

$$\frac{\partial}{\partial x}\left(\Lambda\frac{\partial T}{\partial x}\right)+\frac{\partial}{\partial y}\left(\Lambda\frac{\partial T}{\partial y}\right)=\rho_m c\frac{\partial T}{\partial t} \tag{14}$$

where ρ_m, c, and Λ are the material density, specific heat, and coefficient of heat conduction, respectively. In addition, the following boundary condition was applied to all material sides that are exposed to the environment with different temperature [25]

$$\Lambda\left(\frac{\partial T}{\partial \xi}\right)_{\Gamma}+h(T-T_{\text{furnace}})=0 \tag{15}$$

where h is the heat transfer coefficient, T_{furnace} is the stabilized temperature of the furnace, and ξ is the normal direction to every surface boundary Γ. To solve Eq. (14), the FE formulation based on the standard Bubnov-Galerkin technique considering 4-node isoperimetric elements has been developed [26].

3.4 Modeling Scheme and Model Parameters

A coupled Cellular Automata-Finite Element model is implemented to predict the SRX behavior of a hydroformed steel tube during non-isothermal annealing process. The initial state for the modeling of SRX is created based on the data from prior deformation characteristics (dislocation density), as well as the tube's as-deformed microstructure data (grain topology and texture). The microstructural data are extracted from EBSD maps using MATLAB toolbox MTEX, and directly imported into the spatial region designed for CA model. In addition, the real-time temperature during annealing is imported from the thermal FE model. The solution algorithm for modeling the SRX at each time increment follows these steps:

(I) Compute the time step (Δt) based on the data from previous time increment,

(II) Update the temperature field based on the time step Δt,
*If the maximum temperature change in the solution domain ($\Delta T_{\max}$) is larger than a predefined critical value ($\Delta T_{\text{cr}} = 0.5\,^{\circ}\text{C}$), then update the time step as follows:

$$\Delta t_{\text{new}}=\frac{\Delta T_{\text{cr}}}{\Delta T_{\max}}\Delta t \tag{16}$$

(III) Calculate $\dot{n}$ and $P_{\text{nucleation}}$ for each cell located on the grain boundaries and triple junctions,

(IV) Calculate local velocity of the grain boundary (V) and probability of grain growth for each recrystallized cell surrounded by unrecrystallized cells,

(V) Compare a pseudorandom number to the calculated probability of nucleation and grain growth to decide whether the transformation can take place,
(VI) Update the recrystallization state of cells based on the decisions made in previous step.

4 Results and Discussion

The THF experiment was carried out on the investigated low carbon steel tube using a combination of axial feed and internal pressure as depicted in Fig. 1a. The corresponding distribution of the von-Mises equivalent strain in the bulged tube measured through DIC technique is shown in Fig. 1b. The DIC measurement shows a non-uniform distribution of equivalent strain in longitudinal direction with the highest strain value localized at the pole of the bulged tube. Because of the highest amount of the equivalent strain at the pole of the bulged tube, this region is chosen for calculating the flow characteristic of the tube under deformation, which consequently provides the maximum driving force for the occurrence of SRX in the tube. The equivalent flow curve calculated using Eqs. (1)–(6) is shown in Fig. 2, which is based on the

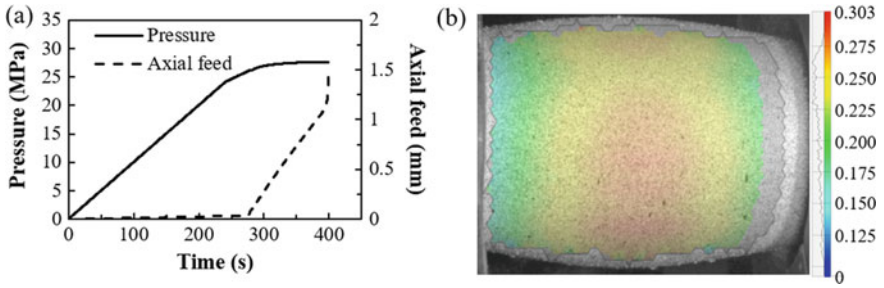

Fig. 1 **a** The applied boundary condition during THF process, and **b** the corresponding distribution of von-Mises equivalent strain obtained from DIC. (Color figure online)

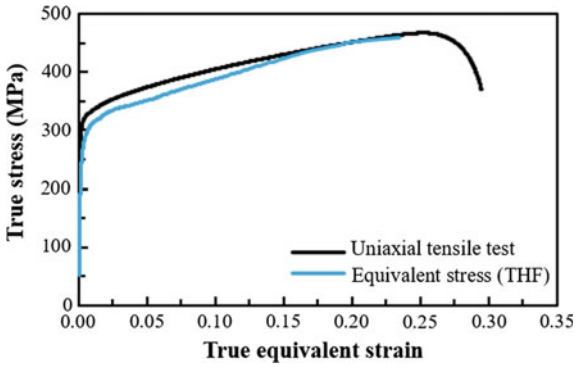

Fig. 2 The von-Mises equivalent flow stress of the bulged tube shown in Fig. 1b, compared to the uniaxial flow curve of low carbon steel. (Color figure online)

strain data obtained from DIC measurements at the pole of the tube. As seen, the flow properties of the bulged tube are different from the uniaxial flow curve of as-received steel tube, so that the tube under THF process yields at lower stress level followed by higher strain hardening coefficient in comparison to uniaxial flow curve.

As explained in the previous section, the progress of SRX within hydroformed steel tube under non-isothermal annealing condition was simulated through a thermo-microstructural model. The material properties as well as the CA model coefficients for the investigated low carbon steel are listed in Table 1 [18, 21]. Among the parameters given in Table 1, the CA model parameters (Q_m, Q_N, and Q_{gb}^{α}) were defined based on the multiple simulations performed to calibrate the model coefficients against the experimental results, while the rest of the parameters are material properties. The calibration approach employed in this study was similar to the approach proposed in references [27, 28]. Furthermore, to solve the thermal model used in this work, the thermal model coefficients in the form of temperature-dependent functions were required to improve the accuracy of predictions. These functions for low carbon steel are listed in Table 2 [13]. Note that, although the material properties given in Tables 1 and 2 can be slightly different for various low carbon steel products, the difference is very negligible to significantly influence the simulation results. Therefore, these parameters were assumed the same for every low carbon steel.

As temperature is the most important factor controlling the kinetics of SRX, it is crucial to account for the temperature variation within the specimen during

Table 1 The properties of low carbon steel required for CA model [18, 21]

Parameters	Value
α	0.5
M	3
G (GPa)	69.3

annealing process. Assuming isothermal annealing condition imposes an extra error to the predictions, since part of SRX can take place during heating up stage. In order to evaluate the accuracy of the developed thermal model, the predicted temperature history is compared to the experimentally recorder data, as shown in Fig. 3. As seen, a good agreement between the experimental and the predicted temperature history within specimen under annealing is obtained. It should be noted that the heating rate within specimen is very high at the beginning of annealing process, while it decreases when getting close to the stabilized temperature of the furnace. In addition, a significant difference between the actual temperature history with the isothermal assumption is seen, which may lead to an increased amount of error in the modeling results.

Figure 4 depicts the EBSD map collected from the hoop cross section of the as-deformed steel tube. As seen, the microstructure consists of a very fine grain

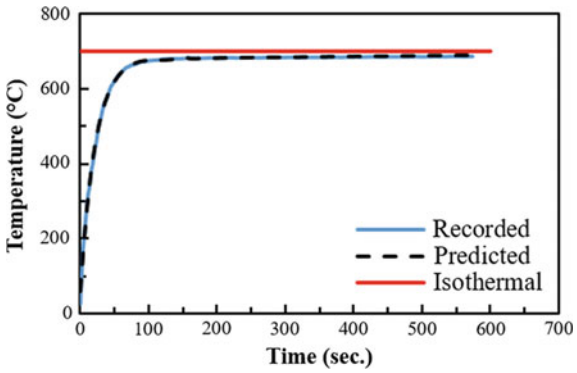

Fig. 3 The recorded and predicted temperature history under non-isothermal annealing condition, as well as the isothermal temperature regime assumption. (Color figure online)

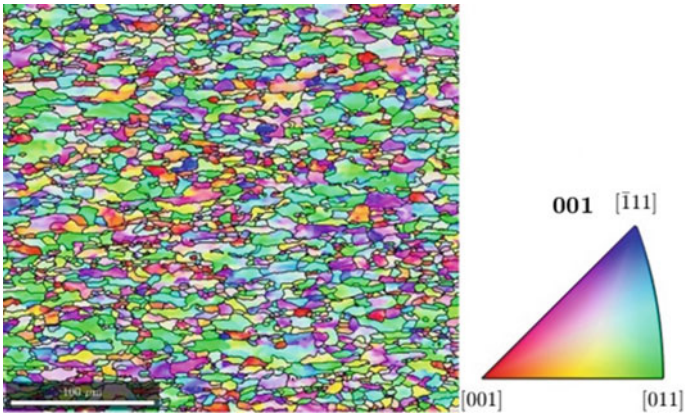

Fig. 4 The EBSD image collected from the hoop cross section of the as-deformed steel tube [18]. (Color figure online)

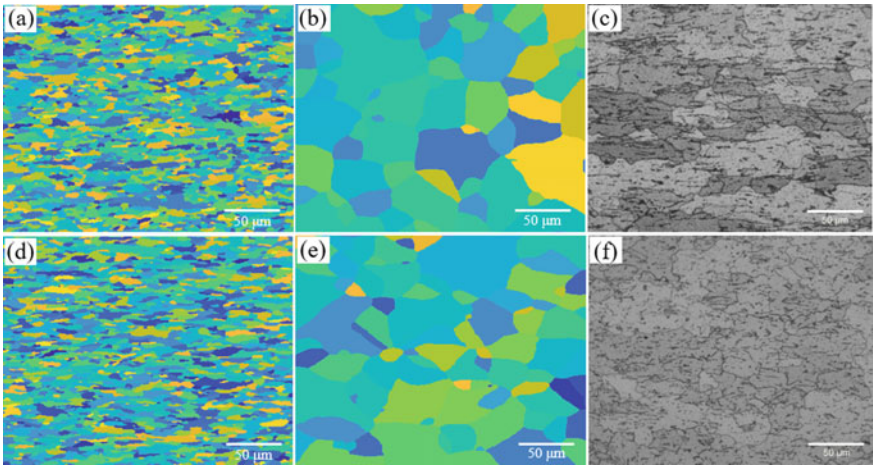

Fig. 5 **a**, **d** The initial grain topology of the annealing specimens, as well as **b**, **e** the predicted microstrure, and **c**, **f** the experimental OM image of fully recrystallized specimen under annealing condition of $T = 700$ °C and $t = 5$ min in the hoop and axial directions, respectively. (Color figure online)

structure, which are slightly elongated toward the longitudinal direction of the tube. In this study, the microstructure changes during annealing process are investigated on the hoop and axial cross sections of the pole of the bulged tube. Figure 5 shows the comparison between the predicted microstructure through FE-CA modeling with the experimental OM images on the two hoop and axial cross sections. The initial microstructures of the annealing specimen in hoop and axial directions are shown in Fig. 5a and d, respectively. These microstructures are generated based on the imported grain topology and orientation data from EBSD maps collected from each cross section. For instance, the initial microstructure of the hoop cross section (Fig. 5a) is generated based on the EBSD data provided in Fig. 4. For this cross section, the predicted fully recrystallized microstructure after annealing time of 5 min is shown in Fig. 5b, while the corresponding OM image is illustrated in Fig. 5c. Similarly, the final predicted and experimental microstructures of the annealed specimen for axial cross section are shown in Fig. 5e and f, respectively. As seen in both cross sections, a close agreement exists between the predicted and the experimental microstructures. The final grain topology of the annealed specimen is more equiaxed in comparison to the as-deformed microstructure. Furthermore, a significantly coarse grain structure in the final microstructure of annealed specimen is seen when compared to the as-deformed microstructure, inferring the faster kinetics of grain growth in comparison to the nucleation.

