Tuning interactions between Dirac states in graphene has attracted enormous interest because it can modify the electronic spectrum of the two-dimensional material, enhance electron correlations, and give rise to novel condensed-matter phases such as superconductors, Mott insulators, Wigner crystals and quantum anomalous Hall insulators. Previous works predominantly focus on the flat band dispersion of coupled Dirac states from different twisted graphene layers. In this work, we propose a new route to realizing flat band physics in monolayer graphene under a periodic modulation from substrates. We take graphene/SiC heterostructure as a prototypical example and demonstrate experimentally that the substrate modulation leads to Dirac fermion cloning and consequently, the proximity of the two Dirac cones of monolayer graphene in momentum space. Our theoretical modeling captures the cloning mechanism of Dirac states and indicates that Moiré flat bands can emerge at certain magic lattice constants of the substrate, specifically when the period of modulation becomes nearly commensurate with the $(\sqrt{3} \times \sqrt{3})R30°$ supercell of graphene. The results show that epitaxial single monolayer graphene on suitable substrates is a promising platform for exploring exotic many-body quantum phases arising from interactions between Dirac electrons.

1 Introduction

The discovery of graphene has revolutionized modern condensed matter physics by providing direct access to the physics of Dirac fermions in solid-state systems[1, 2, 3]. It also sheds light on the path towards a vast field of novel 2D materials including van der Waals (vdW) materials and topological materials such as quantum spin Hall insulators [1, 4, 5, 6, 7, 8, 9, 10]. Single layer graphene possesses two Dirac cones residing at the opposite corners of the Brillouin zone, leaving them essentially isolated from each other. Stacking graphene layers in the graphite order duplicates Dirac cones in the same valley so that the two valleys remain decoupled. Recently, new physics in graphene-like systems have arisen as a consequence of the creation of strongly coupled Dirac states in artificially engineered structures such as twisted bilayer graphene (TBG). The interaction between Dirac states from the two layers can be effectively tuned by the angle. This leads to emergent collective behaviors of electrons including Mott insu-

lating states, unconventional superconductivity, emergent ferromagnetism, quantum anomalous Hall effects [11, 12, 13, 14, 15, 16, 17, 18, 19, 20]. The essential ingredient for these new emergent states is the nearly dispersionless bands at zero energy in the Moiré Brillouin zone. Achieving the required large periodicity of Moiré pattern in real space and the closeness of Dirac cones in momentum space generally requires control over the twist angle between mechanically exfoliated graphene layers. This places stringent constraints on the techniques of sample assembly. Therefore, there is a pressing need for accessing flat band physics in systems without fine tuning of twist angles.

Here we report an alternative route to enable interactions between Dirac electrons in a single layer of graphene and realize flat bands. This comes from the supporting substrate potential. We observed the cloning of Dirac bands in monolayer graphene epitaxially grown on SiC substates by angle-resolved photoemission spectroscopy (ARPES). The periodic substrate potential brings closer the Dirac states from the two valleys and thus turns on intervalley coupling. This is precisely captured by our tight-binding simulations. Our theory further indicates that the perturbed graphene system with nearly commensurate epitaxial relations hosts Moiré flat bands similar to those found in the magic-angle twisted bilayer graphene [11, 21]. The lattice constant of the substate plays the same role as the twist angle in bilayer graphene in the formation of Moiré flat bands. Dispersionless zero-energy bands occur at certain "magic" lattice constants of the substrate.

