Abstract

The Canadian Hydrogen Intensity Mapping Experiment (CHIME)/FRB experiment has detected thousands of fast radio bursts (FRBs) due to its sensitivity and wide field of view; however, its low angular resolution prevents it from localizing events to their host galaxies. Very long baseline interferometry (VLBI), triggered by FRB detections from CHIME/FRB will solve the challenge of localization for non-repeating events. Using a refurbished 10 m radio dish at the Algonquin Radio Observatory located in Ontario Canada, we developed a testbed for a VLBI experiment with a theoretical $\lambda/D \lesssim 30$ mas. We provide an overview of the 10 m system and describe its refurbishment, the data acquisition, and a procedure for fringe fitting that simultaneously estimates the geometric delay used for localization and the dispersive delay from the ionosphere. Using single pulses from the Crab pulsar, we validate the system and localization procedure, and analyze the clock stability between sites, which is critical for coherently delay referencing an FRB event. We find a localization of ~ 200 mas is possible with the performance of the current system (single-baseline). Furthermore, for sources with insufficient signal or restricted wideband to simultaneously measure both geometric and ionospheric delays, we show that the differential ionospheric contribution between the two sites must be measured to a precision of 1×10^{-8} pc cm⁻³ to provide a reasonable localization from a detection in the 400–800 MHz band. Finally we show detection of an FRB observed simultaneously in the CHIME and the Algonquin 10 m telescope, the first non-repeating FRB in this long baseline. This project serves as a testbed for the forthcoming CHIME/FRB Outriggers project.

1. Introduction

Fast radio bursts (FRBs) are bright, millisecond-long flashes of radio emission that were first discovered by Lorimer et al. (2007) and have been observed to be distributed throughout the sky (Josephy et al. 2021). Their origins are among the key unresolved questions in astrophysics, despite hundreds of FRBs having been observed to date (Petroff et al. 2016; The CHIME/FRB Collaboration et al. 2021). A significant challenge toward understanding FRBs lies in our inability to determine their precise on-sky positions, which is critical for identifying their host galaxies (Eftekhari & Berger 2017). Despite the fact that some facilities are able to localize FRBs in limited numbers, localization remains a challenging problem (with the exception of low-redshift nearby events; Bhardwaj et al. 2021). This is mainly due to the fact that most FRBs are non-repeating, and a large field of view (FOV) is required in order to increase the probability of detection. A few astronomical facilities are able to identify single-burst FRBs’ host galaxies (Bannister et al. 2017, 2019; Ravi et al. 2019), but their detection rates and fields of view are low. By achieving more precise localizations of non-repeating FRBs, we can constrain FRB populations (Marcote et al. 2017; Kirsten et al. 2021) and improve the classification for repeaters and non-repeaters, and also put them to use as probes for fundamental astrophysics (Petroff et al. 2019).

The Canadian Hydrogen Intensity Mapping Experiment (CHIME) is a radio telescope operating in the 400–800 MHz band, with an 8000 m² aperture area of semicylindrical paraboloid reflectors, located at the Dominion Radio Astrophysical Observatory (DRAO) near Penticton, British Columbia. Each of the four cylinders is instrumented with 256 cloverleaf feeds suspended along the cylindrical axis, and observes a >200 deg² FOV. The combination of the FOV, wide bandwidth, large aperture area, and a powerful correlator makes CHIME a great tool for FRB detection. The CHIME/FRB Collaboration (CHIME/FRB Collaboration et al. 2018) has already published the detection of 21 repeating and 474 non-repeating FRBs (The CHIME/FRB Collaboration et al. 2021). CHIME/FRB and its baseband system are able to localize FRBs with a resolution higher than $\frac{\lambda}{D}$ ²⁷, and as shown in (Masui et al. 2019), with a best-case limit of $\sim 1'$ (Michilli et al. 2021). In order to determine the host galaxies of FRBs, however, localizations better than $1''$ are required.

Very long baseline interferometry (VLBI) is a technique that combines observations from multiple separated telescopes, effectively turning them into one single telescope with an enhanced angular resolution that scales inversely with the projected baseline length. This technique is one method by which we can improve the diffraction-limited beamwidth of CHIME/FRB’s localizations: by correlating baseband data between CHIME and another site, we can use VLBI to find fringes for a single FRB event and coherently delay reference to a nearby calibrator, hence improving the CHIME/FRB localizations by two to three orders of magnitude. So far, only

repeaters have been localized with VLBI scheduled observations (Marcote et al. 2020) and not one-off events.

In this paper we describe VLBI between CHIME and a 10 m telescope at the Algonquin Radio Observatory (ARO). ARO is 260 km West of Ottawa in Algonquin Park, Ontario Canada. It was established in 1963 by the National Research Council Canada (NRC), and its major instrument was a 46 m radio telescope. The 10 m telescope, a prime-focus paraboloid, was constructed at the same time. The baseline between CHIME and ARO is over 3000 km, offering a diffraction-limited resolution within $\theta \lesssim 30$ mas. The Earth projection of the baseline is shown in Figure 1.

The CHIME/FRB Collaboration is actively developing a new set of CHIME Outrigger, composed of cylindrical telescopes at distances of one ~ 20 to several thousand kilometers from the CHIME telescope. The ARO 10 m telescope dish and the CHIME Pathfinder (Leung et al. 2021) serve as testbeds for the CHIME/FRB Outriggers project. Along with CHIME, the Outriggers will perform an autonomous VLBI survey to localize over 1000 FRBs with 50 mas precision. Outriggers will cover mostly the same area that CHIME does (with up to three baselines), and correlate beams digitally while preserving coherence over the FRB sweep. Further, near in-beam calibration can be performed while digitally pointing to different locations on sky, with only an angular space interpolation (rather than over time; clock system), and eventually will be expanded to a grid of pulsar calibrators. The Outrigger project’s aim is to localize one-off FRBs with a VLBI network particularly designed for this purpose, different from a classical VLBI imaging facility, where the pulse is only visible over \sim millisecond timescales. The ARO 10 m testbed is the initial effort to correlate FRBs for the upcoming project.

This paper will proceed as follows. We provide an overview of ARO, the 10 m telescope, and our new instrumentation of the telescope in Section 2. In Section 3 we describe VLBI experiments between CHIME and the ARO 10 m telescope. Section 4 describes early science results, including the detection of VLBI fringes from one FRB. We discuss our results in Section 5 and present our conclusions in Section 6. Appendix A details the 10 m radio frequency (RF) chain, and Appendix B provides a detailed explanation of visibilities and cross correlation with baseband data.

2. Instrumentation

2.1. The Algonquin Radio Observatory

We note that the very first VLBI observations were made between DRAO and ARO in Broten et al. (1967). ARO provides three benefits for VLBI: a site thousands of kilometers from CHIME at DRAO, a clean radio frequency interference (RFI) environment, and access to a hydrogen maser time standard. Although built by NRC, the ARO 46-m Telescope is currently operated by a private company, THOTH.²⁸ The 10 m telescope was not in use at the time we began our work, and had not been used for many years. To provide a testbed for

²⁷ Compared to a standard circular aperture with diameter D observing at a wavelength λ .

²⁸ For more information visit: <http://thothx.com>.

development of VLBI techniques for the CHIME/FRB Outrigger project, we equipped the 10 m telescope with a new feed and receiver system, sending telescope signals via 200 m of buried coaxial cables (from the 1960s) to our new digital processing system in the control room of the 46 m telescope. The 10 m aperture provides sufficient gain to be a useful complement to CHIME.

2.2. The 10 m Telescope

The 10 m telescope (Figure 2) was inaugurated in 1964 (Medd & Broten 1961; National Research Council of Canada & Division 1969), with an equatorial mount and a manual mechanical engine with decl. and hour angle drive (or polar drive). The paraboloidal dish has a structure with four feed-support struts to support the focus equipment, with a surface accuracy of 0.063 cm rms at the time of its construction (Dawson 1970). Coaxial cables with standard Bayonet Neill–Concelman (BNC) and N-type lines run through the feed-support struts and connect the feed and first-stage amplifiers (power and analog cables). The telescope is equipped with an analog system for pointing and a polar axis drive unit located physically at the telescope exterior.

Table 1 gives specifications of the telescope and its location. The decl. and polar drive and their indicator systems were only partly functional at the beginning of our work, but we were able to point the telescope by applying external torque to the gearboxes. The telescope was set to the decl. of Taurus A to receive pulses from PSR B05321+21, which we used as a test source. The hour angle was set west of the ARO meridian so that area of sky seen by the main beam coincided with that seen by CHIME on the meridian at DRAO (see Figure 7). The azimuth and elevation of this position are 248° and 50° , respectively. We estimate the accuracy of this pointing to be $\sim 1^\circ$, checked by the PSR B05321+21 transit through the telescope beam.

We installed a new analog system on the 10 m telescope, including a new feed and low-noise amplifiers (LNAs) at the focus, and second-stage amplification in the telescope pedestal. We used underground coaxial cables, installed in the 1960s, to connect to a new digital acquisition system in the control room of the 46 m telescope, 200 m away. See Section 2.3 and Appendix A for details of the analog system, and Section 2.4 for a description of the digital system.

With the completion of these upgrades, the telescope is fully operational and working 24/7 with occasional power interruptions during the winter months due to the site’s remote location.

Figure 2. ARO 10 m telescope; photograph taken in 2020 September. The backplane and CHIME feed are visible at the telescope’s focus. The feed in the paraboloid focus is slightly offset toward the vertex.

Table 1
ARO 10 m Telescope Properties

Telescope Mount	Equatorial R.A. and Decl.
Dish diameter	10 m
f/D	0.4
Surface accuracy	0.063 cm rms
Latitude	45.955 deg
Longitude	-78.070 deg
Altitude	~ 50 deg
Azimuth	~ 248 deg

Its day-to-day operations and monitoring are done remotely over a satellite-based internet connection.

2.3. Analog Signal Chain

The decommissioned 10 m telescope, along with its analog chain and cabling, had fallen into disuse prior to beginning this project. Before this project commenced, the system cables were tested and confirmed to still be in good working order but with attenuation due to the age of the cables; the existing connectors were also improved and signal amplification was added. Additionally, the entire back-end and partial front-end systems were updated. The receiver was equipped with a dual linear polarized feed, identical to those used to equip CHIME (Deng

Figure 3. Gains of the amplifiers in stages S_1 , S_2 , and S_3 . Each of the amplifiers was measured and tested on site with a vector network analyzer. The gray area is the bandwidth 400–800 MHz. The y-axis gain G is presented in terms of the scattering parameter or S-parameter, $|G| = |S_{21}|$. Data were taken during the feed installation in 2019 April. The strong ripple in the amplifier response seen in the middle panel is due to cable reflections.

& Campbell-Wilson 2017). The receiver has a working bandwidth of 400 MHz and has a noise injection SubMiniature version A (SMA) connection, used for on-site tests and telescope characterization. The feed was placed in the telescope’s focus and connected to the first-stage amplifiers (which are the same as those on CHIME).

2.3.1. Radio Frequency Signal Chain

There are three amplifier stages: S_1 , S_2 , and S_3 . The first-stage amplifiers are located right next to the cloverleaf feed (telescope’s focus) with an SMA connection. The first-stage amplifiers are connected by dual polarization lines to the second-stage amplifiers in the telescope’s pedestal. The pedestal also contains the power supplies for S_1 and S_2 . The final stage, S_3 , is at the end of the underground connected lines from the telescope’s pedestal to the control room. In the control room there is another set of amplifiers right before the digitizer ICE system (Bandura et al. 2016).

The LNAs in S_1 are custom-built CHIME amplifiers (see the top panel in Figure 3). Each amplifier is bounded with an RF shield enclosure that also protects for weather conditions.

Figure 4. ICE, FPGAs, and ARM processor in the control room of the ARO 10 m telescope.

Due to the large distance spanned by the connection between the 10 m dish and the control room, an extra amplification was required from S_2 to S_3 . These are commercial LNAs placed consecutively and fed with the analog lines that come from the telescope focus in S_1 (see the middle panel in Figure 3).

S_3 contains the last set of amplifiers after the long underground lines (~ 200 m) and before the signal digitalization. This last set of amplifiers is composed of custom CHIME Pathfinder amplifiers (Bandura et al. 2014), a set of commercial line equalizers, and 400–800 MHz bandpass filters. The S_3 amplifiers’ gain (bottom panel of Figure 3) compensates for the gain drop in S_1 .

For a detailed description of components and the analog chain, see Appendix A.

2.4. Digital Processing

The digital processing at the ARO 10 m telescope is similar to that done by CHIME/FRB. The analog signal arrives at the analog-to-digital converters (ADCs) on the ICE, which are clocked by a hydrogen maser, and an initial time stamp for each acquisition is provided by a global positioning system (GPS) signal. The underground analog signals (two polarizations) come from the 10 m, and two extra SMA connections on the board are related to the maser and GPS time stamps. Following this, the same main configuration from CHIME/FRB is applied, i.e., we sample raw voltages at 8 bit, apply a polyphase filter bank (PFB; with an identical number of taps; Price 2016) at 18 bit, and then quantize to 4+4 bit resolution. After channelization is done, baseband data has 1024 frequency channels spanning from 400–800 MHz and a sample rate of 390.625 kHz.

The ICE system hardware (Bandura et al. 2016) at the ARO 10 m telescope is made of two ADC data-acquisition daughter boards attached to the field-programmable gate array (FPGA), and an ARM processor running Linux, which loads the firmware onto the FPGAs (see Figure 4) and provides monitoring functionality. The ICE reads data from the ADCs at 8 bit with a sample rate of 800 mega samples per second, resulting in a data rate of 6.4 Gbit s^{-1} for each of the ADCs. The data products from the ICE (after PFB and quantization) go to the main recording node on site, where the data are carried through two QSFP+ connectors on the motherboard, which then become eight connections with SFP+ ports. The total possible data rate on the recording node is therefore 51.2 Gbit s^{-1} , but the actual data rate used is 6.4 Gbit s^{-1} from two of the 16 ADC inputs (in the 51.2 Gbit s^{-1}).

The main difference between the signal chains of CHIME/FRB and the ARO 10 m telescope is the fact that CHIME/FRB

uses a GPS disciplined crystal oscillator for its 10 MHz clock, thereby keeping the clock in sync with the GPS on long timescales. Separately, we digitize a maser signal (DRAO maser), in order to correct for timing variations of the GPS clock (on short timescales), i.e., CHIME/FRB has effectively a maser-precision. This combines the long-term absolute accuracy of the GPS clock with the short timescale relative precision of the maser (Mena-Parra et al. 2021).