In order to quantify the comparison between the experimental data and CA predictions, the kinetics of SRX in terms of the fraction of recrystallization obtained using both approaches were compared together. The experimental fraction of recrystallization (X_{SRX}) as a function of time can be computed based on the measured hardness values of the specimens annealed under different durations, as follows

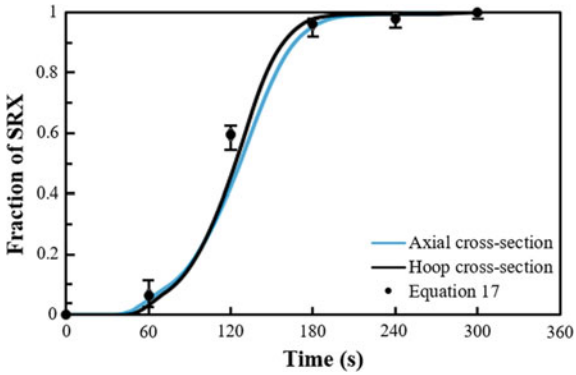

Fig. 6 The fraction of recrystallization obtained from the developed CA model and calculated through Eq. (17). (Color figure online)

$$X_{SRX} = \frac{H_0 - H}{H_0 - H_f} \tag{17}$$

where H_0,H and H_f are the hardness values for the as-received, partially recrystallized, and fully recrystallized specimens, respectively. The fraction of recrystallization obtained from the developed CA model for both hoop and axial cross sections of the bulged tube and calculated through Eq. (17) are shown in Fig. 6. As seen, the predicted rate of SRX in the axial and hoop cross sections are very similar. The minor difference in the kinetics of SRX in axial and hoop cross sections can be due to the difference in their initial grain topologies. In addition, a good agreement between the numerically predicted and the experimentally obtained fraction of recrystallization is seen.

5 Conclusions

In this study, the microstructural changes within bulged steel tube during annealing after THF process were investigated. To that end, a modeling setup based on the Finite Element thermal model and CA model was developed to account for the impact of multiaxial deformation mode as well as the temperature regime during annealing process on the kinetics of SRX. The actual microstructure and texture of the as-deformed specimen were obtained through EBSD test, which were directly imported to the CA model to create the initial state for the simulations. In addition, an analytical solution was developed to characterize the flow behavior of steel tube during THF process. The results showed that the predictions through the developed FE-CA model matches the experimental data in terms of the rate of recrystallization and final grain topology, confirming the accuracy of the developed modeling setup in the prediction of the progress of static recrystallization within hydroformed steel tubes. In addition, the final microstructure of the annealed specimens showed a

significantly coarse grain structure in comparison to the as-deformed microstrure, inferring the faster kinetics of the grain growth in comparison to the nucleation.

Fast Development of New Alloys for Metal Forming Using Additive Manufacturing

Alexander Sviridov, Irina Sizova, and Markus Bambach

Abstract The industrial development of new materials in metal forming is a time consuming, iterative process. Although it is already being attempted to predict the properties of new materials using computational methods, experimental production and characterization must always be carried out. This typically involves casting of larger blocks of material, which are then processed to specimens. Particularly in the case of high-alloyed materials (e.g., nickel-base superalloys) pronounced macrosegregations occur, which must be removed by time-consuming homogenization. In this paper, additive manufacturing of small specimens is investigated as an alternative to traditional ways for developing new alloys for metal forming. The microstructure and thermomechanical transformation behavior of as-built material are analyzed and it is shown that thermomechanical treatment of the as-built state allows for transforming the microstructure in such a way that processing parameters for forming and final product properties can be identified.

Keywords Additive manufacturing · Hot rolling · Microstructure · Alloy development

1 Introduction

Currently, a wide range of sheet materials with excellent mechanical properties and specific features is available for various applications. However, the development of new materials remains an important task that draws upon different scientific fields. Increasing demands on the properties of components set new standards and development trends with high requirements on materials. For instance, in automotive engineering, new materials are developed to achieve higher hardness and better crash properties [1]. The properties, which are relevant for the manufacturing processes, such as formability, are also of great importance. The number of alloying elements in modern sheet metal and various post-processes such as heat treatment makes the

https://doi.org/10.1007/978-3-030-75381-8_158

development of new alloys or the modification of already available alloys difficult and time consuming. Consequently, the success of new materials can only be guaranteed if material development is realized in a short time and with minimum effort.

The typical way of testing new alloys begins with the casting of larger blocks of material. This requires a large volume of alloying elements and is often expensive especially in the case of high-performance alloys. For some materials (e.g. high-manganese steels), heat treatment should be applied to remove the pronounced macrosegregations [2]. This process can also be very time consuming. For the development of materials for sheet metal, the new alloy should first be cast in blocks, homogenized and hot rolled. Finally, the hot-rolled strip is cold rolled to the appropriate thickness in many rolling passes and eventually annealed. Only after this long process chain, the final microstructure and the mechanical properties of the sheet metal can be analyzed. In an iterative process, the alloy can be improved by the casting of the new trials alloy compositions, and the whole process is repeated until a suitable sheet metal alloy is identified.

Currently, there are trends for faster alloy development based on digital approaches, which allow to develop real material solutions for industrial applications [3]. Vecchio and Cheney [4] applied high-performance analysis software for big data to develop new alloys, which enables revolutionary material compositions. By using the software and digital analysis tools, the development time can be reduced from several years to a few months. However, the probability of success of these methods is difficult to estimate without physical tests. Finally, experimental tests are needed to verify the developed alloys.

In recent years, the development of additive manufacturing processes has progressed significantly. Additive manufacturing is not only used to produce prototypes and components but also has great potential as a method for material development. There are wire and powder-based additive manufacturing techniques. Especially the powder-based processes have great potential for alloy development since the samples can be produced from various powder mixtures in a relatively short time. In the case of wire-based processes, mixing materials by supplying several wires made of different materials is possible by means of laser [5] and plasma [6] metal deposition. The wire feed speed of each material determines the mixing ratio. Welding technologies using flux-cored wire could be also an alternative for mixing materials. The conventional material development process can be significantly shortened by the additive manufacturing of smaller samples with different compositions in the first stage of the alloy development (Fig. 1).

Selective laser melting (SLM) uses a powder bed and is suitable for the production of complex components with a relatively small volume. Some studies are already known to implement the SLM process with various powder mixtures in order to operate the alloy development more efficiently—the so-called Rapid Alloy Development. In work of Ewald et al. [7], systematic variation of the mechanical properties was possible by preparing different powder mixtures. The mechanical properties of the investigated Al0.26CoFeMnNi system were significantly improved by the addition of 0.6 wt. % C, resulting in both increased strength and ductility. However, a large amount of powder comparable to the sample volume is required for the SLM

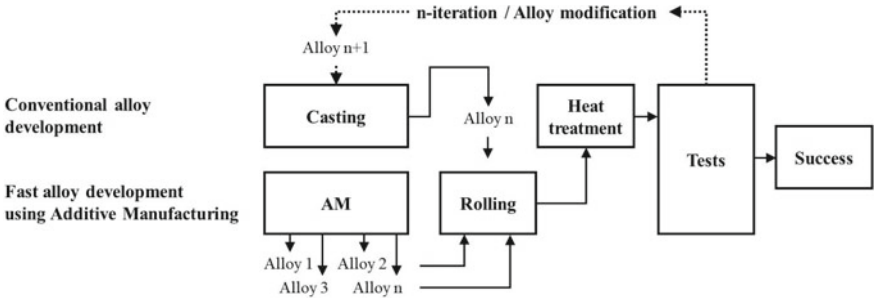

Fig. 1 Optimization of the iterative development process by using additive manufacturing

process, since the entire build chamber has to be filled with powder. In the most cases this causes high costs during development, because the powder blends cannot be separated again after powder mixing [7].

In the laser metal deposition (LMD) process, the powder is fed directly into the process via two or more powder containers [8]. This enables high flexibility of the alloy mixture. Moreover, it is possible to build a component with areas of different alloy mixtures in order to investigate the material more efficiently. The LMD process also enables a higher deposition rate in comparison to SLM and is, therefore, more suitable for productive material development.

The properties and microstructure of the additively manufactured material generally differ from the material which was conventionally produced by casting. The reasons for this are very different and depend on the material, for example, the layer structure of the material, higher cooling rates, phase transformation processes, etc. One of the most important scientific questions is whether the additively manufactured material is comparable to the conventional material in terms of microstructure and properties before and after forming and heat treatment.

In the present work, the stainless steel 316L was used to compare the microstructure and the mechanical properties of the conventional and additively (LMD) produced sheet metal. Materials in both states (conventional and as-build) were processed into sheets by hot rolling, followed by heat treatment under the same conditions and analyzed by means of optical metallography. The main aim was to compare the mechanical properties of the heat-treated sheets to demonstrate the transferability of the additively manufactured materials to the conventional sheets.

2 Material and Methods

2.1 Samples Manufacturing by Laser Metal Deposition

Stainless steel 316L material was used in the present investigation. The 316L stainless steel powder was provided by TLS Technik GmbH & Co. Spezialpulver KG

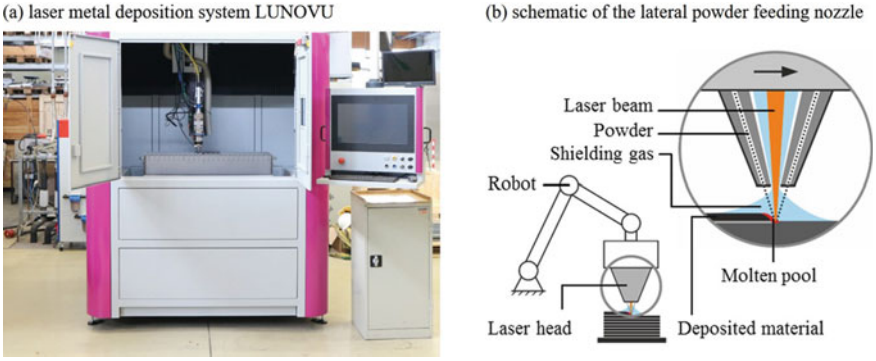

Fig. 2 **a** LUNOVU laser metal deposition system and **b** schematic of the lateral laser beam and feeding lance arrangement. (Color figure online)

with a particle size range of 45–100 μm. The specimens were fabricated using a LUNOVU laser metal deposition system equipped with a 2.5 kW diode laser with a lateral powder feeding nozzle (Fig. 2). Standard good quality build settings for 316L stainless steel were used (laser power 800 W, scan speed 800 mm/s, feed rate 10 g/min). To prevent the melt pool from oxidizing, a flow rate of protecting gas (argon) was set as 8 l/min during the experiment. A bidirectional scanning strategy with a rotation of 90° was chosen for manufacturing. The powder was deposited on 316L stainless steel plates with a thickness of 12 mm. All substrate surfaces were cleaned prior to the deposition process using acetone. Cuboid samples were produced with the dimensions of approximately $50 \times 50 \times 20$ mm^3 (Fig. 6a).

2.2 Rolling Experiments and Heat Treatment

From the deposited cuboids samples with the dimensions of $50 \times 40 \times 10$ mm^3 were cut and used for the rolling process. The LMD samples were joined with conventional wrought plates with a length of 100 mm and the same thickness by means of arc welding to provide samples of suitable dimension for the rolling process. Moreover, welding of LMD specimens to conventional wrought plates allows for the analysis of microstructure evolution and mechanical properties under identical heating and rolling conditions. The schematic of specimens used for the rolling is given in Fig. 3.

The rolling experiments were performed in an instrumented laboratory rolling mill (Carl Wezel KG model No. BW 850/330, Fig. 4). The rolling mill is equipped with a duo roll set, the rolls being 800 mm in width and 330 mm in diameter. Both the rolls and the support table were preheated to a temperature of 300 °C. Tests were carried out at a rolling speed of 1 m/min without lubrication. A true strain of approximately 0.8 was achieved in a single rolling pass. Samples were heated to 1250 °C for 10 min. prior to rolling in a batch-type furnace. The temperature

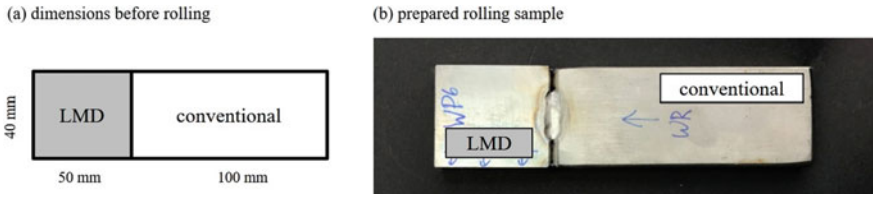

Fig. 3 **a** Schematic representation of rolling sample combining LMD and conventional wrought materials used in the present study and **b** illustration of the prepared rolling sample. (Color figure online)

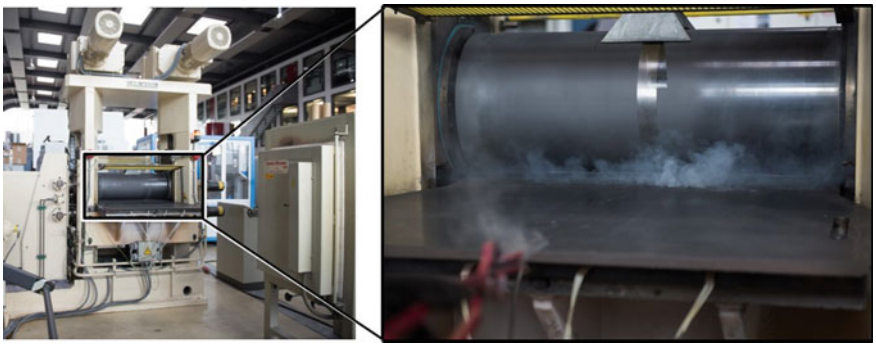

Fig. 4 Hot rolling mill Carl Wezel KG model BW 850/330. (Color figure online)

of the specimens was monitored with an appropriate thermocouple (type K). The transfer time between the furnace and the rolls was less than 5 s. After the rolling process, the samples were cooled in air. To generate the appropriate microstructure and mechanical properties the samples after rolling were subjected to annealing at a temperature of 1050 °C for 10 min followed by air cooling.

