Abstract

Using the N -body+Smoothed particle hydrodynamics code, ChaNGa, we identify two merger-driven processes—disk disruption and supermassive black hole (SMBH) feedback—which work together to quench L^* galaxies for over 7 Gyr. Specifically, we examine the cessation of star formation in a simulated Milky Way (MW) analog, driven by an interaction with two minor satellites. Both interactions occur within ~ 100 Myr of each other, and the satellites both have masses 5–20 times smaller than that of their MW-like host galaxy. Using the genetic modification process of Roth et al., we generate a set of four zoom-in, MW-mass galaxies all of which exhibit unique star formation histories due to small changes to their assembly histories. In two of these four cases, the galaxy is quenched by $z = 1$. Because these are controlled modifications, we are able to isolate the effects of two closely spaced minor merger events, the relative timing of which determines whether the MW-mass main galaxy quenches. This one–two punch works to: (1) fuel the SMBH at its peak accretion rate and (2) disrupt the cold, gaseous disk of the host galaxy. The end result is that feedback from the SMBH thoroughly and abruptly ends the star formation of the galaxy by $z \approx 1$. We search for and find a similar quenching event in ROMULUS25, a hydrodynamical (25 Mpc)³ volume simulation, demonstrating that the mechanism is common enough to occur even in a small sample of MW-mass quenched galaxies at $z = 0$.

1. Introduction

Benchmark astronomical surveys, such as the Sloan Digital Sky Survey (SDSS) and the Cosmological Evolution Survey (COSMOS), have revealed how the bimodality in galaxy properties evolves over redshift (e.g., Strateva et al. 2001; Bell et al. 2003; Baldry 2004; Brammer et al. 2009; Ilbert et al. 2010; Muzzin et al. 2013). Actively star-forming galaxies and non-star-forming, passive galaxies occupy two distinct regions of parameter space in color–magnitude diagrams and exhibit distinct morphologies (e.g., Wuyts et al. 2011; van der Wel et al. 2014) and stellar populations (e.g., Kauffmann et al. 2003b; Gallazzi et al. 2008; McGee et al. 2011; Wetzel et al. 2012; López Fernández et al. 2018). Theoretical studies have been able to reproduce the bimodal galaxy distributions in the star formation rate (SFR; Feldmann et al. 2017), morphology (Snyder et al. 2015), and color (Kang et al. 2005; Nelson et al. 2018); however, no theoretical consensus has yet emerged to explain the increase of quenched galaxies observed from $z \sim 1$ to present day (Bell et al. 2004; Ilbert et al. 2013).

The general decline in the SFR toward $z \sim 0$ has been well described by observational studies (e.g., Noeske et al. 2007; López Fernández et al. 2018), and this process is almost certainly influenced by a decrease in cool gas supply in the local universe (e.g., Putman et al. 2012). However, there are many large-scale and small-scale processes that can impact the star formation properties of a galaxy.

Peng et al. (2010) describe two main quenching pathways: environmental (Kauffmann et al. 2004; Baldry et al. 2006;

Bahé & McCarthy 2015) and mass (Kauffmann et al. 2003a) quenching. Examples of such quenching processes include halo quenching or starvation—two types of mass quenching—each cite a specific source driving their quenching.

For example, halo quenching relies on the long cooling times of high-temperature ($\sim 10^6$ K) halo gas (Rees & Ostriker 1977; Kauffmann et al. 1993; Somerville & Davé 2015). As intergalactic medium (IGM) gas enters a high-mass ($M_{\text{halo}} \gtrsim 10^{11} M_{\odot}$) galaxy through filaments, it shock heats to the virial temperature of the galaxy (Keres et al. 2005; Dekel & Birnboim 2006), ultimately depriving galaxies of their star-forming fuel. However, within these massive halos, star formation suppression through this mode can be less efficient in high baryon fraction galaxies (Benson et al. 2003) and cool gas may still permeate through shocked regions and accrete onto the galaxy (Brooks et al. 2009; Dekel et al. 2009; Nelson et al. 2013).

Similarly, the process that includes the physical removal and suppression of the gaseous fuel of a galaxy is called starvation and occurs in both low- and high-mass galaxies. In low-mass galaxies with small gravitational potential wells, star formation feedback processes—such as stellar winds, radiation, and energy ejected via supernovae—are powerful enough to strip galaxies of some or all of their gas (Larson 1974; Dekel & Silk 1986). In more massive galaxies, active galactic nucleus (AGN) feedback is a likely culprit for ejecting the cool gas from a galaxy disk through powerful outflows (Fabian 2012; Cicone et al. 2014; Feldmann & Mayer 2015; Feldmann et al. 2016) and enriching the circumgalactic medium (CGM) with

metals formed in the disk (Suresh et al. 2017; Nelson et al. 2018; Sanchez et al. 2019). In some cases, the AGN feedback energy can be strong enough to expel gas out of the CGM into the intracluster medium (ICM; Oppenheimer et al. 2020). Additionally, the large-scale cooling regulation that occurs in the CGM may drive gas back toward the galaxy, which can then further fuel the AGN, in a self-regulating galactic fountain (Gaspari et al. 2013; Anglés-Alcázar et al. 2017; Voit et al. 2017; Tremblay et al. 2018; Nelson et al. 2019; Chadayammuri et al. 2020). Nevertheless, the AGN alone may not be capable of fully quenching a galaxy (Di Matteo et al. 2005; Pontzen et al. 2017; Trussler et al. 2020), and observations of highly star-forming galaxies can still show significant AGN activity (Nandra & Iwasawa 2007; Simmons et al. 2012; Rosario et al. 2013; Mullaney et al. 2015; Bruce et al. 2016).

