Paper Number: 2022GL099002

Key Points (maximum 140 characters per line):

- Space and ground-based observations reveal dramatic equatorial electrojet variations caused by the Tonga volcanic eruption
- Strong eastward turning of atmospheric zonal winds in the E-region is responsible for the directional reversal of the equatorial electrojet
- The observed complex spatiotemporal variations can be explained by a large-scale disturbance propagating eastward from the eruption site

Abstract

We present space and ground-based multi-instrument observations demonstrating the impact of the 2022 Tonga volcanic eruption on dayside equatorial electrodynamics. A strong counter electrojet (CEJ) was observed by Swarm and ground-based magnetometers on 15 January after the Tonga eruption and during the recovery phase of a moderate geomagnetic storm. Swarm also observed an enhanced equatorial electrojet (EEJ) preceding the CEJ in the previous orbit. The observed EEJ and CEJ exhibited complex spatiotemporal variations. We combine them with the Ionospheric Connection Explorer (ICON) neutral wind measurements to disentangle the potential mechanisms. Our analysis indicates that the geomagnetic storm had minimal impact; instead, a large-scale atmospheric disturbance propagating eastward from the Tonga eruption site was the most likely driver for the observed intensification and directional reversal of the equatorial electrojet. The CEJ was associated with strong eastward zonal winds in the E-region ionosphere, as a direct response to the lower atmosphere forcing.

Key Words

Tonga Volcanic Eruption, Equatorial Electrojet, Counter Electrojet, Equatorial Electrodynamics, Equatorial Electric Field, Atmospheric Neutral Winds

48 **Plain Language Summary**

49 The Earth's E-region ionosphere (~100-150 km altitude) consists of both ionized and neutral
50 gasses, and the two components are coupled through ion-neutral collisions. The state of this
51 region is closely influenced by neutral atmospheric activities from the bottom and Sun's
52 variability from the top. On 15 January 2022, the Tonga volcano had a massive eruption and
53 injected enormous mass and energy into the atmosphere causing disturbances in the E-region
54 ionosphere or even higher. There was also a moderate geomagnetic storm that started one day
55 before the eruption and ended days after. These conditions offer a unique opportunity to
56 understand the different roles they play in controlling the ionosphere. Coordinated observations
57 including the atmosphere, ionosphere and magnetosphere were made from both space and on the
58 ground during this event. We analyzed the magnetic field and neutral wind data and found that a
59 large-scale atmospheric disturbance generated by the volcano eruption was responsible for the
60 observed directional reversal of the dayside equatorial electric field and electric current.

61

62

1. Introduction

The equatorial electrojet (EEJ) is an intense band of ionospheric electric current flowing eastward along the dayside magnetic equator within a narrow latitudinal extent. The peak of the EEJ occurs near the noon of the E-region ionosphere (~ 110 km altitudes), where a local maxima of the plasma density and conductivity is produced by the balanced acts between the photoionization from solar radiation and chemical losses (e.g., Heelis and Maute, 2020). The EEJ is a result of distinctive E-region electrodynamic processes involving both atmospheric neutrals and collisional plasma in a geometry with a horizontally northward geomagnetic field at the magnetic equator. During solar and geomagnetically quiet times, an eastward zonal electric field is generated in the dayside E-region by collisional interactions between neutrals and plasma as atmospheric tidal winds move ionospheric plasma across the magnetic field lines (known as E-region neutral wind dynamo) (Richmond, 1973; Heelis, 2004). The current density of the EEJ can be readily measured in the magnetic field data both on the ground (Anderson et al., 2004; Yizengaw et al., 2014) or by the low-Earth orbit spacecraft (Lühr et al., 2004; Alken et al., 2015).

Observations show that the EEJ exhibits much variability with longitude as well as in multiple temporal scales, from rapid large changes to diurnal, day-to-day, and seasonal variations e.g., Lühr et al., 2004; Yizengaw and Groves, 2018). Sometimes the EEJ can even experience directional reversals, known as counter electrojets (CEJ) (e.g., Forbes, 1981). The main causes of the EEJ variations are attributed to perturbations in the eastward electric field, which can be driven either from the top through enhanced solar wind-magnetosphere-ionosphere coupling (e.g., Yizengaw et al., 2016), or from the bottom side by neutral wind perturbations arising from the lower atmosphere wave forcing (e.g., Yamazaki et al., 2014). Variations of the EEJ have

86 been used as an indirect measure of the electric field perturbation in the dayside equatorial E-
87 region as well as at the F-region.