2.3 Microstructure Characterization

In order to investigate the microstructure after the processing, the specimens were sectioned in the middle parallel to rolling direction and mounted with the cut cross sections on top. The sections were ground flat on SiC papers with grit sizes from 320 to 1200. The specimens were then polished using two steps diamond suspension (6 and 3 μm) and finally, oxide polish (0.05 μm silica solution, Struers OP-S Suspension) was used. The polished samples were etched at a temperature of 60° C for 40 s in a mixture of (100 ml H_2O, 100 ml HCl, 10 ml HNO_3) and then analyzed by optical light microscopy (Carl Zeiss Microscopy, Jena, Germany).

2.4 Tensile Testing

For the mechanical testing, flat tensile samples were extracted from hot-rolled and heat-treated LMD and conventional wrought materials parallel to the rolling direction. The flat tensile specimen had a gauge length of 26 mm and a thickness of 2 mm. The dimensions of the samples are presented in Fig. 5. The tensile properties, including ultimate tensile strength, yield strength, and elongation, were measured utilizing a tensile testing machine from Hegewald und Peschke 100 INSPEKT with a 100 kN load cell. The specimens were tested at a constant loading rate with a velocity of 0.02 mm/s. The tensile tests were carried out at room temperature according to the DIN EN ISO 6892-1:2016 standard.

3 Results and Discussion

3.1 Laser Metal Deposited Material

As was mentioned above, cuboid samples with the dimensions of approximately 50 × 50 × 20 mm^3 were manufactured using LMD. A sample is shown in Fig. 6a. A relatively smooth surface (with no obvious defects like humps or pits) is observed. The optical microstructure images are presented in Fig. 6b. The LMD material shows a good metallurgical bonding between the deposited layers. Dense samples without gaps or lacks of fusion are observed. Only small single pores can be found in the microstructure. A dendritic microstructure with partial cellular and columnar geometries is found in the samples, which is in good agreement with the literature [9, 10]. The total growth direction was perpendicular to the deposition direction because of the effect of temperature gradients opposite to the direction of heat flow.

3.2 Rolling Experiments: Microstructure Evolution and Mechanical Properties

Figure 7 illustrates the hot-rolled samples with indications of LMD and conventional wrought materials. The samples with dimensions 150 × 40 × 10 mm^3 were hot rolled in a single rolling pass. The rolling time was around 10 s. The rolling process was performed at a temperature of approximately 850 °C. The maximum experimental rolling force reached was around 900 kN. Hot rolling was performed to a strain of 0.8 (based on the initial thickness of 10 mm), i.e. to the thickness of 4.5 mm.

An overview of the microstructure evolution of LMD and conventional wrought materials during processing is presented in Fig. 8. The morphology of the conventional wrought material in the initial state (as-delivered condition) is shown in Fig. 8a. It consists of an austenite grain structure, which is the typical microstructure of 316L stainless steel. The microstructure of material manufactured by LMD is presented as well to provide a direct comparison of different microstructures, Fig. 8d. As can be seen in Fig. 8b, e, after hot rolling, the grains of both materials are elongated to such an extent that a fibrous microstructure results that indicate extensive

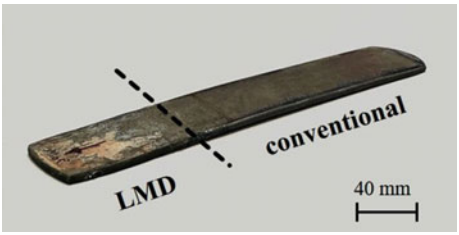

Fig. 7 Illustration of the final hot-rolled sample. (Color figure online)

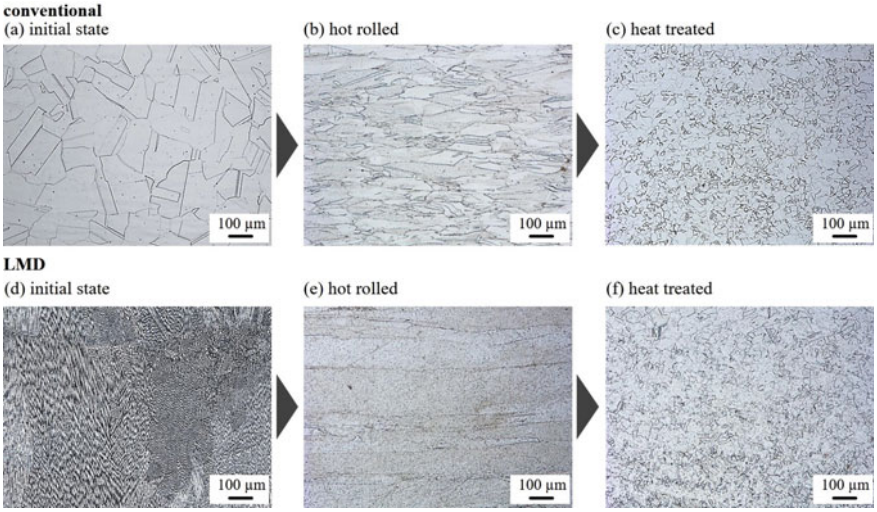

Fig. 8 Microstructure evolution of LMD and conventional wrought material during processing: **a**, **d** initial state, **b**, **e** after hot rolling and **c**, **f** after hot rolling followed heat treatment (1050 °C/10 min/AC). (Color figure online)

deformation. The observed microstructural evolution is comparable to that reported during the hot rolling of conventionally produced 316L stainless steel [11]. However, the microstructure of conventional wrought material after hot rolling appears much finer compared to LMD material. This can be attributed to the differences in the initial microstructure, and the remarkable influence of starting dendritic microstructure on hot rolling behavior. However, after applying a subsequent heat treatment (1050 °C/10 min/AC) both materials become similar and represent a fine homogeneous austenitic microstructure, with similar average grain sizes in both types of materials, i.e. in conventional wrought material about 28 µm, and in LMD material about 30 µm. The grain refinement is due to static recrystallization, which takes place when high temperature is applied to material priorly subjected to intense plastic deformation.

Tensile tests were carried out with hot-rolled and heat-treated materials. As was mentioned above, the tensile samples were extracted parallel to the rolling direction. The resulting yield strength, the ultimate tensile strength, and the total elongation to failure are compared in Table 1.

As can be seen, both materials yield almost the same value of ultimate tensile strength. LMD material shows a slightly lower elongation value of approximately 40.1%, compared to 43.1% in conventional wrought material, which could be a consequence of the residual porosity that appears during LMD. Hence, thermomechanical treatment of LMD material provides microstructures and mechanical properties very similar to conventional wrought material and appears to be a good alternative to conventional development of new materials for sheet metal production.

Table 1 Comparison of yield strength, tensile strength, and elongation at failure for samples produced by LMD and hot rolling followed by heat treatment and of conventional wrought samples treated in the same way

	YS (MPa)	UTS (MPa)	A_5 (%)
LMD	323	633	40.1
Conventional wrought	338	635	43.1
Datasheet 821 for hot-rolled sheet [12]	220	530	40

4 Conclusion

In the present study, the microstructure and thermomechanical transformation behavior of conventional and additively manufactured stainless steel 316L during rolling and heat treatment were analyzed. The following conclusions can be drawn:

- Stainless steel 316L produced by LMD shows a fine dendritic microstructure without defects with only small single pores. The produced microstructure differs significantly from the microstructure of conventional wrought material,
- Hot rolling leads to similar microstructures in both types of materials, i.e. both materials exhibit elongated grains after rolling indicating extensive deformation. However, the microstructure of LMD material exhibits larger grain sizes, probably due to dendritic initial microstructure,
- Applying heat treatment after rolling enables the full transformation of highly deformed grains. A fine homogeneous austenitic microstructure was found in both types of materials after hot rolling and subsequent heat treatment. The average grain sizes were almost identical in both types of materials,
- The results of tensile tests show that both types of materials represent comparable mechanical properties after the presented thermomechanical processing. This confirms that LMD could be a sound alternative to traditional ways of developing new materials for sheet metal production.

Hence, this research represents the viability of the process chain LMD—rolling—heat treatment for alloy development using the example of stainless steel 316L. Future work will focus on studying whether the effect of alloying elements on the mechanical properties can be revealed by the proposed process chain, such that the methods can indeed be used to assist the development of new steel compositions.

Acknowledgments The authors are grateful to the colleagues A. Neumann and I. Ünsal from the Chair of Mechanical Design and Manufacturing of BTU Cottbus-Senftenberg for performing the rolling experiments and to B. Kunze from the Chair of Physical Metallurgy and Materials Technology for the preparation of the metallographic images used in this study.

Effects of Residual Strain on Grain Growth of Extruded Aluminum Micro-channel Tubes During Heat Treatment

Wenli Fang, Xiaole Chen, Ding Tang, Huamiao Wang, Dayong Li, and Yinghong Peng

Abstract Post-extrusion cold deformation followed by brazing has a significant effect on mechanical properties of micro-channel tubes used in heat exchangers. To understand this relationship, cold rolling with different thickness reductions (0–15%) and a following brazing are conducted on extruded tubes, and the microstructure and strength are examined. The results show that with increasing rolling reduction, tensile strength and burst strength of the as-rolled tubes increase monotonously. While after brazing, both strengths decline obviously, and them decrease first and then increase with increasing rolling reduction. The change is attributed to recrystallization and grain growth observed in the post-braze tubes. Driven by different levels of strain from the rolling, recrystallized grain size increases first and then decreases. At 5% thickness reduction, abnormal large grains form in the web and result in the minimum post-braze strength. Finally, the ductile fraction mode is observed in the web, which shear strength determines the burst strength.

Keywords Cold rolling · Brazing · Grain growth · Mechanical strength

1 Introduction

Micro-channel tubes, also known as multi-port extruded (MPE) tubes, are widely used in the heat exchangers of air conditioning systems. The tube, typically made of 1xxx or 3xxx aluminum alloys, is a flat body with a row of side-by-side channels, which allow the refrigerant to flow through and transfer the heat. Apart from the heat transfer requirement, the tube must withstand internal pressure from the pressurized refrigerant, particularly of those for eco-friendly refrigerant systems that operate at higher pressures [1]. Therefore, to maximize the mechanical strength of the final product, especially its pressure bearing capacity, is an important goal of the production.

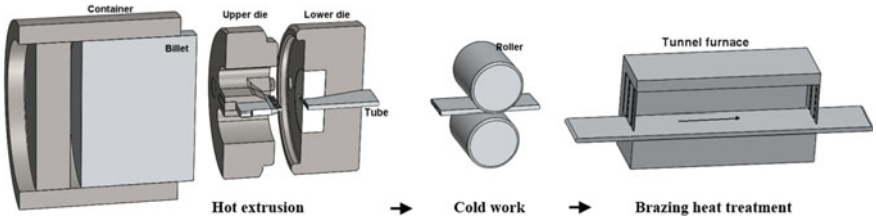

Fig. 1 Schematic of the process chain for the producing the micro-channel tube. (Color figure online)

In general, the process of producing MPE tubes for heat exchanger applications involves multiple manufacturing steps, as shown in Fig. 1. Firstly, the primary forming process of MPE tubes is performed by hot forward extrusion, where a heated aluminum billet is forced through a porthole die. After extrusion, to achieve precise external dimensions required for assembly of heat exchangers, the extruded tubes are straightened, roll-sized, and cut into final lengths. In this process, a small amount of cold work (plastic strain) is imposed on the tubes. Finally, after assembled into heat exchangers, the tubes undergo a brazing (or annealing) heat treatment to join the individual components. The brazing process is generally done at 600–605 °C (about 91% of the melting point for the alloy) inside a tunnel furnace with a nitrogen atmosphere. In this whole process chain, material microstructure and thus mechanical properties will change from step to step [2]. Therefore, it is necessary to understand how process conditions, microstructure, and final properties interact for metal production. Güzel et al. [3] investigated the grain structure evolution in the hot extrusion process of aluminum rods. Fan et al. [4] observed the evolution of the microstructure along the forming path and analyzed the geometrical dynamic recrystallization within the die during extrusion. Murai et al. [5] investigated the effects of billet homogenization and extrusion conditions on microstructure and mechanical properties of AZ31B magnesium alloy.