In both of these cases, halo quenching and starvation, the main source of quenching comes from a specific physical driver—long cooling times and feedback processes—while observational evidence shows that these sources of quenching can be disrupted by other galactic properties such as AGN feedback in bright star formation galaxies. Furthermore, additional studies find that the combination of halo quenching and the AGN activity driving starvation can work together to reduce star formation in some galaxies (Bower et al. 2017; McAlpine et al. 2020). In our study, we focus on the combination of physical processes that drive galaxy quenching through galaxy mergers. A third quenching process described by Peng et al. (2010), merger quenching, is mostly independent of mass and is typically associated with a major merger resulting in the cessation of star formation in a galaxy (Toomre & Toomre 1972; Springel et al. 2005; Cox et al. 2006; Gabor et al. 2010). However, we uniquely investigate this type of quenching through a series of minor merger interactions, rather than as the result of a single major merger.

We use a carefully constructed set of initial conditions to study merger-driven quenching within a controlled environment. Our study follows that of Pontzen et al. (2017, hereafter, P17) who investigate quenching by black hole feedback and merger effects in tandem. P17 utilize the genetic modification technique (GM; Roth et al. 2016) to create a suite of cosmological simulations of Milky Way-mass (MW-mass) halos at $z = 2$ with assembly histories that have been modified in controlled ways. The environment and assembly history of each galaxy in the suite was nearly identical, except for a significant merger event with varying mass ratios (1:10, 1:5, and 2:3) occurring at $z < 2$. The resulting physical state of the main galaxy ranges from star-forming to temporarily quenched to permanently quenched due to the interplay between the major merger and supermassive black hole (SMBH) feedback. In the permanently quenched case (2:3), P17 show that the combined effort of the merger and the SMBH feedback work together to halt star formation: the merger disrupts the disk while the AGN feedback ejects and heats some, but not all, of the cold disk gas. It is the lack of an orderly disk that prevents further star formation despite some cool gas remaining in the galaxy.

We follow the methods of P17 to investigate quenching in a new suite of genetically modified MW-mass galaxies at $z = 0$. However, we note that P17 examines the major mergers likely to occur at high- z for more massive halos, while we focus on MW-mass galaxies which have more quiet recent histories, like our own MW. In this study, we examine the influence of a

more minor modification within these simulations and show that two minor mergers can lead to a unique form of quenching in MW-mass galaxies.

This paper is organized as follows. Section 2 details our set of simulations and describes the genetic modification process. Section 3 reports our findings and results. In Section 4, we summarize our results and discuss the broader implications of our findings.

2. Simulation Parameters

To create our sample of galaxies, we used the modern SPH code, Charm N -body GrAvity solver (ChaNGa; Menon et al. 2015). ChaNGa inherits the same physical models as Gasoline (Wadsley et al. 2004, 2017) and includes the following physical prescriptions: cosmic UV background (Haardt & Madau 2012), star formation (using an IMF given by Kroupa 2001), and blastwave supernova feedback (Ostriker & McKee 1988; Stinson et al. 2012, for more details), including both SNIa and SNII (Thielemann et al. 1986; Woosley & Weaver 1995). SNII feedback imparts 10^{51} erg of thermal energy per supernova onto surrounding gas particles. Low-temperature metal line cooling (Stinson et al. 2006; Wadsley et al. 2008; Shen et al. 2012) is included to allow gas below 10^4 K to cool proportionally to the metals in the gas. Gas above this threshold cools only via H/He, Bremsstrahlung, and inverse Compton. No high-temperature metal cooling is included due to the resolution of our simulations, which does not resolve individual star-forming regions (see Tremmel et al. 2019, for more detailed discussion).

Our simulations use an improved set of black hole (BH) prescriptions including formation, accretion, and dynamical friction (Tremmel et al. 2017). SMBH seeds form from dense, extremely low-metallicity gas particles that allow BHs to form early in low-mass halos, as predicted by the majority of theoretical models. Subgrid models for SMBH accretion and dynamical friction have been implemented, including realistic SMBH mergers and dynamical evolution. SMBH dynamics are accurately followed down to subkiloparsec scales (Tremmel et al. 2015). In particular, the subgrid model for accretion takes into account angular momentum support from nearby gas particles. This model allows for more physical growth compared to strictly Bondi–Hoyle accretion and does not require additional assumptions or free parameters. Angular momentum support is included in the accretion equation

$$\dot{M} \propto \frac{\pi (GM_{\text{BH}})^2 \rho c_s}{(v_\theta^2 + c_s^2)^2}, \quad (1)$$

where ρ is the density of the surrounding gas, c_s is the sound speed, and v_θ is the rotational velocity of the surrounding gas. The quantity v_θ is informed by the angular momentum support of this gas on the smallest, resolvable scale. Additionally, a density-dependent boost factor is implemented to avoid underestimating SMBH accretion rates due to resolution affecting temperature and density calculations of nearby gas. Using the prescription of Booth & Schaye (2009), the standard Bondi rate is scaled by a density-dependent factor, $(n_{\text{gas}}/n_*)^\beta$, where n_* is the star formation density threshold and β is a free parameter. Combined, the density-dependent boost factor and inclusion of angular momentum support results in the full