On the other hand, the 10 MHz clock at ARO is provided by a hydrogen maser (which provides tempo), and the GPS unit only provides an initial reference GPS time stamp via an IRIG-B connection to the ICE system. The clock is therefore free running off the maser and not adjusted to keep time with GPS after the start of an acquisition. In VLBI, clock stability is crucial to understand and localize sources (due to its geometric relation; see Section 3), and its reliability is measured with the Allan variance (standard measure of frequency stability in clocks).

As in CHIME, the data processing system used at the ARO 10 m telescope is *kotekan*²⁹, which is run in the recording node. This is a framework for assigning blocks of processing components. The *kotekan* software works the same as in CHIME, but its configuration is appropriate for single-antenna recording.

There is currently no real-time processing of baseband data at the ARO 10 m telescope; instead, all data are stored in a set of 10 drives of 11 TB each, giving a buffer with a theoretical capacity of 30 hr. In reality, this time period is lower due to the limitation of the data writing to disk, the space used in the drives, and the constantly running disk-cleaner utility. Accounting for this, the actual buffer is roughly ~ 24 h. The recording depends on: maintenance, power outages, and other down times. This window is more than enough to establish a connection with CHIME/FRB and a potential triggering signal. The data are recorded to the set of hard drives simultaneously for fast and efficient storing and processing on the recording node. Data that have been on the disks for longer than the buffer time are eventually deleted by the disk-cleaner (which is a simple script used to remove data after a certain disk usage has been reached), unless the system is stopped manually or data have been hard-linked³⁰ by a CHIME/FRB triggering event.

Important elements in this chain such as the FPGAs, *kotekan*, disk-cleaner, and hard-linker are automatically serviced on the recording node and constantly monitored by users.

Other components of the digital chain are machines, including (1) a controller node, which is in charge of the intensity stream from *kotekan* and receiving trigger signals from CHIME, and (2) an analysis node, the main machine used to check data and early science results before data are transferred to a common location. To minimize the RFI from different components in the analog chain, all systems described in this section are enclosed in an RF-shielded rack; see Figures 5 and 6.

Other network and power elements are the main switch and the power distribution unit (PDU).

Figure 5. RF-shielded rack located in the main control room at ARO. The rack includes (from top to bottom): controller node, analysis node, power distribution unit (PDU), main switch, GPS unit, ICE/FPGAs, and recording node.

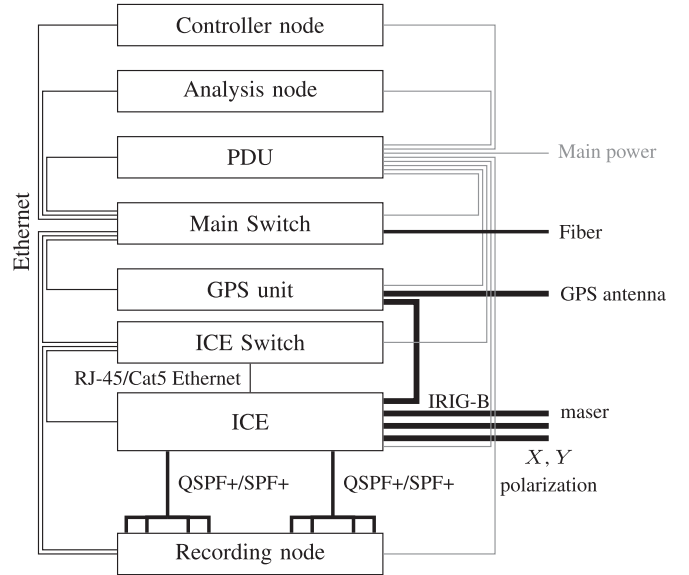

Figure 6. Digital chain connections diagram inside the RF-shielded rack. Thin black lines represent Ethernet connections, thin gray lines are power connections and QSPF+/SPF+, and very thick lines are analog connections (SMA connectors). Terminal cables on the right side are connections that go to the exterior of the RF-shielded rack. This figure represents the schematics of Figure 5.

Site communication is done via Xplornet satellite-based internet. The internet connection varies with weather with an average upload/download of 4.5 Mbit s^{-1} . Nevertheless, we only require checks on the telescope through Secure Shell (ssh), and once a day, pulses (potential FRBs or calibrators) are transferred over to the Compute Canada system SciNet (Ponce et al. 2019). This is a common location where the cross-correlation process between the DRAO and ARO sites is carried out.

²⁹ The *kotekan* software repository: <https://github.com/kotekan/kotekan>.

³⁰ Hard-linking refers to a data link, or in effect a copy, that frees random-access memory (from a normal copying process) and allows the data to be accessed even after the original has been erased (original data bits are preserved).

Figure 7. CHIME and ARO 10 m telescope FOV comparison. Figure is to scale comparing at an observing frequency of 600 MHz. The zoomed-in region shows single CHIME/FRB beams of size $0^{\circ}.32$ with a separation between them of $0^{\circ}.4$. The ARO 10 m telescope beam is located on the southern section of the CHIME beam decl. $+22^{\circ}$. The CHIME/FRB beamformed beams change in shape with zenith angle (Ng et al. 2017).

2.5. Triggering from CHIME

The ARO 10 m telescope data are not searched independently for astrophysical transients. Data are only saved upon receipt of a trigger from CHIME/FRB. Only FRBs that are detected in the shared FOV between CHIME/FRB and the ARO 10 m telescope cause a trigger to the ARO site. The overlapped FOV is centered at decl. $+22^{\circ}$, and only beams in the same sky location as the 10 m are able to trigger events (roughly 36 beams at 60 MHz; see Figure 7). Baseband data for processed events are then triggered at CHIME (within the same CHIME/FRB pipeline as normal events; see CHIME/FRB Collaboration et al. 2018), and a trigger is sent to ARO, which activates hard-link storage and backs up the recently recorded data. For calibration and delay reference purposes, pulses from PSR B0531+21 (the Crab pulsar) are also dumped daily in the same way as an FRB.

CHIME/FRB detection happens in beamformed beams (Ng et al. 2017), which then alert the ARO 10 m telescope with a triggering signal. Figure 7 shows an up-to-scale comparison of CHIME/FRB beams and the single beam from the ARO 10 m telescope. With this current configuration, we expect to observe ~ 4 – 7 FRBs per month (estimated from CHIME/FRB rates without considering down times). However, only the brightest pulses are detected in cross correlation.

The signal-to-noise ratio (S/N) is only computed at CHIME, which is because of the following reasons:

1. PSR B0531+21 pulses are observed through the Crab Nebula, which will increase the system temperature (irrelevant for FRBs).
2. Some pulses are not visible in intensity at the ARO 10 m telescope, but they cross correlate.
3. The ARO 10 m telescope pointing is only known within ~ 1 deg, meaning that some of the detected pulses could fall in a side lobe.
4. System temperature and beam model are unknown for the ARO 10 m telescope.

A single pulse from PSR B0531+21 (J0534+2200; Lyne et al. 2015) is recorded daily at the 10 m and at CHIME. These are giant pulses (GPs), with a flux density of the order of 1–10 kJy, of dispersion sweep 1.1 s (dispersion measure, DM, approximately 56 pc cm^{-3}) at 400–800 MHz, and unknown time of arrival (ToA). Only a single pulse per day is triggered because of limitations of the CHIME/FRB system and the short time over which the two FOVs overlap (roughly ~ 10 minutes). The recording system in CHIME/FRB is limited to 100 ms duration snapshots and has a trigger cooldown time of ~ 5 minute.

The simultaneous baseband dumps are used on a regular basis to check data quality and clock stability, study the ionosphere, and serve as a potential calibrator for an FRB event before or after its recording. The single pulse is selected via an S/N threshold at CHIME of $S/N_{\text{CHIME}} \geq 30$ and then triggered at the ARO 10 m telescope with the selected CHIME/FRB time stamp ± 2.45 ms (geometric delay due to baseline b). An example of a pulse observed simultaneously at CHIME/FRB and ARO 10 m telescope is in Figure 8.

In addition to standard triggering using the CHIME/FRB back-end, CHIME is equipped with a VLBI tracking beam that can digitally point and save baseband data to disk. Observations with the CHIME VLBI tracking beam are a continuous stream of data (similar to the ARO 10 m telescope), and the CHIME VLBI tracking beam does not receive triggers. The CHIME VLBI tracking beam was used to observe PSR B0531+21 in continuum mode (i.e., several minutes recorded) because the CHIME/FRB trigger system could not record raw voltage data from multiple pulses on such short timescales. These observations were used to study the clock stability over a single day in Section 3.5.1.

2.5.1. Baseband Data

As mentioned in Section 2.4, both CHIME and the ARO 10 m telescope return a similar type of baseband data as a product. The complex voltage is stored in an array of $N = 1024$ frequency channels, K time bin width of $2.56 \mu\text{s}$, each of which

Figure 8. PSR B0531+21 pulse triggered at CHIME/FRB and also selected at ARO 10 m telescope. The intensity data are the power of each polarization combined per telescope and averaged over frequency channels. Data have been scaled in order to have the same level of the off-pulse rms. Both pulses have been coherently de-dispersed to $56.7558 \text{ pc cm}^{-3}$. The time stamp corresponds to the ToA measured at CHIME with an uncertainty of $2.56 \mu\text{s}$. The ARO 10 m data will have a different start time adjusted to the geometric delay and clock errors.

is called a *frame*, and dual linear polarizations (in CHIME north-south Y and east-west X polarizations), hereafter called *baseband data* (after passing through the PFB). Figure 9 shows a representation of the baseband data, where the elements $(V_X)_{nk}$ and $(V_Y)_{nk}$ with $k = 0, \dots, K-1$ and $n = 0, \dots, N-1$, are complex numbers, which are part of the X and Y polarizations. Baseband data will be represented as V :

$$\begin{aligned} V_X[n, k] &= (V_X)_{nk} \in \mathbb{C}^{N \times K} \quad \text{or} \\ V_Y[n, k] &= (V_Y)_{nk} \in \mathbb{C}^{N \times K}, \end{aligned} \quad (1)$$

depending on their polarization. The notation $[n, k]$ refers to discrete dependency on frequency channels (n) and frames (k). The first channel $n = 0$ has a center frequency of 800 MHz, and the last channel $n = 1023$ is 400.390625 MHz.

At the ARO 10 m telescope and the CHIME VLBI tracking beam, data are stored to disk as a continuum, i.e., column $n = 0$ has the same start time for all its elements. In contrast, the CHIME/FRB back-end sends callback detections from intensity data and clips around baseband data on buffer; the clipping returns a block of baseband data where frequency channels have different start times and follow the dispersion of a pulsar or FRB.

A higher time resolution than $2.56 \mu\text{s}$ can be achieved by inverting the PFB (raw ADC data); this is a complicated procedure, but in principle is feasible. Alternatively, this can be achieved by studying the phase information in the complex number frames of the baseband data. In this analysis, we will only use the latter, baseband data space. For a more detailed description of the baseband and raw ADC data properties, see Appendix B.

3. VLBI between the ARO 10 m Telescope and CHIME

We are interested in finding the cross correlation that exists between the same wavefront detected on different sites. Once the wavefront reaches CHIME and the ARO 10 m telescope (hereafter site A and site B), it is digitized and transformed to baseband data. The telescopes A and B will observe delayed copies of the same signals. The nondispersive delays contain localization information. But also, other sources of

Figure 9. Visual representation of CHIME and ARO 10 m telescope baseband data, V . For short notation, $k' = K-1$ and $n' = N-1$ were used. Each polarization has $N \times K$ complex numbers, where $N = 1024$ frequency channels and K is the number of frames. The quantities $(V_X)_{nk}$ and $(V_Y)_{nk}$ (with $k = 0, \dots, K-1$ and $n = 0, \dots, N-1$) are complex numbers `np.cdouble`. Each element $(V_X)_{nk}$ or $(V_Y)_{nk}$ has a GPS time stamp associated with a time bin of $2.56 \mu\text{s}$ called frame.

Figure 10. VLBI of a distant source of radio noise. The subframe cross-correlation function $\rho_{A,B}^{sf}(\tau)$ will be maximum when the delay τ_{geo} is applied. The variable b represents the baseline (same as in Figure 1) Euclidian distance between sites A and B , and θ is the baseline angle that is a function of R.A. and decl., $\theta = \theta(\alpha, \delta)$. Notice that the wavefront is only an approximation of a plane wave; the atmosphere and interstellar medium will modify its structure (see total delay, Equation (3)).

nondispersive delay will exist, such as the troposphere and the clock error between stations. In addition, the dispersive delays given by the ionosphere and instrumental effects must be properly calibrated.

Then starting from (V_{P_A}, V_{P_B}) collected from the event at both sites³¹, we will define the subframe cross correlation $\rho_{A,B}^{sf}(\tau)$, a function of delay τ . The quantity $\rho_{A,B}^{sf}(\tau)$ (mathematically defined in Section 3.1) is only computed at a subframe level, and it tells the time difference (lag) relative to time measured at A and B .

Figure 10 shows the basic components from the VLBI system. We are interested in finding the localization given by the baseline angle θ (angle between the baseline vector and the source vector), which is function of the R.A. and decl. $\theta = \theta(\alpha, \delta)$ of the source, and in our case, most of the contribution will be given by the R.A. (Figure 1). The baseline angle is

³¹ Here, the polarizations P_A and P_B can be either a linear (X, Y) or circular (R, L) basis.

expressed simply as:

$$\theta = \arccos\left(\frac{\tau_{\text{geo}} c}{b}\right), \quad (2)$$

with c the speed of light, b the baseline ($b \approx 3000$ km), and τ_{geo} the geometric delay.

For the ARO 10 m telescope testbed, calibrators are pulsars (in particular, PSR B0531+21 pulses), since pulsars are easier to tell apart from the background as compared to standard VLBI (steady-source) calibrators. Pulsars, in addition, are sufficiently compact and with no confusion (time-domain separation from background) at our frequencies.

The CHIME and ARO 10 m telescope stations have system-equivalent flux densities (SEFDs; S_{sys}) of ~ 40 kJy and ~ 1.7 kJy. When Taurus A is in the beam (e.g., during a Crab GP trigger), the SEFD at the ARO 10 m telescope increases to 1 kJy ($S_{\text{TaurusA}} \approx 1$ kJy; Perley & Butler 2017). The CHIME observation will be completely dominated by the Taurus A flux (Cordes et al. 2004). VLBI observations of the Crab pulsar baseline noise level will not be discussed, since the nebula is not correlated (Popov et al. 2017; nebula determines the noise level and does not lead to a correlation), with the exception of Crab's GPs. In addition, Crab GPs can easily exceed the Taurus A emission with fluxes above 1 kJy (Bij et al. 2021; Thulasiram & Lin 2021), i.e., $S_{\text{sys}} \approx S_{\text{GPs}}$ (Section 2.5; since only high enough S/N pulses are correlated).

