Gullett JM, Albizu A, Fang R, Loewenstein DA, Duara R, Rosselli M, Armstrong MJ, Rundek T, Hausman HK, Dekosky ST, Woods AJ and Cohen RA (2021) Baseline Neuroimaging Predicts Decline to Dementia From Amnestic Mild Cognitive Impairment. *Front. Aging Neurosci.* 13:758298. doi: 10.3389/fnagi.2021.758298

**Background and Objectives:** Prediction of decline to dementia using objective biomarkers in high-risk patients with amnestic mild cognitive impairment (aMCI) has immense utility. Our objective was to use multimodal MRI to (1) determine whether accurate and precise prediction of dementia conversion could be achieved using baseline data alone, and (2) generate a map of the brain regions implicated in longitudinal decline to dementia.

**Methods:** Participants meeting criteria for aMCI at baseline ( $N = 55$ ) were classified at follow-up as remaining stable/improved in their diagnosis ( $N = 41$ ) or declined to dementia ( $N = 14$ ). Baseline T1 structural MRI and resting-state fMRI (rsfMRI) were combined and a semi-supervised support vector machine (SVM) which separated stable participants from those who decline at follow-up with maximal margin. Cross-validated model performance metrics and MRI feature weights were calculated to include the strength of each brain voxel in its ability to distinguish the two groups.

**Results:** Total model accuracy for predicting diagnostic change at follow-up was 92.7% using baseline T1 imaging alone, 83.5% using rsfMRI alone, and 94.5% when combining T1 and rsfMRI modalities. Feature weights that survived the  $p < 0.01$  threshold for separation of the two groups revealed the strongest margin in the combined structural and functional regions underlying the medial temporal lobes in the limbic system.

**Discussion:** An MRI-driven SVM model demonstrates accurate and precise prediction of later dementia conversion in aMCI patients. The multi-modal regions driving this prediction were the strongest in the medial temporal regions of the limbic system, consistent with literature on the progression of Alzheimer's disease.

**Keywords:** machine learning, support vector machine, magnetic resonance imaging, mild cognitive impairment, Alzheimer's disease

## INTRODUCTION

While the clinical course of Alzheimer's disease (AD) is fairly well-understood, the ability to predict progression from an earlier stage of the disease using data available upon initial clinical presentation remains poor. With the advancement of machine learning, clinicians are now presented with the opportunity to identify which high-risk patients are likely to convert to AD, such as those diagnosed with amnestic mild cognitive impairment (aMCI) (Petersen, 2004). This ability to provide early identification of at-risk patients additionally has a large medical-economic cost savings given that early intervention to delay the onset of Alzheimer's by just 1 year, for example, could reduce total health care payments up to 14% (Zissimopoulos et al., 2015) and decrease the number of Alzheimer's diagnoses by 9.2 million by 2050 (Brookmeyer et al., 2007).

Patients are given a diagnosis of aMCI when they demonstrate a delayed memory performance score that is 1.5 standard deviations or more from the mean of their like-aged peers (Petersen et al., 2014). The conversion rate to dementia in patients with aMCI ranges from as low as 17.7% in community-derived samples, up to 40.4% in clinic samples (Oltra-Cucarella et al., 2018), regardless of follow-up length. This is compared to 5.4–10.1% of "all" MCI cases and < 1% in healthy older adults in community-derived samples over a 5 year period (Ganguli et al., 2015, 2019). Machine learning models utilizing Support Vector Machines (SVM) offer enhanced predictive accuracy for disease progression by integrating previously uncharacterized features of multiple neuroimaging modalities with or without the addition of cognitive performance data to distinguish between two groups of patients (Ruppert, 2004), such as those who convert from MCI to AD and those who remain classified as MCI. In recent years, prediction of disease progression from MCI to dementia or presumed AD has been explored with SVM using baseline MRI measures of all structural voxels (Moradi et al., 2015), cortical thickness (Eskildsen et al., 2013), cortical and subcortical volume (Hojjati et al., 2018), and resting-state fMRI (rsfMRI) connectivity (Li Y. et al., 2016) in isolation, with prediction accuracies of 66, 76, 89, and 93%, respectively.

Given that the amount of data at an initial clinical visit is often quite limited, a model that could provide strong predictive accuracy of MCI conversion to AD using MRI-alone would be of immense utility. To our knowledge, only one other study has used a combined model of structural and resting-state functional MRI to predict all MCI conversion to AD (Hojjati et al., 2018). Replication of this study in an aMCI population would provide unique information about this higher-risk population, as well as offer the ability to derive the neural regions where structural and functional networks combined to predict conversion from aMCI to AD. Ultimately, acquisition of the combined structural-functional neural regions important for conversion to AD would provide the opportunity for early neurotherapeutic interventions in high-risk aMCI patients.

In the present study, we sought to leverage baseline T1 MRI in a homogenous sample of individuals diagnosed with aMCI to predict longitudinal consensus-based diagnostic decline using a cross-validated SVM approach. Further, we wished to

determine whether the inclusion of an additional MRI modality (resting-state functional MRI; rsfMRI) into the prediction model would improve predictive accuracy of the uni-modal structural model. Lastly, we sought to determine if neuropsychological performance at baseline outperformed objective neuroimaging for the prediction of longitudinal diagnostic decline. We hypothesized that T1 MRI would have a higher level of predictive accuracy than rsfMRI when used individually, but that the combination of these two modalities would provide the highest level of predictive accuracy. Further, we hypothesized that the combined structural-functional model would yield neural regions in the medial temporal lobes underlying the limbic network that would optimally discriminate stable aMCI from progressive aMCI, given the lower network connectivity in MCI compared to controls (Li et al., 2015) as well as the strong association of this network with the presence of Alzheimer's disease (Badhwar et al., 2017). Lastly, given the use of many of the neuropsychological test measures in the determination of the aMCI or dementia diagnosis being predicted, we hypothesized that neuropsychological testing would outperform neuroimaging in the prediction of future decline.