equation from Tremmel et al. (2017),

$$\dot{M} = \alpha \times \begin{cases} \frac{\pi(GM)^2\rho}{(v_{\text{bulk}}^2 + c_s^2)^{3/2}} & \text{if } v_{\text{bulk}} > v_\theta \\ \frac{\pi(GM)^2\rho c_s}{(v_\theta^2 + c_s^2)^2} & \text{if } v_{\text{bulk}} < v_\theta \end{cases}; \quad (2)$$

$$\alpha = \begin{cases} \left(\frac{n}{n_{\text{th},*}}\right)^\beta & \text{if } n \geq n_{\text{th},*} \\ 1 & \text{if } n < n_{\text{th},*}, \end{cases}$$

where v_{bulk} is the smallest relative velocity of the SMBH's 32 nearest gas particles. Thus, in cases where bulk motions dominate over rotational motion, the formula reverts to Bondi–Hoyle.

Thermal SMBH feedback energy is determined by the accreted mass, $\dot{M}$, and imparted on the nearest 32 gas particles according to a kernel smoothing of

$$E = \epsilon_r \epsilon_f \dot{M} c^2 dt, \quad (3)$$

where $\epsilon_r = 0.1$ and $\epsilon_f = 0.02$ are the radiative and feedback efficiency, respectively. Accretion is assumed to be constant over one black hole timestep, dt . Cooling is shut off immediately after AGN feedback events for a short ($\sim 10^{4-5}$ years) time. These choices were calibrated against dozens of zoom-in simulations to broadly reproduce observed galaxy and SMBH scaling relations. Furthermore, this SMBH feedback prescription is shown to produce large-scale outflows (Pontzen et al. 2017; Tremmel et al. 2019). For more details on the SMBH prescriptions, see Tremmel et al. (2017).

Our simulations were each run with the same Λ CDM cosmology, $\Omega_m = 0.3086$, $\Omega_\Lambda = 0.6914$, $h = 0.67$, $\sigma_8 = 0.77$ (Ade et al. 2016), and have a Plummer-equivalent softening length of 250 pc (a spline kernel of 350 pc is used). Initial conditions were generated using genetIC (Stopyra et al. 2020).

2.1. Halo and Merger Identification

Individual halos are selected using the post-processing tool AMIGA HALO FINDER, which selects halos using an overdensity criteria and grid based system that iteratively removes particles that are gravitationally unbound from prospective halos (Knebe et al. 2001; Gill et al. 2004; Knollmann & Knebe 2009). Virial mass, M_{vir} , and virial radii, R_{vir} , are determined using a spherical top-hat collapse technique. Halos are traced backwards through time from $z=0$ to previous snapshots, following the halo from the previous snapshot which contains the majority of the same particles using the analysis tools pynbody (Pontzen et al. 2013) and TANGOS (Pontzen & Tremmel 2018).

Merger ratios are defined at infall, during the snapshot just before the center of the satellite halo has first passed into the virial radius of the main halo (Table 1), and are calculated as $q = M_{\text{vir,halo}}/M_{\text{vir,satellite}}$. Larger infall ratios indicate mergers with smaller satellite galaxies.

These following zoom-in simulations were first described in Sanchez et al. (2019), which compared the O VI column densities within these galaxies to observations from the Cosmic Origins Spectrograph (COS) Halos Survey. This previous study examined the effects of star formation history and SMBH feedback on the circumgalactic medium. They found that while differences in the star formation histories of the galaxies did not

Table 1
Timing of the Minor Merger Scenarios

Sim	Sat 1 Infall Ratio	Sat 1 Flyby	Sat 1 Merger	Sat 2 Infall Ratio	Sat 2 Flyby	Sat 2 Merger	SMBH Accretion Peak
	q	Gyr	Gyr	q	Gyr	Gyr	Gyr
R0	5.4	4.76	7.57	13.6	5.60	6.53	6.95
GM1	7.3	4.69	7.39	14.6	5.40	6.35	6.74
GM2	8.2	4.43	5.42	18.9	5.44	6.80	5.59
GM3	9.5	4.39	5.41	17.9	5.49	7.13	5.84

Note. Details about satellite interactions in our four GM galaxies, including infall merger ratios, flyby times, merger times, as well as the time of the peak accretion rate of the SMBH. Infall merger ratios, q , are defined as $M_{\text{vir,halo}}/M_{\text{vir,satellite}}$ at the simulation output before the satellite enters the main halo. Flyby and merger times were determined by visual examination of ppm image files created on the fly during simulation with a cadence ~ 3 Myr.

result in significant variations in the amount of O VI in the CGM of these galaxies, SMBH feedback was a significant driver of the metals into the CGM.