Earlier tests were performed at CHIME frequencies with steady-source calibrators in VLBI, but correlations were not possible to achieve. Steady-source calibrators are known to be sufficiently unresolved at high frequencies and narrow bandwidths, which is not the case at CHIME and ARO 10 m telescope. Nevertheless, the future CHIME/FRB Outrigger project is taking steady-source VLBI calibrators into consideration, as Low-Frequency Array has been successful in doing so at low frequencies (Moldón et al. 2015). The cross correlation using pulsars is in principle similar to that for an FRB (with the exception of longer dispersion times, as will be discussed in detail in Section 5.6).

We must find and isolate the geometric delay τ_{geo} from the total (observed) delay τ_{total} . We can then decompose it into its different components:

$$\tau_{\text{total}}(t, \nu) = \tau_{\text{clock}} + \tau_{\text{geo}}(t, \theta) + \tau_{\text{iono}}(\nu) + \tau_{\text{inst}}(\nu) + \xi. \quad (3)$$

In Equation (3), left to right, the delays are: total, clock error (constant), geometrical (baseline angle and time dependent, which also includes tropospheric delay), ionospheric (frequency-dependent), instrumentation (frequency-dependent), and noise errors.

A general introduction to VLBI and how to treat and remove delays from Equation (3) is described by Reid & Honma (2014).

3.1. Correlation with Baseband Data

In a traditional XF correlator framework (Price 2016), raw ADC sampled data are cross correlated with efficient fast Fourier transform (FFT) algorithms without any hierarchical separation of time or frequency scales, with the peak of the one-dimensional cross-correlation function yielding a measurement of the geometric delay, τ_{geo} . One drawback of this approach is that the problem is further complicated by the introduction of nanosecond-scale systematic drifts. All of these

drifts change on minute- to day-long timescales, and they exhibit different frequency dependencies. It is desirable to correlate our baseband data in a more hierarchical manner so we can characterize and separate these different shifts by their differing frequency dependence and time dependence. We break down the problem into two parts: first we determine the integer delay, measured in multiples of the baseband period of $2.56 \mu\text{s}$ (number of k to shift), followed by the fractional (or subframe) part of the delay (phase correction), according to

$$\frac{\tau_{\text{total}}}{2.56 \mu\text{s}} = \left\lfloor \frac{\tau_{\text{total}}}{2.56 \mu\text{s}} \right\rfloor + \left\{ \frac{\tau_{\text{total}}}{2.56 \mu\text{s}} \right\}, \quad (4)$$

where $\lfloor \cdot \rfloor$ is the integer part of a frame, and $\{ \cdot \}$ the fractional part. At the integer frame level, the largest delays to compensate for are the geometric and clock delays, i.e.,

$$k_{\text{shift}} = \left\lfloor \frac{\tau_{\text{geo}_0} + \tau_{\text{clock}_0}}{2.56 \mu\text{s}} \right\rfloor, \quad (5)$$

where τ_{geo_0} is given by a prior source localization, which is accurate at the arcminute level (Section 3.2), and τ_{clock_0} is a prior measurement of the constant delay.

If we have measured the frame delay correctly, k_{shift} , the visibility matrix can be constructed:

$$\begin{aligned} \mathcal{V}_{P_A P_B}[n, k] &= V_{P_A}[n, k - k_{\text{shift}}] \overline{V_{P_B}[n, k]} \\ &= (\mathcal{V}_{P_A P_B})_{nk} \in \mathbb{C}^{N \times K}, \end{aligned} \quad (6)$$

with $\mathcal{V}_{P_A P_B}$ the matrix of frames and frequency channels with $(\mathcal{V}_{P_A P_B})_{nk}$ elements, which is simply an array element-by-element multiplication. The complex conjugate of all elements in matrix \mathcal{V} is expressed as $\overline{\mathcal{V}}$. Equivalently we can rewrite Equation (6) in terms of its phase:

$$\mathcal{V}_{P_A P_B} = \|\mathcal{V}_{P_A P_B}\| e^{i\phi}, \quad \phi = \text{Arg}[\mathcal{V}_{P_A P_B}], \quad (7)$$

with ϕ a matrix with each element ϕ_{nk} (frames and frequency channels), and $\|\cdot\|$ the norm of each complex element. The subframe delay of Equation (6) shows up in the phase of each complex number. One approach is to take the Fourier transform of $\mathcal{V}_{P_A P_B}$ over the frequency axis (n). This is approximately equivalent to lag-correlating our baseband data in many small $2.56 \mu\text{s}$ integrations, ignoring spectral leakage effects. If the delay were purely geometric, finding a peak in subframe cross correlation, as a function of τ would perfectly determine the subframe part of the delay. However this approach does not allow us to separate out the different contributions to the delay, as we discussed earlier. Instead, we sum (integrate) over frames, measuring the phase as a function of frequency channel, as shown in Figure 11, left panel. Then the *integrated visibility* is defined as:

$$\langle \mathcal{V}_{P_A P_B} \rangle_t[n] = \sum_{k'} (\mathcal{V}_{P_A P_B})_{nk'}, \quad (8)$$

integrated over a time $t = k' \times 2.56 \mu\text{s}$ proportional to a number of frames, k' . We are left with a sequence of $N = 1024$ complex visibilities, which contain all of the subframe delays.

Figure 11. Imaginary part of visibility, $\text{Im}[\mathcal{V}_{A \times B}]$. Left and top panels are the integrated (summed) visibility angle over time and over frequency. The integration is done along the strongest section of the pulse width (t_w), taking into consideration the scattering tail profile $\propto \nu^{-4}$ (curved black dashed line). For these strong pulses (the same from Figure 8), its phase wrapping is close to 0 rad. Other conjugates of polarization pairs can be seen in Appendix B, Figure 28. Black horizontal lines are dead frequency channels.

We now define the subframe cross-correlation function in terms of the integrated visibility of baseband data as:

$$\begin{aligned} \rho_{A,B}^{\text{sf}}[u] &= \sum_{n=0}^{N-1} \sum_{k'} (\mathcal{V}_{P_A P_B})_{nk'} e^{-\frac{i}{N} 2\pi u n} \\ &= \text{FFT}[\langle \mathcal{V}_{P_A P_B} \rangle_t], \end{aligned} \quad (9)$$

where the norm of the FFT is over the frequency axis with n channels, and it returns the cross-correlation strength as a function of lag with u data points, cross-correlation strength: $\|\rho_{A,B}^{\text{sf}}\|$. Notice that the maximum value of the cross-correlation strength is:

$$\tau_u = \arg \max_{\tau_u \in [-1.28 \text{ } \mu\text{s}, 1.28 \text{ } \mu\text{s}]} \|\rho_{A,B}^{\text{sf}}[u]\|, \quad (10)$$

with τ_u the *lag-correlation* or first estimate of the constant delay that exists between the two data sets. To separate the different contributions to the total subframe delay, we must fringe-fit the visibilities $\langle \mathcal{V}_{P_A P_B} \rangle_t$ from several sources to a delay model (dispersive and nondispersive) using the differing frequency and time dependencies.

3.2. Geometric Correction

Due to the large value of the geometric delay (several frames) and its considerable variation over time $\tau_{\text{geo}}(t, \theta)$, an initial guess for τ_{geo} is required. The geometric delay model, τ_{geo_0} , is used to re-align phase and frames of baseband data for correlation, but since it depends on the precision of the initial localization guess given by CHIME (or the precision of the baseline), a residual will be left to compute $\tilde{\tau}_{\text{geo}}$ here, where:

$$\tilde{\tau}_{\text{geo}} = \tau_{\text{geo}} - \tau_{\text{geo}_0}. \quad (11)$$

This residual calculation will be done in the wideband fringe-fitting algorithm (Section 3.4).

Each baseband frame is tagged with a local atomic clock (or close to atomic performance). As such, we need to know the proper time delay between the arrival of the wavefront at one antenna and the arrival at the second. Computing this is complicated by the reality that the object under observation is only stationary in a frame (of reference) in which the antennas are moving. For short baselines, this motion is negligible compared to the time it takes light to cross the baseline, but for VLBI, it can become significant. Geometric delays will be computed using `difxcalc11` (Gordon et al. 2016), where by giving an observation time, sky coordinates, and Earth locations, a τ_{geo_0} model can be calculated. The software first computes the exact site locations, taking into account crust deformations due to a high-order tide model (and if ocean coefficients are available, it will include those effects). Once it has the baseline, it applies the Consensus (Eubanks et al. 1991) relativity model, which accounts for the baseline motion in the solar system barycenter frame and for gravitational and special time dilation effects. Other additional delays are added afterwards such as the troposphere refractive delay of the source in each site. Geometric delay models are intensively studied in geodetic VLBI and tend to be described by the same models as in astrometry VLBI (Titov et al. 2020). The model at the CHIME and ARO 10 m telescope baseline using `difxcalc11` is able to achieve picosecond precision (Soffel et al. 1991), which is more than sufficient for our purposes.

3.3. Coherent Delay Referencing

In order to localize a target (FRB) given a reference (calibrator), we use *delay referencing*. All astrometric information will be contained only in the phase of the two sets of visibilities, and by computing their phase difference, a good estimate of their sky angular difference ($\Delta\theta$) can be computed. Other frequency-dependent effects such as the instrumentation phase error (given by $\tau_{\text{inst}}(\nu)$) will also cancel off. We then calculate the angle of the visibility ratio, where in the ideal case $\tau_{\text{total}} = \tau_{\text{geo}}$, the ratio becomes:

$$\Delta\phi_{\text{geo}} = \phi_{\text{geo}}^t - \phi_{\text{geo}}^r = 2\pi b \frac{\nu}{c} (\cos\theta_t - \cos\theta_r), \quad (12)$$

where θ_t is the baseline angle of the target, θ_r is the baseline angle of the reference, and ϕ represents the angle of the complex visibility. Notice that to reach Equation (12), we need to first account for all terms from Equation (3) in the phase ϕ (delays smaller than a frame) and by finding the right alignment of the two baseband data matrices, k_{shift} , at the time to form $\mathcal{V}_{P_A P_B}$. In practice, the difference $\Delta\phi_{\text{geo}}$ can be related to a sky angular difference $\Delta\theta$, which will have the reference and target locations, and it will be a function of (α, δ) . The steps and assumptions to reach Equation (12) are in Sections 3.4 and 3.6. Finally in Section 5, we will discuss the limitations of the method.

3.4. Wideband Fringe Fitting

Fringe fitting is the method used to find a likelihood distribution that represents the most accurate parameters for geometric delay and time degeneracies in order to maximize the cross-correlation strength (or equivalently minimize χ^2). As mentioned earlier, the ARO 10 m telescope site is only intended as a coherent delay-reference telescope; hence, we will not take into consideration other source properties for this

Figure 12. Dispersion effect over the 400–800 MHz band in the uv -plane. Two simulated pulses in the CHIME and ARO 10 m telescope baseline were simulated, with $DM = 56.7 \text{ pc cm}^{-3}$ (circle) and $5e5 \text{ pc cm}^{-3}$ (square). The latter is an exaggerated simulation to show the curving track of the uv -plane due to the frequency-dependent pulse ToA. The computation of the (u, v) coordinates depends on the source location (both cases located at PSR B0531+21 RA and DEC), Earth locations, and ToA (same for both pulses at 800 MHz). The u - and v -axes are in 1×10^6 wavelengths units. The (u, v) points are color-coded by the frequency from low (red) to high (blue), in the CHIME observing bandwidth.

analysis. The fringe-fitting algorithm will only be performed over the visibility as a function of frequency and normalizing by a strong (calibrator) visibility, as compared to the classical approach done at higher observational frequencies and narrow bandwidths (where delay and delay rate may be slowly varying quantities and can be computed with a two-dimensional Fourier transform; see Schwab & Cotton 1983).

In a traditional VLBI experiment, the coverage of the uv -plane is a radial line whose length is related to the telescope bandwidth $\frac{\Delta\nu}{\nu_{\text{obs}}}$. Here the track would show curvature due to the changing baseline projection while the pulse arrives as a function of frequency depending on its DM. In the uv -plane, this would be represented as shown in Figure 12. For a lower DM comparable to PSR B0531+21, the effect is linear, but for an FRB, it may not be. Figure 12 shows the Crab pulsar and an exaggerated simulation of an FRB in the uv -plane.

After an FRB (target) and its calibrator (reference) have been observed (i.e., baseband data have been acquired on sites A and B), we can proceed with forming visibilities and fringe fitting. First we independently form two (or more) visibilities (Equation (8)): the target and the reference. The steps to form a visibility are as follows:

1. Select a single polarization (either linear or circular basis) from sites A and B , i.e., \mathbf{V}_{P_A} and \mathbf{V}_{P_B} . If the orientation of linearly polarized feeds is known, then one could take the expected pair that maximizes the cross correlation (e.g., highly polarized source). In our baseline, we do not have this information, and it is a trial and error process.
2. Compute geometric correction (using `difxcalcl1`) for a given (α, δ) ; time stamp on site A , t_A ; and Earth locations of sites A and B . The process is repeated for each frame of the baseband data; hence, $\tau_{\text{geo}_0}[k] = (\tau_{\text{geo}_0})_k \in \mathbb{R}^{K^{32}}$. Then decompose τ_{geo_0} into an integer part of frames and a time residual. Apply the fractional frame part of the geometric correction (or the entire value, since a value larger than the frame size will

wrap around 2π rad) to the phase of the baseband data in a single site,

$$\mathbf{V}_{P_A}^{(\text{geo})} = \mathbf{V}_{P_A} \exp[-i\phi_{\text{geo}_0}], \quad (13)$$

$$\phi_{\text{geo}_0}[n, k] = 2\pi\tau_{\text{geo}_0}^T[k]\nu[n], \quad (14)$$

with ϕ_{geo_0} the geometric phase correction and ν the vector of all $N = 1024$ frequency channels (and elements ν_n). Equation (13) contains a matrix, \mathbf{V}_{P_A} , where its phase is rotated by the vector $\phi_{\text{geo}_0} = (\phi_{\text{geo}_0})_k \in \mathbb{R}^{N \times K}$ and returns $N \times K$ dimensions. Equivalently this correction can be applied to site B with a positive phase term.