88 The main driving mechanism for the EEJ variability is the modulation of the E-region wind
89 dynamo, through which the ionosphere strongly couples with the lower atmosphere forcing.
90 Simultaneous spacecraft observations show that during the normal eastward EEJ the zonal winds
91 across E-region altitudes are mostly in the westward direction whereas the winds reverse to be
92 eastward at ~110 km altitude during the westward CEJ (Yamazaki et al., 2014). Vertically
93 propagating atmospheric tidal waves can achieve sufficient amplitudes in the E-region at order of
94 tens of m/s (e.g., Hagan and Forbes, 2002). These tidal winds directly produce the longitudinal
95 and daily variations of EEJ (e.g., Forbes, 1981; Lühr et al., 2021). Large amplitude planetary
96 waves such as 3-day waves have also been observed in the thermospheric wind field, and they
97 could modulate the wind dynamo and thereby drive the multi-day periodic variations in the F-
98 region ionosphere (e.g., Forbes et al., 2018; Liu et al., 2021). In addition, smaller-scale waves,
99 such as gravity waves triggered by geological hazards of earthquake and tsunami etc., could
100 induce short-period fluctuations in the EEJ and the electric fields (e.g., Aveiro et al., 2009;
101 Hysell et al., 1997).

102 Prompt penetration electric field (PPEF) during geomagnetically active times is an additional
103 source of electric field variations in the low-latitude E-region ionosphere (e.g., Fejer et al., 1979;
104 Wolf et al., 2007). During geomagnetic storms, extreme changes of the EEJ, both enhancement
105 and directional reversals (CEJ), have been observed nearly instantaneously following the IMF
106 changes and rapid variations of the Region-1 field-aligned currents (FACs) that lead to
107 undershielding and overshielding conditions, respectively (Kelley et al., 1979; Kikuchi et al.,

108 2000; Sastri, 2002; Simi et al., 2012; Yizengaw et al., 2016; Astafyeva et al., 2019). High-

latitude ionosphere can also couple with the middle- and low-latitudes through disturbance winds during geomagnetic storms, known as disturbance dynamo (Fejer et al., 1983). Unlike the PPEF, disturbance dynamo electric fields have delayed responses to the high latitude heating events (Richmond and Matsushita, 1975).

On 15 January 2022, Swarm spacecraft observed a much enhanced EEJ and then a strong CEJ in two consecutive dayside equator passes (~ 1.5 hr apart). On the same day, a ground-based magnetometer pair near the magnetic equator in Peru, Jicamarca and Tarapoto, observed an intense CEJ first but then only the normal EEJ. The observed EEJ and CEJ in space and on the ground exhibited complex spatiotemporal variations. The event occurred during a period when both the magnetospheric forcing from the top and atmospheric forcing from the bottom coexisted: a moderate geomagnetic storm and the Tonga volcanic eruption, respectively. In this paper, we present a detailed analysis of the observations from multiple sources, including the IMF and solar wind, ground-based and spacecraft magnetic fields, and atmospheric neutral winds to determine the role of these potential sources on perturbing the equatorial E-region electric field. The goal is to disentangle the mechanisms responsible for the observed intensification and directional reversal of the equatorial electrojet.

2. Dataset Description

Approved for public release. OTR 2022-00609.

127 Swarm is a three-spacecraft mission launched into a high-inclination (87.5°) low-Earth orbit
128 on 22 November 2013 (Friis-Christensen et al., 2006). Swarm-A/C fly side by side at the same
129 altitude (~ 430 km at the start of 2022) with a longitudinal separation of 1.4° and Swarm-B in a
130 slightly higher altitude orbit (~ 500 km). With an orbit period of ~ 90 min, the spacecraft crosses
131 the polar cap every ~ 45 mins and the EEJ region every ~ 1.5 hrs. Highly accurate magnetic field

132 data from Swarm's Vector Field Magnetometer (VFM) provide high cadence in situ
133 measurements of FACs in the auroral zone (Lühr et al., 2015; 2016). The magnetic field strength
134 from the Absolute Scalar Magnetometer (ASM) measurements have been used to obtain the
135 amplitude and direction of the EEJ (Alken et al., 2015; Lühr et al., 2021).