2.2. The Genetic Modifications

We selected a MW-mass organic galaxy, henceforth R0, ($M_{\text{halo}} = 9.9 \times 10^{11} M_\odot$) from an initial, dark-matter-only cosmological volume that had uniform resolution and was 50 Mpc on a side. R0 was selected for the Large Magellanic Cloud-mass (LMC-mass, $M_{\text{sat}} = 2 \times 10^{10} M_\odot$) satellite galaxy which was contained within its virial radius at $z=0$, and was otherwise isolated (>2 Mpc) from other MW-mass galaxies. Once selected, we define a Lagrangian region associated with this halo to create the zoom-in simulation of our R0 galaxy using the technique of Katz & White (1993). This zoom-in R0 includes baryons and their related physics while only resimulating a few virial radii from the main halo at the highest resolution ($M_{\text{gas}} = 2.1 \times 10^5 M_\odot$, $M_{\text{DM}} = 1.4 \times 10^5 M_\odot$) while large-scale structure at farther distances are simulated only in dark matter (DM) at a much coarser resolution.⁷

To create the subsequent GM galaxies, we used the method of Roth et al. (2016) to modify the initial conditions of R0 by decreasing the mean overdensity associated with the particles in the LMC-mass satellite which was present in R0 at $z=0$. With this method, we created three GM galaxies (GM1, GM2, and GM3), each modified to result in a subsequently smaller satellite mass (see Table 1; Sanchez et al. 2019). The benefit of this method is that it allows us to fix the large-scale structure and the final mass of the main halo ($M_{\text{vir}} \sim 10^{12} M_\odot$) while varying specific aspects of the halos assembly history. The simulations resulted in a set of four galaxies which, despite controlling for large-scale environment and only slightly modifying the assembly of the halo, have varying baryonic evolution. Two of these galaxies, R0 and GM1, are star-forming disk galaxies, similar to the MW, while two of these galaxies, GM2 and GM3, unexpectedly become quenched at $z \sim 1$ (Figure 1).

Simulation snapshots of particle data had varying cadences with medians of 700 Myr and 200 Myr for R0 and GM1, respectively, and 400 Myr for both GM2 and GM3. Additional

⁷ Correction: Sanchez et al. (2019) states that the DM mass is $3.4 \times 10^5 M_\odot$, which is the DM mass resolution for ROMULUS25 not the GM galaxies.

Figure 1. Star formation histories of our four GM galaxies. The star-forming galaxies, R0 and GM1, are shown in dark and light blue; the quenched galaxies, GM2 and GM3, are shown in dark and light red; and the main-sequence SFR, for $M_{\text{star}} = 5 \times 10^{10} M_{\odot}$ at $z = 0$, is shown in purple (Whitaker et al. 2012). All four of our galaxies begin with very similar initial conditions that have been genetically modified to shrink the mass of a satellite that enters the main halo at $z = 1$. Despite their similar beginnings, two of the galaxies, R0 and GM1, remain star-forming through their lives, while the others, GM2 and GM3, quench just after $z = 1$ and remain that way until $z = 0$ (~ 8 Gyr).

static images were created on the fly during each simulation with a cadence of 3 Myr.

While first introduced in Sanchez et al. (2019), two of these zoom-in simulations (GM2 and GM3) were additionally discussed in Cruz et al. (2021), which examined the effect of self-interacting DM models on SMBH growth histories. Though the effects of varying assembly and star formation have been explored in these papers, no thorough treatment describing the quenching in these galaxies has yet been put forth. The purpose of the present paper is to explore the physical processes driving quenching in these galaxies.

2.3. The ROMULUS25 Cosmological Volume

ROMULUS25 (Tremmel et al. 2017, hereafter R25) is a 25 Mpc cosmological volume that includes galaxies between halo masses of 10^9 – $10^{13} M_{\odot}$. The galaxies in R25 have been shown to lie along the M_{BH} – M_{star} , stellar mass–halo mass, and M_{BH} – σ relations (Ricarte et al. 2019), and are consistent with observations of star formation and SMBH accretion histories at high redshift (Tremmel et al. 2017). Furthermore, Tremmel et al. (2017) shows that SMBH physics play a necessary role in reproducing MW-mass galaxy evolution and quenching in high-mass galaxies. R25 has a mass resolution of $M_{\text{gas}} = 2.1 \times 10^5 M_{\odot}$ and $M_{\text{DM}} = 3.4 \times 10^5 M_{\odot}$ for gas and DM particles, respectively.

For our study, we examine a set of 26 MW-mass galaxies that have final halo masses, M_{halo} , between 5×10^{11} and $2 \times 10^{12} M_{\odot}$ and that are not satellites of a more massive halo at $z = 0$. Our M_{halo} measurements use the corrections of Munshi et al. (2013).

3. Results

3.1. Differences in Merger Timings

Due to the constraints that maintain the final mass of the main halo while changing the LMC satellite mass, the genetic

Figure 2. SMBH accretion rates for our four GM galaxies across time averaged using a rolling mean of 450 Myr. The peak of accretion and feedback energy occurs earlier in both quenched galaxies, within ~ 100 Myr of the double satellite interaction ($z \sim 1$). The timing of the satellite interactions are indicated in blue for the star-forming galaxies, and red for the quenched cases. Triangles connected with a dashed line indicate the interaction period of the first satellite, from initial flyby (open marker) to time of its merger with the main halo (solid marker). For the second satellite interaction, open and closed squares indicate the initial flyby and time of merger, respectively. See Table 1 for flyby and merger times.

modification technique affects the timing of accretion throughout the evolution of the galaxy. In GM2 and GM3, our two quenched cases and those with the smallest satellite masses, the accretion of satellites onto the main galaxy must occur faster and therefore earlier to maintain the final mass of the main halo. Consistently, SMBH accretion also peaks earlier ($z \sim 1.18$), nearly 1 Gyr before the peak of SMBH accretion in the two star-forming cases, R0 and GM1 (Figure 2, discussed in detail below). The differences in timing and the order of the minor mergers that occur are key to understanding the effect of the quenching in these two galaxies.

We note that the variations between the two star-forming galaxies themselves are minimal. Similarly, the two quenched cases have timing and sequence that are closely similar (Table 1). For that reason, we will generalize to two cases: the star-forming case and the quenched case.