3. Coherently de-disperse (Hankins & Rickett 1975) pulse to an optimum DM (which is the same for both polarizations, $\mathbf{V}_{P_A}^{(\text{geo})}$ and \mathbf{V}_{P_B}), either by optimizing by structure or S/N. A precision of roughly $1 \times 10^{-3} \text{ pc cm}^{-3}$ is needed in this step. The correction needed for a frequency channel is given by the dispersion time:

$$t_{\text{dd}}(\nu) = k_{\text{DM}} \text{DM} \frac{1}{\nu^2}, \quad (15)$$

where $k_{\text{DM}} = 1/(2.41 \times 10^{-4}) \text{ sMHz}^2 \text{ pc}^{-1} \text{ cm}^3$ is the dispersion constant (see Lorimer & Kramer 2012). In practice, we need an algorithm that de-smears frequency channels (intra-channel alignment) and lines up the pulse to a reference frequency (inter-channel alignment). In this case, the natural kernel for coherent de-dispersion is:

$$\Delta\psi = k_{\text{DM}} \text{DM} f \left(\frac{1}{f_r} - \frac{1}{f} \right)^2, \quad (16)$$

with f_r the reference frequency, f the frequency, and $\Delta\psi$ the phase amplitude of the transfer function (see Lorimer & Kramer 2012). After the transfer function has been applied, time stamps will only be relevant in the referenced channel, since the pulse itself will move on the baseband frames. Note that the geometric correction needs to be applied prior to the coherent de-dispersion, and this is only the case because τ_{geo} is time dependent. After coherent de-dispersion, the geometric delay is a function of the frame number and the frequency channel. Most of the dispersion t_{dd} will be removed in this operation leaving a small (but significant) fraction due to the ionospheric electron content (τ_{iono}).

4. Align pulses up to a frame precision $\left\lfloor \frac{\tau_{\text{total}}}{2.56 \text{ } \mu\text{s}} \right\rfloor$; in practice, it is only the geometric and clock error delays, k_{shift} in Equation (5), that are adding an integer frame delay to $\mathbf{V}_{P_A}^{(\text{geo})}$ with respect to \mathbf{V}_{P_B} . The value for τ_{clock} is a changing quantity, varying significantly over days³³, and depends on the rate of the two masers (of site A and B). This value will change more than a frame over a timescale of weeks, but in principle it is a small and known value from previous correlations and an estimate can be chosen τ_{clock_0} ³⁴.
5. Form integrated visibility (same as in Equation (6)), and complex sum along the pulse width t_w (in the case of

³² Notice that for $DM \gtrsim 200 \text{ pc cm}^{-3}$ and $b > 3000 \text{ km}$, the geometric delay across the band may be larger than a single frame, and $\left\lfloor \frac{\tau_{\text{geo}}}{2.56 \text{ } \mu\text{s}} \right\rfloor$ (step 5) will not be constant at 400–800 MHz (see Section 5.6).

³³ In our baseline of the order of $0.1 \text{ } \mu\text{s day}^{-1}$, see Section 3.5.2.

³⁴ Similarly to Equation (11), the clock delay can be expressed as:

$$\tilde{\tau}_{\text{clock}} = \tau_{\text{clock}} - \tau_{\text{clock}_0}$$

Figures 8 and 11, $t_w \approx 0.4\text{ms}$ Equation (8),

$$\mathbf{V}_{P_A P_B}^{(\text{geo})}[n, k] = \mathbf{V}_{P_A}^{(\text{geo})}[n, k - k_{\text{shift}}] \overline{\mathbf{V}_{P_B}[n, k]}$$

$$\langle \mathbf{V}_{P_A P_B} \rangle_{t_w}[n] = \sum_{k=t_0 - \frac{1}{2}t_w}^{k=t_0 + \frac{1}{2}t_w} (\mathbf{V}_{P_A P_B}^{(\text{geo})})_{nk},$$

with t_0 the pulse center, $t_0 \pm \frac{1}{2}t_w$ is an integer number of frames, and $\langle \mathbf{V}_{P_A P_B} \rangle_{t_w}$ (from now on dropping (geo) superscript) will only depend on frequency channels. Note that if strong scattering is present, then we may need to adjust the pulse profile with a frequency-dependent broadening function to increase S/N. Then each frequency channel will have a pulse profile as $t_w \propto \nu^{-4}$.

After the two visibilities are formed, we can start fringe fitting. We first reference the source to the calibrator by making the ratio of visibilities (equivalent to Equation (12)),

$$\mathbf{V}_{\text{norm}}[n] = \frac{\langle \mathbf{V}_{P_A P_B}^t \rangle_{t_w}}{\langle \mathbf{V}_{P_A P_B}^r \rangle_{t_w}}, \quad (17)$$

with \mathbf{V}_{norm} the normalized (integrated) visibility (vector size N), and each element $(\mathbf{V}_{\text{norm}})_n$ (i.e., the sum or integration of each frequency channel n). Notice that a Fourier transform over the frequency channels axis of \mathbf{V}_{norm} (Equation (17)) represents the lag-correlation, discussed in Section 3.1.

By taking the ratio in Equation (17), we are effectively computing Equation (12); the ratio will remove other delay terms such as frequency-dependent instrumentation effects ($\tau_{\text{inst}}(\nu)$) and repetitive errors (ξ). By doing so we are just left with the residuals for τ_{iono} , τ_{geo} , and τ_{clock} . We will define residuals as: $\delta\tau_{\text{iono}}$ ionospheric residual and $\delta\tau$ for all other constant residuals left. The ratio will be most effective (or the residuals will be the smallest) when the source and calibrator are observed closer in time and in sky angle. The former is due to the fact that there will be less clock residual to correct, and the latter because there will be fewer delay contributions from the ionosphere.

Now by finding the residual terms, we can optimize a likelihood function for the visibility model (Pearson 1999),

$$\mathcal{L} \propto \prod_{n=0}^{N-1} \exp \left[-\frac{1}{2} \sigma_n^{-2} \|(\mathbf{V}_{\text{norm}})_n - F(\nu_n; \delta\tau, \delta\tau_{\text{iono}})\|^2 \right],$$

with F the fringe model to be fitted, σ_n^2 the variance³⁵ of the complex random variable \mathbf{V}_{norm} , and N the total number of frequency channels (ν_n channel n). In principle, the localization is only present in the phase of the visibility and not in its

amplitude, and if errors are normally distributed then,

$$\begin{aligned} \chi^2 &= \sum_{n=0}^{N-1} \frac{\|(\mathbf{V}_{\text{norm}})_n - F(\nu_n; \delta\tau, \delta\tau_{\text{iono}})\|^2}{\sigma_n^2} \\ &= \sum_{n=0}^{N-1} \frac{\|(\mathbf{V}_{\text{norm}})_n - \|F(\nu_n)\| e^{i\varphi(\nu_n; \delta\tau, \delta\tau_{\text{iono}})}\|^2}{\sigma_n^2} \\ &= \sum_{n=0}^{N-1} \frac{\|(\mathbf{V}_{\text{norm}})_n e^{-i\varphi(\nu_n; \delta\tau, \delta\tau_{\text{iono}})} - \|F(\nu_n)\|\|^2}{\sigma_n^2} \\ &= \sum_{n=0}^{N-1} \frac{1}{\sigma_n^2} \text{Im} [(\mathbf{V}_{\text{norm}})_n e^{-i\varphi(\nu_n; \delta\tau, \delta\tau_{\text{iono}})}]^2, \end{aligned} \quad (18)$$

where $\varphi(\nu_n; \delta\tau, \delta\tau_{\text{iono}})$ is a phase model independent of the amplitude, flux of the source, and time t . Notice that the real part of Equation (18) can be marginalized without losing information, since $\text{Re}[\|F\|] = \|F\|$ and all astrometric information is only contained in the phase of the visibility, $\text{Arg}[\mathbf{V}_{\text{norm}}]$.

In effect, the fringe phase model, $\text{Arg}[F]$, can be represented as:

$$\begin{aligned} \varphi(\nu; \delta\tau, \delta\tau_{\text{iono}}) &= \varphi(\nu; \delta\tau) + \varphi(\nu; \delta\tau_{\text{iono}}) \\ &= 2\pi\delta\tau\nu + 2\pi\delta\tau_{\text{iono}}\nu \\ &= 2\pi\delta\tau\nu + \frac{2\pi}{\nu} k_{\text{DM}} \delta\text{DM}, \end{aligned} \quad (19)$$

where the site differential DM is given by

$$\Delta\text{DM} = \text{DM}_A - \text{DM}_B \leq 1 \times 10^{-5} \text{ pc cm}^{-3}, \quad (20)$$

and δDM is the difference of differential DM from target and reference:

$$\delta\text{DM} = \Delta\text{DM}^t - \Delta\text{DM}^r. \quad (21)$$

The right term in Equation (19) comes from the differential dispersive delay phase, $2\pi\nu\tau_{\text{dd}}$, from Equation (15). Notice that the ionospheric contribution can be measured in DM units (parsecs per cubic centimeter) or total electron content³⁶ (TEC) units (TECu), and it will depend on the zenith angle at each site (ionosphere column). Similarly to delays, we are only interested in its difference rather than the true value at each site.

The residual delay $\delta\tau$, which does not consider $\delta\tau_{\text{iono}}$, can be expressed as:

$$\begin{aligned} \delta\tau &= \tau_{\text{total}}^t - \tau_{\text{total}}^r - \delta\tau_{\text{iono}} \\ &= \tilde{\tau}_{\text{geo}}^t + \tilde{\tau}_{\text{clock}}^t - (\tilde{\tau}_{\text{geo}}^r + \tilde{\tau}_{\text{clock}}^r) \\ &= \delta\tau_{\text{geo}} - \delta\tau_{\text{geo}_0} + \delta\tau_{\text{clock}} - \delta\tau_{\text{clock}_0}, \end{aligned} \quad (22)$$

with δ always expressing target (t; FRB) minus reference (r; calibrator).

The procedure presented above follows the same approach developed in Leung et al. (2021) but is expanded to an additional degree of freedom for χ^2 , where the differential delay contribution from the ionosphere is non-negligible at this baseline b .

The solution to the presented method can be achieved by either a two-dimensional grid search or by a gradient search (nonlinear least-squares minimization), although the latter needs high precision in the initial guessed values (see results

³⁵ The variance of a complex number is expressed as:

$$\sigma^2 \equiv \text{Var}[\mathbf{V}] = \text{Var}[\text{Re}[\mathbf{V}]] + \text{Var}[\text{Im}[\mathbf{V}]],$$

with $\sigma^2 \in \mathbb{R}^+$.

³⁶ Total electron content and DM have equivalent units: $1\text{TECu} \equiv 1 \times 10^{16} \text{ electron m}^{-2} \equiv 3.24 \times 10^{-7} \text{ pc cm}^{-3}$.

Table 2
DRAO Maser Properties (T4Science 2018)

Operation frequency	10 MHz
Allan variance (at 1 s and 1 Hz bandwidth)	5×10^{-13}
Temperature sensitivity	$<1 \times 10^{-14} \text{ }^\circ\text{C}^{-1}$

from Section 3.6 in Figure 18). A good initial estimate is the FFT over the normalized (integrated) visibility,

$$\|\rho_{A,B}^{\text{sf}}\| = \|\text{FFT}[\mathbf{V}_{\text{norm}}]\|, \quad (23)$$

which returns the cross-correlation strength (lag-correlation in Equation (9)) prior to residual corrections being applied. Further, if dispersive delays were not present in the phase, $\varphi[n]$, the maximum likelihood solution for fringe fitting would be the constant value obtained from the Fourier transform. Then the observable shift over the lag-axis (Equation (10)) is the lag-correlation, a good initial value for $\delta\tau$ or equivalently the center of a grid search.

3.5. Timing Performance

The CHIME clock system is composed of a GPS disciplined ovenized crystal oscillator (Spectrum Instruments 2007) of 10 MHz tempo and absolute time from GPS signal (all coming from the same unit). The clock speeds up and slows down while retrieving the GPS signal and adjusting to it. Measurements to test the reliability of the current CHIME clock and ARO maser were performed while observing the PSR B0531+21 compact source over the course of a day and over multiple days. Here we compare the computed time difference from the cross-correlation process (time difference between PSR B0531+21 pairs) and the CHIME clock stability. Correlations follow the same analysis explained in Section 3.4 (forming visibilities and fringe fitting). The latter is an independent analysis done exclusively at the CHIME clock (and independent of the PSR B0531+21 observations), and it includes a study of the DRAO maser pHMaser 1008 (T4Science 2018; properties in Table 2) with respect to the CHIME clock phase and its raw data calibration in long timescales. The method includes a pipeline to collect raw ADC samples directly from the maser and generate the GPS time stamps associated with them as well as to correct for long scale variations done by the imperfections in the 10 MHz rate of the CHIME clock.

3.5.1. Clock Stability Single Day

During 2020 May 9, six pulses of PSR B0531+21 were observed and baseband data collected at both sites with the CHIME VLBI tracking beam (defined in Section 2.5) and the ARO 10 m telescope, with each pulse separated by minutes. The cross correlation follows the fringe-fitting procedure explained in Section 3.4, but instead of a pair of visibilities from the FRB and calibrator, the six pairs of pulses are referenced to the same pulsar, a single pulse (and the strongest) visibility of the same day³⁷. The PSR B0531+21 (reference) localization was used from the Australian Telescope National Facility pulsar data set³⁸ (Manchester et al. 2005), $\alpha = 5^{\text{h}}34^{\text{m}}31^{\text{s}}.973$, and $\delta = +22^\circ 0'52''.06$ (J2000.0).

³⁷ For the analysis in Sections 3.5.1 and 3.5.2, only a single cross-polarization pair, \mathbf{V}_{YA} and \mathbf{V}_{XB} , is used to compute visibilities.

³⁸ <http://www.atnf.csiro.au/research/pulsar/psrcat>

Figure 13. Phase of normalized (integrated) visibilities, $\varphi[n] = \text{Arg}[\mathbf{V}_{\text{norm}}]$, in a single day of observations for six different pulses from PSR B0531+21. The third panel has zero phase since the normalization is its own visibility. Wrapping lines are the phase of the models from fringe fitting and lag-correlation. Fringe fitting has an improved result since it takes into account the ionospheric contribution.

Figure 13 shows the wrapping phases of the normalized (integrated) visibilities:

$$\mathbf{V}_{\text{norm}} = \frac{\langle \mathbf{V}_{YA XB}^t \rangle_{t_w}}{\langle \mathbf{V}_{YA XB}^r \rangle_{t_w}} = \|\mathbf{V}_{\text{norm}}\| e^{i\varphi}, \quad (24)$$

with $\varphi[n] = \text{Arg}[\mathbf{V}_{\text{norm}}]$ a vector of N channels. The best model fit can be achieved with Equation (19). The quantity in Equation (24) is computed six times for each pair of target pulses $\mathbf{V}_{YA XB}^t$. The matrix of complex numbers $\mathbf{V}_{YA XB}^r$ represents the strongest visibility (selected by measuring the amplitude of its FFT, lag-correlation Section 3.1), and for this observation, it is the third pulse observed on 2020 May 9. Figure 13 also contains the best fit from fringe fitting and lag-correlation phase models (colored lines).