2   Experimental Results

First, we study the substrate effects on the Dirac states of graphene. Our graphene was grown epitaxially on the Si-face of a 6H-SiC substrate. The lattice structure and epitaxial relation between the graphene overlayer and the SiC substrate are plotted in Fig. 1(a). The lattice constant of graphene and SiC(0001) surface is 2.46 Å and 3.07 Å, respectively. The Brillouin zone of graphene and SiC(0001) is depicted by red and blue lines, respectively, in Fig. 1(b). K_{Gr} and K'_{Gr} represent the location of the two valleys of graphene Dirac states. The atomic-resolution STM image of the graphene sample is shown in Fig. 1(c). A superhexagonal Moiré pattern with a period $\lambda = 6(1 + \delta)a_{SiC}$ is observed due to the incommensurate modulation of the SiC interface layer [22, 23]. To examine the structural quality, we performed high-resolution TEM measurements on our graphene samples. A typical TEM image is shown in Fig. 1(d). The sample consists of four well-ordered graphene layers sitting on the carbonized surface of the SiC substrate. A gap between the graphene and the SiC surface is noticeable, indicating a sharp interface between the graphene layers and the substrate. In our experiment, the thickness of graphene layers can be precisely controlled down to a monolayer. We will focus on results obtained from monolayer graphene samples in the following discussion, but the physics discussed here also applies to thicker graphene films. The Fermi surface of the graphene sample mapped by ARPES is presented in Fig. 2(a). The Brillouin zone of graphene is marked by the blue dashed lines. At the corners of the Brillouin zone, the K_{Gr} points, we can see bright Fermi surface contours from the Dirac bands of graphene. Note that our sample is n-typed doped with a Fermi level above the Dirac point. Therefore, the Fermi surface contours are small circles surrounding K_{Gr}, as marked by the black arrows. Beside the Dirac states of graphene, there are extra circular contours located inside the Brillouin zone of graphene, which are absent on the Fermi surface of freestanding graphene. These new contours marked by blue, green, yellow, and gray arrows are referred to as blue, green, yellow, and gray contours (or cones) in the following discussions. The geometric relations between the Brillouin zones of graphene and SiC is depicted in Fig. 2(b). The emergent contour with lesser photoemission intensity are the clones of the graphene Dirac cone generated by the periodic substrate perturbations. Shifting the K'_{Gr} by a reciprocal lattice vector of SiC as shown in Fig. 2(c), we can find the location of the blue and green cones. The yellow and gray contours can be obtained through two successive shifts of the graphene states, see Fig. 2(d). Taking the substrate interaction as a perturbation, we can attribute the blue (green) and yellow (gray) cones to the first-order and second-order perturbation effects, which also explains why the intensity of yellow (gray) cones is apparently lower than that of blue (green) cones. The locations of all the first-order and second-order clones are summarized in Fig. 2(e). It is consistent with the experimental observations shown in Fig. 2(a).

The cloning of Dirac states is rooted in the periodic modulation from the substrate on the electrons in graphene. To understand the mechanism of cloning, we performed a tight-binding simulation in which the substrate effect is approximated by a periodic potential acting on the the graphene electrons. The sample is n-type doped, so the fermi level is shifted in the simulation to match the experimental results. There is a good agreement between the experimental and theoretical Fermi surfaces as shown in Figs. 3(a) and 3(b). All first-order and second-order clones in the simulation show up at the locations observed in the experimental results. The spectrum along the line of 'cut1' (marked in Fig. 3(a)) is plotted in Figs. 3(c) and 3(d). The brightness of bands indicates the photoemission intensity in the ARPES spectrum and the spectral weight (the probability of finding the electron with the corresponding energy and momentum) in the TB simulation. The clones show the same dispersion as the primary Dirac cones but have lower spectral weight compared to the primary cone, consistent with the perturbative picture. This weight reflects the strength of the graphene/substrate interaction. It is important to note that the width of these clones seen in the spectral lineshapes is similar to the main cones, indicating the static nature of the substrate coupling. This is further corroborated by the ARPES spectrum taken along the lines of 'cut2'-'cut5'. Unlike the primary Dirac cones sitting far apart at the corners of the Brillouin zone, the clones are much closer to each other in momentum space. For example, the distance between the yellow and green clones is 0.21 Å^{-1} while the spacing between neighboring primary cones is 1.7 Å^{-1}. The smaller distance between clones enables them to overlap in momentum space, see the iso-energy contours in the supplementary information. The yellow and green cones cross at $E = -1.3$ eV while the blue and green cones cross at $E = -1.8$ eV. Such crossings of Dirac states are unavailable in freestanding graphene films. It is worth noting that there is no gap opened at the crossings of the green and blue bands. This is because both green and blue contours originate from the same valley (see Fig. 2(c)) and thus they do not hybridize. Only Dirac bands from different valleys can interact with each other and open hybridization gaps, as discussed below. The cloning of Dirac bands occurs not only in the monolayer graphene but also in thicker films. Figure 3(f) shows the spectra of the primary Dirac cone from 3-ML and 5-ML graphene samples. The number of Dirac bands in the spectra indicates the thickness of the sample [24, 25]. Despite of the weaker intensity, the clone bands (the blue cone marked in Figs. 2(a) and 3(c)) are still observable in the 3-ML and 5-ML samples as shown in Fig. 3(g). We note that similar π-band replicas have been reported in previous ARPES works[23, 26]. However, a detailed theoretical model of the band duplication remains elusive. In this work, we build up a tight-binding model with the inclusion of electron hoppings between atomic orbitals of graphene and SiC substrate. It shows that the periodic substrate modulation not only duplicates the π-band of graphene, but also induces strong couplings between two valleys of graphene. The effect of Dirac fermion cloning has also been observed in the graphene/h-BN heterostructure, in which the superlattice potential leads to the emergence of Moiré minibands, second-generation Dirac cones, and consequently, the self-similar Hofstadter butterfly states in high magnetic fields[27, 12, 13, 28, 29, 16]. The emergent states are related to the hybridization of the graphene Dirac cone and its clones in the nearly commensurate graphene/h-BN lattice. Those experimental results indicate that the duplication of Dirac states is an intrinsic property of graphene heterostructures rather than a final-state photoelectron diffraction effect as suggested in the previous work[26].