## MATERIALS AND METHODS

### Participant Selection

Participants were recruited through the Florida Alzheimer's Disease Research Center (ADRC) for an IRB-approved longitudinal investigation performed in accordance with the declaration of Helsinki (P50-AG047266-05). Participants from the present study were selected from a larger pool of 287 potential participants if they met the following criteria: (a) valid T1 and rsfMRI neuroimaging scans at baseline, (b) consensus diagnosis of either single-domain or multi-domain amnestic MCI at baseline alone, (c) had no other neurological or cognitive diagnoses (e.g., Parkinson's disease, suspected Lewy Body Dementia, vascular dementia) at baseline, (d) consensus diagnosis available at both baseline and follow-up, (e) no aberrant QC metrics of rsfMRI data at baseline to include greater than  $+/-3$  SD values for in-scanner movement, global correlation of connectivity due to motion, or number of invalid scans.

### Participant Diagnosis

An experienced geriatric psychiatrist administered a standard clinical assessment protocol, which included the CDR® Dementia Staging Instrument (CDR) (Morris, 1997) and the Montreal Cognitive Assessment (MoCA) (Nasreddine et al., 2005). Subsequently, a uniform battery of neuropsychological tests, including the National Alzheimer's Coordinating Center - Unified Data Set (NACC-UDS) (Beekly et al., 2007; Acevedo et al., 2009; Weintraub et al., 2018) battery, was independently administered in the participant's dominant and preferred language (English or Spanish). Participants received a diagnosis of amnestic mild cognitive impairment (aMCI) at the baseline assessment if they met Petersen's criteria for MCI (Petersen et al., 2014) and demonstrated all of the following: (a) subjective cognitive complaints by the participant and/or

229 collateral informant; (b) evidence by clinical evaluation or  
230 history of memory or other cognitive decline; (c) Global Clinical  
231 Dementia Rating scale of 0.5 (Morris, 1997); (d) below expected  
232 performance on delayed recall of the HVLT-R (Brandt, 1991) or  
233 delayed paragraph recall from the Logical Memory subtest of the  
234 NACC-UDS (Beekly et al., 2007) as measured by a score that is 1.5  
235 SD or more below the mean using age, education, and language-  
236 related norms. Participants were classified as multi-domain  
237 amnestic MCI if they met the above criteria as well as  $\leq 1.5$  SD  
238 performance on at least one other domain measure. All of these  
239 standard criteria were reviewed by an experienced behavioral  
240 neurologist (RD) or a board-certified neuropsychologist (DL).  
241 All these criteria were reviewed by a neurologist and a  
242 neuropsychologist and using an algorithmic diagnosis procedure  
243 final clinical diagnoses were made (Duara et al., 2010, 2011). In  
244 the few cases where consensus could not be obtained, at least one  
245 additional neurologist and neuropsychologist were consulted to  
246 render a final cognitive diagnosis.

247 For the purposes of determining diagnostic change at the  
248 follow-up visit, participants must have participated in the above  
249 assessment at least one calendar year (mean = 15.45 months;  
250 range 12.0–17.0 months) subsequent to their initial visit, which  
251 must have included acquisition of their whole-brain MRI. To  
252 be determined as “stable” in their diagnosis, the follow-up visit  
253 consensus diagnosis must be either the same (aMCI) or mildly  
254 improved (pre-MCI). For the purposes of this classification,  
255 pre-MCI diagnosis (see Loewenstein et al., 2012) included the  
256 following: (a) subjective memory complaints by the participant  
257 and/or or collateral informant; (b) evidence by clinical evaluation  
258 or history of memory or other cognitive decline determined after  
259 an extensive CDR interview; (c) Global CDR scale of 0.5; (d) a  
260 neuropsychological battery (see below) was deemed normal by  
261 a clinical neuropsychologist and generally, no measures in the  
262 neuropsychological battery fell 1.0 SD or more below normal  
263 limits, relative to age and education related normative data. To  
264 be considered “declined” in their diagnosis, the follow-up visit  
265 consensus diagnosis must have been determined as Dementia per  
266 the criteria a and b as described for the aMCI group above, and  
267 evidenced all of the following: (a) Global CDR score of 1.0; (b)  
268 below expected performance on the memory measures described  
269 above that scored 2.0 SD or more below the mean using age,  
270 education, and language-related norms.

## 272 **Neuropsychological Battery**

273 Participants completed a comprehensive neuropsychological  
274 evaluation which assessed various cognitive domains. Verbal  
275 memory was measured using the HVLT-R (Brandt, 1991;  
276 Arango-Lasprilla et al., 2015b) and Craft 21 Story Recall (Craft  
277 et al., 1996); confrontation naming was assessed with the MINT  
278 (Gollan et al., 2012); visuospatial cognitive functioning was  
279 evaluated with the Benson Figure Drawing (Possin et al., 2011)  
280 and Block Design (Wechsler et al., 2008); executive function was  
281 appraised with the Stroop Test (Stroop, 1935; Trexerry et al.,  
282 2012; Toberge and Curtis, 2013), as well as TMT B (Reitan, 1958;  
283 Arango-Lasprilla et al., 2015a); and finally, verbal fluency was  
284 assessed using category (Benton, 1968; Ostrosky-Solis et al., 2007)  
285 and phonemic fluency (Ruff et al., 1996).

286 Spanish language evaluations were completed with equivalent  
287 standardized neuropsychological tests. Tasks administered to  
288 primary Spanish speakers had appropriate age, education, and  
289 cultural/language normative data for the translated versions  
290 (Lang et al., 2021). Testing was performed by proficient  
291 Spanish/English psychometricians.

