Abstract

Word count: 199

In the study of microbial life, microscopy plays a unique role due to its ability to detect ordered structure, motility, and fluorescence signals. As such it has also recently gained attention in the context of searching for extant life on distant solar system bodies bearing liquid water. In this paper we introduce a multi-modal volumetric microscopy system for potential future spaceflight missions that combines digital holographic microscopy (DHM) and volume fluorescence imager (VFI), which are volumetric imaging methods that provide high-resolution, high-throughput examination of liquid samples. DHM provides information on the absorption, morphology, and motility of imaged objects without requiring the use of contrast agents. On the other hand, VFI based on light field microscopy focuses on the fluorescence signals from the sample to observe specific structures dyed with targeted contrast agents or providing unique autofluorescence signals. We also present an autonomous sample handling and data acquisition system to allow for an autonomous mission to distant planets or moons, or for autonomous use in bodies of water on Earth. The full system, named ELVIS, or Extant Life Volumetric Imaging System, is capable of autonomously surveying a liquid sample to extract morphology, motility, and fluorescence signals of extant microbial life.

Contribution to the field

We report here the field test result of previously introduced Extant Life Volumetric Imaging System (ELVIS), which is a volumetric microscope suite being developed for potential future NASA life detection missions to ocean worlds. As a volumetric microscope suite that combines high-resolution holographic microscopy and fluorescence light-field microscopy, ELVIS provides a comprehensive imaging-based life detection method sensitive to the sample's morphology, motility, and chemical composition. Moreover, ELVIS combines the microscope with an autonomous sample processing unit (SPU) to allow for a completely autonomous operation, which is crucial for space missions. In this paper, we report the current status of the instrument development and the result of field test held at Newport Beach, CA, which revealed that ELVIS is capable of imaging the microbial lives in ocean water. In addition to the field test results, we also present improvements made to the imaging system based on the findings from the field test. We strongly believe that this imaging system and the field test results provide a strong and robust life detection method that is suitable for future space missions.

Funding statement

The work described in this paper is funded by and performed at the Jet Propulsion Laboratory, California Institute of Technology under contract with the National Aeronautics and Space Administration. The work is also funded by NSF MRI grant 1828793, ELVIS.

Abstract

In the study of microbial life, microscopy plays a unique role due to its ability to detect ordered structure, motility, and fluorescence signals. As such it has also recently gained attention in the context of searching for extant life on distant solar system bodies bearing liquid water. In this paper we introduce a multi-modal volumetric microscopy system for potential future spaceflight missions that combines digital holographic microscopy (DHM) and volume fluorescence imager (VFI), which are volumetric imaging methods that provide high-resolution, high-throughput examination of liquid samples. DHM provides information on the absorption, morphology, and motility of imaged objects without requiring the use of contrast agents. On the other hand, VFI based on light field microscopy focuses on the fluorescence signals from the sample to observe specific structures dyed with targeted contrast agents or providing unique autofluorescence signals. We also present an autonomous sample handling and data acquisition system to allow for an autonomous mission to distant planets or moons, or for autonomous use in bodies of water on Earth. The full system, named ELVIS, or **E**xtant **L**ife **V**olumetric **I**maging **S**ystem, is capable of autonomously surveying a liquid sample to extract morphology, motility, and fluorescence signals of extant microbial life.

1 Introduction

The evidence in recent years for planetary moons, such as Europa and Enceladus, bearing large bodies of liquid water under ice shells (i.e. ocean worlds) in the outer solar system has resulted in a great deal of interest in life detection in aqueous environments [1]. Moreover, recent discovery of subglacial water on Mars increases the attention to life-detection in water [2, 3].The importance of extant life detection is not only in detecting the potential existence of non-terrestrial life, but also in

potentially revealing how early life formed on Earth. Potential life in the ocean worlds, including Europa and Enceladus, is expected to exist in microbial (prokaryotic) form at very low densities, if present at all; estimates for Europa based upon solar energy budgets are ~10^2 cells/mL [4]. Although the low densities and potential sizes of the target organisms down to less than a micron make detection extremely difficult to detect them, methods for studying bacteria and archaea in extreme environments on Earth or in the ocean are being considered for planned NASA missions to find extant life elsewhere. Among these methods, light microscopy is considered one of the most direct life detection modalities, for its capability to capture microscale evidence for life, such as structure, compositional and functional indicators, abundance, and motility. This combination of information is well suited for distinguishing living from non-living particles and serves as a strong biosignature [5].