Figure 3 illustrates the differences in the order and timing of the minor mergers in the star-forming (upper panels) and quenched cases (lower panels). In the star-forming case, (1) satellite 1 and satellite 2 are both infalling toward the galaxy of the main halo by $t \sim 4.7$ Gyr, when satellite 1 does a flyby of the main galaxy. (2) Satellite 2 then does a flyby nearly a gigayear later at $t \sim 5.5$ Gyr. (3) Satellite 2 merges another gigayear after that at $t \sim 6.4$ Gyr. (4) Finally, satellite 1 merges last at nearly $t \sim 7$ Gyr.

In the quenched case, the order and timing of these same interactions are markedly different. (1) Satellite 1 does its flyby nearly half a gigayear earlier ($t \sim 4.4$ Gyr) than in the star-forming case, consistent with the earlier, faster accretion expected from the galaxies with the most significantly shrunken satellite mass. (2) A gigayear after the flyby of satellite 1, satellite 1 merges with the main halo at $t \sim 5.4$ Gyr and the flyby of satellite 2 quickly follows, occurring within the next 100 Myr. In the quenched case, (3) satellite 2 is the last to merge, a little more than 1.5 Gyr after the double interaction

Figure 3. Diagram detailing the order of the satellite merger scenario in the star-forming (upper) and quenched (lower) cases. In the star-forming case, the satellite interactions occur in this order: flyby of satellite 1, flyby of satellite 2, then the merger of satellite 2, and finally satellite 1 merges last. In the quenched case, the order of these interactions is different. Satellite 1 still interacts with a flyby first, however it then merges with the main halo within a gigayear. Shortly after (<100 Myr), the flyby of satellite 2 occurs. Additionally, in the quenched case, the time when satellite 1 merges and satellite 2 does its flyby is shortly followed by the peak of SMBH accretion in these galaxies (a few 100 Myr).

preceding it. The specific order and timing between these interactions are what set the stage for the stark result of quenching in this galaxy rather than continued star formation.

Figure 4 includes a series of gas density maps spanning the time of these interactions. GM1, our star-forming case, is shown on the left, while GM2, our quenched case, is on the right. At $t \sim 5.2$ Gyr in the star-forming case (upper left), satellite 1 has completed its flyby of the main galaxy and is still moving away from it, while satellite 2 is infalling. At this time, our quenched GM2 (upper right) has experienced the same interaction. However, by $t \sim 5.6$ (middle left panel), satellite 2 in GM1 has completed its flyby of the main galaxy and satellite 1 is falling back toward it returning from its initial flyby. In contrast (middle right panel), satellite 1 in GM2 has fully merged with the main halo by this time, with satellite 2 having completed its flyby as well. Finally, at $t \sim 5.9$ (bottom left panel), both GM1 satellites are now infalling back toward the main galaxy. In GM2, (bottom right panel), satellite 2 alone is infalling and will complete its merger in about another gigayear.

3.2. Satellite Interactions and SMBH Feedback

While we have shown that these interactions do not have a large effect on the star-forming cases, R0 and GM1, both GM2 and GM3 experience significant outflows at $z \sim 1$, quenching the galaxy completely for the rest of the simulation (Figure 5). In Figure 6, outflows and inflows are calculated by measuring the velocity of the gas passing through a shell at the virial radius with thickness of $0.1R_{\text{vir}}$. While the inflow rates of the galaxies generally follow a similar shape (dotted lines), a clear and significant difference is present in the outflows (solid lines). While there is no large outflow in the star-forming case (blue solid line), in the quenched case there is a large outflow

(red solid line) directly following the minor satellite interactions and SMBH accretion peak at $t \sim 6$ Gyr. These outflows expel most of the gas from the disk, removing the fuel supply for further star formation (Figure 7).

We investigate the galaxy properties during the time just before quenching in GM2 and GM3 to understand why they quench while the others do not. Specific characteristics of the merger do not appear to be drivers of the quenching (Table 2). No significant differences arise between the primary halos with regard to the total virial mass, gas mass, or stellar mass at the time of the merger or leading up to it. There is also no significant difference between the amount of cold ($<2 \times 10^4$ K) gas in the disk or the entire halo (Figure 7). We do not find significant differences between the properties of the star-forming and quenched galaxies prior to $z = 1$ (Figure 8), instead determining that the main difference between these GM simulations is directly related to the timing of their satellite interactions.

Figure 2 not only shows the accretion rate of the SMBH at the center of each GM main galaxy, but additionally the timing and sequence of the satellite interactions are marked. In the star-forming cases (solid lines in blue), the mass of the SMBH continues to grow during the times of the mergers ($z \sim 1$) and the first peak of SMBH accretion occurs at $t \sim 6.8$ Gyr. This peak in accretion coincides closely with the merger of satellite 2, but without disrupting star formation. In comparison, the peak of SMBH accretion in the quenched cases occurs at $t \sim 5.8$ Gyrs, following both the merger of satellite 1 and flyby of satellite 2 within a few megayears. This set of interactions is followed by a significant outflow at $t \sim 6$ Gyr, after which the galaxies remain quenched for the rest of their lives.