## 292 **Magnetic Resonance Imaging**

293 Participants completed a 1-h MRI acquisition on a Siemens  
294 Skyra 3 T MRI scanner (Siemens Medical Solutions, Erlangen,  
295 Germany) with 32-channel head coil at Mount Sinai Medical  
296 Center, Miami Beach, Florida. The 3D T1 weighted volumetric  
297 magnetization-prepared rapid gradient-echo sequence (MP-  
298 RAGE) consisted of 176 slices at slice thickness = 1 mm isotropic,  
299 FOV =  $256 \times 256$ , TR = 3.0 s, and TE = 1.4 s. The resting-state  
300 functional MRI (rsfMRI) scan was administered with eyes open  
301 consisting of 48 interleaved slices at a slice thickness = 3.0 mm  
302 isotropic, FOV =  $212 \times 212$ , TR = 3.0 s, and TE = 30 ms. For  
303 exclusionary purposes of potential incidental findings, MRI scans  
304 were evaluated by visual inspection as well as with T2 weighted  
305 FLAIR (5 mm thick sequential axial slices), and the MP-RAGE  
306 sequence (which provides high tissue contrast and high spatial  
307 resolution with whole brain coverage).

## 309 **Functional Magnetic Resonance Imaging**

### 310 **Pre-processing**

311 Functional MRI pre-processing was completed in accordance  
312 with past studies by our group (Hausman et al., 2020).  
313 Specifically, functional images were preprocessed and analyzed  
314 using the MATLAB R2019b based functional connectivity  
315 toolbox “Conn toolbox” version 18b and SPM 12 (Penny  
316 et al., 2007; Whitfield-Gabrieli and Nieto-Castanon, 2012). We  
317 followed a pre-processing pipeline which included functional  
318 realignment and unwarping, functional centering of the image  
319 to (0, 0, 0) coordinates, slice-timing correction, structural  
320 centering to (0, 0, 0) coordinates, structural segmentation  
321 and normalization to MNI space, functional normalization to  
322 MNI space, and spatial smoothing with a kernel of 8 mm  
323 FWHM. During pre-processing, the Conn toolbox implements  
324 an anatomical, component-based, noise correction strategy  
325 (aCompCor) for spatial and temporal processing to remove  
326 physiological noise factors from the data (Behzadi et al.,  
327 2007). The implementation of aCompCor combined with the  
328 quantification of participant motion and the identification of  
329 outlier scans through the Artifact Rejection Toolbox (ART)  
330 allows for better interpretation of functional connectivity results  
331 (Behzadi et al., 2007; Whitfield-Gabrieli and Nieto-Castanon,  
332 2012; Shirer et al., 2015). The ART was set to the 97th  
333 percentile setting with the mean global-signal deviation threshold  
334 set at  $z = \pm 3$  and the participant-motion threshold set at  
335 0.9 mm. Applying linear regression and using a band-pass  
336 filter of 0.008–0.09 Hz, data were de-noised to exclude signal  
337 frequencies outside of the range of expected BOLD signals  
338 (such as low-frequency scanner drift), minimize participant  
339 motion, extract white matter and cerebral spinal fluid noise  
340 components, and control for within-participant realignment and  
341 scrubbing covariates.

### 343 Structural Magnetic Resonance Imaging 344 Pre-processing

345 Individual T1-weighted images were converted from DICOM to  
346 NIFTI using dcm2niix (Li X. et al., 2016). T1 images were then  
347 skull-stripped and transformed into MNI space using  
348 the default Conn processing pipeline for anatomical volumes,  
349 which utilizes MNI-space direct normalization (Whitfield-  
350 Gabrieli and Nieto-Castanon, 2012). Manual inspection of  
351 skull-stripping performance was completed to ensure optimal  
352 brain extraction for each subject. To reduce potential bias  
353 introduced by automated segmentation procedures, all voxels  
354 of the skull-stripped, MNI-normalized, T1-weighted data for  
355 each subject were included into the model, with regional  
356 analyses being performed subsequent to feature extraction  
(described below).

### 359 Supervised Machine-Learning

360 Within- and between-network connectivity calculations were  
361 performed using ROI-ROI analyses of the 7-network Yeo  
362 et al. (2011) parcellation atlas. Functional connectivity of  
363 each connection was input as the pairwise connectivity of  
364 the 51 parcellations of the seven Yeo et al. (2011) atlas  
365 networks, which is calculated via Fisher z-transformed bivariate  
366 correlations between brain regions' BOLD time-series that  
367 quantify associations in the activation at rest. Redundant pairs  
368 were removed to result in a final total of 1,275 connections.  
369 Participant classes were determined by separating participants  
370 into binary groups based on maintenance or decline in consensus  
371 diagnostic criteria at the follow-up visit most proximal to  
372 the diagnosis of aMCI. Due to the high dimensionality of  
373 MRI data, feature selection was performed on the training  
374 data to further reduce the number of trained features. One  
375 popular method of feature selection is to filter the features via  
376 voxelwise *t*-tests between classes to select current elements with  
377 a significant group-level difference ( $p < 0.01$ ) as features for the  
378 subsequent prediction step (Iguyon and Elisseeff, 2003; Saeyns  
379 et al., 2007; Dubois et al., 2018). Due to the difference in unit  
380 scale between the T1 and rsfMRI images, the selected features  
381 were standardized via z-score transformation. To classify stable  
382 participants and those who declined, we used SVM; a machine  
383 learning algorithm to search for the optimal hyperplane that  
384 separates two classes with maximal margin under the assumption  
385 of independently and identically distributed (iid) data (Andreola,  
386 2009), which is satisfied in this study. Specifically, LIBSVM  
387 (Chang and Lin, 2011) was used to optimize the objective  
388 function:

$$389 \min_{w, b} \frac{1}{2} w^T w + c \sum_{i=1}^i \max (1 - y_i (w^T x_i + b), 0)^2$$