3 Discussions

Perturbation theory can capture the essential physics of Dirac Fermion cloning in the graphene/SiC heterostructure. The substrate potential can be treated as a small perturbation and exerts a periodic modulation to the Dirac states of graphene [23]. Taking $W(\boldsymbol{x})$ as the potential on the SiC(0001) surface, the

eigenfunction up to the second-order is given by

$$|\Psi_{\boldsymbol{k}}\rangle = |\Psi_{\boldsymbol{k}}^0\rangle + \sum_{\boldsymbol{p}\neq\boldsymbol{k}} |\Psi_{\boldsymbol{p}}^0\rangle \frac{\langle\Psi_{\boldsymbol{p}}^0|W|\Psi_{\boldsymbol{k}}^0\rangle}{E_{\boldsymbol{k}}^0 - E_{\boldsymbol{p}}^0} + \sum_{\boldsymbol{p}\neq\boldsymbol{k},\boldsymbol{l}\neq\boldsymbol{k}} |\Psi_{\boldsymbol{p}}^0\rangle \frac{\langle\Psi_{\boldsymbol{p}}^0|W|\Psi_{\boldsymbol{l}}^0\rangle\langle\Psi_{\boldsymbol{l}}^0|W|\Psi_{\boldsymbol{k}}^0\rangle}{(E_{\boldsymbol{k}}^0 - E_{\boldsymbol{p}}^0)(E_{\boldsymbol{k}}^0 - E_{\boldsymbol{l}}^0)}$$
$$- \sum_{\boldsymbol{p}\neq\boldsymbol{k}} |\Psi_{\boldsymbol{p}}^0\rangle \frac{\langle\Psi_{\boldsymbol{k}}^0|W|\Psi_{\boldsymbol{k}}^0\rangle\langle\Psi_{\boldsymbol{p}}^0|W|\Psi_{\boldsymbol{k}}^0\rangle}{(E_{\boldsymbol{k}}^0 - E_{\boldsymbol{p}}^0)^2} - \frac{1}{2}|\Psi_{\boldsymbol{k}}^0\rangle \sum_{\boldsymbol{p}\neq\boldsymbol{k}} \frac{|\langle\Psi_{\boldsymbol{p}}^0|W|\Psi_{\boldsymbol{k}}^0\rangle|^2}{(E_{\boldsymbol{k}}^0 - E_{\boldsymbol{p}}^0)^2}, \tag{1}$$