Given no significant differences in the physical characteristics of the galaxies, or their SMBHs, prior to the series of

Figure 4. Gas density maps of the star-forming galaxy, GM1, and quenched galaxy, GM2, around the times of the minor satellite interactions. Left: in GM1, satellite 1 and 2 are both infalling at $z = 1.18$ (top panel). About a half a gigayear later (middle panel), satellite 2 has completed its flyby and satellite 1 is still infalling toward the main halo. By $z = 1$, both satellites are making their way toward the main halo where they will finally merge around $t \sim 7.5$ and $t \sim 6.5$ for satellite 1 and 2, respectively. Right: in GM2, one of our quenched galaxies, the order and timing of these interactions have some key differences. At $z = 1.18$ (top panel), like in the star-forming GM1, the main halo of GM2 has experienced the flyby of satellite 1, while satellite 2 is still in its initial infall. However by $z = 1.06$ (middle panel), satellite 1 has fully merged with the main halo and satellite 2 has completed its flyby, in contrast to the star-forming case which still shows both satellites. Finally at $z = 0$ (bottom panel), satellite 2 is infalling back toward the main halo and will merge with it in about 1.5 Gyr.

Figure 5. Gas density (left) and temperature maps (right) of the star-forming galaxy, GM1, and quenched galaxy, GM2. The upper panels show both galaxies long before the minor merger interactions that quenched GM2 while both galaxies experience a time of disk stability. The lower panels of each galaxy show them at a time long after the interaction has impacted the galaxies, showing the stable disk that GM1 has maintained through the series of interaction at $z = 1$ and the complete lack of disk and cold gas in GM2.

Figure 6. The mass flow as a function of time in GM1, the star-forming case, and GM2, the quenched case. Blue lines denote GM1, one of our star-forming galaxies, and red lines denote GM2, one of the quenched cases. Dotted lines indicate inflow at the virial radius, while solid lines indicate outflow at the virial radius. The minor satellite flybys and mergers are indicated as in Figure 2. A significant outflow occurs at $z \sim 1$, directly following the minor satellite interaction (when satellite 1 merges and satellite 2 follows with a flyby) and the peak in SMBH accretion.

interactions that occur at $z \sim 1$, we then look to the dynamics of the disk to better understand how the differences in galaxy accretion history arise. Figure 9 shows the circularity parameter (j_z/j_{circ} ; see Keller et al. 2015; Simons et al. 2019 and references therein) of cold gas ($T < 2 \times 10^4$ K) for the star-forming, R0, and quenched, GM2. The galaxy disk is first oriented on the total angular momentum of the gas within 5 kpc of the galaxy center. Then for each cold gas particle within 20 kpc, the circularity parameter is calculated as the ratio of its specific angular momentum component perpendicular to the disk (j_z) and the specific angular momentum for the theoretical

circular orbit of that particle in its current potential (j_{circ}). Values of j_z/j_{circ} closer to 1 indicate gas that is rotationally supported in a disk, while gas with $j_z/j_{\text{circ}} < 0.5$ is dispersion dominated. Gas prior to the merger (upper panels) is stable and mostly rotationally supported in both galaxies. Differences arise after the mergers occur (lower panels). We see that GM1 (bottom left panel), our star-forming case, retains a stable disk that has become compacted after the merger (Dekel & Burkert 2014). While GM2 (bottom right panel), our quenched case, has cold gas that is no longer rotationally supported in a disk (j_z/j_{circ} values closer to zero). This difference is a key component in our result.

3.3. The Quenching Combination

In both the GM cases where the galaxy quenches after $z = 1$, the difference in the satellite merger combination is present. Additionally, the earlier accretion of satellite 1 feeds the SMBH with its gas, resulting in an earlier peak of SMBH accretion than in the star formation galaxies. We determine that the subsequent disruption of the disk in these quenched cases—through the minor merger interaction of the merger and subsequent flyby—allows the resulting SMBH feedback (from the peak of SMBH accretion) to eject a majority of the cold gas in the disk (Figure 7). This one-two punch combination of minor satellite interactions, in tandem with the SMBH feedback, works to quench the galaxies until $z = 0$. In short, to quench these galaxies, the combination of fuel given to the SMBH by satellite 1 and the disruption of the main galaxy disk by both satellite interactions results in SMBH-driven outflows strong enough to quench the galaxy until $z = 0$.

Our result is broadly consistent with that of Pontzen et al. (2017). Their results from a different set of genetically modified galaxies show that a disk instability resulting from an interaction is necessary for a galaxy to quench. Another requirement for quenching is the presence of an SMBH, and in particular they concluded that continuous bursts of feedback were necessary to maintain their quenched galaxies. Sanchez

Table 2
Properties of Zoom-in Galaxies Prior to Minor Merger Interactions

Sim	Total Halo Mass ($M_\odot$)	Total Gas Mass ($M_\odot$)	Total Stellar Mass ($M_\odot$)	Cold Gas Mass ($M_\odot$)	Dense Gas ($M_\odot$)	R_{vir} (kpc)	T_{vir} (K)
R0 ($z \sim 1.18$)	5.7×10^{11}	7.1×10^{10}	1.3×10^{10}	4.1×10^9	7.0×10^9	122.8	8.3×10^5
GM1 ($z \sim 1.32$)	4.9×10^{11}	6.0×10^{10}	1.2×10^{10}	3.7×10^9	7.0×10^9	110.0	8.4×10^5
GM2 ($z \sim 1.32$)	5.1×10^{11}	6.4×10^{10}	9.1×10^9	5.0×10^9	4.6×10^9	111.4	8.6×10^5
GM3 ($z \sim 1.32$)	5.0×10^{11}	6.0×10^{10}	7.5×10^9	5.0×10^9	3.3×10^9	110.5	8.4×10^5

Note. Details about the simulations prior to the beginning of the minor merger interactions at $z \sim 1$, including total virial halo mass, total gas mass, total stellar mass, cold gas mass, and dense gas mass, all in the main halo. Virial radius and virial temperature of the halo are also included. The properties of R0 are shown at $z \sim 1.18$ due to the limited number of simulation outputs available for this simulation. The properties of the three other simulations are shown at $z \sim 1.32$.

