Long duration electricity storage (LDES) with 10+ hour cycle duration is an economically competitive option to accelerate the penetration of renewable energy into the utility market. Unfortunately, none of the available energy storage technologies can meet the LDES' requirements for duration and cost. We here report a focused kinetic study on Fe-oxide reduction process, which is a key step for solid oxide iron-air battery; the latter has been recently demonstrated as a LDES compatible battery. The study clearly shows that Ir is an excellent catalyst to boost the sluggish Fe-oxide reduction kinetics.

## 1. Introduction

Long duration energy storage (LDES) (10+ hours) is considered a key technical solution for the penetration of renewable energy into the utility market. However, the currently available storage technologies are limited to less than 10 hours for cost reason. The benchmark Li-ion battery technology would be economically prohibitive if the storage time goes beyond 4 hours. Therefore, developing new low-cost LDES-compatible battery technologies is highly desirable.

In recent years, we have been researching on a new type of metal-air battery for LDES applications. The battery is consisted of solid oxide-ion electrolyte and porous electrodes and operated on oxide-ion chemistry. In this battery, the chemical energy of oxygen as transported in the form of O<sup>2-</sup> by the oxide-ion conductor (electrolyte) is reversibly stored in an energy-dense Fe/FeO<sub>x</sub>-bed (or abbreviated as “Fe-bed”) that is integrated within the anode chamber of a reversible solid oxide cell (RSOC) [1-4]. During operation, the oxygen electrode (OE) and hydrogen electrode (HE) are open to air of an unlimited oxygen source and enclosed to a low-cost Fe-bed chamber, respectively. Upon cycling, RSOC alternately operates in fuel cell mode during discharge and electrolyzer mode during charge, while the oxygen is being transferred via a gas-phase H<sub>2</sub>/H<sub>2</sub>O shuttle and stored within the Fe-bed via the Fe-O redox reaction. One unique feature of SOIAB is its free access to oxygen in air (thus no oxygen storage needed for OE), making it suited for LDES applications.

From our early work, we have identified two major problems limiting the overall performance of a solid oxide iron-air battery: 1) sluggish FeO<sub>x</sub>-to-Fe reduction kinetics in

the Fe-bed; [5] 2) RSOC's high electrode overpotentials [1]. To address these issues, we have previously shown that synthesis of nanostructured Fe-bed materials [3] and addition of catalyst (*e.g.*, Pd) nanoparticles can boost the  $\text{FeO}_x$ -to-Fe reduction kinetics [1]. However, our effort to further improve RSOC's electrochemical performance has been very limited until very recently we have demonstrated that adding Ir into Fe-bed can significantly improve the kinetics of  $\text{FeO}_x$  reduction [6].

To understand the slow kinetic issue, we have also previously measured the rate constant of the  $\text{H}_2$  reduction process of  $\text{FeO}_x\text{-ZrO}_2$  [7, 8]. These kinetic data are very useful for our multiphysics modeling effort. However, there is a lack of similar dataset for Ir-catalyzed  $\text{FeO}_x\text{-ZrO}_2$  reduction process. Therefore, the goal of this study is to acquire this set of data for comparison with the rate constant of baseline  $\text{FeO}_x\text{-ZrO}_2$   $\text{H}_2$ -reduction and future multiphysics modeling of the battery.

## 2. Experimental Method

### 2.1 Material Synthesis

**Fe<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> Baseline:** The starting  $\text{Fe}_2\text{O}_3\text{/ZrO}_2$  composite material was prepared by the co-precipitation method. Briefly, the stoichiometric solutions of  $\text{Fe}(\text{NO}_3)_3\cdot 9\text{H}_2\text{O}$  ( $\geq 99\%$ , Sigma-Aldrich) and  $\text{ZrO}_2(\text{NO}_3)_4\cdot x\text{H}_2\text{O}$  ( $\geq 99\%$ , Alfa Aesar,  $x=6$ ) were dissolved in deionized water separately in the mole ratios of 85:15. Then these two solutions were mixed with a cation concentration of 0.1 M in a beaker and polyvinylpyrrolidone (PVP, Sigma-Aldrich) as a surface active agent was added while stirring constantly for 30 min. The mixture solution was then added dropwise to an ammonium carbonate  $(\text{NH}_4)_2\text{CO}_3$  (Sigma Aldrich) solution under constant stirring while maintaining the temperature of the solution to 35°C. To make sure full precipitation of a cation in the solution, the molar ratio of  $(\text{NH}_4)_2\text{CO}_3$  and  $\text{M}^+$  ( $\text{M}=\text{Zr}$  and  $\text{Fe}$ ) was kept as  $n(\text{NH}_4)_2\text{CO}_3:n\text{M}^+=2.5:1$ . The resultant brownish precipitation was left for 20 h in the solution with continuous stirring. Finally, the suspension was filtered and washed several times with deionized water followed by overnight drying at 80°C. To obtain the precursor  $\text{Fe}_2\text{O}_3\text{/ZrO}_2$ , the collected precipitate was calcined at 600°C for 5 h.

