ABSTRACT

The Event Horizon Telescope (EHT) collaboration has produced the first resolved images of the supermassive black holes at the centre of our galaxy and at the centre of the elliptical galaxy M87. Both images show a ring-like emission structure. Spectral index maps can reveal additional information about the plasma properties of black hole accretion flows on event horizon scales. In this work, we predict spectral index maps between 213 and 233 GHz for a variety of models of black hole accretion flows, including radiatively inefficient accretion flows, general relativistic magnetohydrodynamic (GRMHD) simulations. We analytically show that the optically thick synchrotron emission is expected to be in the Rayleigh–Jeans regime, while optically thin emission is expected to be in the Wien regime. We numerically show that spectral index maps can reveal additional information about the plasma properties of black hole accretion flows, such as the electron temperature and the magnetic field strength. We also show that the brightness temperature of the accretion flow with the lowest plasma magnetization, the standard and normal evolution (SANE) model, is the highest, while the brightness temperature of the magnetically arrested disk (MAD) model is the lowest. However, if our understanding of these properties of plasma physics can be improved by future observations, then spectral index maps can be used to distinguish such a black hole accretion model. Because the Event Horizon Telescope Collaboration (EHTC) has tried to exhibit more negative spectral indices than expected, we discuss how the EHTC could modify the standard synchrotron emission magnetar model to explain the observations of negative spectral indices.

Keywords: accretion, accretion discs, black hole physics, magnetohydrodynamics (MHD), quasars, radiative(M87).

Issue Section: Article

1 INTRODUCTION

Every massive galaxy is believed to host a supermassive black hole (supermassive black hole) at its centre (Kormendy & Richstone 1995; Magorrian et al. 1998). Supermassive black holes can grow via accretion of gas and via black hole mergers (Soltan 1982; Yu & Tremaine 2002; Marconi et al. 2004; Shankar et al. 2009). The black hole's gravitational influence on the surrounding gas is believed to power active galactic nuclei (AGN) and quasars (Lynden-Bell 1969; Rees et al. 1982; Antonucci 1993; Urry & Padovani 1995; Netzer & Peterson 2015). The AGN's luminosity can be used to estimate the black hole's mass (Peterson et al. 2004; Vestergaard & Peterson 2006; Kelly & Bechtold 2007; Shen et al. 2008; Peterson & Bentz 2016). The AGN's luminosity can be used to estimate the black hole's spin (Wilms et al. 2001; Reynolds & Fabian 2008; Reynolds 2014; Brenneman et al. 2011; Reynolds & Nowak 2003; Reynolds & Fabian 2011; Walton et al. 2013; Reynolds 2013

Event Horizon Telescope Collaboration (2019). We thereby find M87 models to be less sensitive to the choice of prior than EHT models.

4.3 Resolved spectral index maps: a generic radial decline

A generic property of all considered spectral index maps is that the spectral index grows more negative as radius increases (e.g. $\alpha \approx 2$ at the image centre and $\alpha \approx 3$ at the footprint edge in Figure 6). This is a direct consequence of the fact that, in each model, we prescribe an inversely proportional variation of the spectral index with radius, $\alpha \propto r^{-1}$, as motivated by synchrotron theory (Section 2.2). This is also a natural outcome of the GRMHD simulations we use, because the electron temperature is found to decrease with radius, leading to a power-law dependence of the spectral index, which we assume to be universal (Ressler et al. 2017). Recovering this trend in the reconstructed spectral index maps is therefore a crucial test of the ability of our imaging algorithms to recover physical information from the data.

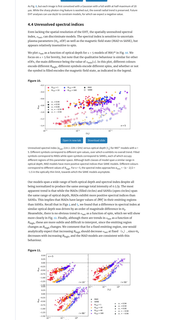
Figure 6.