Since pulses are separated only by a few minutes, the visibility normalization will remove most of the unknown delays (Equation (3)), leaving only a small fraction of $\delta\tau$, and $\delta\tau_{\text{iono}}$ residuals. It's important to note that the ionospheric delay will depend on the zenith angle at each location (see Thompson et al. 2017), $\tau_{\text{iono}} = \tau_{\text{iono}}(z)$, and hence $\delta\tau_{\text{iono}} \neq 0$ ns. This implies that even if ionospheric turbulences are stable over an hour, there will still be a nonzero ionospheric delay since the differential zenith angle is changing over time.

Figure 14 shows the lag fringe fitting and lag-correlation (using Equation (23)), found in each of the phases of Figure 13. Figure 14 also shows the CHIME clock variations with respect to the DRAO maser (stars) plotted on top, which are referenced

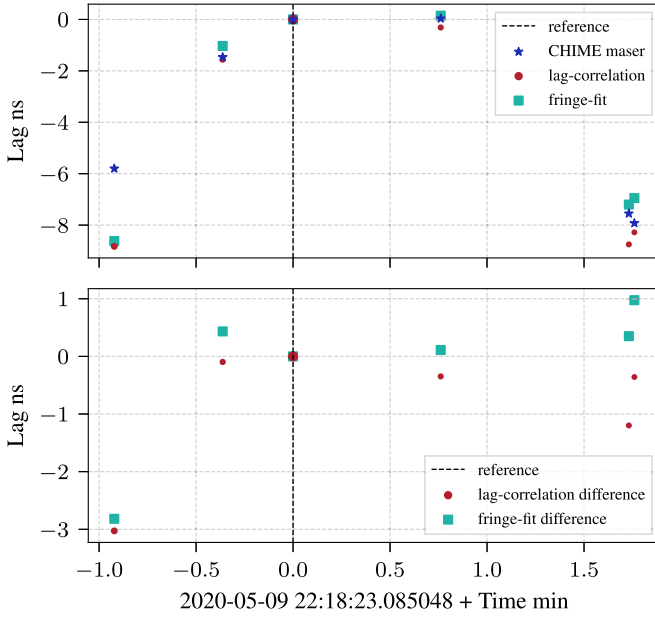

Figure 14. Clock stability between CHIME clock (GPS disciplined crystal oscillator) and ARO 10 m telescope over a single day with six pairs of correlated PSR B0531+21 pulses (separated over minutes scale). Circles are the lag-correlation between pulses (simple FFT over the normalized integrated visibility), and the relative size represents the strength of the fringe amplitude. Stars are the CHIME clock and DRAO maser variations (independent measurement). Squares are the result from the fringe-fitting process. All data sets are referenced to the third point from the left (dashed vertical line). The upper panel shows the comparison of the three data sets, and the lower panel shows the difference between lag-correlation and CHIME maser, and fringe fitting and CHIME maser.

to the same day (Cary et al. 2021). The largest difference between them is roughly 3 ns. The bottom panel in Figure 14 shows the difference between the first-order delay with lag-correlation and with fringe fitting. There exists a better estimation of the delay in the latter, since the δDM has also been fitted.

In addition, the fringe-fitting method (described in Section 3.4) was applied to each normalized (integrated) visibility, and a Gaussian error distribution was assumed. To find the set of two parameters ($\delta\tau$, δDM), we calculated χ^2 over a grid in expected DM and delay values giving lag-correlation as the search start point. The search was conducted over $\pm 1 \times 10^{-6} \text{ pc cm}^{13}$ (centered at zero DM) and $\pm 2.5 \text{ ns}$ centered at the peak of the lag-correlation. The minimum over the grid is selected with a confidence region of 68%, $\chi^2 = \chi^2_{\min} + \Delta\chi^2$, with $\Delta\chi^2 = 2.30$ for a two-parameter model (Wall & Jenkins 2012).

3.5.2. Clock Stability over Multiple Days

Using the same techniques as Section 3.5.1, we now examine clock stability over multiple days using PSR B0531+21 observations of one pulse per day. Observations were performed with the CHIME/FRB baseband back-end (defined in Section 2.5) and the ARO 10 m telescope dish. All pulses are referenced, $\mathbf{V}_{YA X_B}^r$, to the first day of observation, following the fringe-fitting algorithm and forming visibilities. Figure 15 shows the FFT norm of the normalized (integrated) set of visibilities, where the strongest delay component (lag-correlation) is clearly visible as a peak. The phase graph of those visibilities is omitted because it will not add any helpful

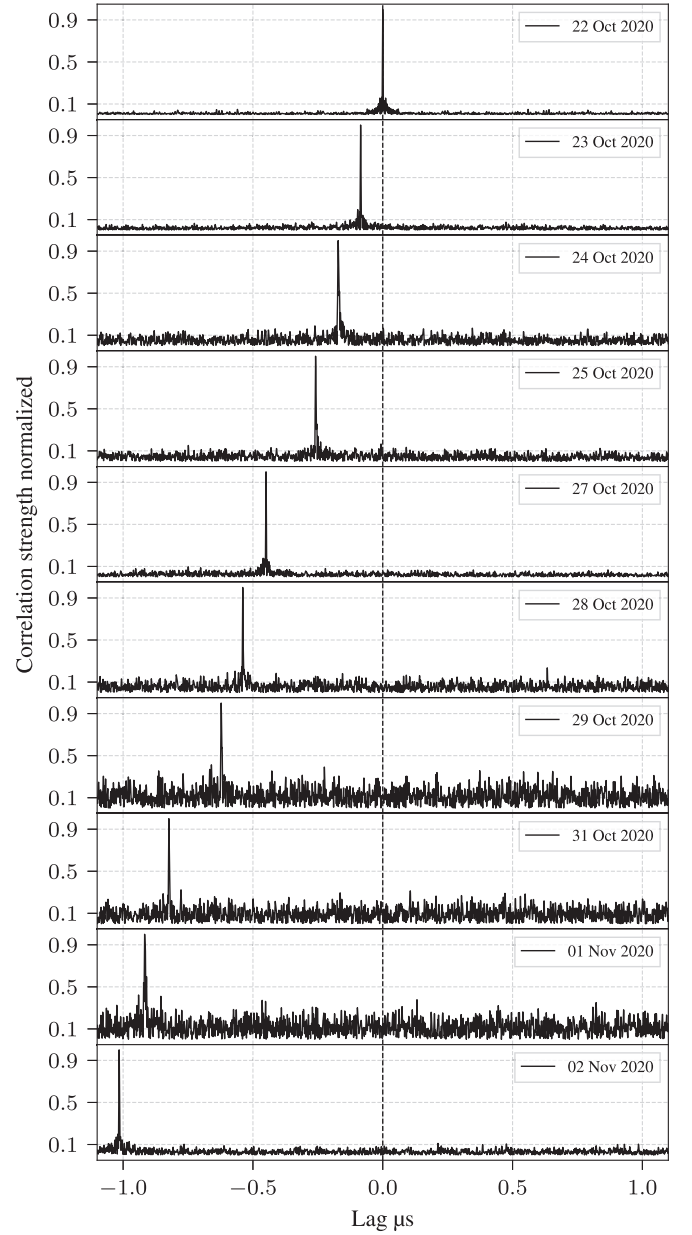

Figure 15. FFT of normalized (integrated) visibilities $\|\text{FFT}[\mathbf{V}_{\text{norm}}]\|$ or equivalently the cross-correlation strength, over several days for PSR B0531+21 pulses. The top panel is the reference pulse, and the dashed line is the zero lag position. The lag-axis, τ_{ll} elements, is of a frame size with limits $\pm 1.28 \mu\text{s}$. The observed drift in the cross-correlation peak is analyzed in Figure 16.

visualization, due to the fact that a lag on the order of $1 \mu\text{s}$ wraps the phase over 400 times.

The same (lag-correlation) delays from Figure 15 are then plotted in Figure 16. In the top panel, it can be seen that for every day of observation, there is a continuous time drift of $\sim 0.1 \mu\text{s day}^{-1}$ (model sloped solid line), the source of which is mainly due to the combined rate between the CHIME GPS crystal oscillator clock and ARO maser relative frequency offset. The slope has been adjusted to lag-correlation (circles) and fringe-fit (squares) independently. Both clocks should be 10 MHz, but it is not precise over the timescale of days; hence, they drift apart. The middle panel shows the difference between the best-fitted model (sloped solid line top panel) of the lag-correlation trend (over several days) and the data points. The same procedure for fringe-fitting data points was used (where

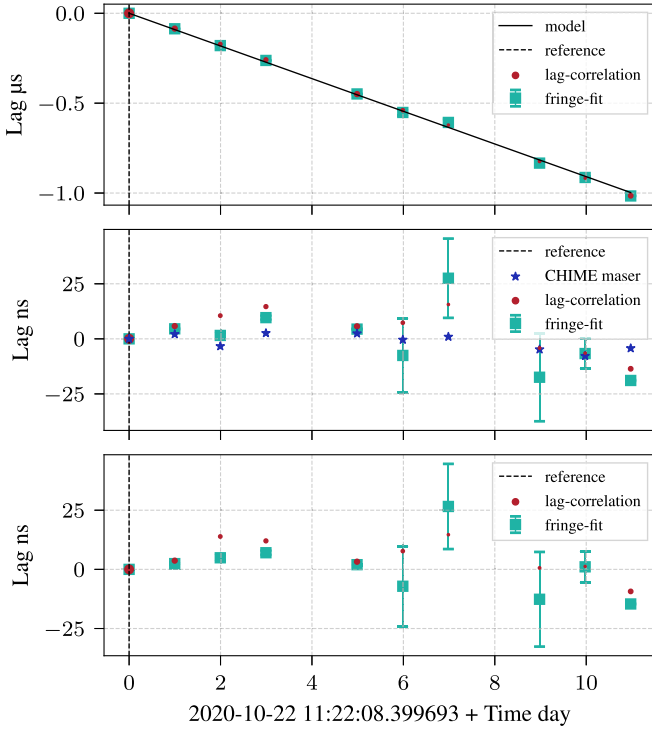

Figure 16. Clock stability between CHIME and ARO 10 m telescope over multiple days. The top panel shows the delays referenced to the first point at (0, 0) (peak respect to the center in Figure 15), and the sloped solid line is the best fit for the time drift. The middle panel shows the DRAO maser with respect to CHIME clock (stars) compared to the residual from the top panel (lag-correlation and fringe fitting). The marker sizes represent the S/N strength in the lag-correlation with respect to the reference visibility (0, 0) point (dashed vertical line). The last observations have a lower S/N, and the fringe-fitting algorithm becomes less constrained in finding DM and lag. The bottom panel is the difference between the CHIME GPS crystal oscillator with respect to DRAO maser (independent from correlations) and the two methods.

errors in the best-fitted line are included). The DRAO maser independent measurements with respect to the CHIME clock are also plotted (stars). Finally, in the bottom panel, the difference between the DRAO maser and the two methods is computed. By comparing stars and the other two sets of points (circles and squares), we see that there is a clear improvement in fringe-fit for earlier days, and only a few corrections need to be applied to the phase of the normalized (integrated) visibilities. The data points from 2020 October 28, 29, 31, and November 1 are less well constrained due to higher noise in the observations (as seen in the Figure 15 noise floor) and expected clock inaccuracies over more than five days. Hence, a clear value in χ^2 is hard to achieve (higher degeneracy in the χ^2 surface).

The other χ^2 degree of freedom is the δDM . This is not only the difference between sites, but since normalization took place (Equation (24)), the computed value from minimizing χ^2 is a differential ΔDM :

$$\delta\text{DM}^j = \Delta\text{DM}^j - \Delta\text{DM}^r, \quad \text{with } j = 1, \dots, 9, \quad (25)$$

where ΔDM^r is the crossed ionosphere from the reference pulse, and j represents all other individual pulses' ΔDM (targets). We can then compare the results from the fringe-fitting routine with the International Global Navigation Satellite System (GNSS) Service (IGS; Noll 2010), which is able to compute TEC values to a precision of $1 \times 10^{-6} \text{ pc cm}^{-3}$ (or

Figure 17. Ionospheric values found from fringe fitting (squares) compared to those same days in the IGS database (Noll 2010). The DM values are the δDM over the referenced day (first day, vertical dashed line, 2020 October 22), see Equation (25). Error bars in fringe-fitting values are larger on the low-S/N cross-correlation cases, i.e., 2020 October 28, 29, 31, and November 1. The TEC difference between sites was computed by using the slant TEC (sTEC). The fringe-fit δDM agrees within errors compared to IGS, even after multiple days away from the referenced pulse.

2.3 TECu). The results are shown in Figure 17. TEC values interpolated with the ionospheric model take into consideration the zenith angle; this is referred to as slant TEC (sTEC), i.e.,

$$\Delta\text{TEC} = \text{sTEC}_A(z) - \text{sTEC}_B(z). \quad (26)$$

The IGS published maps have a fiducial ionosphere height of 450 km, and we assume a thin layer approximation in translating the published vertical TEC maps to sTEC, which estimates the TEC along the line of sight for each Earth location to the source.

3.6. Toward Localization

For CHIME and the ARO 10 m telescope, we have shown that the combined clock systems will not drift apart more than 10–100 ns over 24 hr. In addition, in the case where no calibrators are available over several days, the expected drift can be accounted for and removed. Nonetheless, limitations of the current coherent delay-referencing method (discussed in Section 5) will not provide a full VLBI diffraction-limited resolution.

Of utmost importance is the unknown contribution from the ionosphere, which depends on the Earth location and zenith angle of the observation. More generally, the ionospheric density along the lines of sight to the calibrator may be different from that along the lines of sight to the FRB.

From the analysis in Sections 3.5.1 and 3.5.2, the fringe fitting finds an estimated ionospheric contribution provided that our observations have a strong S/N. An example of a single point is presented in Figures 18 and 19, which shows the χ^2 surface over δDM and lag space (grid search), and a zoom-in or slice section of χ^2 . The correlated pair corresponds to the first burst in Figure 14 observed on 2020 May 9, which has the largest scatter among all points (mainly due to the error in the CHIME GPS crystal oscillator) in a single-day observation.

The minimum χ^2 in Figure 18 is located at the center with cyan dashed lines. It is not surprising that the surface is highly irregular with neighboring values that could reach an equal level of degeneracy (as seen in the nearby lobes from Figure 19), but a high enough S/N and a good prior in lag and DM can solve this problem (no prior information was used in fringe fitting; Sections 3.5.1 and 3.5.2).