**Fe<sub>2</sub>O<sub>3</sub>/ZrO<sub>2</sub>-Ir:** The prepared  $\text{Fe}_2\text{O}_3\text{-ZrO}_2$  was the first ball milled using planetary ball milled (BM4X-04, COL-INT TECH) in a zirconia container for 20h with 300 rpm speed. Then 0.1 g Ir precursor Iridum III 2,4 pentanedionate ( $\text{C}_{15}\text{H}_{21}\text{IrO}_6$ , sigma Aldrich) was dissolved in 2 ml acetone (99.5% Sigma Aldrich). Later, the solution was mixed with 1 g of milled  $\text{Fe}_2\text{O}_3\text{-ZrO}_2$  precursor powder in an agate mortar followed by hand grinding. Finally, the obtained powders were calcined at 600°C for 2h.

### 2.2 Material Characterization

The phase composition of prepared composites  $\text{Fe}_2\text{O}_3\text{/ZrO}_2$  and Ir-added  $\text{Fe}_2\text{O}_3\text{/ZrO}_2$  as well as products of the redox reaction were examined by X-Ray diffraction (XRD, Rigaku D/MAX-2100) at a scan rate of 3°C/min from 20 to 80°. The morphologies of the prepared materials before and after the reaction were also captured by a field emission scanning electron microscope (FESEM, Zeiss Gemini500).

### 2.3 Kinetics Measurement Setup

To create a similar reaction atmosphere to the battery, the reduction of prepared baseline composites  $\text{Fe}_2\text{O}_3\text{-ZrO}_2$  and Ir-added  $\text{Fe}_2\text{O}_3\text{-ZrO}_2$  material and their respective kinetic studies were performed in a fixed bed reactor; the experimental setup is shown in Figure 1.

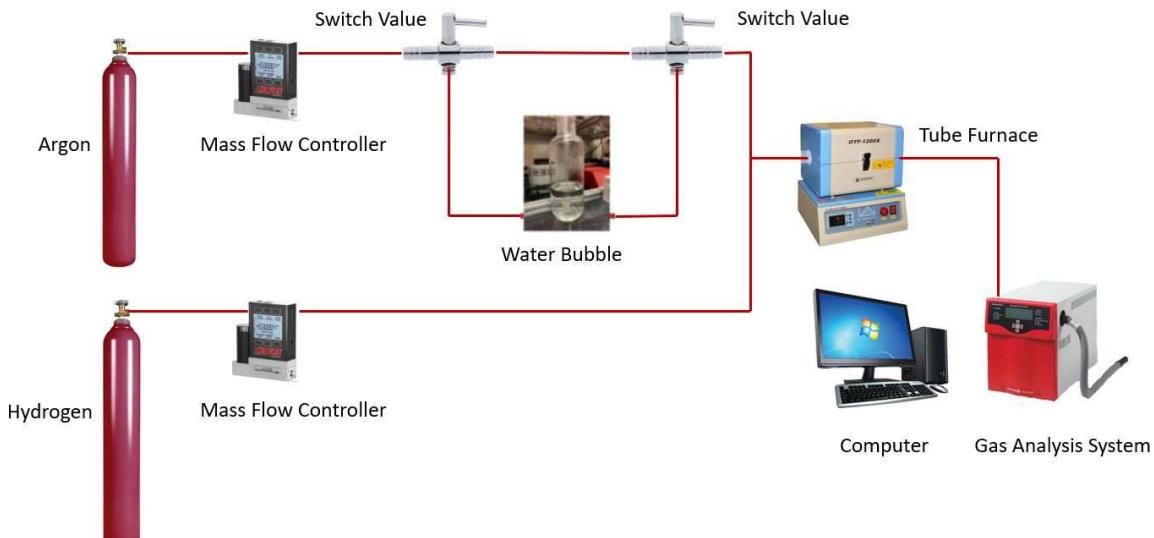

Figure 1. Experimental setup for kinetic study of  $\text{FeO}_x$  reduction.

The experimental setup mainly consists of a quartz reaction tube, fixed bed, water bubbler, mass flow controllers, switch valve, and mass spectrometer (MS, Pfeiffer Omnistar 100) connected at the outlet of the reactor tube. The steam was controlled by a water bubbler at room temperature which will provide fixed  $\text{H}_2\text{O}$  content to a carrier gas. The gas flow rate was controlled by a mass flow controller (Alicat Scientific MFC Series). MS was used to analyze the effluent compositions and confirm a full reduction of the starting oxide  $\text{Fe}_2\text{O}_3$  to Fe. The starting oxide composition for reduction process depends on the ratio of partial pressure of  $\text{H}_2\text{O}/\text{H}_2$ .

To run the experiment, 100 mg of Ir-added  $\text{Fe}_2\text{O}_3\text{/ZrO}_2$  supported on a lump of quartz wool was first placed inside a quartz glass tube, followed by raising furnace temperature to 400 °C with the argon flow rate at 200  $\text{cm}^3/\text{min}$ . Then 10%  $\text{H}_2\text{-Ar}$  mixture gas was introduced in a reactor during the temperature rise to a target temperature, i.e., 500, 525, 500, 575 °C. Mass spectrometer (MS) connected to the tube furnace was used to analyze the outlet gas concentrations during the initial reduction of the  $\text{Fe}_2\text{O}_3$  into Fe and the degree of the reduction is mainly confirmed by  $\text{H}_2$  concentration. Upon full reduction, there will be no  $\text{H}_2$  consumption. After this initial reduction activation process with 10%  $\text{H}_2\text{-Ar}$  concentration (total of 100 sccm), the oxidation process was carried out by switching the gas with a controlled  $\text{H}_2\text{O}/\text{H}_2$  ratio to achieve desired oxide form. The starting oxide form for the reduction cycle depends on the temperature and ratio of partial pressure of  $\text{H}_2\text{O}$  and  $\text{H}_2$ . Therefore, we have chosen  $\text{H}_2\text{O}$  oxidation cycle to create in situ equilibrium Fe oxide composition for the subsequent reduction kinetics study [8].