Azimuthally and time-averaged spectral index maps (α) and 1-σ fractional uncertainties of these maps (σ_α/α) for the 2017 observations of M87. Images are shown for the three models that we consider in this work: the Ring model (left), the Crescent model (middle), and the Double model (right). The spectral index is typically well-constrained in the bright emission region, with fractional uncertainties of $\sim$10%. The spectral index is found to decrease with radius, with $\alpha \approx 2$ at the image centre and $\alpha \approx 3$ at the footprint edge. This trend is a direct consequence of the assumed radial dependence of the spectral index, $\alpha \propto r^{-1}$, which is motivated by synchrotron theory and GRMHD simulations.

For most models, a spike in the spectral index occurs at the location of the photon ring, marked with a vertical grey band. "Interior to the photon ring, M87 models typically have a flat spectral index ($\alpha \approx 0$) and a low fractional uncertainty ($\sigma_\alpha/\alpha \approx 10\%$), because the electron temperature decreases. However, we caution that the region may be sensitive to our choice to use radial basis function coefficients within $r < 1.5\,r_g$ (Section 3.2.2), which could artificially suppress the spectral index in this region. We note that general relativistic ray-tracing simulations predict that the image-domain spectral index in the frequency increases to $\alpha \approx 2$ (Gelles et al. 2021). Thermal models tend to fall off more steeply than $\alpha = -5/2$ (see Fig. 7), so the spectral index is typically less than $\alpha = -5/2$ over the ring. Consequently, the spectral index is optically thin ($\alpha < -0.5$) over the entire image domain for all models.

Figure 7 shows a similar comparison, this time for the Double model. We find that the spectral index is also well-constrained in the bright emission region, with fractional uncertainties of $\sim$10%. The spectral index is found to decrease with radius, with $\alpha \approx 2$ at the image centre and $\alpha \approx 3$ at the footprint edge. Although the spectral index is optically thin ($\alpha < -0.5$) over the entire image domain, we find that the spectral index in the bright region corresponds to different values of $\eta_{\rm max}$: $\eta_{\rm max} \approx 1.76$ (second-order expansion), $\eta_{\rm max} \approx 2$ (first-order expansion), and $\eta_{\rm max} \gg 2$ (optically thin limit).

Figure 7.



Azimuthally and time-averaged spectral index maps (α) and 1-σ fractional uncertainties of these maps (σ_α/α) for the 2017 observations of M87. Images are shown for the Double model. The spectral index is typically well-constrained in the bright emission region, with fractional uncertainties of $\sim$10%. The spectral index is found to decrease with radius, with $\alpha \approx 2$ at the image centre and $\alpha \approx 3$ at the footprint edge. This trend is a direct consequence of the assumed radial dependence of the spectral index, $\alpha \propto r^{-1}$, which is motivated by synchrotron theory and GRMHD simulations.

The models span a wide range of both spectral depth and spectral index degree of freedom, as shown in Figure 8. Despite this variation in model behavior, we find that the spectral index is robust to both the Ring+Thick+Gaussian and Double+Gaussian models, which have the same range of spectral depth. Both exhibit more positive spectral indices than the Ring+Thick model, with $\alpha \approx 0$ in the image centre and $\alpha \approx 2$ at the footprint edge. Because the Ring+Thick+Gaussian model has a flat spectral index, we find that a difference in the spectral index spatial depth was driven by a color of magnitude difference in the Double+Gaussian model. The spectral index in the Double+Gaussian model is also shown clearly in Fig. 7, finally, although there are models (e.g., the Double) at $\eta_{\rm max}$ there are more models and difficult to interpret, since the resulting region $\eta_{\rm max} \gg 2$. Despite this variation in model behavior, we find that the spectral index is robust to both the Ring+Thick+Gaussian and Double+Gaussian models, which have the same range of spectral depth. Both exhibit more positive spectral indices than the Ring+Thick model, with $\alpha \approx 0$ in the image centre and $\alpha \approx 2$ at the footprint edge. This is a direct consequence of the assumed radial dependence of the spectral index, $\alpha \propto r^{-1}$, which is motivated by synchrotron theory and GRMHD simulations. We find that the spectral index is also well-constrained in the bright emission region, with fractional uncertainties of $\sim$10%. The spectral index is found to decrease with radius, with $\alpha \approx 2$ at the image centre and $\alpha \approx 3$ at the footprint edge. This trend

the way to the observer, polarization which is Faraday-rotated to cancel at one frequency may instead sum at another frequency.