Despite the usefulness of microscopy, developing a suitable microscopy system for such applications is challenging for several reasons. First, due to the anticipated low sample concentration and small size of the potential life, the microscope needs to have both a high sample throughput and a high resolution. Typically, a microscope loses its throughput (or the field of view) as the resolution improves. However, in a time- and power-limited mission scenario, both aspects need to be met at the same time. Second, as there is limited time and data budget, the imaging process has to be highly compressive. The estimated data budget for a potential Europa Lander mission is likely to be highly limited at 1260 Kbps, with a baseline science data budget of 600 Mb divided among as many as 6 instruments [6]. Third, the entire system, including the sample handling, imaging, and analysis, will need to be autonomous while being space- and mass-constrained.

Based on these requirements and the eventual goal of future space missions, we developed a volumetric microscopy suite that is capable of capturing high-resolution morphology, motility, and fluorescence of a liquid volume. The suite, called Extant Life Volumetric Imaging System (ELVIS), combines digital holographic microscopy (DHM) with fluorescence light field microscopy (FLFM) in order to capture both high-resolution morphology and fluorescence synchronously [7, 8]. These volumetric imaging techniques capture signals from an extended depth of field and allows for a rapid and compressed imaging of the sample volume. Moreover, in order to enable autonomous operation of the system for a future space mission, we introduce a sample processing unit (SPU) and a custom acquisition software package to control the fluid motion, staining, and image acquisition. The instrument was tested at the Kerckhoff Marine Laboratory in Newport Beach, CA to demonstrate its capability to detect life in oligotrophic ocean water. Lastly, we also present most recent developments made to the system based on the discoveries from the field test.

2 The ELVIS Instrument

ELVIS combines a digital holographic microscope with a fluorescence microscope to have a multi-modal volumetric single-shot imaging. The two microscopes share the same field of view and share the same trigger for spatially and temporally synchronized imaging. Combining the two microscopes, ELVIS is capable of capturing high-resolution morphology, 3D motility and biochemical fluorescence sensitivity, which are all considered biosignatures. In this section, we briefly introduce the full ELVIS instrument suite. Further details on the instruments can be found in the Materials and Methods section.

2.1 Digital Holographic Microscope (DHM)

Digital holographic microscopy (DHM) is an interferometric technique that is capable of capturing volumetric information in a single shot, by capturing the complex electric field (amplitude and phase) at the image plane of the microscope and numerically propagating the captured field [9]. DHM captures a much larger volume of view (VOV) in a single image compared to a conventional microscope by increasing the depth of field; the VOV of DHM is typically 2 – 3 orders of magnitude larger than that of a conventional microscope with the same optical elements. This improves the volumetric throughput of the system without demanding larger data storage or a longer imaging duration, as the holographic image encodes the entire 3D volume into a 2D image, thus providing natural data compression.

Our group has previously introduced DHM as a high-resolution, label-free volumetric imaging method that is suitable for surveying a relatively a large volume of liquid sample [10, 11]. In order to ensure detection of microbial life at a density of 100 cells/mL, it is expected that we must examine 40 µL of liquid [11]. For a conventional microscope with a 500 µm x 500 µm FOV and 2 µm depth of field (DOF), each image examines a 0.5 nL volume. Therefore, in order to examine 40 µL, the device needs to capture 80,000 images. Converting the number of captured images to more relevant numbers in a mission, this corresponds to ~320 GB of data storage and 4,000 seconds of continuous imaging, given 4 Mpixels/image, 8 bits/pixel and 15 fps imaging speed. On the other hand, examining a 40 µL volume using DHM requires only 200 images to be captured, corresponding to 8 GB of data or 15 seconds of imaging, and allows for a mission-suited instrument. This capability has been tested previously at Nuuk, Greenland [10].