136 The EEJ signals are also obtained from a pair of ground magnetometer stations located near
137 the magnetic equator on the same meridian, one at the magnetic equator (within 3.5°) and the
138 other one just off the EEJ region (6° to 9° degree from the magnetic equator) (Anderson et al.,
139 2004; Yizengaw et al., 2014). The EEJ currents are determined from δH , the difference of
140 magnetic field H-components between the two magnetometers. A detailed description of how to
141 extract the EEJ from ground magnetometer observations can be found in Anderson et al. (2004)
142 and Yizengaw et al. (2014). The pair of the ground stations we used in this study are located at
143 Jicamarca (JICA, 11.95°N/76.87°W GEO, MLat=0.6°) and Tarapoto (TARA, 6.59°N/76.36°W
144 GEO, Mlat= 6°) in Peru.

145 The neutral wind measurements are provided by the Michelson Interferometer for Global
146 High-Resolution Thermospheric Imaging (MIGHTI) (Englert et al., 2017) on the 27° low-
147 inclination Ionospheric Connection Explorer (ICON) mission (Immel et al., 2018). Using
148 Doppler shifts, atmospheric wind velocities are derived from the O(¹S) (557.7 nm, green line)
149 and O(¹D) (630.0 nm, red line) airglow emissions at ~3 and 10 km altitude bins, respectively
150 across the range from ~90 to 300 km. The MIGHTI winds have been validated with the ground-

151 based measurements showing a correlation of ~ 0.8 (Harding et al., 2021; Makela et al., 2021).

152 The MIGHTI winds cover low-to-mid latitudes from $\sim 13^\circ\text{S}$ to 42°N , and for each day the data

153 are available from ~ 15 orbits with two local times sampled at the same latitude per orbit.

154

3. Observations

On 14 January 2022, a moderate geomagnetic storm (minimum Dst ~ -91 nT) was triggered by the arrival of the coronal hole high-speed solar wind stream. Figure 1 shows the 5-min resolution OMNI data with IMF/solar wind conditions and SYM-H index for 13-16 January. The start times for the storm main and recovery phases are indicated by the two black arrows on the top, respectively. The storm's main phase was caused by a gradual southward turning of the IMF Bz component which lasted for ~ 7 hours (~ 16 -23 UT on 14 January). The recovery phase started when the IMF Bz suddenly turned strongly northward associated with a minor shock and then fluctuated between northward and southward directions. It took about 5 days for the magnetosphere to fully recover. On 15 January, coincident with the early stage of the storm's recovery phase, a powerful, quasi-continuous eruption of Hunga Tonga-Hunga Ha'apai Volcano occurred about 65 km north of Tonga's main island, starting at ~ 0402 UT for about 12 hours, which is indicated as the magenta bar on the top of Figure 1. Atmospheric waves produced by the eruption were observed globally in the first few hours and circled the Earth multiple times subsequently (Yuen et al., 2022; Zhang et al., 2022). These are the background conditions under which the 15 January EEJ and CEJ events were observed.

Figure 2 presents an overview of the observations. Figure 2a displays 5 days of the magnetic

172 field perturbations (13-17 January) from Swarm A. The red traces are the azimuthal component
173 of the perturbations over the polar cap from Swarm A's VFM. The magnetic field perturbations
174 in high latitudes are mainly caused by FACs, and the azimuthal component (δB_{FAC} , positive
175 for westward deflection) is expected to bear the largest FAC signatures (Le et al., 2016). The
176 black traces in Figure 2a are the perturbations of the field strength during the equatorial crossing
177 over the EEJ region (within 10° latitude from the dayside magnetic equator) from Swarm A's

178 ASM. The eastward EEJ would cause a magnetic field depression ($\delta B < 0$) and the westward CEJ

179 a field enhancement ($\delta B > 0$).