where '0' indicates the original wavefunction of the graphene in the absence of the substrate surface potential. The second term in Eq. (1) is the first-order correction. To have non-vanishing $\langle\Psi_{\boldsymbol{p}}^0|W|\Psi_{\boldsymbol{k}}^0\rangle$, the difference between $\boldsymbol{p}$ and $\boldsymbol{k}$ must align with the period of $W(\boldsymbol{x})$. Here we simulate the substrate surface potential by using a periodic function in the simplest harmonic form, that is, $W(\boldsymbol{x}) = 2w\big(\cos(\boldsymbol{b_1}\cdot\boldsymbol{x}) + \cos(\boldsymbol{b_2}\cdot\boldsymbol{x}) + \cos(-(\boldsymbol{b_1}+\boldsymbol{b_2})\cdot\boldsymbol{x})\big)$. A detailed discussion on the substrate surface potential can be found in the Methods Section and Supplementary Information. Since the period of $W(\boldsymbol{x})$ is described by the two reciprocal lattice vectors $\boldsymbol{b_1}$ and $\boldsymbol{b_2}$, non-zero spectral weight appears only at $\boldsymbol{p} = \boldsymbol{k}\pm\boldsymbol{b_1}$, $\boldsymbol{k}\pm\boldsymbol{b_2}$, and $\boldsymbol{k}\pm(\boldsymbol{b_1}+\boldsymbol{b_2})$. As $\boldsymbol{k}$ represents the momentum of the Dirac states, there are 12 duplicates of the first order (the green and blue clones in Fig. 2(e)) within the Brillouin zone of graphene, which is in agreement with the experimental observation. The strength of the substrate coupling w can be obtained by comparing the photoemission intensities from the primary Dirac cone and the clones. The observed photoemission intensities from the blue clone, the green clone, and the primary Dirac cone at the energy of Dirac nodes have ratios of $I_{\text{blue}} : I_{\text{green}} : I_{\text{primary}} = 0.48:1.00:61.91$. According to Eq. 1, the intensity from the cloned states is that from the primary Dirac state multiplied by the spectral weight of $(2w/E_{\boldsymbol{p}}^0)^2$ (here we assume the transition matrix element is same for primary and cloned Dirac states), where $\boldsymbol{p}$ is the momentum of the cloned Dirac nodes. $E_{\boldsymbol{p}}^0$ is 6.65 and 4.39 eV for the blue and green Dirac nodes, respectively. Then, the ratio of the emission from the green and blue nodes is $(4.39/6.65)^2 = 0.44$, which is close to the observed value. The coupling strength w can be estimated by using $w = E_{\boldsymbol{p}}^0\sqrt{I_{\text{green}}/I_{\text{primary}}}/2$. With $E_{\boldsymbol{p}}^0 = 4.39$ eV for the green node and $I_{\text{green}} : I_{\text{primary}} = 1:61.91$, we find $w = 0.279$ eV $\approx 0.1t$, where $t = 2.8$ eV is the nearest-neighbor hopping parameter of graphene[1]. The observed value of w is consistent with the estimate from the tight-binding simulation (see the Supplementary Information). Since $t = 2.8$ eV is the characteristic energy scale of the graphene band dispersion, it is justified to consider the substrate potential of size $w \approx 0.1t$ as a perturbation in Eq. 1. The last three terms of $|\Psi_{\boldsymbol{k}}\rangle$ correspond to the second-order perturbations. The second last term on the right side of Eq. (1) vanishes due to the fact that $\langle\Psi_{\boldsymbol{k}}^0|W|\Psi_{\boldsymbol{k}}^0\rangle = 0$. The last term only induces a renormalization of the primary cone at $\boldsymbol{k}$. Only the first term of the second-order survives in certain conditions and give rise to clones in momentum space. To have non-vanishing $\langle\Psi_{\boldsymbol{l}}^0|W|\Psi_{\boldsymbol{k}}^0\rangle$, the momentum obeys $\boldsymbol{l} = \boldsymbol{k}\pm\boldsymbol{b_1}, \boldsymbol{k}\pm\boldsymbol{b_2}, \boldsymbol{k}\pm\boldsymbol{b_1}\pm\boldsymbol{b_2}$. Likewise, the momentum of the final wavefunction satisfies $\boldsymbol{p} = \boldsymbol{k}\pm2\boldsymbol{b_1}, \boldsymbol{k}\pm2\boldsymbol{b_2}, \boldsymbol{k}\pm2(\boldsymbol{b_1}+\boldsymbol{b_2}), \boldsymbol{k}\pm(\boldsymbol{b_1}-\boldsymbol{b_2}), \boldsymbol{k}\pm(2\boldsymbol{b_1}+\boldsymbol{b_2}), \boldsymbol{k}\pm(\boldsymbol{b_1}+2\boldsymbol{b_2})$. In this regard, the second-order perturbations duplicate 24 Dirac cones (the gray and yellow clones in Fig. 2(e)) at various $\boldsymbol{p}$, consistent with the experimental observation.
The perturbative corrections to the wavefunction in Eq. (1) give rise to the clones of Dirac cones. The clones represent a redistribution of spectral weight of the primary Dirac cone in the momentum space. That is why the observed clones share the same band dispersion as the primary Dirac cones. The clones derived from the same primary Dirac cone do not hybridize with each other. On the other hand, the hybridization are allowed for the clone or primary contours from different valleys. The hybridization between two valleys is mediated by the substrate potential. Here the two valleys of monolayer graphene behave like the two sets of Dirac cones from the two layers of TBG. Flat bands can be created under certain substrate conditions, as discussed below.
Our ARPES and tight-binding results indicate that the substrate potential creates a periodic modulation of the graphene band structure and thus produces clones of the Dirac states. They effectively shorten the distance between the two valleys by the reciprocal vectors of the substrate. This mechanism yields a direct coupling between the Dirac states from the two valleys when the substrate lattice is nearly commensurate with graphene. To date, various graphene-based heterostructures such as graphene/metals [30, 31, 32], graphene/boron nitride [33, 34, 35], and graphene/chalcogenide compounds [36, 37, 38, 4,

39, 40] have been experimentally realized. To investigate the substrate effects in the nearly commensurate condition, we performed a tight-binding simulation for a generic graphene heterostructure with a hexagonal substrate rotated by 30° relative to the graphene unit cell. The substrate lattice constant is chosen to be 3.8 Å, which is about 10% smaller than the commensurate value $\sqrt{3}a_{\mathrm{Gr}} = 4.26$ Å. The calculated band structure is shown in Fig. 4(a). At the Fermi level, there are two primary Dirac points (DP) denoted by D and D' and six duplicated DPs denoted by C1, C1', C2, C2', C3, and C3'. The clones of C1-C3 are from the valley of the 'D' Dirac cone while those of C1'-C3' are from the other valley. When two Dirac bands from different valleys (for example, C1' and D, or C2 and C2') intersect, an energy gap is opened at the crossing point. The gapped band structure gives rise to van Hove singularities (VHS) in the density of states (DOS) as marked by the yellow and red arrows. The iso-energy contours at $E = -0.08$ eV are plotted in Fig. 4(b). Close to the zero energy, all the primary and cloned contours are isolated in momentum space and thus contribute to the DOS as independent Dirac cones. Therefore, the DOS vanishes at zero energy as shown in Fig. 4(a). The effective distance between the two primary Dirac points in the presence of substrate perturbations is