Figure 7. Cold disk gas ($T < 2 \times 10^4$ K, $R < 0.1R_{\text{vir}}$) and cold gas mass ($T < 2 \times 10^4$ K, $R < R_{\text{vir}}$) in our GM galaxies. Upper: prior to ~ 6 Gyr, the amount of cold gas in the disk of the star-forming and quenched galaxies is not significantly different. Lower: similarly, we see consistent amounts of total cold gas mass in all four of the halos prior to this time. However, in both figures, once the minor satellite interactions occur (red filled triangle and open red square) and the SMBH accretion rate peaks in GM2 and GM3 (lower down-turned black arrow), the majority of this cold gas is removed in a large outflow from the disk (Figure 6). Line colors, styles, and marker styles are as those in Figure 2.

et al. (2019) further refined the latter requirement by examining R0 and the same GM galaxies explored in this paper, both with and without BHs. Unlike in P17 however, we find that a single burst of SMBH is enough to quench two of our galaxies for

nearly 8 Gyr without further episodes of SMBH feedback. We attribute these varying results to the differences in redshift and galaxy mass in each study, ours exploring lower mass galaxies at low redshift.

3.4. Quenching Galaxies in a Broader Context

Each of our quenched galaxies has an interaction timescale of ~ 100 Myr between when satellite 1 merges and satellite 2 does its subsequent flyby. The timescale between the mergers of each satellite in the quenched cases are on the order of 1 Gyr (bottom panels in Figure 3). In contrast, the order and timing of the flybys and mergers are markedly different for the two cases in which star formation does not cease. While in these cases satellite 2 merges before satellite 1, these distinct events are separated by a similar 1 Gyr (top panels, Figure 3). We use the timing constraints above to guide an analysis of quenching in the larger, cosmological simulation, ROMULUS25 (Tremmel et al. 2017). The purpose of this analysis is to understand the role of minor mergers in quenching MW-mass galaxies, which has thus far been unexplored.

To constrain how likely this type of event might be in the ($z \sim 2$) universe, we examine a population of MW-mass galaxies from the cosmological volume of R25. While a larger DM-only volume may provide a more statistically significant measurement for how often these minor mergers occur in MW-mass galaxies overall, we choose instead to select our additional sample from R25. First, it provides a larger, uniform sample of isolated MW-mass galaxies with the same physics and resolution as the GM simulations. Second, as we are interested in determining whether the combination of minor mergers and the effects of the SMBH can result in a quenched galaxy similar to what we see in the GM suite, a larger DM-only simulation would not be sufficient due to the lack of baryonic physics.

From R25, we examined 26 MW-mass galaxies, 8 of which are quenched by $z = 0$. To create this sample, we selected all the MW-mass galaxies in R25 with M_{vir} between $5 \times 10^{11} M_\odot$ and $2 \times 10^{12} M_\odot$ at $z = 0$ that were not satellites of a more massive halo. There were 26 MW-mass galaxies with these characteristics, each with varying star formation and accretion histories. From each galaxy, we selected every minor satellite merger ($q > 3$) that had a mass ratio between 3 and 20 that occurred within $z = 0.5 - 2$.

We find that 70% (18/26) of MW-mass galaxies in R25 experience multiple minor mergers occurring within 1 Gyr of each other. Of this population, one galaxy experiences a peak in SMBH activity associated with the merger event which then quenches within a few hundred megayears, similar to our two

Figure 8. The total gas and total stellar mass for the four GM galaxies. Prior to ~ 6 Gyr, there is little variation in either the total gas mass (upper) or stellar mass (lower) of the star-forming or quenched galaxies. The key difference affecting the overall properties of the galaxies after $z \sim 1$ is the timing between the minor mergers. Line colors, styles, and marker styles are as those in Figure 2. The timing between the mergers in the star-forming case (~ 1 Gyr) is significantly longer than that of the quenched case (~ 100 Myr) in which the timing of the minor merger interaction coincides with the peak of the SMBH accretion in the quenched case.

Figure 9. Plots of the circularity parameter j_z/j_{circ} of the cold gas ($T < 10^5$ K) for the star-forming MW-mass galaxy, GM1, and a quenched MW-mass galaxy, GM2, around the time of the satellite merger in each galaxy. Gas that has j_z/j_{circ} closer to 1 is rotationally supported (i.e., in a disk), while gas with j_z/j_{circ} closer to zero is dispersion supported. Top: prior to the satellite mergers, which result in GM2 quenching, both galaxies have fairly stable gaseous disk components. Bottom: after the interaction and mergers occur, however, the star-forming galaxy (left) retains a stable disk. You can also see compaction of the gas in the post-merger case (Dekel & Burkert 2014). Meanwhile the quenched galaxy (right) at the post-merger time lacks a stable cold gas disk.

quenched GM simulations. This quenched galaxy is one of eight MW-mass galaxies that are quenched at $z=0$ in the simulation. The total number of galaxies in R25 is therefore too

small to make a meaningful statistical statement. Nevertheless, the existence of a single example within such a small volume confirms that the minor merger and AGN scenario we have

outlined will arise completely naturally and contribute to quenching in Λ CDM cosmologies. Future analyses based on larger volume simulations can confirm this result.