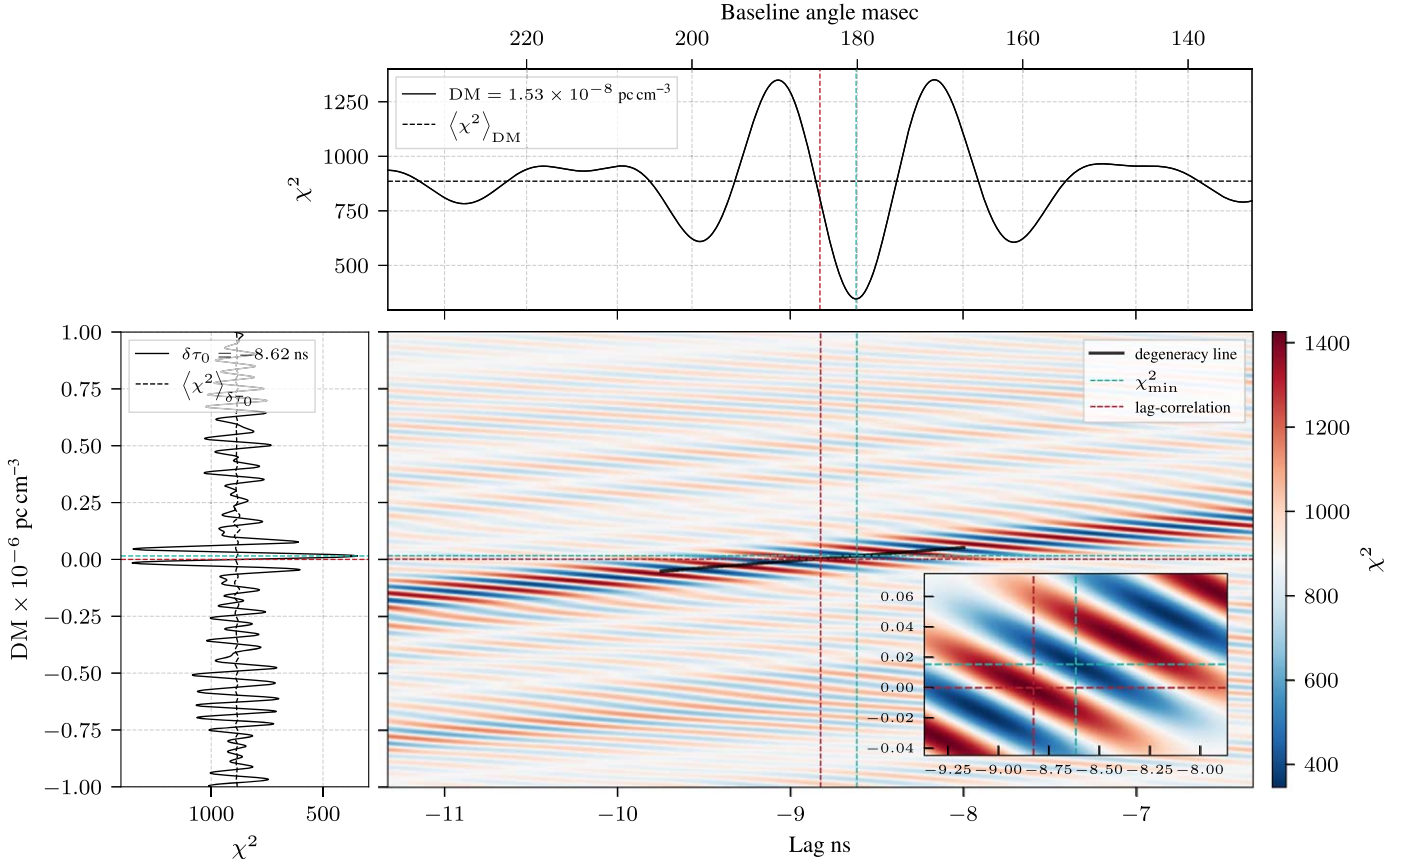

Figure 18. Grid search over lag and δDM space for χ^2 . The solution corresponds to the first burst of the 2020 May 9 observations (see Figure 14), which is the largest deviated point from its reference (first data point from left to right). The top panel shows the slice of the optimum DM, and the left panel shows the slice of the optimum lag ($\delta\tau$). The top panel top axis shows the differential baseline angle ($\delta\theta$), and it has directly translated from the obtained lag (see Equation (27)). The grid search is centered at the lag-correlation result (in this case -8.8 ns) and zero DM, over $\pm 1 \times 10^{-6} \text{ pc cm}^{-3}$ and ± 2.5 ns windows. The bottom-right zoomed-in section is centered at the minimum χ^2 value with axes units the same as the major axes. Dashed cyan and red lines show the location of the χ^2_{\min} and the lag-correlation. In Figure 19 the degeneracy line or slice with the most degeneracies is plotted with their confidence levels, and Figure 20 shows the same lobe in a corner plot using the obtained χ^2 weights (likelihood).

Figure 19. Degeneracy line, one-dimensional slice from the χ^2 grid in Figure 18. The slice shows a zoomed-in section of the grid search along the most degenerated lobes. Horizontal dashed lines are the confidence levels from the χ^2_{\min} value, 68%, 90%, and 99%. Vertical dashed lines are the lag-correlation and χ^2 minimum. The plot corresponds to the most deviated point in a single-day observation (Section 3.5.1), and the one that has most degeneracies.

To coherently find the delay-referenced localization of a target pulse with respect to the reference pulse, we calculate it as a function of the residual baseline angle $\delta\theta$ (defined in

Figure 10 and Equation (2)), i.e.,

$$\begin{aligned} \varphi &= 2\pi\delta\tau\nu \approx 2\pi\delta\tau_{\text{geo}}\nu = 2\pi b \frac{\nu}{c} (\cos\theta_t - \cos\theta_r), \\ \frac{c\delta\tau_{\text{geo}}}{b} &= \cos\theta_t - \cos\theta_r = -\delta\theta \sin\theta_r, \\ \delta\theta &= -\frac{c\delta\tau_{\text{geo}}}{b \sin\theta_r} \end{aligned} \quad (27)$$

where $\delta\theta(\alpha, \delta) = \theta_t - \theta_r$ (difference from target pulse with respect to reference pulse on sky) is a function of R.A. and decl. (see Thompson et al. 2017), but higher restrictions will be given to R.A. due to the east–west baseline. The angle of the normalized (integrated) visibility $\varphi \approx \varphi_{\text{geo}}$ is the same as defined in Equation (12), but now the small angle approximation has been used for $\delta\theta$. The reference angle, θ_r , is the known position of the calibrator, and (as with the geometric delay) it will depend on: Earth locations, observation time (t_A), and R.A. and decl. of the reference source. Then we simply use Equation (2) and compute $\tau_{\text{geo}} = \tau_{\text{geo}_0}(\text{difxcac111})$ since there will be no residual using the assumed reference pulse. For the single-day observations (Section 3.5.1), this value corresponds to $\theta_r = 1.29$ rad. Equation (27) will only be true when

Figure 20. Example of a well-constrained minimum χ^2 lobe from Figure 18. The centered dashed line is the minimum χ^2 (or equivalently maximum \mathcal{L}). The quantiles (10% and 90%) show a rough estimate required for a good cross correlation in δDM space of $1 \times 10^{-8} \text{ pc cm}^{-3}$. Contour lines correspond to 68%, 90%, and 99% confidence levels. The lobe is also shown in Figure 19, where it is compared to the closer and most degenerated lobes in the degeneracy line from the entire χ^2 grid (Figure 18). The example corresponds to the first burst (left to right) from Figure 14.

the residual of the clock delay $\delta\tau_{\text{clock}}$ is very small, viz., $\delta\tau \approx \delta\tau_{\text{geo}}$ (same as in Equation (2); Section 3).

The top panel top axis from Figure 18 shows the baseline angle, $\delta\theta$, with respect to the delay $\delta\tau$ (centered panel bottom axis), and for this case, the localization error is 180 mas. Fringe-fitting errors can also be estimated. Figure 20 shows the main lobe from Figure 18 with a subnanosecond error, and a $1 \times 10^{-8} \text{ pc cm}^{-3}$ DM. The 180 mas error in localization represents the largest scatter (as seen in the first point of Figure 14). In contrast to single-day observations, the worst case over multiple days (October 31) is in Figure 21, which shows the largest scatter from all points mainly due to the low S/N in the lag-correlation and calibration after several days. In particular, days 2020 October 28, 29, 31, and November 1 do not have a clear Gaussian lobe, and their error bars were estimated from the 99% ($\chi^2_{\text{min}} + 9.21$) confidence region (Figures 16 and 17).

In general, errors in fringe fitting over a single day and even over a few consecutive days are within ± 10 ns from the expected CHIME clock drift (with the exception of low S/N over multiple days running clock). Beyond that, the combination of clocks is not reliable. Careful measurements from clocks at each station can improve the performance beyond a 50 mas localization by adjusting the delay from the known CHIME GPS crystal oscillator jitter.

4. Early Science Results

As mentioned earlier, CHIME/FRB statistics predict that we should observe ~ 4 – 7 FRBs per month in the ARO 10 m telescope and CHIME shared FOV. However, this does not take into account the up time from CHIME and the ARO 10 m telescope combined, plus the estimated altitude, azimuth, and Earth location of the 10 m telescope; i.e., the total portion covering the CHIME FOV may not be complete. Nevertheless, FRBs have been recorded in simultaneous dumps at CHIME and ARO 10 m telescope, but unfortunately their S/N

Figure 21. Differential DM and lag selection of the minimum χ^2 lobe. Large uncertainties are due to the poor S/N of pulses and maser clock drift over several days. The corner plot corresponds to the 2020 October 31 observation. Multiple lobes are formed in the case where a true optimum cannot be determined and non-Gaussian uncertainties are high. Black dashed lines correspond to the 10% and 90% quantiles, the center line is the obtained minimum χ^2 , and off-center dashed lines are the grid search center given by the lag-correlation. Contour lines correspond to 68%, 90%, and 99% confidence levels.

($\text{S/N}_{\text{CHIME}} < 25$) on the ARO site was insufficient for both visualization in data and cross correlations. One of the most prominent observations produced thus far is of the magnetar SGR 1935+2154 (CHIME/FRB Collaboration et al. 2020), where the ARO 10 m telescope recorded baseband data but CHIME unfortunately did not.

Lastly, observations from the FRB 20210603A (not known to repeat) were recorded simultaneously at CHIME and ARO 10 m telescope on 2021 June 3, and initial results show a strong cross correlation after delay referencing to a calibrator (PSR B0531+21 pulse). Figure 22 shows the cross-correlation strength (Equation (23)), where the reference pulse is in the top panel. The known drift between the CHIME and ARO 10 m clocks can again be seen in the PSR B0531+21 pulses (similar to Figure 15), but not in the FRB since its sky location is different.

The FRB burst, not visible at the ARO 10 m telescope, was triggered and successfully correlated hours after the event happened. The FRB 20210603A had a high S/N at CHIME of $\gtrsim 100$ and $\text{DM} = 500.162 \pm 0.005 \text{ pc cm}^{-3}$ (with a dispersion time $t_{\text{dd}} = 9.728\text{s}$ over the band).

The phase of the normalized (integrated) visibility $\text{Arg}[\mathcal{V}_{\text{norm}}]$ can be seen in Figure 23. No clear signal is visible since phases are wrapping fast (see Section 3.5.2) due to the CHIME clock and ARO maser combination, and due to the difference in sky location of the FRB (only applicable in the second panel from top to bottom).

By taking the estimated delay from the lag-correlation (Figure 22), we can partially fringe stop the phases in Figure 23. This is:

$$(\mathcal{V}_{\text{norm}})_n \times e^{-i2\pi\nu_n\tau_{\text{lc}}}, \quad (28)$$

with τ_{lc} the solution obtained from the subframe cross-correlation function, the lag-correlation (Equation (10)). There will be four τ_{lc} , one for each panel. Figure 24 shows the angle of the normalized (integrated) visibility after being corrected by

Figure 22. First FRB 20210603A detected and correlated at CHIME and ARO 10 m telescope in baseband data. The plot is similar to that in Figure 15, where we computed the cross-correlation strength (norm of the subframe cross-correlation function; Equations (9) and (23)). The plot shows three pulses from PSR B0531+21 and the single FRB pulse. The PSR B0531+21 (referenced to 2021 May 29) has a similar trend to that seen in Figure 15, but only over the pulsar pulses, since the FRB burst is expected to be at a different R.A. sky location. The normalized (integrated) visibility phase can be seen in Figure 23.

Figure 23. Normalized (integrated) visibility phase $\text{Arg}[V_{\text{norm}}]$ from PSR B0531+21 pulses and FRB 20210603A. Phases have been referenced to the PSR B0531+21 pulse on 2021 May 29, and there is no correction applied on them. Figure 24 shows the same phases but corrected by the estimated lag τ_{lc} Equation (28), a partial fringe stop.

the delay found in Figure 22. This early study shows a clear detection of an FRB referenced to a calibrator as seen in Figure 24 (second panel from top to bottom).

A more in-depth analysis will be carried out in a separate study showing the proper localization results as well as the

Figure 24. Normalized (integrated) visibility phase after phase correction (Equation (28)) from PSR B0531+21 pulses and FRB 20210603A. As in Figure 22, phases have been referenced to the pulse from 2021 May 29. In this early analysis, only a phase correction over a constant delay (partial fringe stop) has been applied, and the ionospheric correction has been set free (not corrected). The linear and nonlinear wrapping can be seen since the strong ionosphere has not been removed. The early study shows a clear detection of the FRB referenced to a calibrator (second panel top to bottom).

ionospheric and long dispersion corrections required at these frequencies.

5. Discussion

The VLBI experiment from CHIME and the ARO 10 m telescope at low frequencies presents several challenges that have been partially addressed in the previous sections. In particular, we have addressed the clock stability: maser and GPS crystal oscillator, and the implementation of the fringe-fitting algorithm (correlator model) with two degrees of freedom ($\delta\tau$ and δDM) and the localization uncertainty, which is mainly due to the ionospheric delay. It follows the discussion of other important uncertainty contributions to the experiment: clock stability (during target and reference), ionospheric and tropospheric delay, error in antenna positions (phase center interferometer), and Earth orientation parameters.

5.1. Clock Stability

The CHIME GPS crystal oscillator is a GPS disciplined clock, which returns absolute time stamps but lacks the nanosecond precision required for VLBI. In contrast, the DRAO maser fulfills the nanosecond precision but it does not support absolute GPS time stamps. A VLBI GPS disciplined maser is expensive and not feasible for the scale of the ARO 10 m telescope testbed. Nevertheless, our analysis has demonstrated that such deviations can be, in principle, corrected (e.g., by measuring pulsars; Figures 14 and 16) and measured using the CHIME GPS crystal oscillator with respect to the DRAO maser (Mena-Parra et al. 2021; Cary et al. 2021). Such measurements can measure uncertainties and correct clock variations to achieve nearly ~ 50 mas for the future CHIME/FRB Outriggers project.

The limiting factor for this calibration will be given by the FRB position and its proximity to the Galactic Plane (higher pulsar density) as well as the S/Ns of both the calibrator and the source.