However, most of the previous studies on mechanical behaviors of the extruded profile are focusing on the process of the hot extrusion. In fact, these subsequent processes following the extrusion sometimes have a significant influence on the mechanical behaviors of extruded profiles, which has been rarely investigated. Taking the MPE tube as an example, the combination of the cold work and the brazing heat treatment induce recrystallization and grain growth, and this greatly influences mechanical properties of the final tubes.

In this study, a post-processing experiment (including cold work and brazing) of MPE tubes after extrusion is carried out. Through imposing thickness reduction with different levels on the tubes, the effect of residential strain on grain growth of the tube during brazing heat treatment is investigated. In addition, the mechanical strength of the tubes is examined by uniaxial tensile and burst pressure tests. The relationship between cold work, microstructure, and strength for the brazed tube is established.

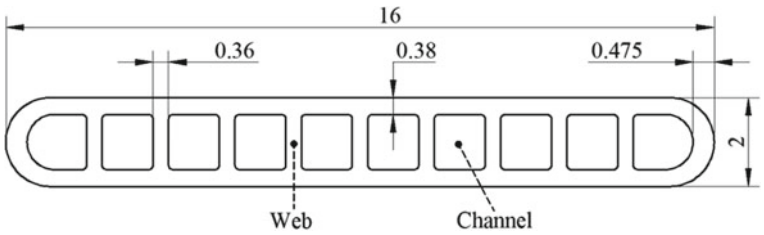

Fig. 2 Cross section of the MPE tube (unit: mm)

Table 1 Chemical composition of the AA1100 alloy (wt%)

Si	Fe	Cu	Mn	Zn	Al	Others
0.09	0.23	0.18	0.0005	0.0035	99.39	0.106

2 Experimental Procedure

2.1 Material

The specimens used in this study are AA1100 extruded micro-channel tubes, which are produced by hot extrusion using homogenized billet. The cross section and main dimensions of the tube are shown in Fig. 2. The chemical composition of the alloy is listed in Table 1. The experimental specimens with 300 mm in length are prepared for the cold rolling and brazing heat treatment.

2.2 Rolling Experiments

Rolling process is designed to simulate the practical straightening and sizing operation. The rolling equipment is shown in Fig. 3. In the experiment, different amount of thickness reductions are imposed on the tube specimens, and thus different residential strains will be left. The tubes after rolling are denoted as x% E–R tubes, where x% is the amount of the reduction ratio. In this work, x% is chosen as 0% (without rolling), 0.7, 3, 5, 9, 12, and 15%, respectively.

2.3 Brazing Experiments

After rolling, the specimens with different residual strains are put into a brazing furnace which simulates the actual heat treatment process. Figure 4 shows the tubes

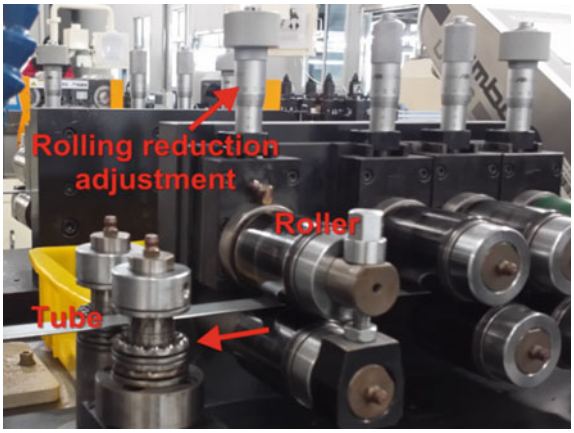

Fig. 3 Rolling of the MPE tube. (Color figure online)

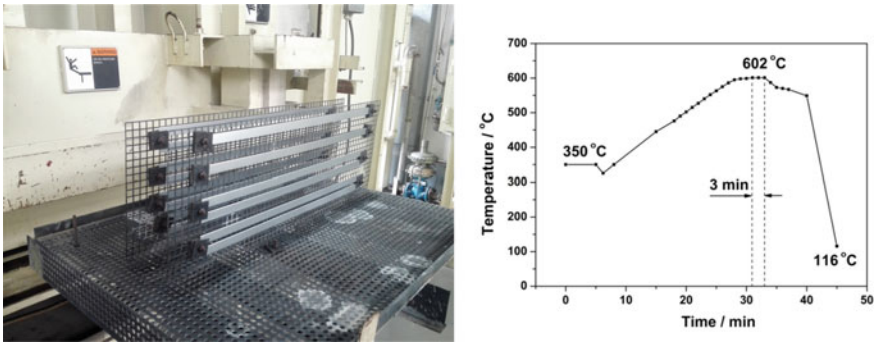

Fig. 4 The tubes to be brazed and temperature curve of the brazing process. (Color figure online)

to be brazed and temperature curve of the heat treatment, respectively. These tubes are hold at temperature of 602 °C for 3 min.

2.4 Mechanical Tests

The mechanical properties of the tubes are examined by uniaxial tensile and burst pressure tests, respectively. Strength along the extrusion direction is measured using an INSTRON EM3367 testing machine (Fig. 5a), while pressure bearing capacity of the tubes is measured with pressure bearing testing machine that is specially designed for this application. The testing equipment is shown in Fig. 5b and the testing procedure is described in detail in the work of Tang et al. [6].

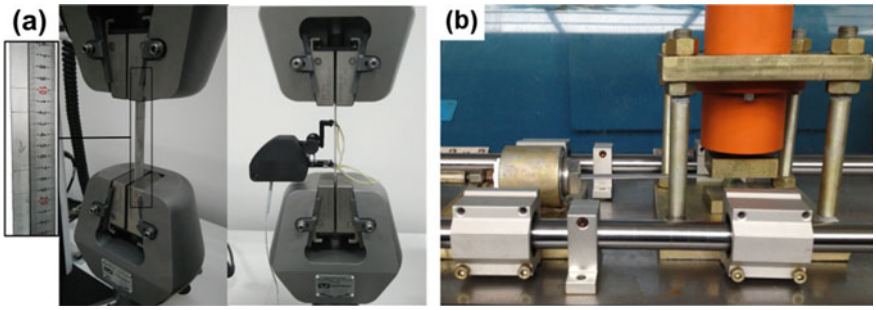

Fig. 5 Equipments for mechanical tests: **a** INSTRON EM3367 for uniaxial tension; **b** pressure bearing capacity testing machine for burst pressure. (Color figure online)

2.5 Microstructure Observation

Optical microscopy (OM) and electron backscattered diffraction (EBSD) techniques are used to characterize the microstructure of the tubes. Samples for OM are ground and polished using alumina suspension and 0.02 μm colloidal silica suspension, then etched with modified Keller's etchant. For EBSD mapping, they are ground with SiC paper up to 2000, and then electro-polished by LectroPol 5 with electrolyte A2. EBSD examination is carried out by NOVANanoSEM 230 with AZtec HKL Max System.

3 Results and Discussion

3.1 Mechanical Properties of the Tubes

The tensile strength of the tubes as a function of rolling reduction ratios are shown in Fig. 6a. It is found that, for the as-rolled tube before brazing, the strength increases gradually with increasing of the rolling reduction ratio. This can be due to the strain hardening effect and a slight increase in the thickness of internal walls. However, after brazing, the tensile strength is lower than that of the tubes before brazing. Moreover, the trend becomes different. The strength first drops sharply, then rises. At the reduction ratio of about 5%, the tensile strength of the brazed tube reaches the minimum.

Figure 6b compared the equivalent internal web strength of the tubes before and after brazing obtained by pressure bearing tests. From the results, the strength of the as-rolled and heat-treated tubes shows the same trend as that of tensile tests. Similarly, at the reduction ratio of about 5%, the strength of the brazed tube reaches the minimum, which decreases about 40%.

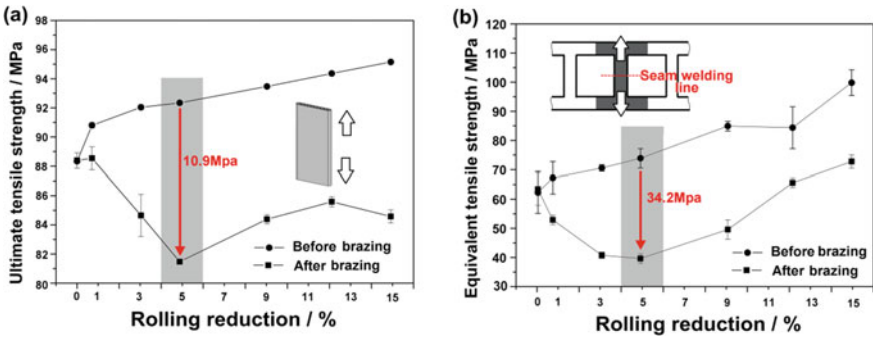

Fig. 6 Measured strengths: **a** tensile strength; **b** equivalent internal web strength. (Color figure online)

These mechanical behaviors are relevant to the change in the microstructure of the tubes during rolling and brazing process, which are discussed later.

3.2 Microstructure of the Tubes

Figure 7 shows the microstructure in the cross section of the brazed tubes with different rolling reduction ratios. It can be seen that the grain size in the web varies significantly with different amount of rolling reduction. There is little difference in the grain size between the as-extruded and brazed tubes without rolling (Fig. 7a, b). However, individual grain growth is observed when 0.7% of rolling reduction is

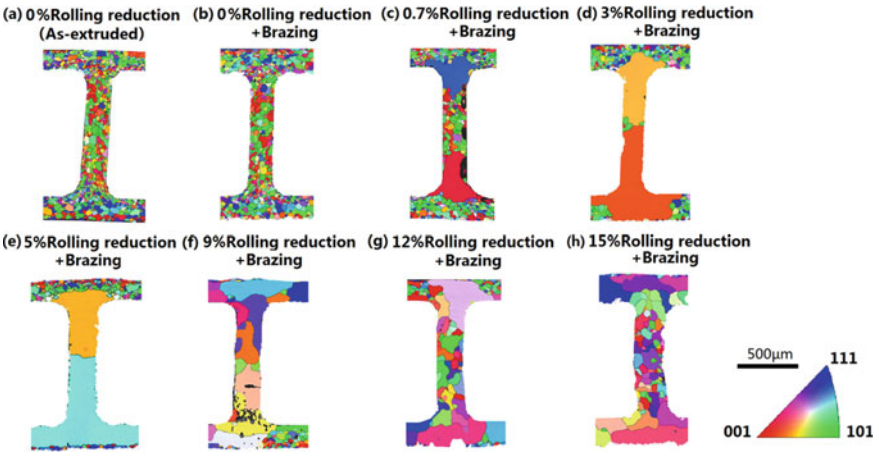

Fig. 7 Effect of rolling reduction ratio on the microstructure of the tubes after brazing. (Color figure online)

applied (Fig. 7a). With increasing of the rolling reduction ratio, the grains continue to grow until the grain size increases to a maximum at reduction ratio of 5%, where abnormal large grains envelop the entire web. After that, the grain size decreases gradually. Clearly, variation of the grain size is due to the recrystallization and grain growth during the brazing process, which is induced by the residual strain from the cold rolling. Note that a certain amount of cold work (critical strain) is required to initiate recrystallization during heat treatment. At this point, few nuclei are formed in the material and the growth of relatively few recrystallized grains is allowed to proceed with minimum resistance. However, as the amount of cold work increases, more nuclei are produced and the recrystallized grain size decreased.

In the rolling process, strain distribution in the cross section of the tube is uneven. Because of the "I" shaped structure, the deformation mainly concentrates at the web and the maximum residual strain locates in the zone close to the intersections of internal webs and out walls. The deformation feature gives rise to the inhomogeneous distributions of recrystallization nuclei and stored energy (dislocation density), which are responsible for inhomogeneous growth rates of the recrystallizing grains. As the rolling reduction increases, the levels of strain vary in both webs and out walls, as well as the amount of stored energy and the number of nuclei. A small strain only activates a very low number of nuclei. These nuclei then consume the remainder of the structure resulting in local grain structure where only a few large grains are left. While a high strain provides more nuclei per unit volume and growth of the grains will be restricted by impingement with their neighbors, resulting in relatively small grains. Consequently, the microstructure in the cross section of the tube will change with the amount of rolling reduction. At 0% rolling reduction, without the introduction of strain, the microstructure of the brazed tube is almost unchanged compared to that of as-extruded tube. At the rolling reduction of 0.7, 3, and 5%, with the extension of low level of strain (critical strain) from the intersection to the web, large grains first appear in the intersection and gradually spread along the web. With the further increase in the rolling reduction (9, 12, and 15%), the strain in the web is high enough to form relatively small grains, while the strain in out walls reaches critical strain and induces the formation of large grains.

Figure 8a–h shows polarized optical micrographs of the tube along the longitudinal section of the web with different rolling reduction ratios. The variation of the grain size is consistent with that in the cross section in Fig. 7. Without the limitation of the wall size, the grains grow to be as large as 10 mm at 3 and 5% of rolling reduction.