390 where  $C$  is a penalty parameter on the training error. In other  
391 words, to address the issue of unbalanced data, the penalty  
392 parameter,  $C$ , was proportionally scaled for the minority class  
393 (i.e., greater penalty for incorrect classification of decline class  
394 compared to stable). A linear kernel was generated with the  
395 function:

$$396 K(x_i, x_j) = x_i^T x_j$$

400 Model performance was evaluated across 10 permutations of  
401 two-level nested stratified cross-validation (Lindquist et al., 2017;  
402 Varoquaux et al., 2017; Polosecki et al., 2020). To elaborate, we  
403 began by splitting the data into randomized folds and performed  
404 an outer cross-validation loop consisting of  $k$  iterations. In each  
405 iteration, leave-one-out cross-validation was used to separate a  
406 single test case per fold in an outer loop. An inner stratified cross-  
407 validation loop was then performed on the training data ( $N = 54$ )  
408 with 10-folds, providing an optimal hyper-parameter  $C$ . A voxel-  
409 level *t*-test on T1w signal intensity/functional connectivity values  
410 within each cross-validation fold (i.e., 55 times) was performed  
411 on the training data only. Following training, predictions of held  
412 out test data were performed with the decision function:

$$413 f(x) = \text{sgn}(w^T x + b)$$

415 As a sub-investigation of the effect of single-domain aMCI  
416 and multi-domain aMCI on prediction outcomes, model  
417 performance was further evaluated as above after separating  
418 subgroups with single-domain impairment ( $N = 23$ ) and multi-  
419 domain impairment ( $N = 32$ ). In other words, the above model  
420 was evaluated for its ability to predict diagnostic decline at follow-  
421 up in patients with single-domain impairment, and again in  
422 patients with multi-domain impairment.

423 Lastly, to assess the predictive capabilities of baseline  
424 neuropsychological data (see Table 1), we employed identical  
425 SVM procedures as above to predict aMCI decline to  
426 dementia. Both a class-mean filling approach and a list-  
427 wise deletion approach were compared in their ability to handle  
428 neuropsychological data missing at random (MAR). As a note,  
429 when removing cases with missing data, further decreased group  
430 balance was observed and as such, we proportionally adjusted  
431 the penalty parameter  $C$  (as above) to account for the unbalanced  
432 data prior to running the final SVM model.

### 434 Statistical Analysis

435 After all  $k$  iterations in the outer cross-validation loop were  
436 performed, predicted labels of all participants were compared  
437 against ground truth labels to calculate performance metrics.  
438 A Precision-Recall curve of positive predictive value against  
439 true positive rate was plotted to demonstrate the separability  
440 of classes within each model by calculating the area under  
441 the curve (AUC). The F1 score was generated given that it  
442 (1) takes both precision and recall into account to ultimately  
443 measure the accuracy of the model while accounting for false  
444 positives and false negatives, (2) is often more useful in models  
445 with unequal groups, such as the present study. Essentially,  
446 the F1 score ranges from 0 to 1 and gives more weight  
447 to false negatives and false positives while not letting large  
448 numbers of true negatives influence the score, which is helpful  
449 in dichotomous prediction models such as the present study.  
450 A high F1 score (e.g., over 90%) means that the model has  
451 limited false positives and false negatives, indicating the model  
452 has correctly identified real threats while not being disturbed  
453 by false alarms. Lastly, the Matthew's correlation coefficient  
454 (MCC) was also calculated for each modality given that it may  
455 represent a more reliable statistical approach in binary prediction

**TABLE 1 |** Demographics and cognitive performance at baseline for total sample, consensus diagnosis change, and single- vs. multi-domain amnestic MCI groups.

	Total (N = 55)	Stable at follow-up <sup>f</sup> (N = 41)	Decline at follow-up <sup>f</sup> (N = 14)	p-value
Age	72.5 (7.7)	72.0 (6.6)	73.8 (10.3)	0.466
Education	15.0 (3.14)	14.9 (3.0)	15.3 (3.5)	0.735
Gender (% Female)	56.4	53.7	64.3	0.489

models that achieve good results in all possible outcomes (Chicco and Jurman, 2020).

## Functional Regions of Interest

The 7-network Yeo et al. (2011) parcellation atlas was utilized for determination of regions of interest (ROIs). In

this atlas, the seven main networks include the Cingulo-Opercular Network (consisting of the parietal operculum, temporal occipital cortex, frontal operculum, lateral prefrontal cortex), Default Mode Network (prefrontal cortex, posterior cingulate cortex, parahippocampal cortex, and parietal and temporal cortices (corresponding to the angular gyrus and middle temporal gyrus, posterior division, respectively), the

571 Dorsal Attention Network [posterior cortex (corresponding to  
 572 the lateral occipital cortex, superior division), frontal eye fields,  
 573 precentral ventral cortex], the Fronto-Parietal Control Network  
 574 [parietal cortex (corresponding to the posterior division of  
 575 the supramarginal gyrus), temporal cortex (corresponding to  
 576 the posterior division of the middle temporal gyrus), dorsal  
 577 prefrontal cortex, lateral prefrontal cortex, orbitofrontal cortex,  
 578 ventral prefrontal cortex, medial posterior prefrontal cortex,  
 579 precuneus, and the cingulate cortex], the Limbic Network  
 580 [orbitofrontal cortex (corresponding to the frontal pole,  
 581 temporal pole], the Somatomotor Network [somatomotor cortex  
 582 (corresponding to the precentral gyrus)], and the Visual Network  
 583 [visual cortex (corresponding to the superior division of the  
 584 lateral occipital cortex)].

## 586 Feature Weight Calculation

587 For feature weight generation and deployment, a final model  
 588 was trained on features of all participants to derive overall  
 589 classification weights. Specifically, the classification weights  
 590 generated through feature selection were based upon the model  
 591 parameters learned by the optimization function *only* during the  
 592 training phase, *cf.* Equation (3). These weights can be applied  
 593 to independent data from a new participant to predict their  
 594 cognitive decline status associated with specific observed T1 and  
 595 functional connectivity features in test data. The feature weights  
 596 at each voxel, representing the relative contribution of each voxel  
 597 to the classification, were separated by positive and negative  
 598 weights that predict cognitive stability and decline, respectively  
 599 (Cole et al., 2015). Positive and negative weights were divided  
 600 by their respective sum of weights to compute the percent  
 601 contribution of each voxel toward either positive or negative  
 602 predictions. To demonstrate specific brain regions that predict  
 603 decline to dementia, ROIs were defined using the 51 Yeo Atlas  
 604 parcellations and ranked based on their average voxel percent  
 605 contribution. Since features are selected based on the training  
 606 data, the number of features varies per fold and data type.