Because DHM relies on the intrinsic contrast of the samples, specifically their absorption (amplitude) and refractive index difference from the surrounding medium (phase), the technique captures objects in the liquid sample without a need for dyes. However, DHM lacks the biochemical specificity that can be obtained by fluorescence tagging. A fluorescence-based volumetric imaging method could be used to indicate internal cell structures, which could further aid in the determination of whether biological structures are present in the sample. To improve the system and provide a higher confidence in life detection, we combined the DHM system with a fluorescence light field microscopy system, named Volume Fluorescence Imager (VFI), to simultaneously capture the same VOVs. Figure 1A shows the schematic of the system, which combines the DHM system with a volumetric fluorescence imager using a dichroic mirror.

2.2 Volume Fluorescence Imager (VFI)

Light field microscopy (LFM) is a volumetric imaging method that allows for a post-capture refocusing of an image by encoding the position and the direction of propagation of the light using a microlens array (MLA) located at the image plane of a conventional microscope [12]. The image is then captured by a detector array placed one focal length away from the microlens array. Effectively, each microlens acts as a pixel that encodes the directional information in the physical detector pixels that are underneath it. Once the image is captured, using a simple ray optics principle, the image can be reconstructed to recover multiple images at different focal points. Compared with a conventional fluorescence microscope, LFM is capable of capturing a volumetric fluorescence image over a larger depth of field that is determined by the system magnification and the number of detector pixels covered by each microlens. While LFM can increase the depth of field (DOF) of a microscope by 2 orders of magnitude, this does not come for free. As explained previously, each microlens acts as an effective pixel for the imaging system and limits the spatial resolution of the system to d/M, where d is the diameter of each microlens and M is the system magnification.

The two microscopes combined in our ELVIS system complement each other. While the DHM captures high-resolution images with high-sensitivity for the sample's morphology and motility, the VFI looks for chemical/fluorescence biosignatures that are missed by DHM. By sharing the same objective lens and the same trigger, they capture a spatially and temporally synchronized scene in two different modalities. Moreover, with a careful selection of spectral filters and dichroic mirrors (Figure 1B), the two microscopes are free from cross-talk, removing any ambiguity in signal origin. The large shared VOV (350 µm x 480 µm x 150 µm) is shown in Figure 1C. The depth of field, 150 µm, was limited by VFI DOF, which is taken here to be the reconstruction depth that maintains the lateral resolution. For reconstruction depths larger than 150 µm, the lateral resolution degrades. The overall performance of the system is summarized in Table 1.

Table 1. DHM and VFI performance specifications

	DHM	**VFI**
Lateral resolution (µm)	0.87	5.1
Magnification	15	10
FOV width (µm)	480	650
FOV height (µm)	480	650
Depth of field (µm)	1000	150
Shared VOV (um^3)	350 x 480 x 150	

2.3 Sample Processing Unit (SPU)

Another significant portion of the ELVIS system is its automated sample processing unit (SPU), which handles automated control of sample delivery, staining and cleaning the system in conjunction with a sample aliquot chamber (SAC). The SAC is a simple microfluidic flow-through device consisting of two internal fluid channels, the design of which is shown in Figure 2. The SAC was designed with reference and sample channels to match those of the DHM. For this field test, disposable versions of the SAC were constructed (Aline Inc., Rancho Dominguez, CA). This was a three-layer device with optical quality glass on top and bottom. As shown in Figure 2, channels were cut into a 1mm thick middle polymer layer with channel dimensions measuring ~12mm x 3mm and ~7mm x 3mm (sample and reference channels respectively). The device design ensured that both the sample and reference beams only passed through optical quality glass.