According to the Hall–Petch relationship [7], the changes in grain size of the brazed tubes are responsible for the different strengths of tubes with different rolling reduction ratios shown in Fig. 6. The 5% of rolling reduction that the biggest decrease in the tensile strength and the pressure bearing capacity of the tube after brazing occurs is exactly the one where the largest grains appear. The pressure bearing capacity decreases by ~40%, while the tensile strength decreases by ~10%. It is suggested, from current study, that certain range of residual strain which degrades the strength of the seam welding zone should be avoided in the process chain during manufacturing.

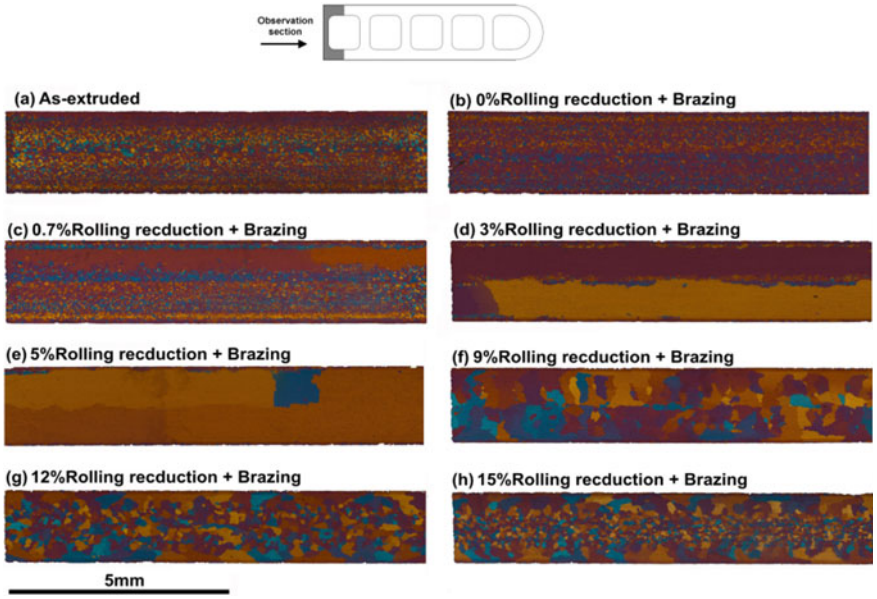

Fig. 8 Polarized optical micrographs in the longitudinal section. (Color figure online)

3.3 Fracture Mode of the Tubes

Figure 9 exhibits the polarized microscopic graphs of the internal webs after burst pressure tests. The profile of all the breaking interfaces shows a typical ductile fracture mode, which is governed by the maximum shear stress. This finding is consistent with the previous experimental observations by Yu et al. [8]. The failure happens mainly within the webs, whose shear strength determines the pressure bearing strength of the tube. In other words, the pressure bearing strength of a tube can be estimated in terms of the material's property of shear strength. Therefore, either increasing the thickness of the webs or reducing the area of the channels can enhance the pressure bearing strength of the tube.

4 Conclusion

The mechanical behaviors of MPE tubes through cold rolling and brazing operation are investigated. Through imposing thickness reduction with different levels on the tubes, the relationship between cold work, microstructure, and strength for the brazed tube is discussed. The following conclusions can be drawn:

(1) Before brazing, the mechanical strength of the MPE tube increases monotonically with the increasing of the rolling reduction ratio, which is due to strain

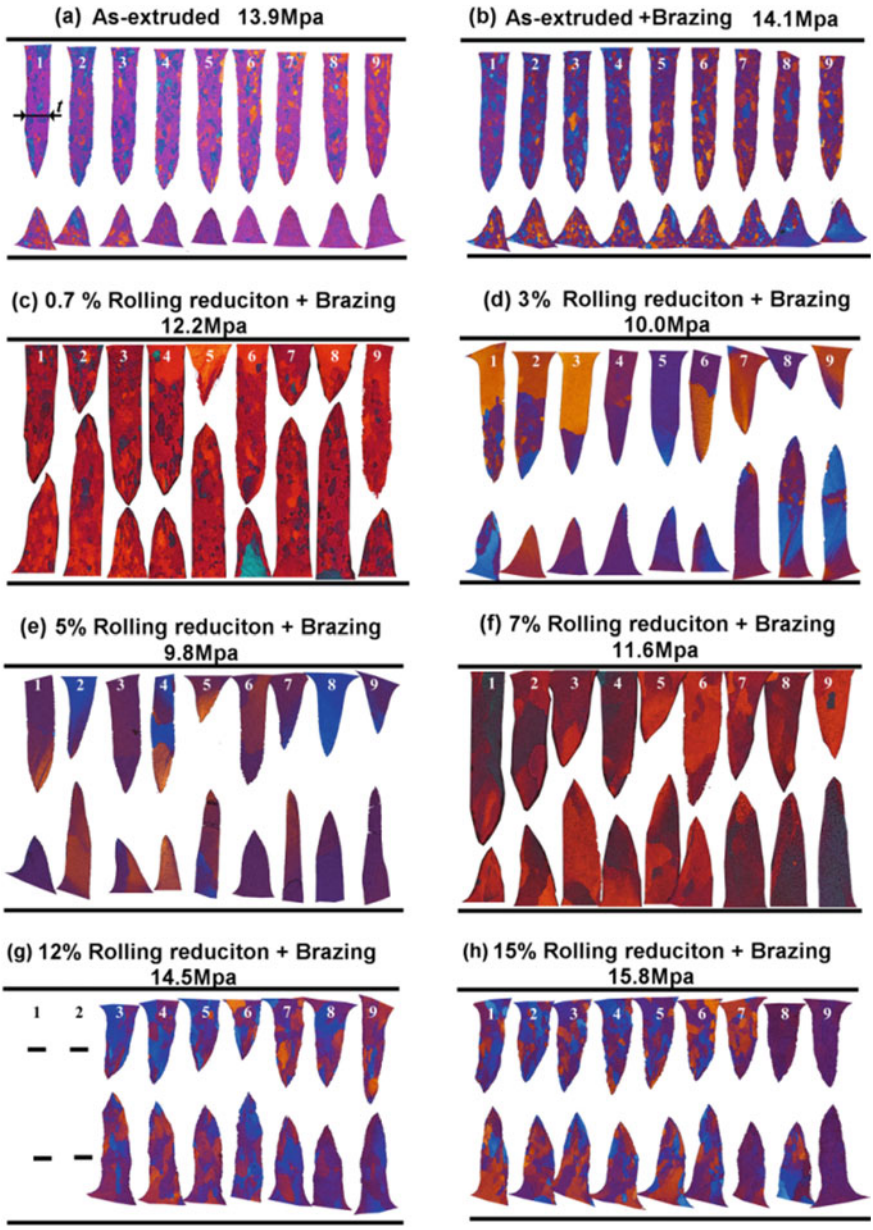

Fig. 9 Polarized optical micrography in the cross section of micro-walls after burst testing. (Color figure online)

hardening from the cold rolling. After brazing, the overall strength of the tube decreased significantly. The strength of the tube reaches its minimum at 5% rolling reduction.

(2) Due to the recrystallization and grain growth during the brazing process, the grain size in the tube web varies significantly with different amount of rolling reduction. The largest grains that form at rolling reduction of 5% result in a minimum strength of the tube.

(3) The fracture surface observed by OM shows ductile fracture mode. The lowest strength (largest grain size) induced by 5% pre-rolling reduction and brazing should be avoided in real manufacturing.

Forming of Parts with Locally Defined Mechanical and Ferromagnetic Properties by Flow-Forming

Eugen Wiens, Werner Homberg, Bahman Arian, Kerstin Möhring, and Frank Walther

Abstract To generate the highly efficient use of material resources for formed parts, local adaptation of the required strength and integrated functions is advised. When using austenitic steel, the volume fraction of deformation-induced α'-martensite, which has an influence on the strength and the magnetic permeability of the material, is highly dependent on the degree of deformation and the workpiece temperature in the deformation zone. Through selective adjustment of the process parameters of wall thickness reduction Δs and deformation temperature T_d it proved possible to produce locally restricted areas with an α'-martensite volume from almost negligible to 80% at an identical stage of deformation, using a spinning or flow-forming process. In this way, axially graded and locally varying mechanical and sensory properties can be produced, such as for a magnetic displacement sensor. The aim of this ongoing work is the closed-loop control of properties through the use of micro-magnetic sensors during spinning processes.

Keywords Spinning process · Property control · Strain hardening · Martensite content · TRIP-effect · Micro-magnetic measurement · Actuators and soft sensors

1 Introduction

Today, the responsible handling of resources is more important than ever before. It is thus necessary to adapt the characteristics of the part to the requirements placed on it. First of all, the mechanical properties can be adapted to the expected loads and, secondly, a specific functionality can be integrated in the part. By using austenitic steel, it is possible to achieve a locally varying strength and hardness within an individual part through work hardening while forming the part. In addition, a further

increase in strength and hardness can be generated by using deformation-induced α′-martensite formation, which is highly dependent on the degree of deformation and the workpiece temperature in the deformation zone. The α′-martensite is ferromagnetic, contrary to the case for austenite, and can be used for sensory properties, such as for a magnetic displacement sensor or to produce invisible labeling on a product. This paper examines the influence of the process parameters of wall thickness reduction Δs and deformation temperature T_d of a flow-forming process on the mechanical properties and the α′-martensite volume of the austenitic steel 1.4301(AISI 304, X5CrNi18-10).

2 Process Principles

2.1 Deformation-induced α′-martensite

The austenitic phase of a metastable austenitic steel is not in the equilibrium state and can be converted by a thermally or mechanically induced energy input [1]. In an austenitic chrome-nickel steel, mechanical energy input through deformation results in a diffusion-free phase transformation in which deformation-induced martensite is formed by crystal shearing within the austenite grains. The austenite and martensite phases have the same chemical composition but differ in their lattice structure. The main impact factors for martensite formation in metastable austenites are the degree of deformation, the forming temperature, and the chemical composition. In addition, the grain size, sample size, and type of deformation can have a quantitative impact on the result. Above an alloy-dependent temperature limit, no martensite is formed even with the highest degrees of deformation [2]. The phase formation of α′-martensite occurs directly from austenite, via deformation-induced ε-martensite as intermediate stage. While ε-martensite and austenite are paramagnetic, α′-martensite is ferromagnetic and can therefore easily be detected in volume terms by using magnetic measurement methods [3, 4]. The strong dependence of the α′-martensite formation on the forming temperature and the degree of deformation is shown in the diagram on the left of Fig. 1a as an example for the material 1.4301 (AISI 304, X5CrNi18-10). The data were determined by Angel [5] in a uniaxial tensile test. The additional increase in strength of a Cr–Ni steel due to martensite formation, over and above the other work hardening mechanisms, is shown schematically in the yield stress curves of the diagram on the right in Fig. 1b. Most of the investigations into α′-martensite formation have been carried out in tensile tests, whereby it is assumed that tensile stresses favor phase transition and pressure loads hinder it on account of the volume increase that takes place during α′-martensite transformation. Knigge [1] has used compression tests to demonstrate that local deformation-induced α′-martensite formation is also possible under compressive stresses.

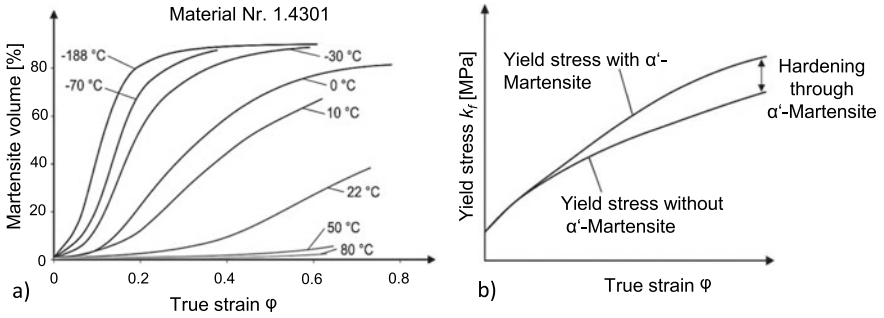

Fig. 1 **a** Martensitic phase volume fraction in tensile specimens as a function of the degree of deformation and the temperature [5]; **b** theoretical hardening of a Cr–Ni steel through deformation-induced martensite formation [6]

2.2 Flow-Forming

The manifold advantages of spinning processes, e.g., in terms of flexibility and efficiency, are countered by what is frequently a highly complex process characteristic with a multitude of process parameters [7]. The flow-forming of workpieces is employed for machining mostly prefabricated tubular or cup-shaped tubular parts with a defined reduction in wall thickness. The forming process is often carried out with a multi-roller arrangement in a single or multiple overrun. Flow-forming can be used to produce hollow bodies with a very good shape and dimensional accuracy as well as very good surface qualities [8]. In addition, the multi-axial compressive stress state in the forming zone also permits the forming of less ductile and high-strength materials. The material flow during flow-forming has axial, radial, and tangential components. The ratio of each component is decisively determined by the roller attack angle, the transition radius, and the exit angle. The ratio of the axial to the radial contact area of the roller and the workpiece determines the ratio of the axial to the radial material flow. This dependence has already been investigated experimentally on several occasions, among others by Tsivoulas et al. [9] and Jahazi and Ebrahimi [10]. Roy et al. [11] have developed an analytical model for calculating the contact surface between the roller and the workpiece for different roller geometry elements. In addition, the related feed rate has an influence on the contact area ratio of the axial to circumferential tool/workpiece contact in the forming zone [10]. The hardness devolution over the wall thickness, which is important for many components, can be influenced by the wall thickness reduction [12] and by the roller attack angle, which also influences the direction of the hardness distribution (axial/circumferential) [9]. Kleditzsch developed an analytical approach to the calculation of the equivalent plastic strain [13]. No investigations into the strain hardening and phase transformation of metastable austenites by flow-forming are known at present.