## 609 RESULTS

610 A total of 55 participants met study criteria and were utilized  
 611 for this secondary data analysis. Mean age of the participants  
 612 was 72.5 (SD 7.7); the average educational attainment was 15.0  
 613 years (SD 3.14). The mean MoCA score was 22.0 (SD 3.0)  
 614 (**Table 1**). Of the 232 potential participants who were excluded,  
 615 152 were excluded because they did not have aMCI at baseline  
 616 (or had multiple diagnoses), 44 did not have valid T1 *and* rsfMRI  
 617 baseline scans, 30 were missing the follow-up visit that came  
 618 after the MRI visit, and 6 had aberrant QC metrics of rsfMRI  
 619 data at baseline. Forty-one participants remained diagnostically  
 620 stable over the study period and 14 declined to dementia at  
 621 the most proximal follow-up evaluation to baseline. Of these 55  
 622 participants, 28 had fully complete neuropsychological battery  
 623 test results, while 27 subjects had between one and two missing  
 624 neuropsychological measures determined in *post-hoc* analyses to  
 625 be missing at random (MAR). Participants who met criteria for  
 626 multi-domain aMCI at baseline were significantly more likely to

627 decline to dementia at follow-up when compared to participants  
 628 with single-domain aMCI (chi-square = 5.85; odds ratio = 6.5;  
 629 *p* = 0.016) (**Table 1**). Otherwise, groups did not differ significantly  
 630 on any of the examined demographic or clinical factors.

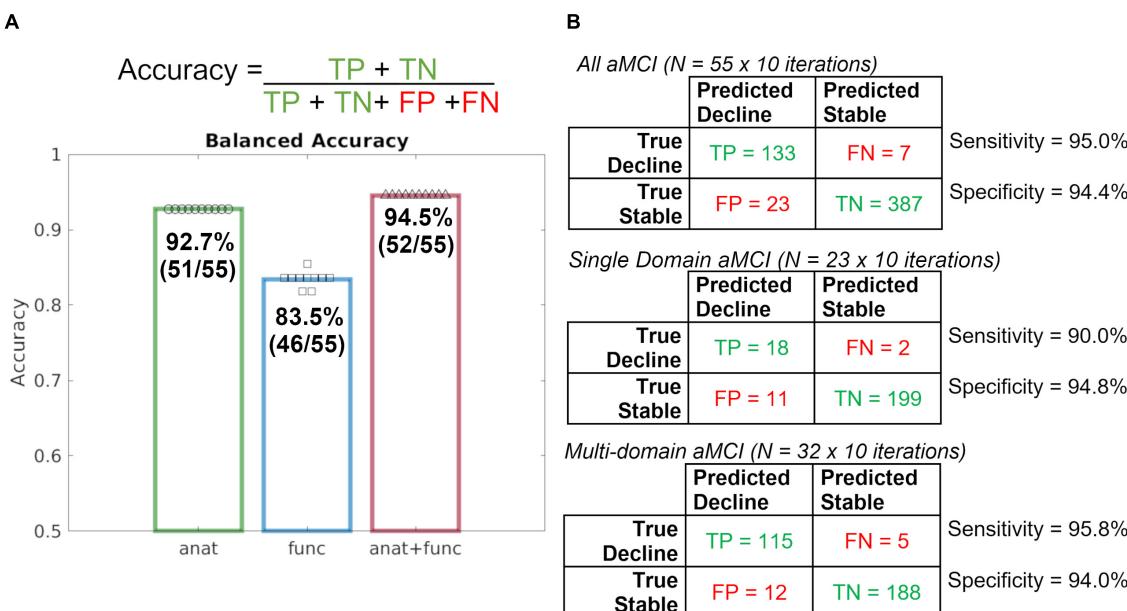

631 Results of a repeated, nested cross-validation reveal a total  
 632 accuracy for predicting diagnostic change at follow-up was 92.7%  
 633 using baseline T1 imaging alone, 83.5% using rsfMRI alone, and  
 634 94.5% when combining T1 and rsfMRI modalities (**Figure 1**). As  
 635 such, 51 of 55 participants were accurately classified using T1, 46  
 636 of 55 participants were accurately classified using rsfMRI, and 52  
 637 of 55 were accurately classified using both modalities together.

638 Given the significant statistical difference in the rate of single-  
 639 and multi-domain aMCI across stable and decline groups, follow-  
 640 up model performance investigation was completed. Follow-  
 641 up investigation of single-domain and multi-domain aMCI  
 642 subgroups revealed nearly identical model performance such  
 643 that the combined T1 and rsfMRI achieved 94.4% total accuracy  
 644 in the single-domain aMCI subgroup and 94.7% total accuracy  
 645 in the multi-domain aMCI subgroup. These results indicate  
 646 that although the prevalence of aMCI subtypes differs, the  
 647 performance of the full, original model is comparable, and  
 648 further model performance metrics will be calculated using all 55  
 649 participants together.

650 **Figure 2** shows that the baseline T1 image alone is highly  
 651 discriminant in the prediction of diagnostic decline as evidenced  
 652 by a precision recall area under the curve (AUC) value 0.961,  
 653 while the AUC for the baseline rsfMRI prediction was 0.836, and  
 654 the combined T1 and rsfMRI model was 0.960. Further, the mean  
 655 F1 score for each modality at the prediction of diagnostic decline  
 656 was greater than 90% (94% for T1 alone, 88% for rsfMRI, and  
 657 96% for the multi-modal T1 and rsfMRI model). Lastly, results  
 658 indicate an MCC value of 0.84 for the T1 image alone, an MCC  
 659 value of 0.65 for the rsfMRI image alone, and an MCC value of  
 660 0.88 for the combination of T1 and rsfMRI.