$$q = \left|\left|\mathrm{K'_{Gr}K_{Gr}}\right| - b\right| = \left|\left|\Gamma\mathrm{K_{Gr}}\right| - b\right|, \tag{2}$$

where b is the length of the substrate reciprocal lattice vector, as schematically shown in Fig. 4(c). That is also the separation between DPs C1' and D in Fig. 4(b). As the substrate constant approaches the commensurate value $\sqrt{3}a_{\mathrm{Gr}}$, the clone contours move closer to the the primary cone (see Fig. 4(d)) and enhance the coupling between the two valleys, since the effective coupling is described by a dimensionless parameter $\alpha = \frac{w}{\hbar v_{\mathrm{F}}q}$, where w is the amplitude of the substrate potential and v_{F} is the Fermi velocity of electrons in graphene [11]. In this simulation, w is set to be $0.05t = 140$ meV, a value comparable to that of TBG, $w \approx 110$ meV)[11]. When the substrate lattice constant is equal to 4.166 Å and 4.370 Å, a sharp peak shows up at zero energy in DOS and an energy gap of size $\sim 2w$ emerges between the conduction and valence bands, as shown in Figs. 4(e,f). The zero-energy peaks in DOS cannot be described by isolated Dirac cones, therefore there must be dispersionless bands emerging at low energy as a consequence of hybridization of Dirac states from the two valleys.

The effective separation between the two DPs of monolayer gaphene in the presence of substrate modulation is described by three vectors, $\boldsymbol{q}_1 = q(1, 0)$, $\boldsymbol{q}_2 = q(\frac{-1}{2}, \frac{-\sqrt{3}}{2})$, and $\boldsymbol{q}_3 = q(\frac{-1}{2}, \frac{\sqrt{3}}{2})$. Repeated hopping between the two valleys generates a k-space honeycomb lattice shown in Fig. 5(a). The unit vectors of this lattice are same as reciprocal vectors of the Moire pattern (MP) of this hybrid structure, namely, $\boldsymbol{b}_1^{\mathrm{MP}} = \boldsymbol{q}_1 - \boldsymbol{q}_2$ and $\boldsymbol{b}_2^{\mathrm{MP}} = \boldsymbol{q}_1 - \boldsymbol{q}_3$. The low-energy electron dynamics can be described by an effective Hamiltonian,

$$H_{\mathrm{eff}}(\boldsymbol{k}) = \begin{bmatrix} D(\boldsymbol{k}) & T_1 & T_2 & T_3 \\ T_1^\dagger & \overline{D}(\boldsymbol{k} - \boldsymbol{q}_1) & 0 & 0 \\ T_2^\dagger & 0 & \overline{D}(\boldsymbol{k} - \boldsymbol{q}_2) & 0 \\ T_3^\dagger & 0 & 0 & \overline{D}(\boldsymbol{k} - \boldsymbol{q}_3) \end{bmatrix}, \tag{3}$$

where $D(\boldsymbol{k}) = \hbar v_F \boldsymbol{k}\cdot\boldsymbol{\sigma}$, $\overline{D}(\boldsymbol{k}) = -\hbar v_F \boldsymbol{k}\cdot\boldsymbol{\sigma}^*$, and $T_m = w \exp(i\frac{2(m-1)\pi}{3}\sigma_z)$, $m = 1$, 2, and 3. Here $\boldsymbol{\sigma} = (\sigma_x, \sigma_y)$ and σ_z are Pauli matrices associated with the A and B sublattices of graphene. $D(\boldsymbol{k})$ and $\overline{D}(\boldsymbol{k})$ describe the Dirac cone at K and K', respectively, as the two cones are time-reversal partners. The derivation of the effective Hamiltonian can be found in the supplementary information. Using this effective Hamiltonian, we calculated the band structure along the path A-B-C-D-A and the DOS, see Fig. 5(b). For $\alpha = 0.1$, the DPs at B and C remained isolated meanwhile an energy gap is opened at the crossing point of two Dirac bands. The DOS shows a nearly linear dependence of energy and several peaks from VHSs, which is consistent with the tight-binding result in Fig. 4(a). When α increases to 0.586, a pair of absolutely flat bands exist at zero energy inside the band gap ($\Delta E \sim 2w$). This leads to a sharp zero-energy peak in DOS, which agrees remarkably well with the tight-binding DOS with $a_{\mathrm{sub}} = 4.370$ Å and $w = 0.05t$ as shown in the inset of Fig. 5(b). The perfect flatness of zero-energy bands is due to the chiral symmetry of the Hamiltonian, since H_{eff} is equivalent to the chirally symmetric continuum model proposed by Tarnopolsky et al.[21] (see the proof in the Methods Section). The intervalley transition matrices T_m ($m = 1$, 2, and 3) in H_{eff} contain only the diagonal AA and BB sublattice couplings

