Keywords: Azides – Frustrated Lewis Pairs – Photochemistry – Small Molecule Activation – Staudinger Reaction

**Abstract.** Phosphoryl nitride (NPO) is a highly reactive intermediate, and its chemistry has only been explored under matrix isolation conditions so far. Here we report the synthesis of an anthracene (**A**) and phosphoryl azide-based molecule (N<sub>3</sub>P(O)**A**) that acts as a molecular synthon of NPO. Experimentally, N<sub>3</sub>P(O)**A** dissociates thermally with a first order kinetic half-life that is associated with an activation enthalpy of  $\Delta H^\ddagger = 27.5 \pm 0.3$  kcal mol<sup>-1</sup> and an activation entropy of  $\Delta S^\ddagger = 10.6 \pm 0.3$  cal mol<sup>-1</sup> K<sup>-1</sup> that are in good agreement with calculated DLPNO-CCSD(T)/cc-pVTZ//PBE0-D3(BJ)/cc-pVTZ energies. In solution N<sub>3</sub>P(O)**A** undergoes Staudinger reactivity with tricyclohexylphosphine (PCy<sub>3</sub>) and subsequent complexation with tris(pentafluorophenyl)borane (B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub>, BCF) to form Cy<sub>3</sub>P-NP(**A**)O-B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub>. Anthracene is cleaved off photochemically to form the frustrated Lewis pair (FLP) stabilized NPO complex Cy<sub>3</sub>P<sup>⊕</sup>-N=P-O-B<sup>⊖</sup>(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub>. Intrinsic Bond Orbital (IBO) analysis suggests that the adduct is zwitterionic, with a positive and negative charge localized on the complexing Cy<sub>3</sub>P and BCF, respectively.

Phosphoryl nitride is the mono phosphorus analogue of well-known and studied nitrous oxide (N<sub>2</sub>O), a naturally abundant gas that has been recognized as the dominant ozone-depleting substance in the Earth's stratosphere emitted in the 21<sup>st</sup> Century.<sup>1</sup> In chemical transformations N<sub>2</sub>O is primarily used as a powerful oxidant, as it is a poor ligand to transition metals due to its weak  $\sigma$ -donating and  $\pi$ -accepting capabilities.<sup>2-3</sup> Nitrous oxide has been shown to coordinate to transition metal center in an end-on, as well as side-on, fashion.<sup>4-12</sup> Additionally, nitrous oxide easily forms stable complexes with frustrated Lewis pairs (FLPs) and N-heterocyclic carbenes (NHCs) under mild conditions.<sup>13-15</sup>

In contrast, little is known about the chemistry of linear two-fold coordinated phosphorus (V) NPO due to the lack of a suitable molecular precursor that releases the molecule under mild reaction conditions. Phosphoryl nitride was first generated 10 years ago via the irradiation of explosive phosphoryl triazide (O=P(N<sub>3</sub>)<sub>3</sub>)<sup>16-18</sup> and characterized under cryogenic matrix isolation conditions.<sup>19-20</sup> Phosphoryl nitride undergoes photochemically induced isomerizations to PNO and cyclic PON (Figure 1) and reversibly combines with carbon monoxide.<sup>19-20</sup> On the other hand, the phosphorus(III) isomer PNO has been known since 1988

and was formed after photolysis of an O<sub>3</sub>/PN mixture diluted in solid argon under cryogenic matrix isolation conditions.<sup>21</sup> In later experiments, namely gas-phase IR laser absorption spectroscopy of NO/P<sub>4</sub>/O<sub>2</sub>/noble-gas mixtures<sup>22</sup> and a microwave spectroscopic study of a dc glow discharge of NO/H<sub>2</sub> over red phosphorus,<sup>23</sup> there was also no experimental evidence for NPO, only PNO was observed. This is surprising given a recent high-level electronic structure focal point analysis suggesting that NPO is energetically preferred by 1.87 kcal mol<sup>-1</sup> over PNO.<sup>24</sup> The Lewis structures of NPO and PNO are best described with formal charges rather than the neutral N≡P=O form (Figure 1).<sup>19, 25-26</sup> In the solid state, a material of the composition NPO is known to exist in both a β-cristobalite and a slightly thermodynamically less stable amorphous form.<sup>27</sup> Furthermore, isomers of NPO and NPS are also considered potential interstellar molecules,<sup>19, 24-25</sup> given the presence of PN in interstellar media.<sup>28-29</sup>