## 663 Supervised Machine Learning Feature 664 Weight Classification

665 In the present dataset, T1-weighted data averaged 331,945  
 666 features, functional data averaged 85 features, and the  
 667 combination of these data averaged 331,860 features. Given  
 668 that a linear classifier was used to discriminate between aMCI  
 669 patients who remained stable and declined diagnostically at the  
 670 follow-up visit immediately after their baseline MRI, each feature  
 671 in a given MRI sequence influenced this classification via its  
 672 weight. As such, the larger the absolute magnitude of a given  
 673 feature's weight, the more strongly it influenced the optimal  
 674 participant discrimination. As seen in **Figure 3**, this weight  
 675 vector is projected onto the MNI-registered brain in order to  
 676 display how strongly a given region of the brain influenced  
 677 the optimal discrimination between aMCI patients with stable  
 678 vs. declined diagnostic classification at follow-up. Given that  
 679 combined structural and resting-state features were most  
 680 predictive of diagnostic decline (see **Figure 2**), we developed  
 681 a deployable model of combined structural and functional  
 682 feature weights to demonstrate the importance of each brain  
 683 region for the prediction of diagnostic decline. As such, we

**FIGURE 1 |** Repeated, nested, cross-validation test accuracy results for the prediction of aMCI patient ( $N = 55$ ) diagnostic change at follow-up using baseline MRI alone, where a leave-one-out approach was used to predict whether or not a patient declined to dementia. **(A)** Accuracy formula and case predictions for each imaging modality overlaid with balanced case accuracy values. **(B)** Confusion matrices for all aMCI patients, Single Domain aMCI patients, and Multi-domain aMCI patients and their respective sensitivity and specificity values.  $anat = T1$ ;  $func = rsfMRI$ .

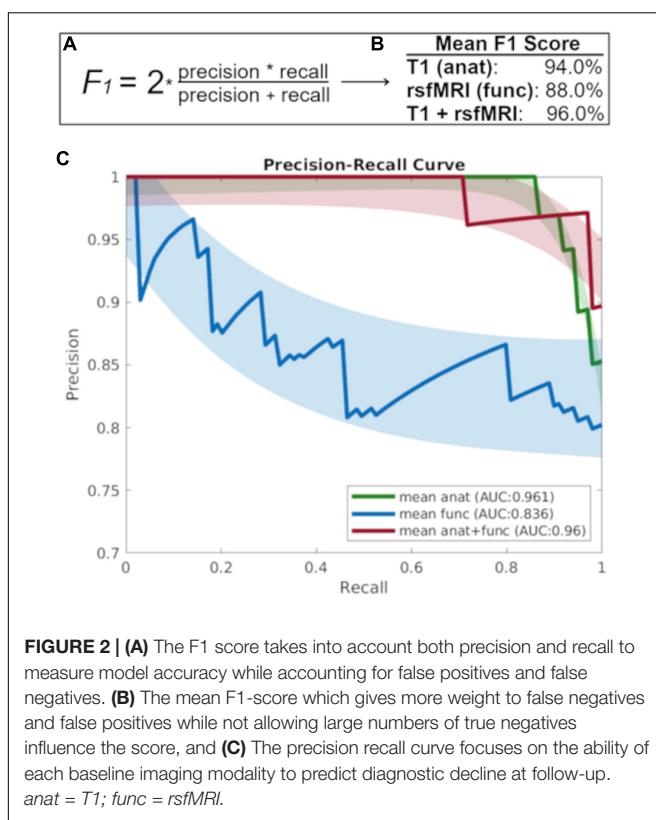

calculated a classifier for the group pairing (stable vs. decline) based on the MNI-registered normalized combination of the T1 voxelwise intensity values and the rsfMRI connectivity matrix using a *t*-test filter ( $p < 0.01$ ) to select features with a significant difference between groups (**Figure 3**). Results indicate that when considering the mean feature weight of each multimodal region for predicting diagnostic decline, the limbic system results in the highest degree of group separation, yet the lowest percentage of total significant voxels by volume (2.90%). Conversely, the visual system demonstrated the lowest degree of group separation by feature weight, yet the highest total voxels by volume (5.24%). Rankings of remaining multimodal regions can be seen in **Figure 3**.

When examining baseline neuropsychological testing data alone, use of a class-mean filling approach to deal with missing data resulted in overall poor accuracy (60% repeated, nested, cross-validated test accuracy) for the prediction of decline from aMCI to dementia at follow-up ( $N = 55$ ). To assess the effect of class-mean filling, observations with missing data were removed and the above analyses were repeated on the 28 subjects with complete data, yielding a 82.1% repeated, nested, cross-validated test accuracy for the prediction of decline from aMCI to dementia at follow-up. Lastly, when combining the class-mean filled neuropsychological data with the functional and anatomical model, nearly identical performance was observed to the multimodal imaging model, including a repeated, nested, cross-validated test accuracy of 94.5%, a mean AUC of 0.96, MCC of 0.88, and F1-Score of 0.96. However, when utilizing only those subjects with complete neuropsychological data ( $N = 28$ ) along with multimodal neuroimaging data, repeated,

nested, cross-validated test accuracy was 82.1%. In other words, in a limited subset sample of 28 participants, dementia conversion prediction based on neuropsychological performance is not improved by the addition of neuroimaging into the model. However, in a larger sample of 55 participants, multi-modal neuroimaging provides the greatest predictive ability and the model is not improved further by the addition of neuropsychological data.