To control the pressure ratio  $\text{H}_2\text{O}/\text{H}_2$ , a fixed flow rate of  $\text{H}_2$  was added to a flow rate of moistened Ar steam (100 sccm) at room temperature. For reference, a thermodynamic phase diagram was used to guide the pressure ratio of  $\text{H}_2\text{O}/\text{H}_2$ , i.e., for

reduction  $\text{Fe}_3\text{O}_4$  to Fe at 500-575°C,  $p\text{H}_2\text{O}/p\text{H}_2$  was set to 2. Once desired oxide is obtained, the reduction ( $\text{Fe}_3\text{O}_4$  to Fe) was carried out in 20%  $\text{H}_2\text{-Ar}$  concentration (total 100 sccm). The reduction kinetics was calculated based on the change in  $\text{H}_2\text{O}$  concentration in the effluent measured by MS. The starting oxide composition for the reduction kinetics study as  $\text{Fe}_3\text{O}_4$  is confirmed by X-Ray Diffraction.

### 3. Results and Discussion

#### 3.1 Confirmation of the Starting Oxide for $\text{H}_2$ Reduction

To confirm the starting oxide composition, i.e.,  $\text{Fe}_3\text{O}_4$ , after oxidizing Fe by using 3%  $\text{H}_2\text{O}$  mixed with  $\text{H}_2$  ( $\text{Fe}$  was obtained from the initial reduction of  $\text{Ir-Fe}_2\text{O}_3/\text{ZrO}_2$  by  $\text{H}_2$ ), the partial pressure ratio of  $\text{H}_2\text{O}$  and  $\text{H}_2$  in equilibrium with the formed  $\text{Fe}_3\text{O}_4$  was calculated by the measured outlet concentrations of  $\text{H}_2\text{O}$  and  $\text{H}_2$  with MS. The thermodynamic phase equilibrium diagram shown in Figure 2 indicates a three-phase domain:  $\text{Fe}$ ,  $\text{FeO}$ , and  $\text{Fe}_3\text{O}_4$  [9]. At  $T < 550^\circ\text{C}$ ,  $\text{Fe}$  and  $\text{Fe}_3\text{O}_4$  are in equilibrium with a pressure ratio of  $\text{H}_2\text{O}$  and  $\text{H}_2$  of ~0.8, which means  $\text{Fe}_3\text{O}_4$  can be directly reduced into  $\text{Fe}$  in a single step by  $\text{H}_2$ . On the other hand, at  $T > 600^\circ\text{C}$ , there is an intermediate phase  $\text{FeO}$  before  $\text{Fe}_3\text{O}_4$  is reduced to  $\text{Fe}$ . Therefore,  $\text{P}_{\text{H}_2\text{O}}/\text{P}_{\text{H}_2}=2$  is chosen to obtain  $\text{Fe}_3\text{O}_4$  oxide phase composition for  $\text{Fe}_3\text{O}_4$  to  $\text{Fe}$  reduction at  $T < 550^\circ\text{C}$ .

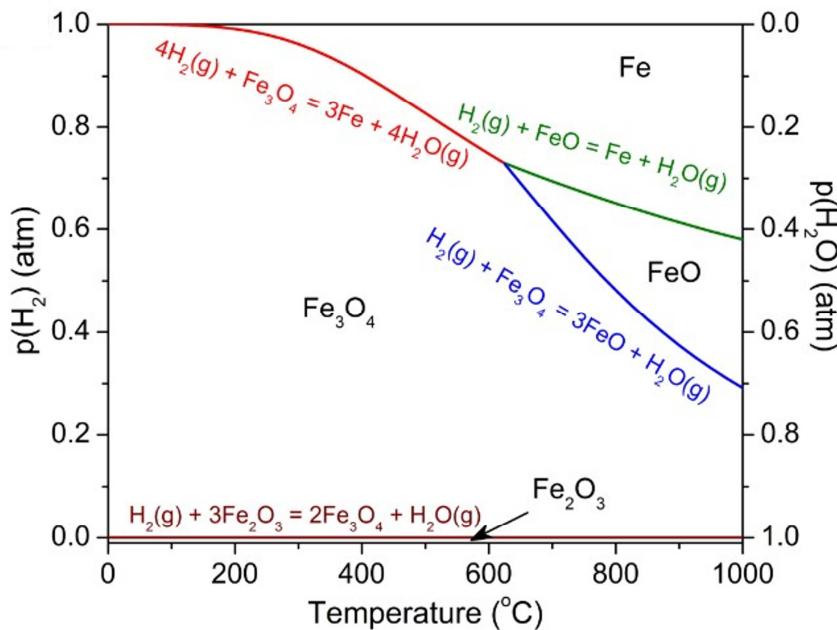

Figure 2. Thermodynamics phase equilibrium a function of temperature and  $p(\text{H}_2)$  and  $p(\text{H}_2\text{O})$ . [9]