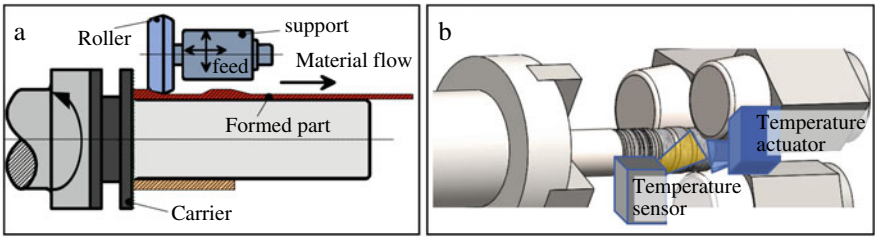

Fig. 2 Setup of the flow-forming (**a**) and the temperature devices (**b**). (Color figure online)

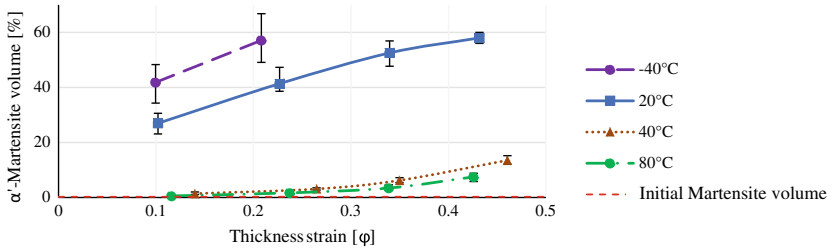
3 Experimental Methods

3.1 Forming Process

The investigation was carried out on the flow-forming machine BD 40 from Bohner-Köhle. The roller used in the experiments have an attack angle of $\alpha = 12°$, a rolling diameter of 158.4 mm and were arranged as a triple configuration in a 120° formation. Figure 2 shows a pictogram of the setup. On the left, a diagram of the reverse flow-forming employed is shown (a). The tube samples are of an austenitic chrome–nickel stainless steel (EN 1.4301) and have an (outer) diameter of 80 mm and a wall thickness of 4 mm in the initial state. Figure 2b illustrates the tool setup as well as the temperature sensor and actuator (cooling and heating device). The samples as well as the mandrel were warmed up or cooled down to the desired start temperature T_d right before the forming process. During the process the sample temperature was kept by cooling with liquid nitrogen (tests under room temperature (RT)), with a cooling lubricant (RT) or heating with a hot-air blower (above RT). All presented tests were conducted with a rotation speed of 400 rev/min and a feed of 50 mm/min.

3.2 Testing Methods and Instruments

The α'-martensite volume fraction was measured with a Fischerscope MMS. The measurements of each state are mean values of six measuring points over the tube circumference and were taken on the outer surface of the deformed tube. The logging of the specimen temperature was performed with the thermographic camera VarioCam hr head 600 of the company InfraTec with a measuring frequency of 50 Hz. The samples for the tensile test were eroded from the tube in axial direction. The shape of the sample is illustrated in Fig. 6. For each parameter combination 4 tensile samples were tested with the universal testing machine Z020. The sample heads were flattened by clamping jaws and the eroded flanks in the area of the free forming length were ground to a surface roughness of at least Rz 6.3. The hardness tests were carried out on the INNOVATEST Nexus 4303 with hardness testing methods



to Vickers with a testing force of 9,807 N and a holding time of 10 s which is equal to hardness unit HV1. Each hardness value is a mean value of three measurements with an equal distance to the rolling surface.

4 Experimental Results and Discussion—Influence of the Process Parameters on the Material Properties

4.1 Degree of Deformation and Forming Temperature

In Fig. 3, the evolution of the α′-martensite volume by deformation through flow-forming in a metastable austenite (1.4301) reveals the same characteristic development as a tensile test [5] or compression test [1]. The wall thickness reduction in this diagram is generated by 0.25 mm in each overrun step, so that each point in a curve from left to right means an additional overrun. The results show that the deformation-induced α′-martensite volume increases with a declining forming temperature and an increasing degree of deformation. The curve characteristics for higher temperatures reveal a progressive growing trend while the lower temperatures show a degressive growing trend. Though the overall trend is comparable with the curves of the tensile test, the $T_d = 20$ °C curve here already has a degressive progression, while the $T_d = 22$ °C curve in the tensile test displays a progressive trend. By comparison to the tensile test, the high temperature curves ($T_d = 20$ to $T_d = 80$ °C) tend to have a higher α′-martensite volume, with the values of the $T_d = -40$ °C curve being comparable to the ones of the tensile test. The α′-martensite volume for room temperature and elevated temperatures in the flow-formed specimens compared to the values of compression-formed specimens by Knigge [1] tends to reveal a higher α′-martensite volume.

Which forming method leads to a higher α′-martensite volume can be differentiated by the wall thickness reduction steps of the flow-forming deformation. For small

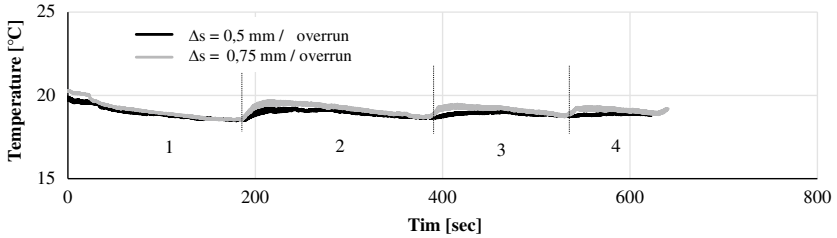
overrun steps (0.25 mm) the flow-forming process leads to a higher α′-martensite volume than the Knigge compression tests. Figure 4 shows the influence of the forming history. The study revealed that the smaller the forming steps of the commutated deformation are (here the thickness strain φ), the higher the α′-martensite volume will be for an equal total wall thickness reduction. These findings agree with the findings of Müller-Bollenhagen et al. [14] which revealed the martensite formation to be strongly dependent on the strain rate. This tendency is independent of the forming temperature. In Fig. 4, the diagrams show the trend for $T_d = 20$ °C and $T_d = 80$ °C in overrun steps of 0.25, 0.5, and 0.75 mm. For small overrun steps the curve progression does not show an asymptotic pattern toward a limit value of α′-martensite like it shows for bigger overrun steps.



The specimen temperature, which is proven to influence the α′-martensite volume, does not remain constant during a forming operation of several overruns when using a liquid-cooling system with a constant volume flow. The higher the wall thickness reduction in a single overrun, the higher the temperature scatter will be. This is shown, for example, by the comparison in Fig. 5 of the temperature profile during flow-forming in four overrun steps for a set value of 0.5 and 0.75 mm per overrun.

Besides the wall thickness reduction, a higher feed also leads to an increased scatter due to the higher energy input over the same period of time. Among other mechanisms, the higher energy input of a bigger wall thickness reduction, leading to a local increase in the deformed material temperature, can be the reason for a lower α′-martensite volume by comparison with an identical degree of deformation in smaller deformation steps. This correlation is still part of the ongoing investigations, however, and requires further research.

4.2 Mechanical Properties

The mechanical properties of the flow-formed specimens at different degrees of deformation and forming temperatures show the expected correlation with the α′-martensite volume. The higher the α′-martensite volume, the higher the tensile strength and hardness of the deformed material will be. By way of an example, Fig. 6 demonstrates the tensile strength of flow-formed tubes with a single and four-overrun wall thickness reduction in steps of 0.25 and 0.75 mm per overrun. The higher α′-martensite volume with a decreasing deformation temperature leads to a

higher tensile strength for similar wall thickness reductions. The spread in the thickness strain at different temperatures for identical reduction steps is caused by the varying material behavior at different temperatures, the machine stiffness, and the thickness scatter of the initial tube. The gradient of tensile strength with an increasing wall thickness reduction is greater with smaller overrun steps. For a predictable curve progression, the amount of the difference in thickness-strain values has to be extended by a long way, which is part of the ongoing research project. The yield stress shows the assumed behavior of Fig. 1b. The gap of yield stress between samples with small and higher martensite volume fraction gets bigger with increasing true strain.

By way of an example, Fig. 7 shows the hardness development of two tube cross sections with a wall thickness reduction of $\Delta s = 0.25$ mm in a single-step (left) and $\Delta s = 3$ mm in four steps of 0.75 mm (right) at different deformation temperatures. The increase in the α'-martensite volume with a decreasing deformation temperature leads, in the same way as the tensile strength, to an increasing hardness. With a small deformation, it is obvious that the hardness increase mainly takes place in the area of the tube's outer surface, where the rolling surface is located and where the local deformation is higher. As of 2 mm rolling distance, there is only a slight increase in hardness and this does not really depend on the deformation temperature (Fig. 7, left).

With a high deformation, the hardness gradient across the tube wall is far smaller. In addition, the increase in hardness over the degree of deformation is far less significant than the increase in tensile strength. For example, the tensile strength shows an increase of about 35% when the wall thickness reduction is increased from $\Delta s = 0.25$ mm to $\Delta s = 3$ mm at a deformation temperature of $T_d = 80$ °C. The hardness increase near the rolling surface for this same condition is only 2%. But the increase

Fig. 7 Vickers hardness development across the tube wall of flow-formed tubes for a wall thickness reduction of $\Delta s = 0.25$ mm (left) and $\Delta s = 3$ mm (right) at different deformation temperatures. (Color figure online)

in the average hardness across the wall thickness of these two conditions is then again 30%, which is similar to the increase in the tensile strength.

4.3 Microstructure

As shown in Fig. 8a, b, a comparable martensite volume partition of 40% measured using the Fischerscope, corresponds additionally to the different hardness degrees shown in Fig. 7, with a different elongation of grains and a different radial gradient of the martensite volume partition distribution. This is shown for a deformation of 0.5 mm, respectively, 0.25 mm, achieved through two deformation steps of 0.25 mm wall thickness reduction per overrun, together with a forming temperature of T_d = 20 °C (material state A), respectively, by one step with 0.25 mm thickness reduction per overrun with a forming temperature of $T_d = -40$ °C (material state B). As can be seen in Fig. 8(I–III), in qualitative terms, the grain size in the radial direction is reduced, while the grain size in the tangential direction is increased. The measurement

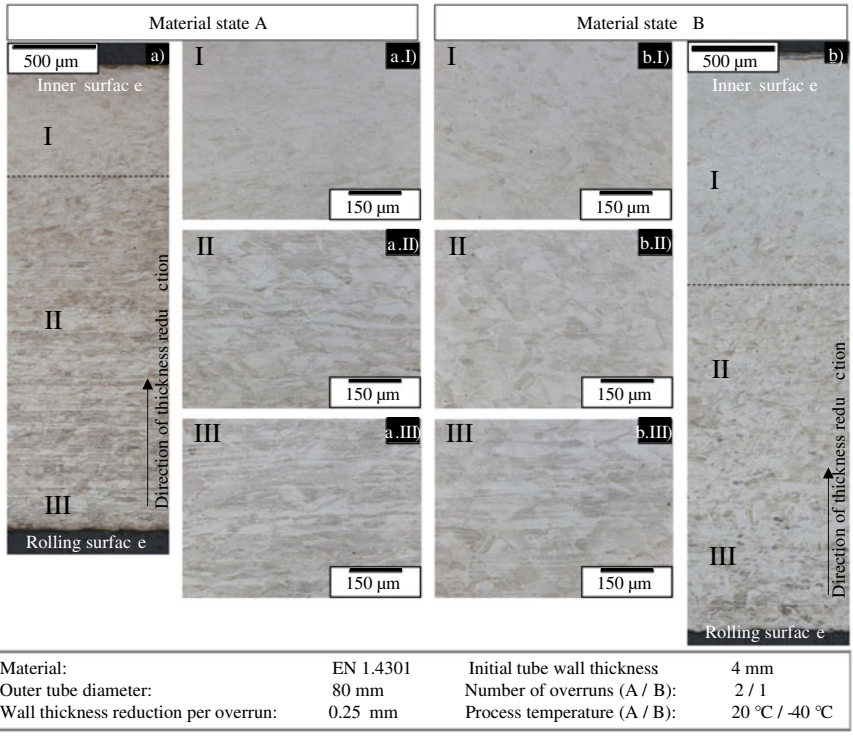

Fig. 8 Radial gradient of microstructure for material state **a** A and **b** B (overview) and detailed information (I–III). (Color figure online)

value used, which is detected with the Fischerscope (compare Fig. 3), is based, ceteris paribus, on an increased number of grains. The measured value relating to the martensite volume partition is influenced by the grain orientation due to deformation, the real martensite volume partition, the hardness (compare Fig. 7), and also the penetration depth of the measurement technique. Segregation of these parameters needs to be achieved in further investigations.