APPENDIX A: COMPLETE SCATTER PLOTS OF POLARIZATION SPECTRAL INDICES

In Section 5.2, we explore polarization spectral indices $\eta_{\rm pol}$ and $\kappa_{\rm pol}$ how rapidly the fractional linear and circular polarization change as a function of frequency. We plotted broad trends as a function of eDF in Fig. 15. Now in Fig. A1, we provide full scatter plots of $\eta_{\rm pol}$ and $\kappa_{\rm pol}$ for our 9815[3] models from 2.1.1 and 2.1.2 (+ GRs), using the plotting scheme introduced in Fig. 10. Note the different extents of both axes in each panel. We do not find any significant trends in these parameters as a function of spin, magnetic field state, or $R_{\rm high}$. However, each eDF does cluster in a different region, as plotted in Fig. 15.

Figure A1.

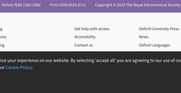
Polarization spectral indices between 214.1 and 350.0 GHz for our 9815[3] models, using the plotting scheme introduced in Fig. 10. Each panel plots a different eDF. Note the different extents of each of the axes for each eDF. We do not find any trend as a function of spin, magnetic field state, or $R_{\rm high}$, but the models of each eDF cluster in different regions, as shown in Fig. 15.

APPENDIX B: TESTS OF THE $q_{\rm r}$ PARAMETER

As mentioned in Section 2.3, we zero all radiative transfer coefficients in regions with plasma $\sigma > \sigma_{\rm cut} = 1$. This choice is frequently made in analytic and tracing GRMHD studies due to numerical fluxes that artificially inject material in high-σ regions. By construction, this results in the removal of otherwise-emitting material near and within the jet. While a complete survey of $\sigma_{\rm cut}$ is beyond the scope of this paper, we briefly gauge the impact of one choice of $\sigma_{\rm cut} = 3$ by recomputing our MAD $a^* = 0.5$ models with $\sigma_{\rm cut} = 50$. We do not compute new values of $\mathcal{M}$ and thereby adjust the same values computed for $\sigma_{\rm cut} = 1$.

A comparison of $\sigma_{\rm cut} = 1$ and $\sigma_{\rm cut} = 50$ models in the style of Fig. 12 is shown in Fig. B1. While the general trends remain the same, the current sheets tend to become more positive with $\sigma_{\rm cut} = 50$. This is because more material is allowed to contribute to the emission, increasing the optical depth, and this additional emission also originates from hot magnetized regions. Larger differences are seen for models with larger values of $R_{\rm high}$, which have larger $\mathcal{M}$. Models where σ varies based on local plasma properties (e.g. Davelaar et al. 2018; Fromm et al. 2022; Scepi et al. 2022) are likely to be more sensitive to the choice of $\sigma_{\rm cut}$.

Figure B1.



A comparison of models with $\sigma_{\rm cut} = 1$ (top) and $\sigma_{\rm cut} = 10$ (bottom) for our 9815[3] $a^* = 1$ models in the style of Fig. 12. When comparing images with $\sigma_{\rm cut} = 50$, we simply adopt the same values of $\mathcal{M}$ as used with $\sigma_{\rm cut} = 1$. Since more material is allowed to contribute to the emission, and this emission originates from hot magnetized regions, $\kappa_{\rm pol}$ may increase. The effect is larger for larger values of $R_{\rm high}$, since models with larger $R_{\rm high}$ also have larger $\mathcal{M}$, so the density in $\sigma < 1$ regions is rescaled to be higher.