180 On 14 January, the magnitude of δB_{FAC} was enhanced to ~ 500 nT after the storm onset at

181 ~ 16 UT. But the EEJ did not change markedly compared with the previous EEJ passes,

182 indicating the lack of the penetration electric field. This is most likely due to the rather gradual

183 southward turning of the IMF, under which conditions the shielding of the convection electric

184 field in middle and low latitudes was still effective. The intensity of the EEJ remained relatively

185 stable until around ~ 14 UT on 15 January, when a much enhanced EEJ was observed by Swarm,

186 denoted by 1 in Figure 2a and the blue arrow on top of Figure 1. A very strong CEJ was

187 observed subsequently by Swarm in the next dayside equatorial pass at around 15.5 UT, denoted

188 by 2 in Figure 2a and the red arrow on top of Figure 1. Figure 2c shows an expanded view of the

189 Swarm observation for 1200-1725 UT on 15 January, containing the observations from both

190 Swarm A and B. Similar to Swarm A, Swarm B also observed the much enhanced EEJ and then

191 the strong CEJ, but its δB magnitudes were smaller because of its higher altitude. The

192 geographic locations of Swarm A and B for the dayside equatorial passes are shown in Figure 2d

193 as the line segments in black and gray, respectively. The CEJ region at ~ 15.5 UT was observed

194 to the west of the EEJ region observed at ~ 14 UT although Swarm's local time remained to be

195 the same, near the local noon.

196 Figure 2b shows the ground-based observations near the magnetic equator for 13-17 January.

197 The solid black traces are for δH , the differences between the H-components recorded at the

198 geomagnetic equator (JICA) and off the equator (TARA). The red traces are the estimated $E \times B$

199 drift in the F-region based on δH using the technique described in Anderson et al. (2004).
Note

200 that the data from JICA and TARA were not recorded on 16 January, and we used the data from

201 Huancayo (HUA, 12.05°S/75.33°W GEO, Mlat=-0.63°) and San Juan (SJG, 18.11°N/66.15°W
202 GEO, Mlat=28.79°) to obtain δH (dotted line). Since the location of SJG is not ideal for EEJ
203 estimation, these δH data are used only for obtaining general information about EEJ
behaviors,
204 but not for quantitative comparison with the other days. The start times for the Tonga eruption
205 and the storm main and recovery phases are indicated by the arrows in the 14 January panel. We
206 note that the ground stations did not measure significantly different EEJ strengths between 13
207 and 14 January. In addition, no significant changes, instantaneous or delayed, were observed at
208 the storm onset and recovery on 14 January. These observations indicate that the storm's impact
209 on the equatorial electric field was minimal in this case, consistent with the Swarm observations.

210 On 15 January, JICA immediately entered a CEJ period with the strong magnetic field
211 depression ($\delta H < 0$) at ~12 UT (~ 7 local time), which is about the same time as it entered the
212 normal EEJ region in previous days. This means the CEJ was probably already present before
213 ~12 UT. After ~ 4 hr, JICA transitioned into an EEJ region ($\delta H > 0$) at ~15.5 UT (~10.5 local
214 time). The peak magnitude of δH in the EEJ region was only slightly larger than the
previous
215 two days, so it appeared to be a nominal EEJ. During the following two days (16 and 17
216 January), only normal EEJ was observed. In Figure 2d, the geographic location of JICA is
217 marked as a red triangle. The CEJ was also observed on the ground to the west of the Swarm

218 CEJ locations.

219 We now focus on how neutral wind perturbations caused the electric field perturbations. On
220 15 January, ICON spacecraft observed neutral winds for the same regions and times as Swarm
221 and JICA. Figure 2d marks the locations (blue dots) and timings of the daytime low-latitude
222 zonal winds (from green-line emission, $<90^\circ$ Solar Zenith Angle, $< 25^\circ$ latitude) measured by
223 MIGHTI. Due to the low-inclination, MIGHTI samples a relatively wide range of longitudes

during each orbit pass. The zonal winds observed along 7 orbits (each ~ 1.5 hr apart and during <10 minutes time interval) are presented in Figure 3. The brown curve passing through JICA (red triangle) is a part of the circle centered at the Tonga eruption site, showing locations of equal distance from the eruption site. At ~ 14 UT, the ICON observations were located across the brown curve, MIGHTI and JICA would thus concurrently detect the wind perturbations propagating from the eruption site. The observations for a few hours before and after 14 UT are also shown.