**Figure 1:** Top: Photochemical formation of all three NPO isomers. Bottom: Lewis structures of NPO.

We reported recently the synthesis of an anthracene-based azido phosphine (N<sub>3</sub>PA) that releases molecular PN in solution and shown to transfer PN to an iron complex under mild conditions.<sup>30</sup> Here we report the oxidation of N<sub>3</sub>PA to anthracene-based phosphoryl azide (N<sub>3</sub>P(O)A, Figure 2). Given the poor thermal stability of N<sub>3</sub>PA at room temperature (*t*<sub>1/2</sub> = 29.1 ± 1.6 min) we selected 2,4,6-trimethylbenzonitrile *N*-oxide (MesCNO) as a fast and effective oxygen atom transfer (OAT) reagent (Figure 2).<sup>31</sup> Single crystals of N<sub>3</sub>P(O)A grown from diethyl ether at –20 °C were characterized in a single crystal X-ray diffraction experiment (Figure 2). The structure is in line with strong infrared bands for the azide group at 2154 and 2141 cm<sup>-1</sup> (Figure S4) as well as a single resonance in the <sup>31</sup>P NMR spectrum at δ 75.9 ppm (t, <sup>2</sup>*J*<sub>PH</sub> = 11.1 Hz; Figure S3). The configuration of the OPN<sub>3</sub> moiety is similar to other phosphoryl azides, e.g., F<sub>2</sub>P(O)N<sub>3</sub>.<sup>32</sup>

**Figure 2:** Top: Synthesis of  $N_3P(O)A$  using mesityl nitrile oxide (MesCNO) as an OAT reagent. Bottom: Molecular structure of  $N_3P(O)A$  with thermal ellipsoids shown at the 50% probability level. Hydrogen atoms are omitted for the sake of clarity. Selected interatomic distances (Å): P1–N1, 1.7066(17); P1–O1, 1.4754(13); P1–C1, 1.8520(19); P1–C8, 1.861(2); N1–N2, 1.243(2); and N2–N3, 1.128(3). Selected interatomic bond angles (°): C1–P1–C8, 83.51(9); N1–P1–O1, 111.61(8) and P1–N1–N2, 115.09(13).

$N_3P(O)A$  was heated under vacuum and the release of molecules into the gas phase was monitored by mass spectrometry using a molecular-beam mass spectrometer (MBMS). We observed a strong increase in signals for  $N_2^+$  ( $m/z = 28$ ),  $P^+$  ( $m/z = 31$ ),  $PN^+$  ( $m/z = 45$ ), and  $A^+$  ( $m/z = 178$  and smaller fragments) starting at around 60 °C in the chromatogram (Figure S24). Additionally, a signal for  $m/z = 59$  was observed that may originate from isomers of  $CPO^+$  or  $PN_2^+$ . However, no signal at  $m/z = 61$  for any NPO isomer was observed. Even reducing the voltage from 70 to 35 V in the electron impact ion source did not lead to the detection of any new signal for  $m/z = 61$ . Consistent with the observed decomposition at 60 °C in the MBMS experiment, solid  $N_3P(O)A$  melts at 45 °C and forms a yellow-brown solid at 60 °C (Figure S25).

We followed the thermal decay of  $N_3P(O)A$  in benzene-*d*<sub>6</sub> by <sup>1</sup>H NMR spectroscopy (Figure S20-S22, Table S1-S2) and found that the azide decomposes at 52.5 °C with a first-order kinetics half-life of around half an hour ( $t_{1/2} = 25.5 \pm 0.4$  min). Further kinetic measurements on  $N_3P(O)A$  decomposition were performed over the temperature range of 52.5–70.0 °C. An Eyring analysis revealed activation parameters of  $\Delta H^\ddagger = 27.5 \pm 0.3$  kcal mol<sup>−1</sup> and  $\Delta S^\ddagger = 10.6 \pm 0.3$  cal mol<sup>−1</sup> K<sup>−1</sup> (Figure S23). The first-order behavior is indicative of a unimolecular rate-determining step, consistent with fragmentation of  $N_3P(O)A$  into  $A$  and presumably a  $O=PN_3$  fragment (*vide infra*).

**Figure 3:**  $\text{N}_3\text{P}(\text{O})\text{A}$  decomposes into  $\text{N}_2$ , cyclic and linear NPO isomers, and anthracene (A) either by dinitrogen and subsequent anthracene loss or via anthracene loss and further dissociation of the  $\text{OPN}_3$  fragment into NPO and  $\text{N}_2$ . The latter pathway is energetically preferred. Gibbs free energy values are computed for  $T = 298.15$  K. Color code: carbon = grey, hydrogen = white, nitrogen = blue, phosphorus = orange, oxygen = red.