5.2. Ionospheric Contribution

The ionospheric delay is a problem that has been partially solved in the analysis sections. This is due to the fact that for FRB detections, it is highly unlikely that the event will cross the same portion of the ionosphere as the calibrator. In reality, the two will likely be off by a few degrees in the sky, and the calibrator will be observed minutes before or after the event. In contrast, the analysis presented here relied on single pulses from the same pulsar as both target and reference, and the only differences in ΔDM^t and ΔDM^r are cases given by the zenith angle over minutes (Section 3.5.1) and day-to-day ionospheric changes (Section 3.5.2). In the case of an FRB, we expect a higher degree of uncertainty since $\mathcal{V}_{\text{norm}}$ will have a considerable fraction of residual ionospheric delay, $\delta\tau_{\text{iono}}$, in its phase after normalizing (Equation (24)). Ionospheric models such as IGS (Noll 2010) do not have the required TEC precision that we need to successfully correlate at a desired angular precision of 50 mas, and $\delta\text{DM} \sim 1 \times 10^{-8} \text{ pc cm}^{-3}$ (Figure 20). However, high enough S/N levels can partially remove this restriction and return a clear minimum in the χ^2 domain. An additional resource to improve the search is to add a prior probability over the ionospheric delay, using time-series GPS data to estimate the scale and type of ionosphere fluctuations ($\sim 10 \text{ TECu}$). Adding this prior in the χ^2 search can be expressed as:

$$\chi_{\text{eff}}^2 = \chi^2 + \chi_{\text{prior}}^2(\Delta\text{DM}^t, \Delta\text{DM}^r), \quad (29)$$

where χ_{eff}^2 is the effective χ^2 weighted by an extra term, χ_{prior}^2 , which can be a function of the ionospheric delay or differential DM.

5.3. VLBI Delay and Rate

In practice, the geometric phase correction, ϕ_{geo0} (Equation (13)), applied to the data (Section 3.4, step 2) partially corrects for the delay rate. Since the location of PSR B0531+21 is well known, the delay rate $\frac{\partial\tau}{\partial t}$ vanishes for the analysis thus far. However, a significant delay rate can cause a drop in sensitivity because we correlate over the pulse width (which is on the order of a millisecond) per frequency channel. This delay rate can be significant and is on the order of,

$$\frac{\partial\phi}{\partial t} = 2\pi\nu \frac{\partial\tau}{\partial t} \Rightarrow \frac{\partial\tau}{\partial t} \approx \frac{\Delta\tau_{\text{geo}}}{1 \text{ ms}} = 0.667 \text{ } \mu\text{s s}^{-1}. \quad (30)$$

This estimate was computed while using a PSR B0531+21 pulse with the software `difxcalc11` using the same baseline b , i.e.,

$$\Delta\tau_{\text{geo}} = \tau_{\text{geo0}}(t_1 + 1 \text{ ms}) - \tau_{\text{geo0}}(t_1). \quad (31)$$

To solve this problem, the Global Fringe Fitting approach developed by Schwab & Cotton (1983) for VLBI could be used. In this method, the phase model is explicitly dependent on time,

$$\phi(t, \nu) = \phi(t_0, \nu_0) + \frac{\partial\phi}{\partial t}(t - t_0) + \frac{\partial\phi}{\partial\nu}(\nu - \nu_0), \quad (32)$$

where the term $\frac{\partial\phi}{\partial t}$ is the fringe rate and $\frac{\partial\phi}{\partial\nu}$ is the delay (or delay residual). The continuous phase distribution ϕ is analogous to $\phi[n, k]$ of the visibility (Equation (7)). When the ionospheric contribution also cannot be neglected, it may be necessary to use a model of the form

$$\phi(t, \nu) = \phi(t_0, \nu_0) + 2\pi\nu\tau + 2\pi\nu\frac{\partial\tau}{\partial t}t + \frac{2\pi}{\nu}k_{\text{DM}}\Delta\text{DM}, \quad (33)$$

to capture the delay rate within each channel.

5.4. Earth Locations and Phase Center of an Interferometer

Acquiring a good localization requires knowing our baselines to within a centimeter precision, which is not the case for the ARO 10 m telescope (the location of which is only known up to a $\sim 1 \text{ m}$ precision). Additionally, CHIME and future Outrigger stations will need to account for the fact that the phase center location of CHIME at the time of beamforming may vary. These variations can result in the Earth location moving on the order of centimeters, which makes the geometric delay correction uncertain. Variations of this scale will have an impact within a frame (below $2.56 \text{ } \mu\text{s}$, but multiple nanoseconds), and will result in degeneracies in the FRB localization search. However, this problem can be solved by observing two or more calibrators daily (pulsars and expanding to VLBI calibrators for the CHIME/FRB Outriggers project), and instead of fringe fitting over a source, we use these observations to find the baseline positions.

5.5. Ionospheric Faraday Rotation

The ARO 10 m telescope has been used to study polarization properties (CHIME/FRB Collaboration et al. 2020), but a linear polarization calibration (e.g., daily monitoring of a weakly polarized source) to solve for polarization leakage and other errors has not previously been carried out. This implies that a true transformation from the Cloverleaf feed linearly polarized to circular polarizations (\mathbf{V}_{Rb} , \mathbf{V}_{Lb}) is not obvious, and needs a complex gains correction. For longer baselines, it may be important to work in a circular basis since ionized plasma in the ionosphere could produce Faraday rotation (e.g., when the Sun's activity is high) and add a constant offset in right-left phase difference (Cotton 1995), where this effect has been noted at lower frequencies than 400 MHz. Additionally, note that we do not have a good estimate of the north-south or east-west estimate of the linear polarizations orientation at the ARO 10 m telescope feed. This treatment has been neglected in the present analysis.

5.6. Geometric Delay and High DM

FRB events detected at CHIME and the ARO 10 m telescope will also have to contend with a larger dispersion, which will cause large differences (compared to PSR B0531+21) in geometric delay at the top and bottom of the 400–800 MHz band. As stated in the geometric correction method (Section 3.4), the integer part of the geometric delay (floor part) in terms of frames $\left\lfloor \frac{\tau_{\text{geo0}}}{2.56 \text{ } \mu\text{s}} \right\rfloor$ may not be constant along the pulse over each frequency channel; hence, the data aligned between correlated polarizations will change slightly as well as the subframe correction over the phase in the pulse's coherent

Figure 25. Geometric delay difference over the start (800 MHz) and stop (400 MHz) over a pulse dispersion, $\Delta\tau_{\text{geo}}$. The geometric delay was computed using PSR B0531+21 coordinates (CHIME and ARO 10 m telescope baseline) and varying the R.A. component $\pm 180\text{deg}$.

de-dispersion. This effect becomes relevant at $\text{DM} \gtrsim 200 \text{ pc cm}^{-3}$ at comparable baselines. Figure 25 shows the effect of the geometric delay over the dispersion delay. The quantity $\Delta\tau_{\text{geo}}$ is the difference of geometric delay (CHIME and ARO 10 m telescope baseline) at the start and end of the pulse dispersion (400 MHz bandwidth). The calculations were done on `difxcalc11` centered at PSR B0531+21 coordinates, similarly as in Equation (31). A special treatment of the band may be required: for example, separating the band in two or more sections with a $k_{\text{shift}}[n]$, forming visibilities, and then concatenating phases. But in general, combining a coherent de-dispersion with a time variable geometric delay is not a trivial problem to solve.

As explained in Section 3.4, we are interested in the differential DM between sites, which is more than just the ionospheric contribution at sites *A* and *B*. There will also be a Doppler effect given by the Earth’s rotation respect to the solar system barycenter (SSB), which will impact the velocity of each telescope (Rankin et al. 1970; Pennucci et al. 2014). This results in $\text{DM} \rightarrow \widetilde{\text{DM}}$, a modified DM,

$$\widetilde{\text{DM}}(v) = \text{DM} \frac{1}{1 + \frac{v}{c}}, \quad (34)$$

with c the speed of light, and v the velocity of one site. Equation (34) is equivalent to mapping the frequencies as $f \rightarrow f\left(1 + \frac{v}{c}\right)$ in the coherent de-dispersion kernel (Equation (16)). Doppler-shifting the DM during coherent de-dispersion is equivalent to applying the time-dependent geometric phase correction (which is equivalent to Lorentz transforming the data to the CHIME rest frame), ϕ_{geo_0} , followed by coherent de-dispersion to a reference DM (steps 2 and 3; Section 3.4). We take the reference DM to be that measured at CHIME site, averaged over the $\sim 1.1 \text{ s}$ duration of the PSR B0531+21 sweep, and neglect the transformation to the SSB. This effect could be of an order of $1 \times 10^{-4} \text{ pc cm}^{-3}$ (above the required δDM from fringe fitting), where other experiments such as the Pulsar Timing Array correct for it.

5.7. Single Baseline in VLBI and Localization

CHIME/FRB is capable of localizing FRBs up to $\sim 1'$ with its own baseband localization pipeline (Michilli et al. 2021), and adding the extra VLBI baseline will provide constraints mostly in only one dimension (R.A.). Nevertheless, CHIME-

ARO 10 m telescope localizations with $\sigma_\alpha \sim 200 \text{ mas}$ and $\sigma_\delta \sim 1'$ may be sufficient to robustly associate an FRB with its host. The upcoming CHIME/FRB Outriggers project will have three baselines that will further improve these localization errors.

The localization error will also affect the first guess of the phase geometric correction ϕ_{geo_0} (and not more than a frame since its order will be less than $2.56 \mu\text{s}$ in our baseline), step 2 fringe-fitting algorithm (Equations (13) and (14)). Corrections in the case of an unknown target will be applied to the phase in order to find the true R.A. and decl. from the residual delay $\delta\tau$ (result from fringe fitting).

5.8. CHIME/FRB Outriggers Project

The CHIME/FRB Outriggers project will have multiple CHIME single cylinders with two baselines thousands of kilometers from CHIME in order to observe and localize FRBs down to a 50 mas precision. Confirmed sites are: Allenby BC, Canada, Green Bank Observatory WV, USA, and Hat Creek Radio Observatory CA, USA. For calibration, the project will make use of pulsars (which have well-known localizations of 10–20 mas) as an alternative compared to steady-source calibrators, and because of CHIME’s FOV, the longest period of time without a pulsar on beam is roughly $\sim 1 \text{ h}$. These Outriggers will have tracking beams in each station, beam-forming capabilities, and a triggering system, similar to the one implemented at the ARO 10 m telescope testbed. Correlation routines and methods described here will serve as a basis for the project. In particular, the Outriggers beamforming capabilities will have pulsars available for calibration (most of the time), with a nearly in-beam calibration scheme (Leung et al. 2021), by digitally pointing to target and references simultaneously (leaving only a sky angular distance interpolation), i.e., preserving coherence along the FRB dispersion time.

The project will also be interested in steady sources (VLBI calibrators) in order to account for the list of potential challenges described in this section. Such observations will enable us to characterize the VLBI network and measure our precision/uncertainties compared to the proposed pulsar calibration method.

6. Conclusions

In the presented work we have developed a testbed for the CHIME/FRB Outriggers project with the capability of studying FRB localizations, using pulsars to coherently delay reference, and demonstrated clock stability between an independent maser (ARO 10 m telescope) and GPS crystal oscillator (CHIME). The 1960s-era telescope at ARO was refurbished and updated to a modern system. The 10 m dish is able to receive triggers from CHIME/FRB, record baseband data, and transfer it back to the cross-correlation site in a semiautonomous process. We are currently recording single PSR B0531+21 pulses everyday (for potential calibration and clock stability), and in the future, this will be increased to several pulses per day as well as other potential sources. The 10 m dish has also demonstrated reliability over extreme weather conditions, poor internet connections (satellite), and low maintenance on site during the 2020 COVID-19 pandemic.

Our worst localization scenario is $\theta \approx 200 \text{ mas}$ (or equivalently -10 – 10 ns ; baseline angle) in multiple-day observations, where only high-S/N bursts from the first five days in

Figure 16 were considered for this estimate. Other sources of localization error are: the on-sky separation between FRB (target) and calibrator (reference), the simultaneity of the observations, whether or not the ionospheric contribution is known in the FRB and calibrator directions, the clock jitter (CHIME and ARO 10 m telescope clock combination), and lastly whether or not assumptions in our correlator model remain true (Equation (19)). Nevertheless, future calibrations (CHIME/FRB Outriggers project) will have access to pulsars (calibrators) $\lesssim 1$ hr with respect to the observed target (with the possibility of a nearly simultaneous beamformed baseband recording), plus comparing CHIME clock and DRAO maser can add an extra set of corrections to the clock (CHIME end; Mena-Parra et al. 2021). Clock corrections can be done by constantly monitoring calibrators in VLBI, in addition to using measurements of the DRAO maser to correct the clock jitter to the expected delay (given by calibrators). This leaves a comfortable window for the requirement of 50 mas proposed by the CHIME/FRB Outriggers project.

On the other hand, testbed delays over a single day behaved as expected given the precision of the CHIME and ARO 10 m telescope clock system, yielding the required precision of $DM \sim 1 \times 10^{-8} \text{ pc cm}^{-3}$ for a strong cross correlation (below Doppler effect, Section 5.6, and without any ionospheric prior in \mathcal{L} , Equation (18)) and eventual localization.

Lastly, we showed proof of an FRB candidate cross correlated with baseband data, providing enough S/N and phase information to be considered as a true VLBI correlation. A proper and more in-depth study of this event will be discussed in an upcoming paper.

We wish to acknowledge this land on which the University of Toronto operates. For thousands of years, it has been the traditional land of the Huron-Wendat, the Seneca, and the Mississaugas of the Credit. Today, this meeting place is still the home to many Indigenous people from across Turtle Island, and we are grateful to have the opportunity to work on this land.

We acknowledge that CHIME is located on the traditional, ancestral, and unceded territory of the Syilx/Okanagan people.

We wish to thank Rebecca Lin and Marten van Kerkwijk for the useful discussions on VLBI; and Gwendolyn Eadie, Joshua Speagle, and Luke Pratley for discussions on fringe fitting and statistical methods. We wish to thank all people involved in the telescope refurbishment and data acquisition: Dana Simard, James Willis, Vincent MacKay, José Jauregui García, Jacob Taylor, and Nolan Denman. We wish to thank those useful discussions: Andrew Zwaniga, Emily Deibert, and Victor Chan.