Figures 3a and 3b display the zonal wind sequences and averaged profiles, respectively, observed at the given times and locations. The wind components have been transformed into the local magnetic coordinates assuming zero vertical winds. At ~ 14 UT, eastward winds dominated across the E-region altitudes from ~ 95 -120 km, and the largest winds reached ~ 200 m/s with the averaged peak values of ~ 150 m/s. Strong eastward winds are thus observed in the E-region in coincident with the strong CEJ at JICA. Following this, the winds were weaker (<100 m/s) and tended to gradually turn westward at ~ 15.5 and 17 UT. The winds were also almost all westward throughout the altitude region at ~ 7.5 UT. From ~ 9 to 11 UT, the winds remained westward at most altitudes with few values barely being eastward around 105 km. Near 12 UT, both eastward and westward winds occurred around 67.5° W longitudes, showing the winds changed from strongly eastward to westward especially below ~ 110 km. This indicates the transition from the

Approved for public release. OTR 2022-00609.

242 CEJ to EEJ. Figure 3c presents the sequence of zonal wind observations at ~103 km altitude
243 versus longitude. Compared to the day before (in black), the dayside zonal winds on 15 January
244 (blue) exhibited a large variation having strong eastward winds over ~60° - 120° W longitude.
245 This is again consistent with the directional turning from the EEJ to CEJ.
246

4. Discussion

The observations presented in the previous section showed complex spatiotemporal variations of the CEJ and EEJ, which can be explained by a large-scale disturbance propagating eastward from the Tonga eruption site. As illustrated in Figure 4a, the light green and blue areas represent the leading and trailing fronts of the disturbance, respectively. The leading front is associated with a westward neutral wind perturbation, which reinforces the background westward wind in the dayside and causes an increase in the eastward electric field. This front is expected to result in an enhanced EEJ region that has been observed by Swarm. On the west, a strong eastward wind perturbation by the trailing front is opposite to the background wind and thus reverses the eastward electric field causing the directional reversal of the EEJ (i.e., CEJ) and downward vertical drift inferred by JICA. This explanation is further illustrated in Figure 4b and the timelines of the observed features are summarized as follows.

- **At ~12.5 UT** (Figure 4b – top panel): The wind disturbance fronts had moved to cross the day-night terminator and reached the ICON measurement locations, but yet to reach Swarm so that a nominal EEJ was observed by Swarm (see Figure 2c). However, JICA just emerged from the nightside and entered directly into the trailing front to start detecting the CEJ, but completely missed the leading front for the enhanced EEJ (Figure

264 2b). Because the ICON measurements were near the center of the disturbance moving
265 from trailing to leading fronts, eastward and then westward zonal winds were observed
266 (Figure 3a). Given that JICA observed the CEJ at the time ~8 hrs after the volcanic
267 eruption and the great circle distance is ~10,000 km from JICA to Tonga, the speed of the
268 propagating disturbance was estimated to be at least ~350 m/s. Because the CEJ may

have arrived before JICA turned into sunlit conditions, the disturbance could be

propagating faster.

- **At ~14 UT** (Figure 4b, 2nd panel from the top): The disturbance fronts continued its eastward propagation. Swarm's next equatorial crossing cut through the leading front so that a much enhanced EEJ was observed (see Figure 2c). Based on Swarm A's timing (~10 hr) and the great circle distance from the eruption site (~14,000 km), the speed of the leading front was estimated to be ~400 m/s. JICA remained within the trailing front and thus still observed the CEJ (Figure 2b). At this time, ICON measurements were within the trailing front (and at the same distance to Tonga as JICA) and strong eastward zonal winds were observed (Figure 3), which is consistent with the CEJ observation at JICA. This convincingly demonstrated that the CEJ was caused by the Tonga eruption associated wind perturbation that changed the dayside zonal wind to eastward in the E-region.

- **At ~15.5 UT** (Figure 4b – 3rd panel from the top): Swarm crossed the equatorial region inside the trailing front and was able to detect the strong CEJ (see Figure 2c). However, the front almost moved away from JICA as the JICA meridian was exiting from the CEJ region into the normal EEJ region (Figure 2b). Based on these timings, the CEJ observations by JICA lasted for ~ 3 hr and the scale size of the disturbance should be in

287 the order of ~5,000 km. On the other hand, the location of the ICON measurements was
288 far to the west of the disturbance, near the terminator, and weaker winds were observed.