During operation, the reference channel was filled with deionized (DI) water, providing an index of refraction match to the sample. A sample was then passed through the sample chamber for analysis. Prior to observation, valves on both the inlet and outlet of the SAC were closed and fluid motion was allowed to cease completely before analysis, requiring approximately 30 seconds.

The SPU was designed to interface with the SAC and provide a means of automated sample handling. It provided delivery of sample, rinsing using water and/or ethanol, and staining of up to three fluorescent cell dyes to a sample. After each dye staining, the sample was routed back to the SAC for subsequent analysis.

A logical schematic of the SPU can be seen in Figure 3A. A minimum of 100 µL of a sample could be delivered to the sample chamber of the SAC for analysis as a series of aliquots. The sample was transported with the aid of two, 10 µL fixed volume dispensing pumps (LPMA1251110L) and three varieties of electrically actuated, face-mounted solenoid valves: three-way (LHLA0521111H) and two-way (LHLA0552311H) latching valves and non-latching normally closed two-way valves (LHDB0552115H) (all from The Lee Company, Westbrook, CT). Latching valves can hold their state without constant application of voltage. The two pumps worked in concert but in opposite directions to pull the sample through the SPU and into place for analysis with one upstream and one downstream of the chamber. This pump arrangement was chosen in order to prevent the sample passing through a pump, thereby avoiding the possibility of damaging any cells present. A top-down view of the SPU is shown in Figure 3B.

2.4 Acquisition Software

As the ELVIS system is intended to be applicable to future space missions, we also developed autonomous acquisition software that is capable of capturing the images simultaneously from the two cameras. The acquisition software, named DHMx, is based on Allied Vision Vimba SDK and controls the essential functions such as exposure, gain and frame rate. DHMx also includes a DHM reconstruction module that can be loaded to process the interferogram in real-time. The software is open-source and can be found on GitHub [13]. The DHM reconstruction module can run on the same computer as used for acquisition or a remote computer, allowing remote users to operate the instrument from any distance over which a network link can be established. Furthermore, we have added a hardware trigger using an Arduino microcontroller to provide synchronous capture signal to the two cameras. By opening two instances of DHMx to capture images from the two cameras, and by providing a script to simultaneously capture the data, we were able to capture images from the two cameras with a less than 0.2 ms offset in the start times, which is insignificant for our frame rate of 15 fps.

3 Results and Discussion

The complete ELVIS system was tested at the Kerckhoff Marine Laboratory, Newport Beach, CA [14]. Samples were collected from the ocean (representing a low biomass sample) and a tidal pool (representing a high biomass sample) in sterile 500 mL bottles. Four different sample types were used for the field test: Blank samples (pure water), unconcentrated low biomass sample, filter-concentrated low biomass sample, and high-biomass sample. Each of the samples were processed via the following steps:

1. SPU/sample chamber was cleaned with ethanol and flushed with water
2. Reference chamber was loaded with refraction index matched fluid (extracted from sample)
3. Sample chamber was loaded with sample
4. Sample was imaged using DHM and VFI (15 fps, 30 seconds, 3 time series)
5. Sample was routed back to SPU to be stained with dye #1

6. Dye #1 (Acridine Orange) applied to sample for 5 minutes (2:1 sample to dye ratio)
7. Dyed sample was routed back to the sample chamber
8. Dyed sample was reimaged with both DHM and VFI (15 fps, 30 seconds per FOV, 3 time series)
9. Sample was routed back to SPU to be stained with #2
10. Dye #2 (FM1-43) applied to sample for 20 minutes (2:1 sample to dye ratio)
11. Dyed sample routed back to the sample chamber
12. Dyed sample was reimaged with both microscopes (15 fps, 30 seconds per FOV, 3 time series)
13. Sample was flushed with water and the chamber was cleaned with ethanol

From the initial few aliquots, we were able to detect signs of life in DHM, both prokaryotes and eukaryotes. In VFI, only large eukaryotic cells were detected. In the high-biomass sample, a wide variety of organisms of different sizes were seen by both autofluorescence and dye labeling (Figure 4). Shown in Figure 4 are the correlative images from DHM and VFI showing a eukaryotic cell swimming in the FOV over 4 seconds. The minimum z- (along the optical axis) and t- (time) projection for the DHM data and the maximum *z*- and maximum t-projection for the VFI data are shown to capture the 4D stack. The fluorescence signal was detected before dye addition, indicating that the signal was from the native fluorophore such as chlorophyll.