## DISCUSSION

The present study demonstrates that with limited baseline data (<45 min total MRI protocol), a multi-modal SVM model could predict diagnostic decline from amnestic MCI to dementia with over 94% accuracy and 96% precision. In fact, we show that 92.7% accuracy and 96% precision was achieved with a < 10 min T1 alone, and that neuroimaging outperformed a cognitive battery for predicting future decline. This finding has considerable clinical significance as it demonstrates the ability of easily obtained objective biomarkers to provide accurate and precise predictions about which high-risk aMCI patients will go on to develop dementia or potential Alzheimer's disease (AD). While one other study has achieved a similar predictive accuracy in an MCI population also using MRI alone (Hojjati et al., 2018), the present study investigates higher risk aMCI patients and offers unique neuroanatomical information about the combined structural and functional regions that were optimally discriminative for the conversion to dementia in a relatively short time frame. Given the focus on amnestic MCI

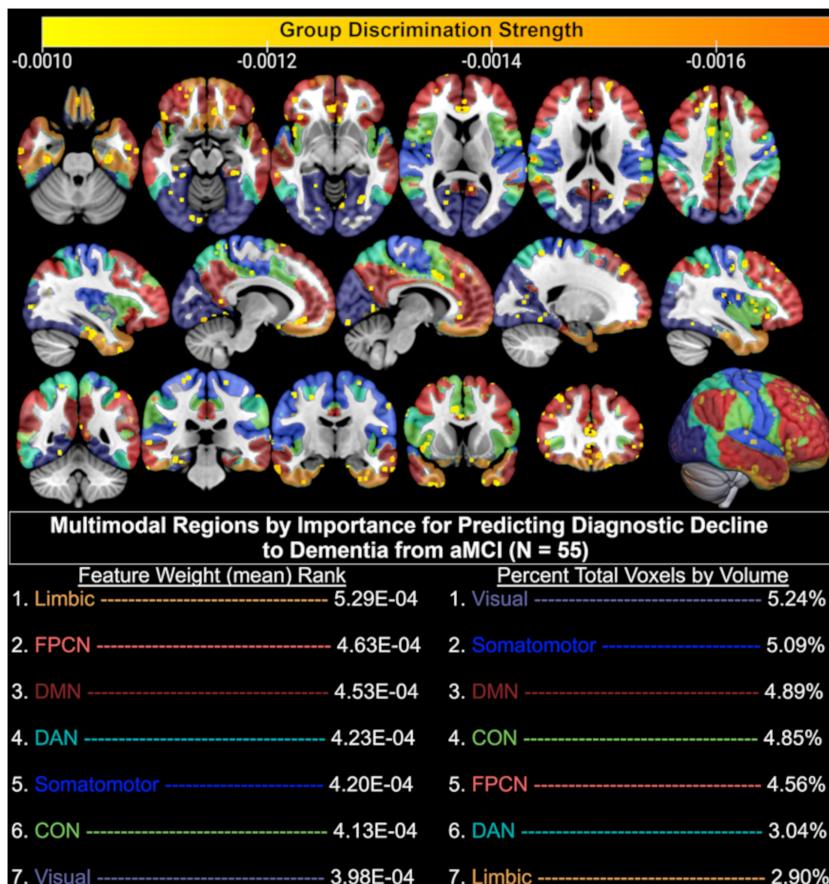

patients, the findings here provide a potentially stronger link to the increased incidence of AD as opposed to an all-MCI cohort, where true AD conversion rates are considerably lower (Ganguli et al., 2015, 2019; Oltra-Cucarella et al., 2018).

The performance of structural T1 MRI alone as a predictor for diagnostic decline to dementia was quite strong, and suggests that structural features were the largest driving force in both the prediction model as well as the resulting feature weights that separated stable patients from converters. This may in part be due to the use of all structural voxels in the model rather than restriction to known ROIs generated by outside parcellation algorithms, as has been done in prior MCI-to-dementia conversion prediction studies (Hojjati et al., 2018). Generation of multimodal feature weights, or combined neural regions that were optimally discriminative for the separation of aMCI patients who did and did not progress to dementia, revealed several important findings. We found that the combined structural and functional regions underlying the limbic system were the smallest in relative size after thresholding for significance, yet showed the strongest degree of group separation as seen by the mean feature weight of significant voxels in that region. Neuroanatomical regions within the limbic system, as defined by the Yeo atlas, include the orbitofrontal cortex and temporal pole. Similarly strong group separation performance was achieved by the regions underlying the frontoparietal control network (FPCN), which encompasses the anatomical regions of the temporal lobe, prefrontal cortex, cingulate cortex, and precuneus. These findings are highly consistent with the meta-analytic literature that suggest neural regions in the medial temporal lobe are associated with

the progression from aMCI to AD (Ferreira et al., 2011), that alterations of the trans-entorhinal limbic regions are seen in MCI patients who eventually convert to AD (Schroeter et al., 2009), and that hypoactivation of the FPCN is observed in MCI patients relative to controls (Li et al., 2015).

We also found the combined structural and functional features underlying the default mode network to be highly important for dementia conversion prediction. This is consistent with the findings of a large meta-analysis in which MCI patients demonstrated hypoactivation in the default mode network, frontoparietal, and visual networks relative to healthy controls (Li et al., 2015). Feature weight generation also revealed that a large number of voxels in the multimodal regions underlying the visual system were significantly predictive of dementia conversion. This is consistent with meta-analytic work suggesting that relative to controls, both MCI and AD patients demonstrate hypoactivation of the visual system during rsfMRI (Li et al., 2015). We propose this finding may be related to degree of impairment, as more impaired patients are more likely have difficulty disengaging their visual systems during a resting paradigm and are thus more likely to fixate on the in-scanner screen. Regardless, this finding may be of clinical utility, as it in itself may be akin to a pathognomonic sign predictive of risk for dementia conversion. It is noted that the slightly higher accuracy of the combined structural-functional model for dementia conversion prediction may be a factor of the previously demonstrated reduced resting-state connectivity among MCI patients who convert to dementia compared to those who do not (Li Y. et al., 2016). A prior study used SVM to predict dementia conversion in an MCI-only cohort and found slightly lower predictive utility of sMRI than the present study (91% vs. 94% accuracy), higher predictive utility of rsfMRI (93% vs. 84% accuracy), and nearly identical combined predictive utility (97% vs. 96% accuracy). Differences observed in the predictive accuracy of rsfMRI may be the result of the use of different atlases for identification of functional connectivity data. Hojjati et al. (2018) utilized the 160-region Dosenbach rsfMRI atlas, while the present study utilized the Yeo 7-network atlas (Yeo et al., 2011). While not explicitly stated in their work, it is presumed that the interconnection of these 160 regions resulted in a total of 12,720 unique connections (using the formula:  $x = \frac{n(n-1)}{2}$ ) available for predictive analyses, whereas the present study was limited to 1,275 unique connections. Thus, the inclusion of a higher number of data points appears to be, at least in part, a potential driver of higher accuracy in the SVM model. To this end, the present study's higher accuracy for sMRI may also be driven by the use of all potential viable white and gray matter voxels in the brain rather than restriction to ROIs generated by an automated parcellation program (e.g., Freesurfer). As such, future work may seek to utilize a greater number of rsfMRI internodal connections to increase predictive ability of the uni- and multi-modal models.