due to the on-site substrate potential and the fact that the wavefunctions of Dirac states at K and K' are defined with respect to the same A and B sublattices of monolayer graphene. As a result, monolayer graphene perturbed by an on-site substrate potential is a natural realization of the chirally symmetric model of flat bands[21]. The unique coupling $\alpha^* = 0.586$ corresponds to two 'magic' lattice constants according to Eq. 2,

$$a_{\mathrm{sub}}^* = \sqrt{3}a_{\mathrm{Gr}} \pm \frac{3wa_{\mathrm{Gr}}}{2\pi t \alpha^*}. \tag{4}$$

Plug in $\alpha^* = 0.586$, $a_{\mathrm{Gr}} = 2.46$ Å and $w = 0.05t$, we find that $a_{\mathrm{sub}}^* = 4.161$ and 4.361 Å. The magic lattice constants match the values (4.166 and 4.370 Å) we found in the tight-binding simulations. The small discrepancy between two results can be attributed to the finite size of the supercell we used in the tight-binding simulations. The effective Hamiltonian gives rise to a series of magic coupling a^* with a periodicity of $\Delta\alpha \simeq 1.5$ [11, 41, 42]. The second magic coupling is $a^* = 2.221$. The band structure with this magic coupling (the bottom panel of Fig. 5(b)) exhibits absolute flat bands at zero energy and a smaller band gap ($\Delta E \sim 0.2w$). The second and higher magic couplings correspond to a very small deviation from the commensurate lattice constant, $\Delta a \lesssim 0.02$ Å. It is technically challenging to detect such small lattice deviations in experiments, just like the smaller twists corresponding the higher magic couplings in the TBG systems. We note that the perfect flatness of the zero-energy bands is due to the absence of off-diagonal AB sublattice coupling in the model described by Eqn. 3. A detailed modeling of the substrate interaction indicates that substrate-mediated AB sublattice coupling exists and is smaller ($< 50\%$) in magnitue than the on-site AA(BB) coupling. The band calculation shows that the Moiré bands at zero energy remain highly flat even with the inclusion of off-diagonal AB coupling. The details can be found in the Supplementary Information.

4 Summary and Outlook

The low-energy dynamics in the graphene heterostructures is essentially governed by the coupling α, and α is determined by the separation q between two adjacent Dirac cones in the Moiré lattice. For $w = 0.05t$ (~ 140 meV) and $\alpha^* = 0.586$, $q = 0.04$ Å$^{-1} \ll |\Gamma K_{\mathrm{Gr}}| = 1.7$ Å^{-1}, which means the reciprocal lattice vectors of substrate must almost connect the two DPs at K and K' in momentum space, see Fig. 4(c). This places a constraint on the possible substrate lattice constants and orientations. To have flat bands, the largest possible substrate lattice constant corresponds to a $(\sqrt{3} \times \sqrt{3})R30°$ supercell of graphene, i.e., $a_{\mathrm{sub}} \approx \sqrt{3}a_{\mathrm{Gr}} = 4.26$ Å. This commensurate relation is also known as the Kekulé superlattice[43]. For other commensurate relations between graphene and substrates, the substrate lattice constant has to be $\lesssim \frac{\sqrt{3}}{2}a_{\mathrm{Gr}} = 2.13$ Å, which is very rare in real materials. Therefore, the substrate materials for the flat-band heterostructure must have a surface with C_3 rotation symmetry and lattice constant close to 4.26 Å. In Table 1, we list several materials which can be potentially employed in the proposed heterostructures. The suggested materials are all elemental or binary vdW materials and can be straightforwardly synthesized, for example, by the method of molecular beam epitaxy (MBE). The vdW nature of graphene and the suggested substrate materials facilitates the formation of an atomically sharp interface and thus enhances substrate interaction as well as intervalley couplings. In addition to the conventional assembly method by growing or transferring graphene onto the substrate surface, the proposed flat-band heterostructures can be readily synthesized via a "top-down" approach, as schematically plotted in Fig. 5(c). High-quality graphene layers can be epitaxially grown on the SiC(0001) surface, and the Dirac states of graphene remain isolated due to the large lattice mismatch. Therefore, the graphene/SiC structure can serve as a supporting substrate for the growth of various materials with nearly commensurate relations as suggested in Table 1. For example, Bi_2Se_3 ($a = 4.136$ Å) thin layers have been grown on the graphene/SiC(0001) surface [44].