While the VFI detected autofluorescent cells of size ≥10 μm, the DHM was capable of detecting smaller bacteria-sized cells as well by recording motility. The inset of Figure 4 shows a bacterium from the ocean water captured using DHM. Note that there was no structural information detected even with the high-resolution DHM because the size of bacterial cells (~ 1μm) is very close to the spatial resolution of the system. Although clear motility was detected from DHM, there was no corresponding signal detected from the VFI on such small entities, either before and after staining. While it was expected that there would not be a detectable VFI signal from bacterial cells before staining, the cells were still not visible after staining, indicating that system improvements were necessary.

The initial system showed high levels of background fluorescence that made detection of small cells impossible. One significant source of background was the ABS (RenShape® SL 7820) used to mount the objectives. A new objective holder was machined from anodized aluminum, making detection of bacteria possible. Further iterations improved the signal to noise, specifically reducing dye concentration. Although the dyes tested here were chosen for their enhancement upon specific binding, unbound dye nevertheless resulted in significant background, making the SNR for 1 μm size particles to be less than 1. Therefore, it was crucial to identify and use the minimal dye concentration to stain the sample to avoid high background. With these changes, we have improved our sensitivity allowing us to detect individual bacterial particles of 1 μm size. Moreover, we have introduced multiple laser bands for DHM and a color camera for VFI to allow for multi-color imaging with a goal to detect information regarding the pigment in the samples and multiple fluorescence signals in a single shot and allowing the dyes to be applied simultaneously in future field tests. The results of the recent advances are summarized in Figure 5.

Figure 5A) shows an amplitude reconstruction of a multi-wavelength DHM image capturing a sea flea. DHM images of three different wavelengths (405 nm, 520 nm, and 635 nm) are captured in a single image, separated in the Fourier plane, reconstructed and overlaid to show the wavelength-dependent absorption of the object. Figure 5B) shows the sensitivity improvement in VFI, which is

now capable of imaging 1 μm sized single *Serratia marcescens* dyed with Syto-9. Serratia marcescens was obtained from the American Type Culture Collection (ATCC) (ATCC 13880 type strain) and maintained in lysogeny broth (LB, Fisher Scientific) at 30°C. The background dye concentration has also been optimized at 50 nM to minimize the background signal without losing the dyeing efficiency. Figure 5C) shows two different z-positions of a volume reconstructed multi-color VFI image of an algae sample dyed with FM1-43. The membrane dye shows up as green while the native chlorophyll shows up as red in a single image. This result shows the improved specificity information obtained from VFI.

In this paper, we have demonstrated the ELVIS system's capability, detecting and studying microbial life in liquid sample. The system is capable of capturing 3D high-resolution morphology and motility through its DHM arm and also 3D fluorescence information from the same field of view via its VFI arm. Therefore, the system serves as a high-throughput, high-resolution, multi-modal imaging suite for studying microbial life. Moreover, the addition of SPU to the microscope system allows for an autonomous operation of the sample examination. We demonstrated the capabilities through the field test performed at Newport Beach, CA, during which ambient life was successfully detected. Further improvements have been made based on the findings from the field test, and now the ELVIS system demonstrates its future capabilities providing access to more sample characteristics including multiple fluorescence signals and pigments.

Overall, we have demonstrated that, although the system was built as a prototype for a future space mission, the ELVIS system provides a new means to studying microbiological samples in general. Moreover, since it is developed with a goal of future space missions to find extant life in the ocean worlds, it accommodates the resource limitates of such missions. The details of a potential flight system can be tailored to match science performance to specific mission goals while staying within mass, power, and data constraints to provid a powerful instrument for the detection of potential extant life.