With respect to the use of neuropsychological tests as predictors of future diagnostic decline, we found that the combination of six cognitive measures in an SVM model demonstrated the lowest accuracy of all predictor variables in the present study. This is particularly intriguing, as many of these cognitive measures were used in the formulation of the very consensus diagnosis being predicted, and we hypothesized

**FIGURE 3** | Brain regions (yellow-orange scale) where combined structural (T1) and functional (resting-state fMRI) MRI baseline data significantly discriminated between aMCI patients who remained diagnostically stable and those who declined to dementia at follow-up. Only the top 50% of significant ( $p < 0.01$ ) voxels are displayed based on discrimination strength (voxels with weights 0.000 through  $-0.0009$  excluded for visualization purposes); CON, Cingulo-opercular (Salience) Network; DAN, Dorsal Attention Network; DMN, Default Mode Network; FPCN, Fronto-parietal Control Network.

it to have much higher predictive value for that reason. However, we note our own human nature lends to the ability to ignore missing data and maintain the goal of diagnosis, whereas a machine (SVM) does not deal well with such missing data. It is common to encounter missing neuropsychological test data in human studies, which certainly contributed to a smaller sample size and likely to the lower performance of the neuropsychological SVM model. While our model includes a disproportionately larger number of neuroimaging based features (331,945 structural features, 85 rsfMRI features) in comparison to the six neurocognitive measures in the combined model, if the neurocognitive measures were to have true predictive value, they would have been assigned a weight reflective of such. The fact that in the full 55-subject sample the model did not improve with their addition suggests neuroimaging likely outperforms these six neurocognitive measures for the prediction of future decline. Future work should aim to ensure all cases used for MRI prediction also retain full neuropsychological data to avoid the effects of missing data on SVM analyses.

The present single-center study has several limitations. First, only 14 participants progressed to dementia over a relative short

time period, and slightly over half of these individuals were amyloid positive compared to a much lower amyloid positive rate in our cognitively normal individuals. While not statistically significant, those who converted to dementia tended to be older, have lower cognitive performance at baseline, and a higher rate of amyloid positivity; all of which suggest they may have been at an increased risk of conversion even apart from the MRI findings. Relatedly, we found a higher rate of conversion to dementia in a sub-group of participants with multi-domain amnestic MCI, though follow-up analysis determined the model equally successful at predicting dementia conversion within the two subgroups. Further, baseline neuroimaging outperformed a baseline battery of cognitive performance measures in the prediction of diagnostic decline at follow-up. Thus, we believe the high degree of accuracy and specificity in larger group prediction suggests our model is successful at identifying *individuals* who would ultimately decline to dementia despite the sample heterogeneity. With a larger sample, use of a single-domain aMCI only population may have led to stronger feature weights in the regions ultimately implicated in Alzheimer's disease, such as the limbic system and temporal lobe regions. We used

1027 cross-validation strictly for model performance reporting and  
 1028 not for building a final deployment model. As such, the final  
 1029 model was trained on all subjects and was only used to generate  
 1030 weight maps for deployment to make predictions about new,  
 1031 future data. Future studies are required to determine whether  
 1032 our final algorithm could as accurately predict additional cases  
 1033 from our cohort and importantly to different cohorts such as  
 1034 the Alzheimer's Disease Neuroimaging Initiative (ADNI) and  
 1035 other datasets to assess generalizability of results. While we found  
 1036 that the performance of the combined structural and functional  
 1037 model exceeded the performance of each modality alone, it did so  
 1038 by only a small percentage when compared to the unimodal T1  
 1039 model. While our data do not provide the ability to comment on  
 1040 how the strength of rsfMRI activation in the important networks  
 1041 influenced multimodal predictive accuracy, our future work aims  
 1042 to investigate the patterns of hyper- and hypo-activation in these  
 1043 identified networks and compare between patients who do and  
 1044 do not convert to dementia. Lastly, in the future, we seek to  
 1045 determine the utility of this model to predict conversion to MCI  
 1046 in a population of healthy older adults with no evidence of MCI  
 1047 but with subjective cognitive complaints.

1048  
 1049 **CONCLUSION**  
 1050  
 1051 We demonstrate that a combination of structural and functional  
 1052 information undetected by the human eye can be used to  
 1053 accurately identify high-risk amnestic MCI patients who will  
 1054 develop dementia a short time later. The model deployed in  
 1055 this study independently revealed that several neuroanatomical  
 1056 regions commonly implicated in the development of Alzheimer's  
 1057 disease were the largest drivers in identifying amnestic MCI  
 1058 patients who progress to dementia at follow-up. Further  
 1059 evaluation of our model with larger cohorts, longer follow-up  
 1060 periods, evaluation of amyloid load, and diverse ethnic and  
 1061 cultural groups have the potential to advance the field. If further  
 1062 validated, this technique has the potential to contribute to the  
 1063 identification of individuals with aMCI who are at high risk of  
 1064 progression to dementia, and thus could be prioritized for studies  
 1065 targeting disease modification.