Our ARPES experiments demonstrated the cloning of Dirac fermions in the graphene/SiC(0001) heterostructure due to the periodic modulation of the substrate potential. Our theoretical calculations showed this modulation effect from the substrate can effectively couple the two valleys of Dirac states in monolayer graphene in the nearly commensurate condition. The graphene heterostructures can be a promising

alternate system for exploring the intriguing flat-band physics that was found in TBG. The criterion for realizing flat bands is a matchup of the surface potential strength and the periodicity of the substrate to reach the magic effective coupling α^*. There are a vast number of possible substrate materials that could be potentially used in this hybrid structure. In addition, the charge and spin orderings in the substrates such as antiferromagnetism in MnTe[45], superconductivity in PdTe$_2$[46], and topological surface states in Bi$_2$Se$_3$[44] can further enrich flat-band physics in graphene via proximity effects, systematic investigations of which are left to future works.

5 Methods

5.1 Sample synthesis and characterizations

The graphene films were prepared by annealing a 6H-SiC(0001) substrate at 1150 °C in an integrated MBE-STM-ARPES ultrahigh vacuum (UHV) system with base pressure below 2×10^{-10} mbar. After the growth, the graphene samples were *in-situ* transferred the ARPES stage. ARPES measurements were performed at 100 K using a SPECS PHOIBOS-150 hemisphere analyzer with a SPECS UVS-300 helium discharge lamp (photon energy = 21.2 eV). The size of the beam spot on the sample was ~1.5 mm. The topography of the sample surface was mapped *in-situ* by an Aarhus STM equipped in the growth chamber.
The TEM samples were prepared by a lift-out method in a ThermoFisher Scientific Scios focused ion beam (FIB) instrument at room temperature, and imaged in the ThermoFisher Scientific G2 Tecnai F30 FEG high resolution TEM operated at 300 kV. The SiC substrate was tilted to the [100] zone axis and the lattice fringes from both the graphene and the SiC can be clearly resolved. Great care has been taken to reduce the beam damage on the thin film samples both during the FIB lift out and during the sample tilting and high-resolution image acquisition process.

5.2 Tight-bind modeling

To simulate the observed spectrum of the graphene on the top of the SiC film, we use the simplest graphene model with the inclusion of only the nearest neighbor hopping. Since SiC is an insulator with large gaps, the main low energy physics can be described by the graphene monolayer embedded in the surface potential of the SiC substrate. Although the details of the SiC surface potential is unknown, it suffices to employ an approximate potential that preserves the crystalline symmetry. The SiC surface belongs to the wallpaper group $P3m1$, thus the SiC surface potential can be written in this simplest form

$$W(x,y) = w\left(\cos(\pi\frac{4y}{3b}) + \cos(\pi\frac{-2\sqrt{3}x - 2y}{3b}) + \cos(\pi\frac{2\sqrt{3}x - 2y}{3b}) \right) \tag{5}$$

where b (1.77 Å) is the in-plane silicon-carbon distance on the SiC(0001) surface and $\boldsymbol{b}_{1,2} = \frac{2\pi}{3b}(\pm\sqrt{3}, -1)$. That is, the SiC potential includes only the first order of the Fourier series and breaks the C_6 rotation symmetry due to the different potentials stemming from Si and C atoms. We can write the effective low-energy Hamiltonian in the second quantization form

$$\hat{H} = \sum_{n,m} \left[t(a^\dagger_{n,m}b_{n,m} + a^\dagger_{n+1,m}b_{n,m} + a^\dagger_{n,m+1}b_{n,m} + \text{h.c.}) + W(x^+_{nm}, y^+_{nm})a^\dagger_{n,m}a_{n,m} \right.$$
$$\left. + W(x^-_{nm}, y^-_{nm})b^\dagger_{n,m}b_{n,m} \right], \tag{6}$$

where $x^\pm_{nm} = (\mp 1 + 3n - 3m)a/2$, $y^\pm_{nm} = (\sqrt{3}n + \sqrt{3}m)a/2$ and $a \approx 1.42$ Å is the carbon-carbon distance in graphene. A 400×400 supercell is employed in the calculations of band structure and DOS. By diagonalizing the Hamiltonian, we find the eigenstates within $E \pm \delta$. Then we transform the eigenstates to momentum space so that at energy E, the density of the wavefunctions can be plotted in momentum space.