#### 3.2 Phase Composition and Morphologies of Fe Oxides before and after Reduction

The phase compositions of  $\text{Fe}_2\text{O}_3\text{-ZrO}_2$  and Ir-added  $\text{Fe}_2\text{O}_3\text{-ZrO}_2$  composite are confirmed by XRD patterns in Figure 3. The composite powder  $\text{Fe}_2\text{O}_3/\text{ZrO}_2$  shows the peaks at 24, 33.2, 35.6, 40.8, 49.5, 54.1, 62.4, 63.98° related to planes (012), (104), (110), (024), (116), (214), (300) of  $\text{Fe}_2\text{O}_3$  (PDF# 84-0308). These sharp peaks show high crystallinity and purity of sample synthesized by co-precipitation. After introducing  $\text{IrO}_2$ , a wide peak at 28.1° appears and can be indexed to the plane (110) of  $\text{IrO}_2$ . The low

intensity and broader peak of  $\text{IrO}_2$  suggest low its crystallinity. Figure 4 shows the phase composition of the material after experiencing the first redox cycle at  $500^\circ\text{C}$ . It is evident that all XRD peaks of  $\text{ZrO}_2$  remain unchanged even though the peak at  $28.2^\circ\text{C}$  is weak due to the high crystallinity and high content of Fe and  $\text{Fe}_2\text{O}_3$ , suggesting its chemical stability to Fe-based materials and  $\text{H}_2$ . Note the initial  $\text{IrO}_2$  will become Ir metal at above  $200^\circ\text{C}$ .

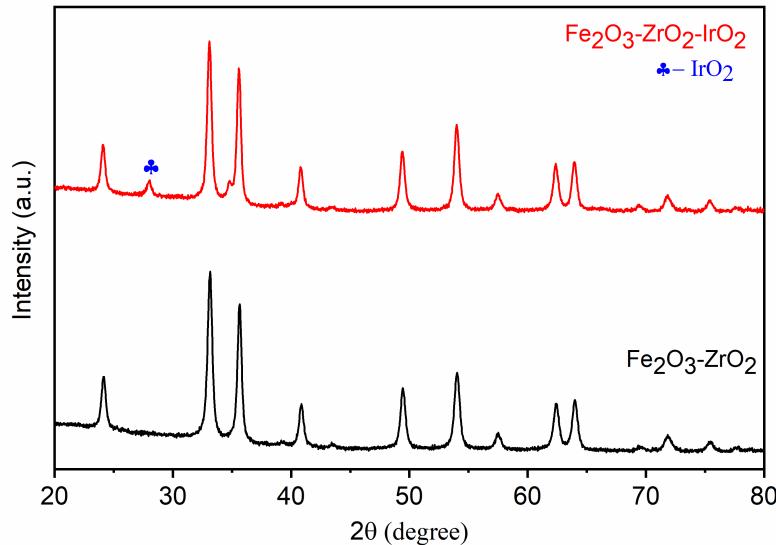

Figure 3. XRD patterns of the baseline  $\text{Fe}_2\text{O}_3/\text{ZrO}_2$  and Ir-added  $\text{Fe}_2\text{O}_3/\text{ZrO}_2$ .

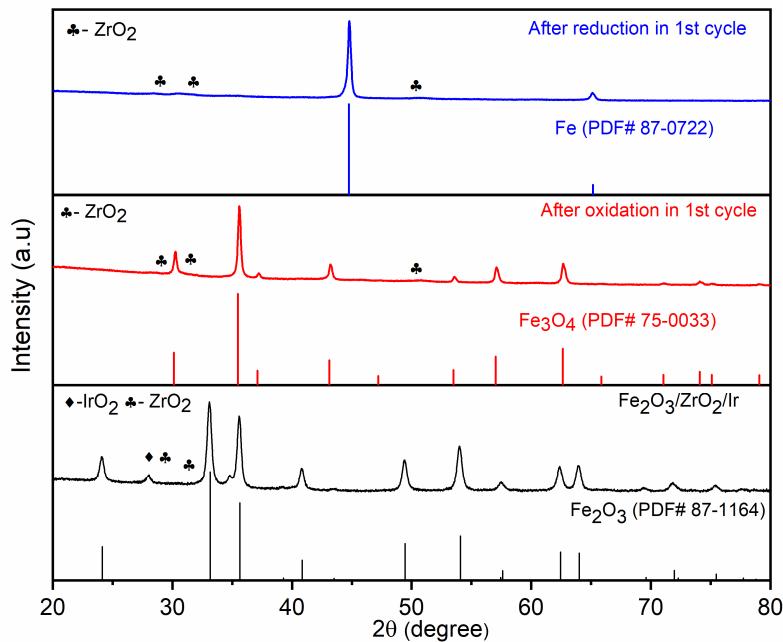

Figure 4. XRD patterns of Ir-added  $\text{Fe}_2\text{O}_3/\text{ZrO}_2$  before and after the 1<sup>st</sup> redox cycle at  $500^\circ\text{C}$ .

The morphologies of  $\text{Fe}_2\text{O}_3/\text{ZrO}_2$ -Ir before reduction are shown in Figure 5(a), featuring uniform spherical nanoparticles. After the reduction in  $20\% \text{H}_2$ , Figure 5(b)-(d), particles are slightly agglomerated and shown with the worst agglomeration at  $575^\circ\text{C}$ , see Figure

5e. But still, there are some nanoparticles seen on the surface of large particles. The elemental mapping of the reduced sample is shown in Figure 5(f1)-(f3), where a uniform distribution of Fe, Zr and Ir elements is observed.