We computed the most essential part of the potential energy surface around  $\text{N}_3\text{P}(\text{O})\text{A}$  at DLPNO-CCSD(T)/cc-pVTZ//PBE0-D3(BJ)/cc-pVTZ + Gibbs free energy correction (Figure 3). Note that the decomposition of phosphoryl azides has been studied previously.<sup>33-35</sup> We located two minima for  $\text{N}_3\text{P}(\text{O})\text{A}$ , and the energetically preferred conformer is in line with our crystal structure depicted in Figure 2. In the higher energy conformer, the P–N single bond is rotated by  $180^\circ$  and the azide group takes a parallel position to a terminal aromatic ring that results in an energy rise of  $2.1 \text{ kcal mol}^{-1}$ . Both conformers are connected by a low lying transition state **TS3** ( $3.5 \text{ kcal mol}^{-1}$ ). For the fragmentation of  $\text{N}_3\text{P}(\text{O})\text{A}$ , we initially considered cleavage of dinitrogen from the azide group. For each of the two  $\text{N}_3\text{P}(\text{O})\text{A}$  conformers, we located, in contrast to  $\text{N}_3\text{PA}$ , an energetically high lying transition state (**TS4** ( $44.6 \text{ kcal mol}^{-1}$ ) and **TS6** ( $39.5 \text{ kcal mol}^{-1}$ )) that is associated with dinitrogen loss and a ring expansion to form tricyclic **APNO** in a highly exothermic ( $-43.2 \text{ kcal mol}^{-1}$ ) and cyclic NPO attached to anthracene (*c*-**APNO**) in a highly endothermic ( $25.9 \text{ kcal mol}^{-1}$ ) reaction, respectively. The dissociation reactions are completed with anthracene loss to form linear NPO via **TS5** ( $43.7 \text{ kcal mol}^{-1}$  barrier) and cyclic NPO via **TS7** ( $17.3 \text{ kcal mol}^{-1}$  barrier). However, in general these high reaction barriers cannot be overcome by simple heating at  $80^\circ\text{C}$ . Therefore, we investigated a second dissociation pathway that is initiated by the cleavage of anthracene. We located a concerted transition state **TS2** that is associated with a reaction barrier of  $25.2 \text{ kcal mol}^{-1}$ , leading to the fragmentation of  $\text{N}_3\text{P}(\text{O})\text{A}$  into A and  $\text{OPN}_3$ . These calculations also suggest that the latter fragment eliminates  $\text{N}_2$  via **TS1** ( $26.2 \text{ kcal mol}^{-1}$ ) to form linear NPO.

Based on the computed free energy values involving the elimination of **A** in the first step is energetically favored. The pathway via **TS2** with a total barrier of 25.1 kcal mol<sup>-1</sup> is in good agreement with the experimental value of our Eyring analysis ( $\Delta G^\ddagger = \Delta H^\ddagger - T\Delta S^\ddagger = 24.4 \pm 0.1$  kcal mol<sup>-1</sup> at 298.15 K). However, the fate of the OPN<sub>3</sub> fragment remains unclear. The experimentally observed resonance at  $\delta$  112.7 ppm in the <sup>31</sup>P{<sup>1</sup>H} after thermolysis cannot be assigned to the OPN<sub>3</sub> fragment or the NPO molecule.

**Figure 4:** Top: Synthesis of Cy<sub>3</sub>P-NPO-B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub>. Bottom: Molecular structures of Cy<sub>3</sub>P=NP(O)**A**, Cy<sub>3</sub>P-NP(A)O-B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub> and Cy<sub>3</sub>P-NPO-B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub> with thermal ellipsoids shown at the 50% probability level. Hydrogen atoms are omitted for the sake of clarity. Selected interatomic distances (Å) and bond angles (°): **A**: (Cy<sub>3</sub>)P–N, 1.5765(8); N–P, 1.5813(9) and P–O, 1.4889(8); (Cy<sub>3</sub>)P–N–P, 147.62(6) and N–P–O, 119.59(4). **B**: (Cy<sub>3</sub>)P–N, 1.5761(12); N–P, 1.5465(12); P–O, 1.5171(10) and O–B, 1.5110(18); (Cy<sub>3</sub>)P–N–P, 165.17(9); N–P–O, 114.43(6) and P–O–B, 148.83(9); **C**: (Cy<sub>3</sub>)P–N, 1.6289(9); N–P, 1.5555(9); P–O, 1.5549(8) and O–B, 1.5454(13); (Cy<sub>3</sub>)P–N–P, 140.18(6); N–P–O, 110.73(4) and P–O–B, 131.50(6).