5.3   Proof of equivalence to the chirally symmetric continuum model

In this section we show that the effective low-energy Hamiltonian of Eq. (3) is equivalent to the chirally symmetric continuum model of twisted bilayer graphene proposed by Tarnopolsky, Kruchkov, and Vishwanath [21], hereafter referred to as the TKV model. This model is noted for producing absolutely flat bands at special values of the twist angle when the interlayer hopping matrix is assumed to contain only off-diagonal AB and BA elements.

We start from Eq. (1) of Ref. [21] and rotate the spin matrices so that they are aligned along a common direction. This gives

$$H_{\text{TKV}} = \begin{pmatrix} -i\hbar v_F \boldsymbol{\nabla} \cdot \boldsymbol{\sigma} & \mathbf{T} \cdot \boldsymbol{\sigma} \\ \mathbf{T}^* \cdot \boldsymbol{\sigma} & -i\hbar v_F \boldsymbol{\nabla} \cdot \boldsymbol{\sigma} \end{pmatrix} \tag{7}$$

where $\mathbf{T}$ is a complex vector field with components in the (x, y)-plane,

$$T_x = t_\perp \sum_{n=1}^{3} \cos[(n-1)\phi]e^{-i\mathbf{q}_i \cdot \mathbf{r}}, \quad T_y = t_\perp \sum_{n=1}^{3} \sin[(n-1)\phi]e^{-i\mathbf{q}_i \cdot \mathbf{r}}, \quad \phi = 2\pi/3 \tag{8}$$

and $t_\perp$ is an interlayer hopping amplitude that connects A sites to B sites. The Hamiltonian (7) is a 4×4 matrix in the basis 1 ↑,1 ↓, 2 ↑, 2 ↓, where the first index denotes the layer and the second (pseudospin ↑ or ↓) refers to the A or B sublattices. The Pauli matrices act on the pseudospin indices.

We now perform a unitary transformation which interchanges the basis states 2 ↑ and 2 ↓. It is straightforward to verify that after this transformation the TKV Hamiltonian takes the form

$$\tilde{H}_{\text{TKV}} = \begin{pmatrix} -i\hbar v_F \boldsymbol{\nabla} \cdot \boldsymbol{\sigma} & T_x \sigma_0 - iT_y \sigma_z \\ T_x^* \sigma_0 + iT_y^* \sigma_z & -i\hbar v_F \boldsymbol{\nabla} \cdot \boldsymbol{\sigma}^* \end{pmatrix} \tag{9}$$

Lastly we perform the unitary transformation $U = \text{diag}\{1, \sigma_z\}$, which leads us to

$$\tilde{H}_{\text{TKV}} = \begin{pmatrix} -i\hbar v_F \boldsymbol{\nabla} \cdot \boldsymbol{\sigma} & T_x \sigma_z - iT_y \sigma_0 \\ T_x^* \sigma_z + iT_y^* \sigma_0 & i\hbar v_F \boldsymbol{\nabla} \cdot \boldsymbol{\sigma}^* \end{pmatrix} \tag{10}$$

Two important things have happened. First, the two diagonal blocks now describe a Dirac cone $-i\hbar v_F \boldsymbol{\nabla} \cdot \boldsymbol{\sigma}$ and an anti-Dirac cone $+i\hbar v_F \boldsymbol{\nabla} \cdot \boldsymbol{\sigma}^*$ rather than two homologous Dirac cones. Second, the off-diagonal blocks have become diagonal in pseudospin space, involving only the matrices σ_0 and σ_z.

Compare this with the real space representation of our effective Hamiltonian, Eq. (3) of the main text. This is

$$\tilde{H}_{\text{eff}} = \begin{pmatrix} -i\hbar v_F \boldsymbol{\nabla} \cdot \boldsymbol{\sigma} & w \sum_{n=1}^{3} e^{i\phi(1-n)\sigma_z} e^{-i\mathbf{q}_i \cdot \mathbf{r}} \\ w \sum_{n=1}^{3} e^{-i\phi(1-n)\sigma_z} e^{i\mathbf{q}_i \cdot \mathbf{r}} & i\hbar v_F \boldsymbol{\nabla} \cdot \boldsymbol{\sigma}^* \end{pmatrix} \tag{11}$$

where w is the amplitude of the substrate potential. Expanding the exponential we see that the off-diagonal block of this matrix is

$$w \sum_{n=1}^{3} \{\cos[(n-1)\phi]\sigma_0 - i\sin[(n-1)\phi]\sigma_z\} e^{-i\mathbf{q}_i \cdot \mathbf{r}} \tag{12}$$

which, in view of Eqs. (8), coincides with the off-diagonal element of the transformed TKV Hamiltonian (10), provided we set $t_\perp = w$.

Thus the diagonal substrate potential which connects the two valleys of monolayer graphene in our model corresponds to the off-diagonal interlayer hopping of the TKV model.