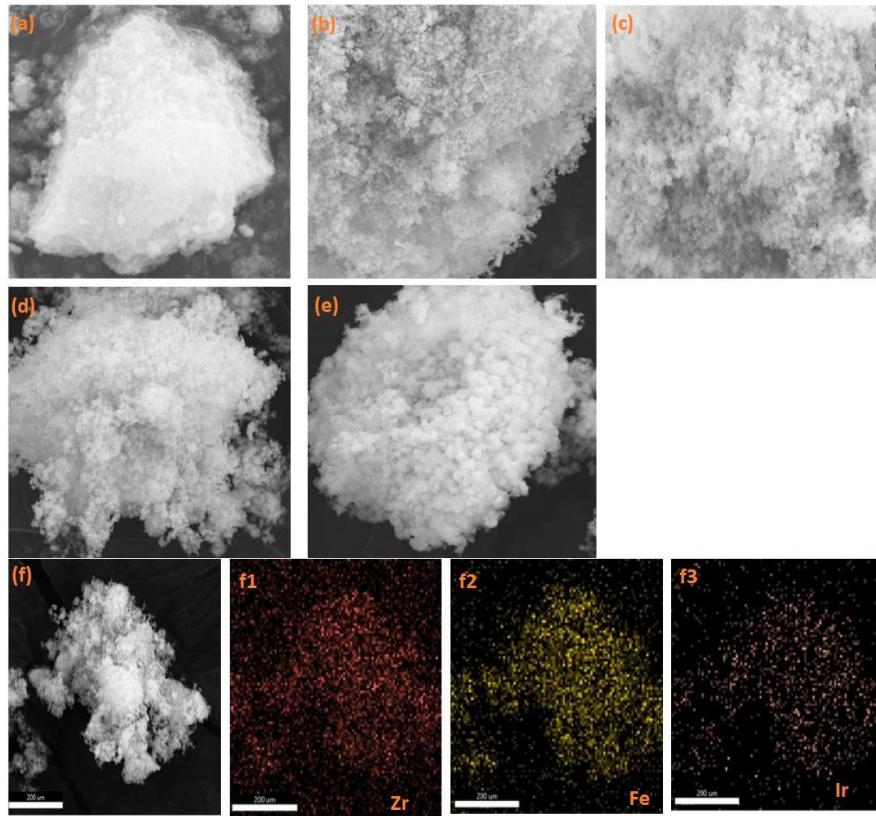

Figure 5. SEM images of powders of (a) fresh Ir-catalyzed  $\text{Fe}_2\text{O}_3/\text{ZrO}_2$  and after reduction in 20%  $\text{H}_2$  at (b) 500 (c) 525 (d) 550 and (e) 575 °C.

### 3.3 Reduction Kinetics Modeled by Johnson-Mehl-Avrami Theory

The Johnson-Mehl-Avrami, *aka.* JMA, theory describes isothermal reduction kinetics with solid-state transformation consideration [10-12]. The reduction process of  $\text{FeO}_x$  by  $\text{H}_2$  normally involves a sequence of nucleation and growth steps [7]. The JMA model is related to the reaction fraction ( $\xi$ ) at constant temperature and reaction time. Referring to [8], the reduction extent ( $\text{Fe}_3\text{O}_4$ -to-Fe)  $\xi$  vs. time  $t$  is expressed by

$$\xi(t) = \frac{\int_0^t (I_{\text{H}_2\text{O prod}}) dt}{S_{\text{red}}} \quad [1]$$

Here,  $I_{\text{H}_2\text{O prod}}$  is time-dependent ion current of MS related to  $\text{H}_2\text{O}$  production;  $S_{\text{red}}$  is the peak area of full reduction process.

The kinetic rate constant  $k(T)$  is calculated by the following if  $\xi$  is known.

$$\xi(t) = 1 - \exp[-k(T)t^n] \quad [2]$$

where  $k(T)$  is a rate constant expressed by  $k(T) = A * \exp(-\frac{E_a}{RT})$ .  $\xi(t)$  shows certain kind of topochemical solid-state reaction and is analyzed by the kinetic model proposed by

Avrami and Johnson [13-16]. In this model, a new phase is germ nucleated and distributed throughout the solid, followed by grain growth of an old phase until transformation is completed [10].

Sharp-Hancock equation can be derived by taking logarithmic of eq. (2) to study the order of solid-state reaction [17]:

$$\ln[-\ln(1-\xi)] = n\ln(t) + \ln(k) \quad [3]$$

where  $n$  is Avrami exponent, which depends on the nucleation and crystal growth of a phase boundary surface [17]. Generally,  $n = \lambda + \beta$ , where  $\lambda$  is the dimensionality of growth,  $\lambda = 1, 2$  or  $3$  and  $\beta$  depends on the nucleation process to the overall kinetics ( $0 < \beta < 1$ ,  $0$  represents instantaneous nucleation and  $1$  means a very slow nucleation rate) [7]. The value of  $n = 1-2$  signifies to 1D growth,  $n = 2-3$  for 2D growth and  $n = 3-4$  for 3D growth for each process of a different temperature [10].