4. Summary and Conclusions

Using the genetic modification technique of Roth et al. (2016), we have created a suite of genetically modified galaxies using an initial organic MW-mass galaxy with an LMC-mass satellite at $z = 0$. We use the GM process to create galaxies within DM halos with identical large-scale structure environments and nearly identical halo growth histories but for slight variations in their satellite accretion history. The result is a set of four MW-mass halos with accretion histories that have been modified in this controlled way. Despite their overall similarities, we find significant differences in their baryonic evolution. Two of these galaxies remain star-forming and two become quenched at $z = 1$. By examining the two quenched cases, we determine that a pair of minor satellite interactions at $z = 1$, concurrent with the peak SMBH accretion rate in the galaxy, can fully quench its star formation until $z = 0$.

In the two quenched galaxies, the genetic modification process results in a change to the timing of early satellite mergers. Thus, the two satellites interact with the main galaxy within a period of ~ 100 Myr at $z = 1$. The first satellite merges with the main galaxy, adding to the fuel available to the SMBH, while the second passes through the main galaxy in a flyby. These minor satellite interactions disrupt the disk, and are followed by a peak of SMBH activity within a few hundred megayears.

The timing of these events is roughly consistent with the rapid delay times observed between mergers and AGN activity by Schawinski et al. (2014). They examined Galaxy Evolution Explorer (GALEX) SFRs and SDSS colors of a sample of galaxies from the Galaxy Zoo Citizen science project (Lintott et al. 2011) and found that early-type galaxies are quenched by rapid processes ($t_{\text{quench}} < 250$ Myr). Other observational results find longer quenching timescales using similar methods (e.g., Schawinski et al. 2010; Smethurst et al. 2015).

To better understand our results on a broader scale, we estimate the number of these nearly simultaneous events within a cosmological volume that eventually quench a MW-mass galaxy. In a sample of 26 isolated MW-mass galaxies from the ROMULUS25 simulation, there are 10 galaxies that quench by $z = 0$ and one experiences multiple minor mergers that coincide with a peak in SMBH accretion that result in a quenched galaxy.

Given current observational capabilities, assessing the impact of minor mergers on star formation history remains a challenge. However, work disentangling minor merger effects on star-forming galaxies has been ongoing (Maschmann et al. 2020, and references therein) and the James Webb Space Telescope (JWST) will likely improve upon these observations in the future.

Major mergers ($q < 3$) between massive galaxies have long been thought to be the primary means by which spiral galaxies transform into ellipticals (Di Matteo et al. 2005; Springel et al. 2005; Hopkins et al. 2006; Somerville et al. 2008; Johansson et al. 2009; Schawinski et al. 2010). In addition, these mergers drive starbursts and fuel central SMBHs, where the latter process may suppress star formation in the remnant galaxy (Richards et al. 2006; Reddy et al. 2008; Hopkins & Quataert 2010; Sanchez et al. 2018). The tidal torques,

combined with the angular momentum of infalling gas, funnel gas into the center of the galaxy, which subsequently increases the accretion rate of the SMBH (Barnes & Hernquist 1996; D’Onghia et al. 2006; Hopkins et al. 2009). However, recent observational and theoretical studies have called into question the efficacy of major mergers in driving SMBH fueling (Fanidakis et al. 2012; Hirschmann et al. 2012; Del Moro et al. 2016; Hewlett et al. 2017; Steinborn et al. 2018; Villforth et al. 2019). For example, Del Moro et al. (2016) examined a sample of luminous mid-infrared quasars and found no direct evidence linking SFRs and AGN luminosity.

While previous work has explored the galaxy-scale physical consequences of major mergers, the role of minor merger disruption in galactic evolution and SMBH fueling is less understood (but see Toomre & Toomre 1972; Ostriker 1980; Carlberg et al. 1986; Kormendy 1989; Hopkins et al. 2009). A recent simulation study by Hani et al. (2020) explores the relationship between mergers and galaxy evolution. They find that both major ($q \lesssim 3$) and minor mergers ($q \gtrsim 3$) can significantly increase the SFR of the post-merger galaxy. However, the enhancement of the SFR is a factor of ~ 2 for minor mergers ($q \sim 3-10$) and ~ 2.5 for major mergers. While Hani et al. (2020) do not find that galaxy mergers are globally quenching their post-merger galaxies, they conclude that the strongest merger-driven galaxies become quenched faster than their control galaxies.

We therefore explore the role of minor mergers, in tandem with the feedback of the SMBH, as drivers for quenching massive galaxies. The closely timed interaction of the minor merger and flyby ultimately disrupt the galaxy disk, and drive gas into the vicinity of the SMBH, thereby fueling it (Kormendy & Ho 2013). Thus, it is the sequence and combination of these events that occur during a short period of few hundred megayears—the SMBH fueling and subsequent feedback coupled with the disruption of the disk—that fully quench both MW-mass galaxies in GM2 and GM3 by $z = 1$. Our study has revealed a complex story where the dual impact of two minor mergers, and the increased SMBH fueling that these mergers drive, create a viable pathway for quenching in MW-mass galaxies and supports the growing evidence that the mechanisms that quench a galaxy are numerous and varied.