We treated N<sub>3</sub>P(O)**A** with tricyclohexylphosphine (PCy<sub>3</sub>) in diethyl ether and immediate gas evolution and precipitation of the Staudinger reaction<sup>36</sup> product Cy<sub>3</sub>P=NP(O)**A** was observed (Figure 4).<sup>37</sup> The product was isolated by vacuum filtration in 82% yield (Figure S6-S8). Cy<sub>3</sub>P=NP(O)**A** exhibits two doublets at  $\delta$  82.9 and  $\delta$  32.3 ( $^2J_{PP}$  = 21.4 Hz) in the <sup>31</sup>P{<sup>1</sup>H} NMR spectrum (Figure S8). Additionally, Cy<sub>3</sub>P=NP(O)**A** was characterized in a single crystal X-ray diffraction experiment and the molecular structure is depicted in Figure 4A.

Considering that nitrous oxide<sup>13</sup> and many other small molecules have already been reported to form complexes with frustrated Lewis pairs (FLPs),<sup>38-39</sup> we added tris(pentafluorophenyl)borane (B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub>, BCF) to a solution of Cy<sub>3</sub>P=NP(O)**A** in dichloromethane, leading to new <sup>31</sup>P NMR resonances at  $\delta$  52.5 and  $\delta$  32.9 ( $^2J_{PP}$  = 16.8 Hz) in the <sup>31</sup>P{<sup>1</sup>H} NMR spectrum (Figure S11). An analytical sample was crystallized in diethyl ether and the crystals were analyzed in a X-ray diffraction experiment, leading to the structure depicted in Figure 4B. For the complete complexation of NPO, **A** can be cleaved off by irradiating ( $\lambda$  = 254 nm) a solution of Cy<sub>3</sub>P-NP(A)O-B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub> in benzene or toluene for 220 min. Anthracene photodimerizes during the irradiation and can be separated from the reaction mixture by filtration.<sup>40</sup> The slightly yellow colored filtrate was mixed (in the case of benzene as a solvent) or layered with pentane and placed in the freezer. After three days colorless crystals formed and the crystals were collected by vacuum filtration, washed with pentane and isolated in 42% yield (Figure S14-S18). When the isolated material was dissolved in

chloroform a doublet signal at  $\delta$  44.1 ( $J$  = 78.2 Hz) for PCy<sub>3</sub> and a doublet of quintets signal at  $\delta$  271.1 ppm ( $J$  = 77.4, 25.5 Hz) for NPO were observed in the  $^{31}\text{P}\{^1\text{H}\}$  NMR spectrum (Figure S16). X-ray diffraction analysis on a single crystal directly grown from a benzene/pentane solution after irradiation reveals the Cy<sub>3</sub>P-NPO-B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub> structure (Figure 4C). The latter splitting originates from through space coupling of phosphorus to fluorine in B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub> as only a doublet signal is observed in the  $^{31}\text{P}\{^1\text{H}, ^{19}\text{F}\}$  NMR experiment.<sup>41</sup> The compound is thermally unstable and decomposes after one day at room temperature or by heating over night at 50 °C. In the  $^{31}\text{P}\{^1\text{H}\}$  NMR spectrum, two major doublet signals at  $\delta$  42.2 and  $\delta$  40.7 ppm together with some minor signals at around  $\delta$  -20 ppm were observed that could not be unambiguously assigned (Figure S19).

**Figure 5:** Computed Intrinsic Bond Orbitals (IBOs) of the N-P (left) and P-O (right)  $\pi$ -bonds based on the geometry of the X-ray structure depicted in Figure 4C at  $\omega$ B97M-D3(BJ)/def2-TZVPP.

The interatomic distances in the single crystal for the NPO fragment are almost the same for the N–P (1.5555(9) Å) and P–O (1.5549(8) Å) linkages. Intrinsic Bond Orbital (IBO) analysis<sup>42</sup> shows the bonding of the  $\pi$  system, where there is visual evidence for both N–P and P–O  $\pi$  bonding (Figure 5). The Wiberg bond order (WBO) for the N–P bond is 1.47 and for the P–O bond 1.05. The bond orders are reflective of the high electronegativity of N and O and the consequent greater coefficients on N and O rather than P in the  $\pi$  system, which acts to bring down the WBO numbers. Hence, the main resonance contributor is the one with the Cy<sub>3</sub>P<sup>+</sup>-N=P-O-B<sup>-</sup>(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub> bonding pattern, and formal positive and negative charges on the phosphine and borate, respectively. Compounds of the type R-N=P-OR' exhibit a similar bonding pattern, but they are rare and mainly derive from the combination of an alkoxide with the Mes\*NP<sup>+</sup> cation.<sup>43-50</sup> Gaseous NPO is predicted to be linear, and has two bonds of almost equal length, a N–P bond distance of 1.4965 Å at the CCSD(T)/CBS level and a P–O bond distance of 1.4656 Å at the same level.<sup>25</sup> Similar to N<sub>2</sub>O, the geometry of NPO is bent in its FLP complex.