The local  $n(\xi)$  is calculated by differentiating eq. (3)

$$n(\xi) = \frac{\partial \ln(-\ln(1-\xi))}{\partial \ln(t)} \quad [4]$$

For  $\text{FeO}_x$  reduction process, the reaction rates can also be expressed by

$$\frac{d\xi}{dt} = k(T) * f(\xi) \quad [5]$$

where  $f(\xi)$  is an integral mathematical function depending on kinetic model. For the reduction kinetics under isothermal condition, it can be integrated to yield

$$g(\xi) = \int_0^\xi \frac{d\xi}{f(\xi)} = k * t = A * \exp\left(\frac{E_a}{RT}\right) t \quad [6]$$

where  $g(\xi)$  is an integral mathematical function related to the mechanism of reduction reaction. Using logarithmic form and rearrangement of eq. (6), we get

$$\ln(t) = (-\ln(A) + \ln(g(\xi))) + \frac{E_a}{RT} \quad [7]$$

where  $t$  is the reaction time corresponding to reduction extent  $\xi$ . By plotting  $\ln(t)$  vs.  $1/T$ , activation energy,  $E_a$ , can be obtained at different  $\xi$ .

### 3.4 Modeling Experimental Data

The reduction kinetics of  $\text{Fe}_3\text{O}_4$  to Fe in  $\text{H}_2$  gas environment was evaluated by measuring the change in  $\text{H}_2\text{O}$  concentration in the effluent through MS. The data was processed using the JMA model. During the reduction process, the change in  $\text{H}_2\text{O}$  concentration vs. time is caused by oxygen removal from iron oxide. The outlet  $\text{H}_2\text{O}$  concentration vs. time from 500 to 575 °C during reduction process under 20%  $\text{H}_2$  is shown in Figure 6. Figure 7 shows the corresponding reduction extent of  $\text{Fe}_3\text{O}_4$  vs. time.

From Figure 6, the  $\text{H}_2\text{O}$  production is faster in early stage than later stage. The kinetic rate constant is determined by applying JMA model (eq. (1)) to the experimental data, the fitted lines is shown in the Figure 7. All  $\xi(t)$  isotherm plots are of sigmoid shape and can be divided into 3 distinct regions: incubation period ( $0 < \xi < 0.1$ ), acceleration regions ( $0.1 < \xi < 0.65$ ) and deceleration region ( $0.65 < \xi < 1.0$ ). It can be observed that with increasing temperature,  $\xi$  shows shorter incubation period. The incubation period is dominated by nucleation events, while the acceleratory region can be related to the development of a new phase and the deceleration region corresponds to the termination

of the growth due to the coalescence of Fe particles and thus affects the diffusion [7]. The values of  $k$ ,  $n$  and  $E_a$  are calculated from the fitting results and summarized in Table 1. An average value of  $n = 1.08$  was obtained. This value indicates the phase transitions continues as a 1D growth process ( $\lambda = 1$ ) with a small nucleation contribution. The activation energy was found to be 44.97 kJ/mol for temperature 500-575 °C at 20 % H<sub>2</sub>, see Figure 8.

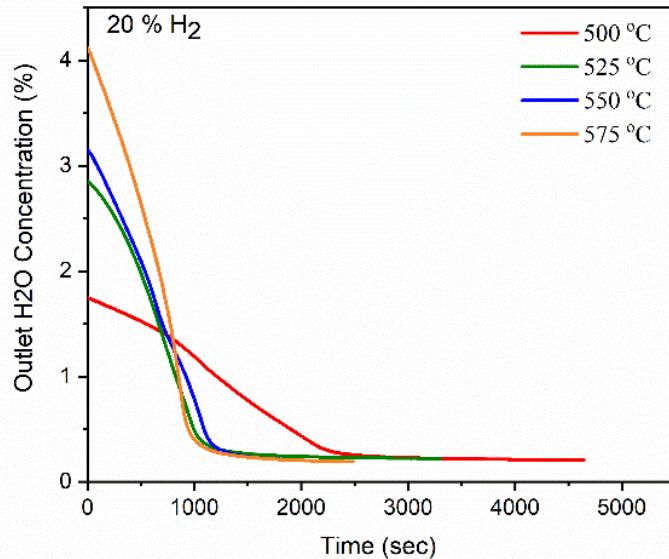

Figure 6. Profile of outlet water concentration during reduction process in 20% H<sub>2</sub>-Ar at 500 to 575 °C.

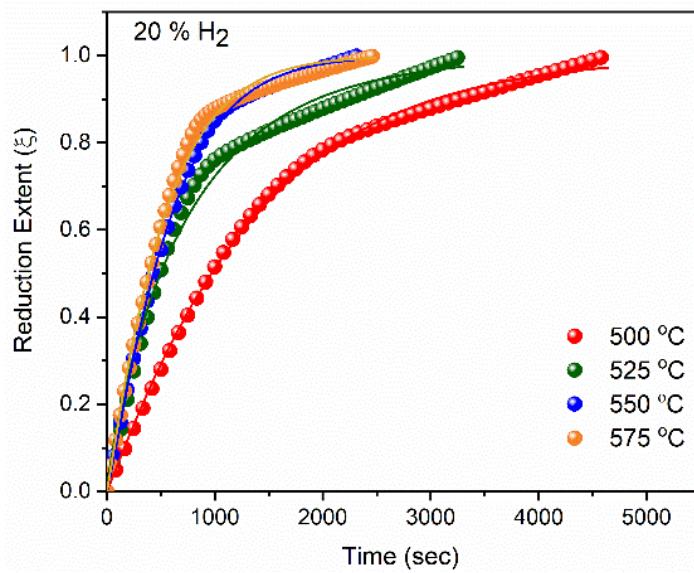

Figure 7. Reduction extent profile of Fe<sub>3</sub>O<sub>4</sub> vs. time and JMA model fitting curves at 500-575 °C.