Appendix A Radio Frequency Chain

The RF chain at the ARO 10 m telescope has three main stages: telescope focus (\mathcal{S}_1), telescope pedestal (\mathcal{S}_2), and main control room (\mathcal{S}_3). Each stage is equipped with LNAs for the two polarizations. Long lines that go from the pedestal to the main control room are labeled LINE2 and LINE3 (N-type connection). Figure 26 contains an all-analog signal chain from the CHIME feed up to the digitalization at the ICE. Lines are extended for over 200 m from the pedestal to the main control room (right next to the 46-m dish), where the modernized equipment for the facility is located. The lines and connection naming conventions have been kept from the original installation in the 1960s, and only SMA and N-type connections feed the RF chain. BNC provides power to the amplifiers. Underground lines LINE2 and LINE3 present a

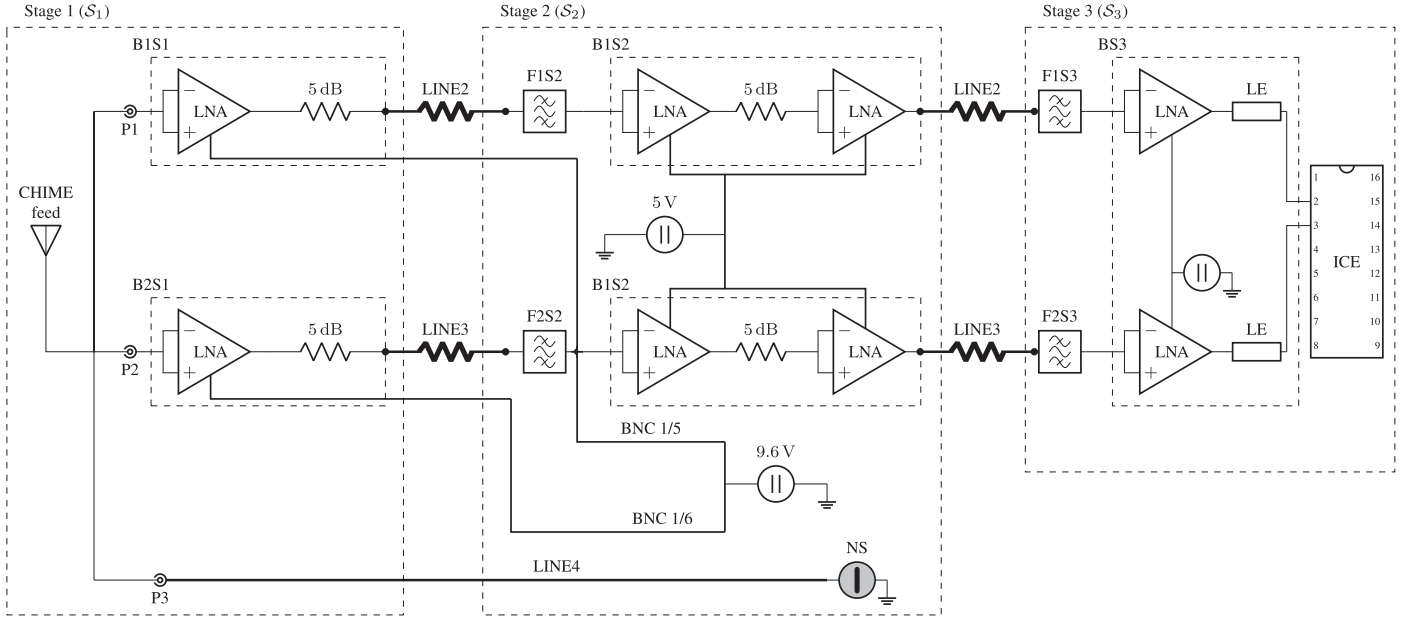

Figure 26. RF chain at the ARO 10 m telescope. Large dashed boxes are stages, and small dashed boxes are LNA assembled boxes. The amplification signal is a combination of CHIME custom and commercial amplifiers, and both polarizations undergo the same devices and cabling with the exception of LINE4. Thin, thick, and very thick lines are SMA, BNC, and N-type connections. LINE2 and LINE3 carry polarization information from the feed (left-hand side) to ICE (right-hand side), and LINE4 is a noise injection for the CHIME feed. Changes in the RF chain were done 2 yr ago, and it has been stable since then.

substantial loss and reflections (as seen in Figure 3), but with the current setup, they fulfill the telescope purpose.

The amplification in the RF chain involves:

1. First-stage amplifier boxes B1S1 and B2S1 are connected to the feed and contain a CHIME custom amplifier (Bandura et al. 2014) and a 5 dB attenuator to avoid reflections and feedback loops.
2. Second-stage amplifier boxes B1S2 and B2S2 have two commercial amplifiers, Mini-Circuits ZX60-112LN+ (Mini-Circuits 2017a), and a 5 dB attenuation between them.
3. Third-stage amplifier box BS3 is located after 200 m of underground cabling, and the amplification is done by CHIME Pathfinder custom amplifiers (Bandura et al. 2014). The third stage ends with a line equalizer TLE LE7 400-800(29) S50.

Each bandpass filter in stages one and two is a Mini-Circuits ZABP-600-1+ (Mini-Circuits 2017b). The system temperature of the telescope has not been properly computed so far. Future measurements of RF chain sections and sky observations will provide this information.

Appendix B

Visibility and Cross Correlation with Baseband Data

The defined data format from Section 2.5.1 in the CHIME and ARO 10 m telescope baseband data, $V[n, k]$, corresponds to a matrix of frequency channels (390.625 kHz channel width), frames (2.56 μ s frame width), and two polarizations (either linear or circular basis).

The process to form baseband data from a wavefront follows: Once the wavefront ($v(t)$) is detected in the feed, the analog signal travels through until reaching the ICE system. Here it is digitized to discrete raw ADC data $\mathbf{v} = \mathbf{v}_q \in \mathbb{R}^Q$ (with Q an arbitrary total of data points of samples but larger than 2048) with a sample size of 1.25 ns, a purely real quantity. This

digitized wavefront is then channelized (to form baseband data) through a polyphase filter bank (PFB; Price 2016; Harris & Haines 2011) of four taps. Figure 27 shows a simplistic graphical representation of a PFB. When the a frame size of 2048 samples is reached ($2048 \times 1.25 \text{ ns} = 2.56 \mu\text{s}$), the frame is multiplied by a section of a window function of the same number of points. The process repeats until all four taps are completed. Then the taps are averaged together yielding 2048 points, which then pass through a one-dimensional FFT. From the complex channelized spectrum, half of it is discarded since the Fourier transform of a real-valued function is Hermitian and placed as a column of $N = 1024$ frequency channels in the baseband data \mathbf{V} . The entire process is again repeated to form the following frame, where the first frame (first tap) used is discarded and a new frame is added. In general, the PFB method is used to reduce side-lobes and minimize the leaked power between frequency channels.

Although the original wavefront changed its initial form, all physical information is still contained in the phase of the complex elements in the \mathbf{V} matrix, viz., $\phi = \text{Arg}[\mathbf{V}]$. Since a PFB has been applied (recorded data from ARO 10 m telescope and CHIME only return baseband data), going back to raw ADC data would imply undoing the transformation, which is, in principle, revertible but not simple to accomplish. Nevertheless, working in baseband data does not affect the performance of the presented VLBI experiment.

Summary of data definitions follow:

1. **Raw ADC data** $\mathbf{v}_p = (v_p)_q \in \mathbb{R}^Q$: de-channelized real-valued raw voltage, before PFB, with element called sample 1.25 ns.
2. **Baseband data** $\mathbf{V}_p = (V_p)_{nk} \in \mathbb{C}^{N \times K}$: channelized complex-valued raw voltage, after PFB, with element called frame 2.56 μ s.

Here, P represents the polarization.

Figure 27. Graphical representation of the transformation of digitized raw ADC data \mathbf{v} (with real-valued elements v_q) to baseband data \mathbf{V} passing through a PFB. The discrete wavefront \mathbf{v} (of Q samples) is first divided into four sections of a frame size, then multiplied by a window function (of four taps), and summed over the frame size. The summed portion has the same number of points as a frame (2048 points with 1.25 ns sample size). The summed section is then Fourier transformed (FFT over time), where its spectra are then placed as a column of 1024 complex data points of the baseband data \mathbf{V} . The first iteration is shaded to gray, and the second iteration (dashed lines) will have another four (taps) frames (removing the initial left side and adding an extra side frame to the right).

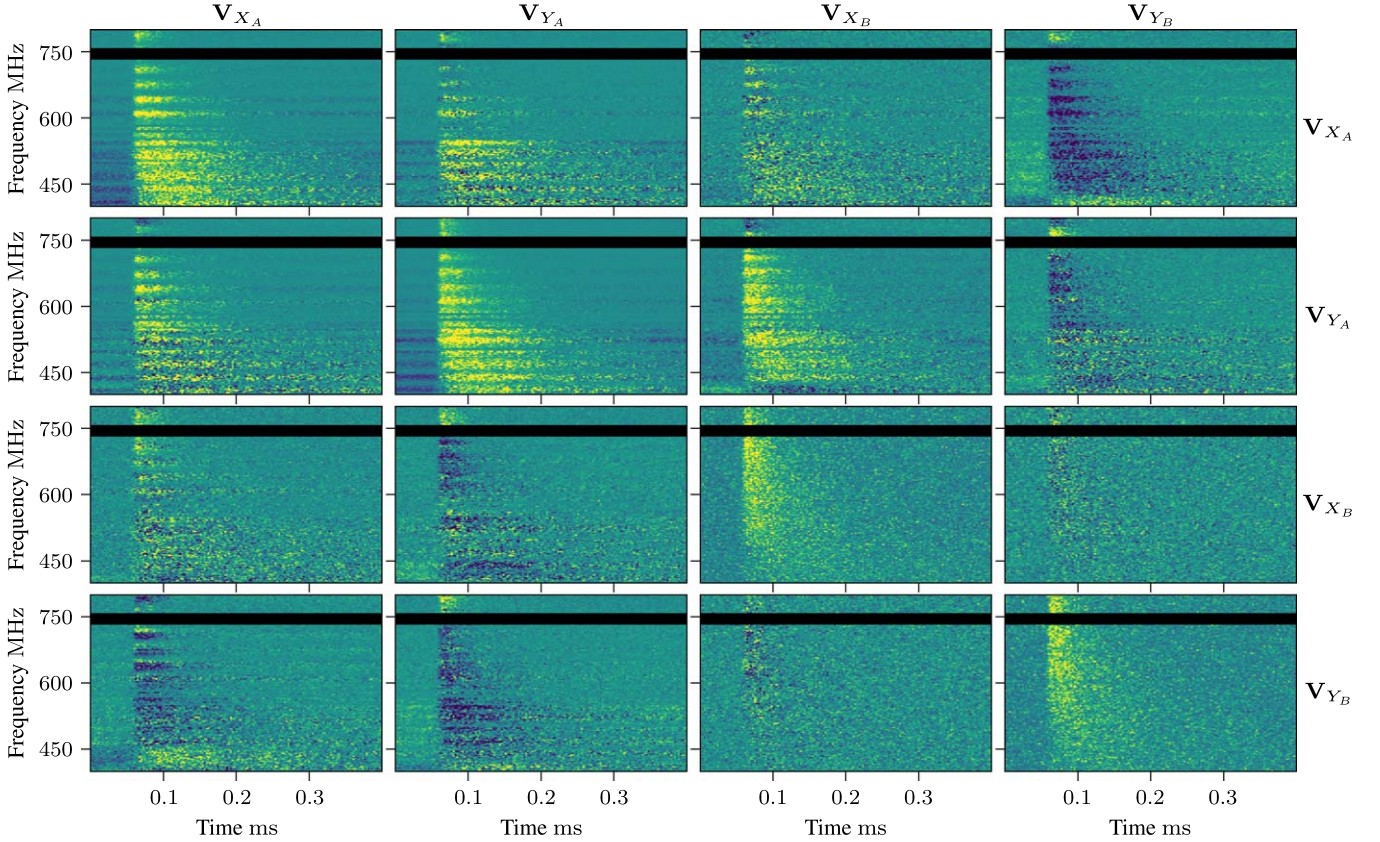

Figure 28. Visibility pairs for PSR B0531+21. The diagonal represents the intensity of PSR B0531+21 pulse for each polarization at each site A and B . Off-diagonal sections are real parts (upper triangle) and imaginary parts (lower triangle) of the computed visibilities. The pair of pulses corresponds to the same as that in Figure 8 and referenced to the CHIME time stamp 2020-10-22 11:22:08.399687685. Visualization is done by taking $\mu \pm 3\sigma$ from the amplitude value in each panel, and they are not normalized to each other.

To find the cross-correlation function $\rho_{A,B}^{\text{sf}}(\tau)$ (Section 3.1) in the baseband data, we need to first form the visibility $\mathbf{V}_{P_A P_B}$, which is nothing more than the element-by-element multiplication of two (same-sized) matrices of baseband data: $\mathbf{V}_{P_A P_B} = \mathbf{V}_{P_A} \overline{\mathbf{V}_{P_B}}$ (same as in Equation (6)), with P_A and P_B the polarization basis of each site. The correct “frame alignment” between the two baseband pairs (\mathbf{V}_{P_A} , \mathbf{V}_{P_B}) must be perfectly aligned within a frame (as in, the frame from site A time stamp corresponds to the frame from site B time stamp within $2.56 \mu\text{s}$, applying the necessary corrections k_{shift} , Equation (5), Section 3.4 forming visibilities, step 5). Otherwise the visibility will not correlate, and signal will vanish (even if only one frame off). From a single pair of pulses (e.g., those in Figure 8), we can generate four visibilities given by the polarization pairs: (\mathbf{V}_{X_A} , \mathbf{V}_{X_B}); (\mathbf{V}_{X_A} , \mathbf{V}_{Y_B}); (\mathbf{V}_{Y_A} , \mathbf{V}_{X_B}); and (\mathbf{V}_{Y_A} , \mathbf{V}_{Y_B}). Figure 28 shows a matrix of all possible combinations of visibilities, in cross correlation and within single sites (i.e., X and Y pairs from the same site). The matrix diagonal is the pulse autocorrelation of single polarizations $\mathbf{V}_k \overline{\mathbf{V}_k}$ with $k = A, B$ and $P = X, Y$. The off-diagonal panels are the real part (upper section) and imaginary part (lower section), $\text{Re}[\mathbf{V}_{P_A P_B}]$ and $\text{Im}[\mathbf{V}_{P_A P_B}]$, respectively. The set of shown visibilities went through a partial fringe fitting (Section 3.4) until step 5.

All analyses done over single and multiple days, Sections 3.5.1 and 3.5.2, were performed with a single pair of polarizations \mathbf{V}_{Y_A} and \mathbf{V}_{X_B} , i.e., the one with the strongest cross correlation and most stable phase. The imaginary part of the visibility $\mathbf{V}_{Y_A X_B} = \mathbf{V}_{Y_A} \overline{\mathbf{V}_{X_B}}$ is plotted in Figure 11.