4.4 Measurement Technique and Local, Non-destructive Measurement of Martensite Content

For the non-destructive detection of the martensite volume partition on each sample, use was made of different measurement techniques. The Fischerscope measures a ferrite equivalent based on the magnetic-inductive-created voltage signal of the material compared to a reference voltage signal and is thus appropriate for detecting the content of the ferromagnetic phase. In the case of the investigated 1.4301 material, this measurement value corresponds to the partition of α'-martensite after deformation. The measurement depth is fixed and material-specific. Both the 3MA-II (Fraunhofer IZFP) and the μ-magnetic (Qass) measurement principle are based on the accelerating-current-supported induction of magnetic fields in the material investigated. The measurement depth depends on the frequency of the applied current and can be adapted to the material prior to testing by means of the quality/height of the output signal or the measurement depth, ceteris paribus. The change in the output signal for different volume partitions of the material is dependent on the microstructure of the material investigated, as is the type of material, the grain size and orientation, the hardness, and the residual stresses. The change in the output signal is transformed with the 3MA-II per Fourier transformation and can be analyzed using different analysis methods (harmonic analysis of the tangential-magnetic field strength, the Barkhausen noise, the incremental permeability signal, and multi-frequency eddy-current technique) and different key parameters. The selection of the key parameters is made as a function of the material and microstructural feature investigated. The Qass system is also based on the induction of magnetic fields. The change in these fields is detected by means of an energy level parameter.

A comparison of the gradient and the results of the integrally measured martensite volume partition of the Fischerscope indicates a correlation between the martensite volume partition detected by the measurement technique and the microscopically characterized partition up to a depth of non-definable distance from the surface. It was thus possible to detect the martensite volume partition independently of the deformation state. Nevertheless, the different microstructure can be discussed as an explanation for the different tensile strengths. Further information regarding a more detailed detection of material properties might be obtained by frequency-dependent measurement techniques for ferromagnetic material behavior, like the Fraunhofer IZFP 3MA-II or the Qass μ-magnetic technique. Due to the variation of the frequency,

different depths of the material volume and hence different volume partitions of martensite will be characterized.

5 Conclusions

The study is carried out to analyze the influence and adjustability of deformation-induced α′-martensite volume in a flow-forming process for a metastable austenite. It shows that the incremental forming character of the process leads to a higher α′-martensite volume for identical deformation degrees than the known values for single-step forming processes, such as compression or tensile tests. The study revealed that, besides the overall degree of deformation and the deformation temperature, the forming history also has an impact on the amount of the plasticity-induced α′-martensite volume. The division of the overall deformation into smaller forming steps leads to a higher α′-martensite volume than with big wall thickness reduction steps. Mechanical properties, like tensile strength and hardness, show an increase that correlates with the α′-martensite volume for an equal deformation degree, whereby the hardness of the near-rolling-surface areas tends to depend more on the α′-martensite volume than on the degree of deformation. The scatter of the temperature profile and the influence of the wall thickness reduction and the feed on this scatter shows the need for closed-loop control of the temperature actuator and the flow-forming process for the precise induction of a specifically α′-martensite volume in a predefined area.

The results presented indicate that further investigations are necessary in order to quantify the martensite volume partition in a depth that is deterministic for the material properties, thus making stable dynamic control of material properties feasible. In addition, the integration and application of measurement techniques and sensors in the machine, the identification, and reduction of forming-induced effects on signal detection during the forming process will be a matter of research. Additionally, the just-in-time valuation of measurement signals based on deformation-state-dependent thresholds remains topic for further investigations.

Constitutive Modeling and Processing Map of Ti–5Al–5Mo–5V–3Cr–1Zr Alloy During Hot Deformation

Yuting Zhou, Jie Zhou, and Peng Wang

Abstract To investigate the hot deformation behavior of Ti–5Al–5Mo–5V–3Cr–1Zr (Ti55531) alloy, a series of compression tests were performed within the temperature range of 1033–1153 K at constant strain rates 0.001–1 s^{-1} on a Gleeble-3500 isothermal simulator. The results show that the flow stress decreases with an increase in temperature and a decrease in strain rate. At high strain rate, the flow curves are characterized by obvious discontinuous yielding, followed by slight strain hardening before flow softening and/or steady-state flow. The magnitude of the discontinuous yield drop increases with an increase in temperature. The flow behaviors were described by the Arrhenius equation in $\alpha + \beta$ phase region and in β phase region respectively. The processing maps considering strains of 0.05, 0.4, 0.6, and 0.9 were drawn. In combination with microstructural observations, it is found that this alloy represents typical instability of flow localization and flow rotation in an unstable flow region. The optimum conditions for hot deformation were found at 0.001–0.1 s^{-1} and 1003–1153 K.

1 Introduction

Near-β titanium alloys show good corrosion resistance and workability, together with a superior combination of strength and ductility as well as excellent fatigue strength as compared to α/β alloys. Due to these characteristics, these alloys have been widely used in the production of critical components for aerospace, automotive, and offshore industry by hot working processes [1, 2]. The hot deformation of near-β titanium alloys has been studied in many previous works. For example, Ti-7333 has been found weaker deformation resistance compared to Ti5553, and its main instability mechanism is the bands of flow localization [3]. Qu et al. [4] investigated the

effects of different thermomechanical parameters on the deformation behavior and microstructure characteristics of Ti–4Al–2.5V–1.5Fe. Jackson et al. [5] investigated the effect of initial microstructure on plastic flow behavior during the isothermal forging of Ti–10V–2Fe–3Al and found that the flow behavior was highly dependent on the initial morphology of α phase.

Usually, near-β titanium alloys are sensitive to initial microstructures and working parameters (like temperature, strain, and strain rate) during hot working process. Therefore, to optimize the processing procedure and obtain desired microstructure characteristics of a near-β titanium alloy, it is essential to investigate the relationship between initial microstructure, processing conditions, and final microstructure. In this regard, Prasad [6] proposed the dynamic material model (DMM) to conduct these studies for metallic material. In this approach, parameters to describe the formability are developed as a function of temperature, strain, and strain rate using the true stress–true strain curves; and processing map is constructed to provide the distinct stable/unstable region for manufacture. The simplicity of DMM model has resulted in its widespread use. Bao et al. [7] constructed the processing maps of Ti1023 alloy based on its deformation behavior and mechanisms. Seshacharyulu et al. [8] developed a process map of Ti–6Al–4V titanium alloy on the basis of flow stress data and calculated the apparent activation energy of Ti–6Al–4V when the deformation is performed in the $\alpha + \beta$ region and β region. Hao et al. [9] determined the hot deformation characteristics of the new near-β titanium alloy Ti-1300 by constructing the processing maps within the temperature range of 920–1010 °C and strain rate range of 0.01–10 s^{-1}.

These studies provide a broad perspective on the microstructural evolution, constitutive model, processing map and deformation mechanism of β alloys during hot deformation. However, few studies have been reported regarding the hot deformation behavior and microstructure evolution of Ti–5Al–5Mo–5V–3Cr–1Zr. The objective of this work is to investigate the high-temperature deformation behavior of the Ti55531 alloy using hot compression test. Thus, the processing map is constructed to acquire the optimum processing conditions and the flow instability regions by using the experimental flow stress curves. Also, the Arrhenius constitutive equation is established to correlate the relationships among the stress, strain rate, temperature. Finally, the microstructural observation is used to determine the effect of deformation temperature and strain rate on the microstructure characteristics.

2 Experimental Procedure

The material used in this research was an as-forged block of Ti55531 alloy machined with a diameter of 360 mm. Figure 1 shows the initial microstructure image of the as-received material. It consists of a large number of globular α phase surrounded by soft β matrix. The β transus temperature (T_β) previously reported [10] for this alloy is 1076 K.

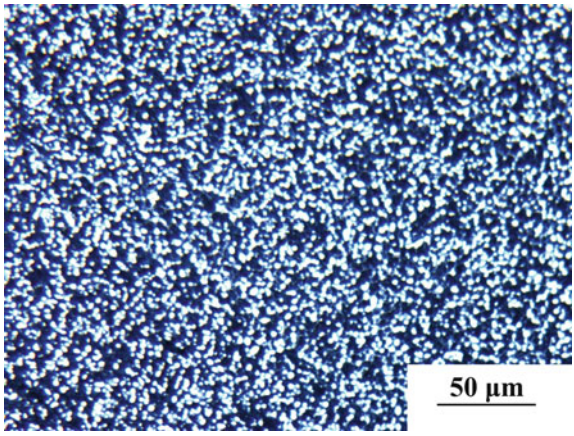

Fig. 1 The as-received material of Ti55531 where α phase is bright and β phase is dark. (Color figure online)

The hot deformation tests were conducted on a Gleeble-3500 machine using cylindrical specimens of 12 mm diameter and 8 mm length machined. Graphite lubricant was used between sample and anvil to reduce the temperature gradient and the interface friction. The compression tests were carried out at temperatures between 1003 and 1153 K with 30 K increment and at four strain rates from 0.001 to 1 s^{-1}, then up to true strain of 0.9. During the process, the samples were heated at 10 K/s to deformation temperature, held for 180 s, deformed, finally water quenched. All specimens were compressed in an isothermal environment and the deformation reduction was 60%. Finally, the processed specimens were cut along the load axis. The longitudinal section was mechanically polished under the standard metallographic procedure and etched in Kroll's reagent. Optical microscopy (OM) and scanning electron microscope (SEM) were carried out to characterize the microstructures.

3 Results and Discussion

3.1 Flow Behavior

The true stress–true strain curves of the Ti55531 alloy after hot deformation are shown in Fig. 2. It is apparent that the flow stress decreases with an increase in temperature and a decrease in strain rate. From Fig. 2a–d, it can be seen that the $\alpha + \beta$ field (1003–1063 K) stress–strain curves show larger degrees of flow softening than β field stress–strain curves. Following the peak stress, evident drops of flow stress curves are observed. When the hot deformation was carried out near or above β-transus, the curves exhibit almost constant flow, which suggests dynamic restoration processes (dynamic recrystallization or dynamic recovery) in operation. At the low-temperature cases of 1003 K, except for the high strain rate examined (1 s^{-1}), the flow curves exhibit strain hardening at low strains from 0.05 to 0.3. Moreover, at

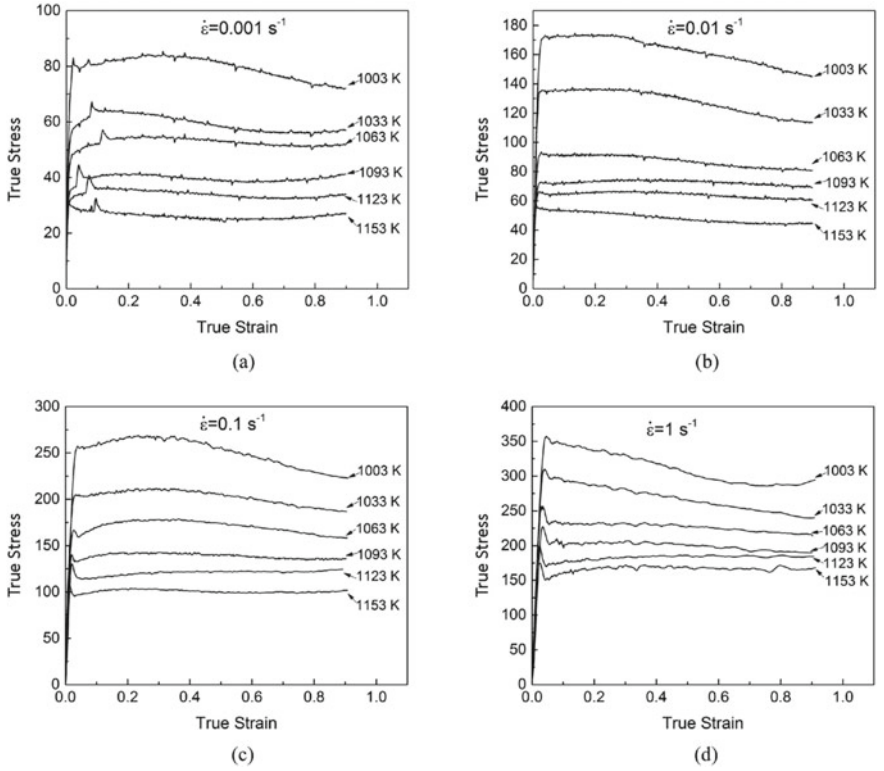

Fig. 2 True stress–true strain curves for the Ti55531 alloy deformed at strain rates of **a** 0.001 s^{-1}; **b** 0.01 s^{-1}; **c** 0.1 s^{-1} and **d** 1 s^{-1} at temperatures from 1003 to 1153 K

strain rates of 0.001 s^{-1} (Fig. 2a) and 1 s^{-1} (Fig. 2d), some curves also exhibit strain hardening at high strains. In addition, discontinuous yielding (a sharp initial peak stress) in the stress–strain curves is observed when the material was deformed at strain rates of 0.1 s^{-1} (Fig. 2c) and 1 s^{-1} (Fig. 2d). The discontinuous yielding phenomenon is consistent with the dynamic yield theory where the discontinuous yield behavior is related to sudden multiplication of mobile dislocations in grain boundaries [11]. As shown in Fig. 2c, d, the amplitude of yield drop increases with an increase in temperature, and this phenomenon is more distinct for deformation in β-phase field.