The Sharp and Hancock eq. (3) is used to evaluate the order of solid-state reaction rate and the plots of  $\ln(-\ln(1-\xi))$  vs.  $\ln(t)$  is based on the experimental data at 500-575°C at 20% H<sub>2</sub>-Ar; the results are shown in the Figure 9. It shows 3 distinct stages with different Avrami exponent ( $n$ ) in the whole conversion process. It can be clearly seen that when reduction extent is close to 1,  $n$  tends to be infinite ( $\xi \neq 1$  boundary condition for

eq. (3)). The variation of local exponent with reduction extent implies the different dominating mechanism in each stage of reaction [7] and are also plotted Figure 10.

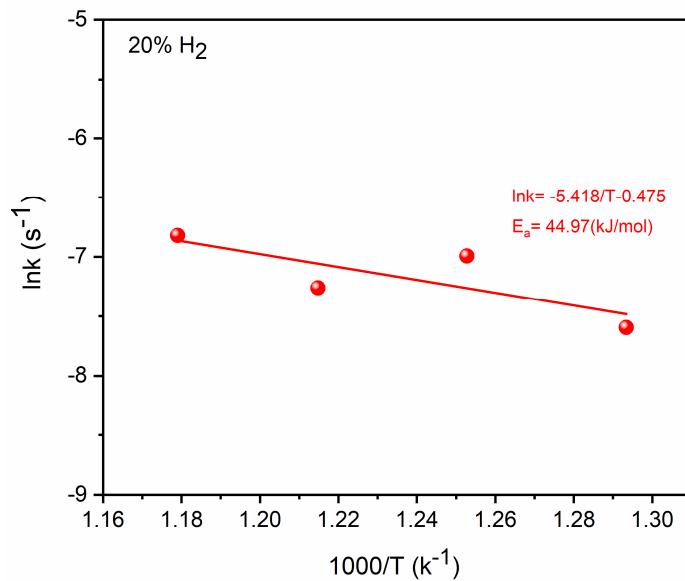

Figure 8. Arrhenius plot of rate constant of  $\text{Fe}_3\text{O}_4$  to Fe reduction extracted from JMA model.

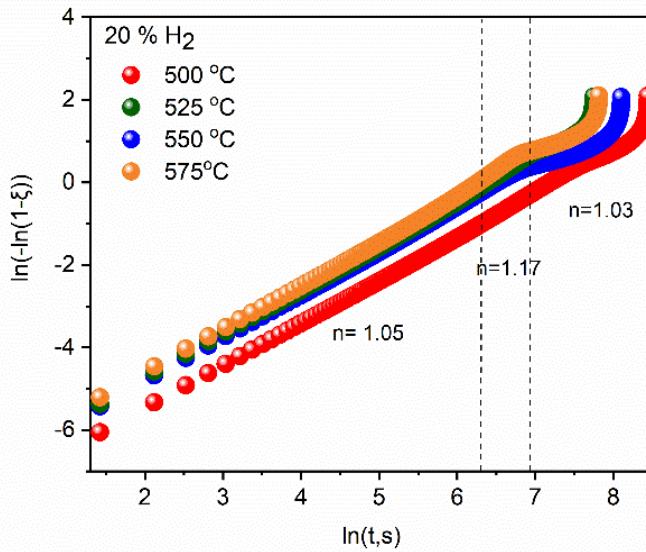

Figure 9. Sharp-Hancock plots based on the data at 500-575°C in 20%  $\text{H}_2$ .

At the beginning of reaction,  $n$  slowly increases and reaches a maximum value, indicating 1D growth with decreasing nucleation rate, which agrees well with Figure 10. At end of the reaction,  $n$  tends to fall below 1, implying slower diffusion due to sintering of Fe particles. To get the clear idea of mechanism, we plotted eq. (7),  $\ln(t)$  vs.  $1/T$  in figure 11 at  $\xi = 0.05 - 1$ , from 500-575°C in 20%  $\text{H}_2$ . For a given  $\xi$ ,  $E_a$  is calculated from the slope of each line and shown in Figure 12. In this case with increasing  $\xi$ ,  $E_a$  first increases from 53.39 to 55.6 kJ/mol within  $0.05 < \xi < 0.15$ , then very slowly increases to 60.38 kJ/mol within  $0.15 < \xi < 0.7$  and then increases again to 78.54 kJ/mol for  $0.75 < \xi < 0.85$ , and finally decreases to 57.22 kJ/mol at the end of reduction. This

variation indicates the changes in growth and nucleation mechanism during reduction process.