- 289 • **At ~17 UT** (Figure 4b – bottom panel): The disturbance had propagated further east.

290 Both Swarm and JICA were completely outside the disturbance region to the west and

observed regular EEJ current (see Figures 2b and 2c). ICON was even further away from the disturbance and also near the terminator and thus observed weaker winds.

The disturbance responsible for the observed EEJ and CEJ signatures is most likely related to atmospheric gravity wave activities that were produced by the Tonga volcanic eruption and detected globally within the first few hours of the eruption (Yuen et al., 2022). This volcanic eruption generated a broad spectrum of atmospheric waves, such as gravity waves, that propagated into the upper atmosphere and even affected the F-region ionosphere (Zhang et al., 2022; Themens et al., 2022). By combining space and ground-based observations, our analysis shows that this disturbance propagated eastward from the volcano eruption site with a propagation speed in the order of $\sim 350\text{-}400$ m/s. We also found that the disturbance has a spatial scale size of $\sim 5,000$ km in which the zonal wind perturbation reached up to ~ 200 m/s. These fall within the features of gravity waves that have been identified before for driving F-region ionospheric irregularities (e.g. Yizengaw and Groves, 2020), as well as those reported for the Tonga volcanic eruption (Yuen et al., 2022; Zhang et al., 2022; Themens et al., 2022). Such a large wind disturbance should be able to significantly modify the E-region dynamo and cause the dramatic variations on equatorial electric field and current as the observations we present

309 revealed.

310 **5. Summary and Conclusions**

311 We present multi-instrument observations demonstrating the impact of the 15 January 2022
312 Tonga volcanic eruption on dayside equatorial electrodynamics using magnetic field and neutral
313 wind data from Swarm, ground-based magnetometers, and ICON. The Tonga eruption coincided

with the early recovery phase of the 14-17 January 2022 geomagnetic storm. A strong CEJ was observed by both the Swarm satellites and JICA ground-based magnetometers on 15 January after the Tonga eruption and during the storm recovery phase. The CEJ observed by Swarm was preceded by a much enhanced EEJ in the previous orbit about 1.5 hr earlier. But JICA observed a normal EEJ after leaving the CEJ region. The EEJ and CEJ, observed both in space and on the ground, exhibited complex spatiotemporal variations. We linked the magnetic field observations in coincidence with atmospheric neutral wind observations from ICON to disentangle the potential mechanisms. Our analysis indicates that the moderate geomagnetic storm had minimal (almost no) impact on the equatorial electric field for this case. Instead, large-scale atmospheric disturbances propagating outward/eastward from the Tonga eruption site were the most likely driver for the observed intensification and directional reversal of the equatorial electrojet. We propose that the reversal of the equatorial electrojet is attributed to the strong eastward turning of atmospheric zonal winds in the E-region. While the leading wave front appeared to enhance the westward zonal winds responsible for the observed EEJ intensification, the trailing wave front caused strong eastward zonal winds resulting in the strong CEJ in the E-region ionosphere.

Figure 1

Figure 1. The 5-min resolution OMNI data with IMF/solar wind conditions and SYM-H index for 13-16 January 2022.

Figure 2

Figure 2. An overview of the observations on 13-17 January 2022. (a) The magnetic field perturbations from Swarm A. (b) The magnetic field perturbations from the ground stations near the magnetic equator and the estimated $E \times B$ drift in the F-region. (c) Expanded view of the magnetic field perturbations from Swarm A and B on 15 January. (d) Geographic locations of the observations on 15 January.

Figure 3

Figure 3. Daytime zonal winds observed by MIGHTI along 7 ICON orbits on 15 January 2022. (a) Altitude profiles of zonal wind sequences (blue color represents eastward winds and green color corresponds to westward winds). (b) Averaged zonal wind profiles. (c) The sequences of zonal wind observations at ~103 km altitude versus longitude from two days.

514

Figure 4

516 Figure 4. (a) Schematic illustration of the E- and F-region ionosphere responses to a large-scale
 517 disturbance propagating eastward from the Tonga eruption site. (b) Summary of the timelines of
 518 the observed features by the propagating disturbance.