3.2 Constitutive Model

In this study, Arrhenius-type equations were used to depict the constitutive relationship among flow stress, temperature, and strain rate during hot deformation of the Ti55531 alloy, which can be expressed as follows [12, 13]:

$$\dot{\varepsilon} = A\sigma^{n'} \exp(-Q/RT), \alpha\sigma < 0.8 \tag{1}$$

$$\dot{\varepsilon} = A \exp(\beta\sigma) \exp(-Q/RT), \alpha\sigma > 1.2 \tag{2}$$

$$\dot{\varepsilon} = A[\sinh(\alpha\sigma)]^n \exp(-Q/RT), \text{ full all } \sigma \tag{3}$$

where, σ is the flow stress (MPa) for a given strain, $\dot{\varepsilon}$ is the strain rate (s^{-1}), T is the deformation temperature (K), Q is the apparent activation energy (kJ/mol), R is the gas constant (8.314 J/mol/K), n' and n are the stress exponent, A, α and β are the material constants.

Taking natural algorithms on both sides of Eqs. (1–3) respectively, then β, n', n, and α can be calculated at a constant temperature by following Eqs. (4–7), generally, the average slope values of the linear plots of $\ln\dot{\varepsilon}$ versus $\ln\sigma$ and $\ln\dot{\varepsilon}$ versus σ, n' and β respectively.

$$n' = \left.\frac{\partial \ln\dot{\varepsilon}}{\partial \ln\sigma}\right|_T \tag{4}$$

$$\beta = \left.\frac{\partial \ln\dot{\varepsilon}}{\partial \sigma}\right|_T \tag{5}$$

$$n = \left.\frac{\partial \ln\dot{\varepsilon}}{\partial \ln[\sinh(\alpha\sigma)]}\right|_T \tag{6}$$

$$\alpha = \beta/n'. \tag{7}$$

When the strain rate is a constant, the activation energy of the deformation process can be estimated by the average slope of the plot $\ln[\sinh(\alpha\sigma)]$ versus $1/T$ within the linear range, as shown in Eq. (8):

$$Q = nR \left.\frac{\partial \ln[\sinh(\alpha\sigma)]}{\partial(1/T)}\right|_{\dot{\varepsilon}}. \tag{8}$$

In addition, the coupling effect of temperature and strain rate on the hot deformation behavior is expressed by Zenere–Hollomon (Z) parameter as:

$$Z = \dot{\varepsilon}\exp(-Q/RT) \tag{9}$$

According to Eqs. (3) and (9),

$$Z = A[\sinh(\alpha\sigma)]^n \tag{10}$$

Then the Eq. (10) can be written as:

$$\ln Z = \ln A + n\ln[\sinh(\alpha\sigma)] \tag{11}$$

where ln$A$ is the intercept of the linear plots ln[sin$h(\alpha\sigma)$] versus ln$Z$.

To apply the Arrhenius constitutive model at different strains, a series of six-order polynomial regression functions (as shown in Eq. (12)) were employed to fit the relationship between material constants and strain [13].

$$\begin{cases} \alpha = B_6\varepsilon^6 + B_5\varepsilon^5 + B_4\varepsilon^4 + B_3\varepsilon^3 + B_2\varepsilon^2 + B_1\varepsilon + B_0 \\ Q = C_6\varepsilon^6 + C_5\varepsilon^5 + C_4\varepsilon^4 + C_3\varepsilon^3 + C_2\varepsilon^2 + C_1\varepsilon + C_0 \\ n = D_6\varepsilon^6 + D_5\varepsilon^5 + D_4\varepsilon^4 + D_3\varepsilon^3 + D_2\varepsilon^2 + D_1\varepsilon + D_0 \\ lnA = E_6\varepsilon^6 + E_5\varepsilon^5 + E_4\varepsilon^4 + E_3\varepsilon^3 + E_2\varepsilon^2 + E_1\varepsilon + E_0 \end{cases} \tag{12}$$

Finally, the Arrhenius-type equation can be expressed as:

$$\sigma = \frac{1}{g(\varepsilon)} \ln \left\{ \left(\frac{\dot{\varepsilon} \exp[j(\varepsilon)/8.314T]}{f(\varepsilon)} \right)^{1/h(\varepsilon)} + \left[\left(\frac{\dot{\varepsilon} \exp[j(\varepsilon)/8.314T]}{f(\varepsilon)} \right)^{2/h(\varepsilon)} + 1 \right]^{1/2} \right\}. \tag{13}$$

where $g(\varepsilon)$, $f(\varepsilon)$, $h(\varepsilon)$, $j(\varepsilon)$ are polynomial functions of strain for α, Q, n, ln$A$.

Figures 3 and 4 show the comparison between the predicted values using the above Arrhenius equation (Eq. (13)) and experimental values for the strain range of 0.05–0.9. These plots illustrate good correlations and the regression coefficients R2 were 0.99159 and 0.99801 for $\alpha + \beta$ and β field respectively. The absolute average relative errors (AARE, as defined in Eq. (14), calculated to quantitatively describe the accuracy of the Arrhenius equations, are 6.6571% and 3.7691%, respectively, meaning that this constitutive equation has a good predictive ability for this alloy.

$$\text{AARE} = \frac{1}{N} \sum_{i=1}^{N} \left| \frac{P_i - E_i}{E_i} \right| \tag{14}$$

where E_i is the experimental value and P_i is the predicted value, N is the number of data employed in present work.

3.3 Processing Maps

In last few decades, many researchers have studied the hot formability of titanium alloys by using processing maps based on the dynamic material model (DMM) developed by Prasad et al. [14, 15]. In that procedure, a visual map of formability

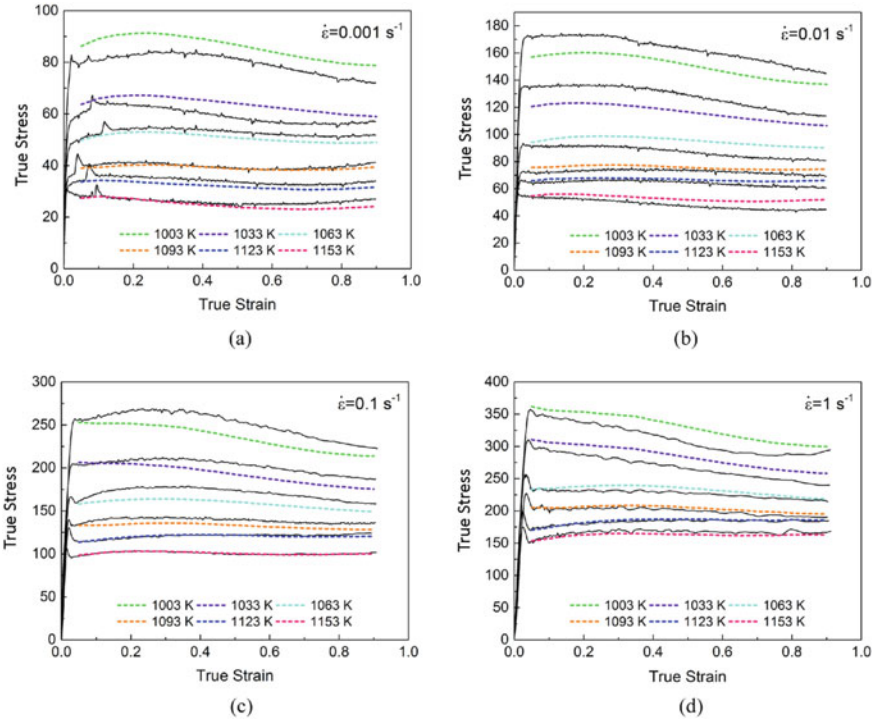

Fig. 3 The comparison between the values predicted by the Arrhenius equation and experimental values at different temperatures (1003–1153 K) and strain rates **a** 0.001 s^{-1}; **b** 0.01 s^{-1}; **c** 0.1 s^{-1}; **d** 1 s^{-1}. (Color figure online)

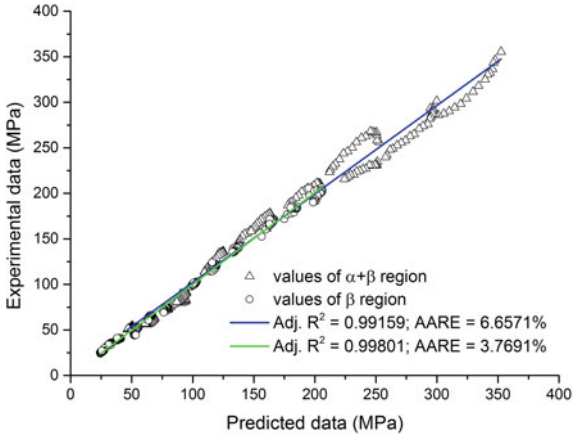

Fig. 4 The linear correlation relationships between predicted and experimental stress values. (Color figure online)

is developed to give an idea of deformation mechanism and processing window of a metallic material by using experimental flow stress. More details about DMM model are given by Refs. [6, 16, 17].

In general, the DMM model derives from the separation of the total power of dissipation P to two complementary parts, G associated with the plastic deformation and J related to microstructural changes [15]. The relation among them is shown as follows:

$$P = \sigma\dot{\varepsilon} = G + J = \int_0^{\dot{\varepsilon}} \sigma d\dot{\varepsilon} + \int_0^{\sigma} \dot{\varepsilon} d\sigma. \tag{15}$$

Furthermore, Eq. (16) defined the power positioning between G and J for the given temperature and strain, where m is the strain rate sensitivity.

$$\left.\frac{\partial J}{\partial G}\right|_{T,\varepsilon} = \left.\frac{\partial \ln\sigma}{\partial \ln\dot{\varepsilon}}\right|_{T,\varepsilon} \approx \left.\frac{\Delta \ln\sigma}{\Delta \ln\dot{\varepsilon}}\right|_{T,\varepsilon} = m. \tag{16}$$

The DMM processing map consists of two parameters, identified by the efficiency of power dissipation (η) and the instability parameter (ξ) [14, 18]. First, the efficiency of power dissipation (η) can be calculated by:

$$\eta = \frac{2m}{1+m}. \tag{17}$$

The flow instabilities can be predicted by the following equation:

$$\xi(\dot{\varepsilon}) = \frac{\partial \ln[m/(1+m)]}{\partial \ln\dot{\varepsilon}} + m < 0. \tag{18}$$

Then the variation of power dissipation efficiency (η) with strain rate and temperature constitutes a power dissipation map and the variation of instability parameter (ξ) constitutes an instability map. As a result, the DMM processing map is constructed by superimposing the instability map over the power dissipation map, where good hot formability is given by high η values and no instabilities.

The efficiency of power dissipation map with the superimposed instability values for different strains (0.05, 0.4, 0.6, 0.9) is plotted in Fig. 5. The values of η as a function of temperature and strain rate are given by Eq. (17), which is associated with the strain rate sensitivity $\left(m = \frac{\partial \log(\sigma)}{\partial \log(\dot{\varepsilon})}\right)$. As shown as the contour lines in Fig. 5, the highest η values (>0.5) are mostly observed at low temperature, T <1033 K, and low strain rate, $\dot{\varepsilon}$ <0.01 s^{-1}. As the deformation strain increases, there is no significant change in η values. Generally, high η values (0.35–0.55) indicate much less thermal dissipation during hot processing and more significant microstructural changes such as DRX, corresponding to good formability [19–22]. Thus, the power dissipation map in the present work can be divided into two areas: (I) the area with η <0.35, mostly at high strain rates (0.1–1 s^{-1}) over all test temperatures, which is