### 3.5 Comparison of Reduction Kinetics between Baseline and Ir-added $\text{Fe}_2\text{O}_3/\text{ZrO}_2$

The kinetics of baseline material  $\text{Fe}_2\text{O}_3/\text{ZrO}_2$  and Ir-added  $\text{Fe}_2\text{O}_3/\text{ZrO}_2$  are compared in Figure 13. It is evident that Ir significantly boosts the reduction kinetics of  $\text{FeO}_x$ . The  $E_a$  of both materials is calculated and indicated in the Figure 13. Since  $E_a$  for Ir-added  $\text{Fe}_2\text{O}_3/\text{ZrO}_2$  is slightly higher (44.97 kJ/mol) than baseline material (40.13 kJ/mol), the high pre-exponential factor (A) must be the reason for the boosted kinetics, see Figure 13. From Figure 14, we can find that  $E_a$  of the baseline material decreases with  $\xi$ , implying that  $E_a$  of nucleation is higher than growth of new phase, which means it follows nucleation and growth model. In contrast,  $E_a$  slowly increases with  $\xi$  up to 0.7 and then decreases at the end for Ir-added  $\text{Fe}_2\text{O}_3/\text{ZrO}_2$ . In addition, at the end of a reduction period, there might be possibility of densification of Fe-particles, resulting in higher  $E_a$ . Compared to the  $\text{Fe}_2\text{O}_3/\text{ZrO}_2$  reduction, the kinetic rate constant of Ir-added  $\text{Fe}_2\text{O}_3/\text{ZrO}_2$  is one order of magnitude higher. The values of  $n$  and  $E_a$  of both materials are summarized in the Table 1.

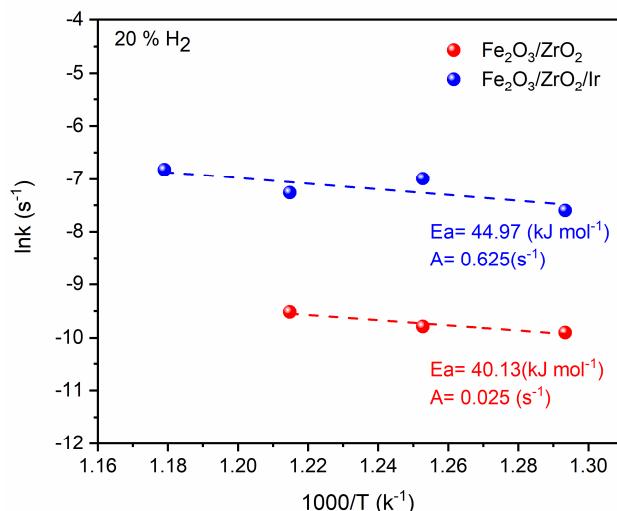

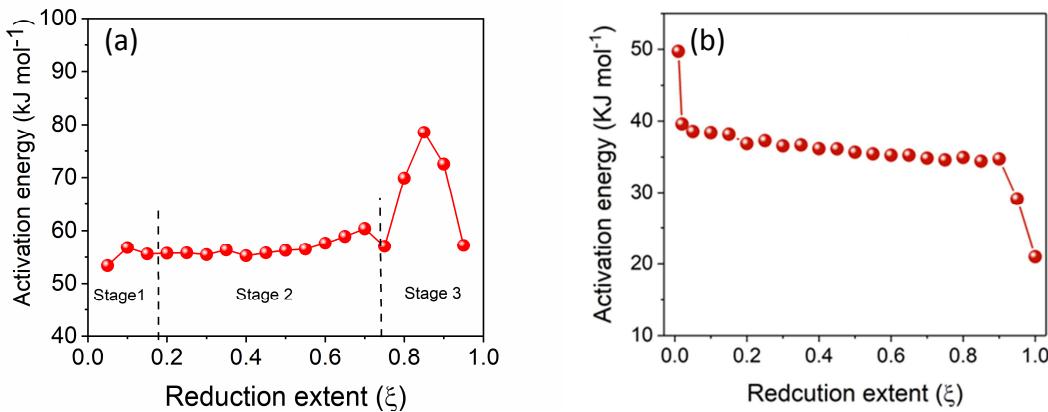

Figure 13. Comparison of  $E_a$  of  $\text{Fe}_2\text{O}_3/\text{ZrO}_2$  with Ir-catalyzed  $\text{Fe}_2\text{O}_3/\text{ZrO}_2$ .

Table 1. Summary of fitting results of reduction of  $\text{Fe}_3\text{O}_4$  using JMA model

	$\text{Fe}_2\text{O}_3/\text{ZrO}_2$			$\text{Fe}_2\text{O}_3/\text{ZrO}_2 - \text{Ir}$			
$T(^{\circ}\text{C})$	500	525	550	500	525	550	575
$k(\text{s}^{-1})$	$5.01 \times 10^{-5}$	$5.62 \times 10^{-5}$	$7.37 \times 10^{-5}$	$5.024 \times 10^{-4}$	$9.17 \times 10^{-4}$	$7.029 \times 10^{-4}$	$1.09 \times 10^{-3}$
$n$	1.45	1.45	1.45	1.08	1.08	1.08	1.08
$R^2$	0.999	0.995	0.998	0.997	0.98	0.99	0.99
$E_a$ (kJ mol $^{-1}$ )	$40.1 \pm 2.3$			44.5			

Figure 14.  $E_a$  vs.  $\xi$  of (a) Ir-added  $\text{Fe}_2\text{O}_3/\text{ZrO}_2$  and (b) baseline  $\text{Fe}_2\text{O}_3/\text{ZrO}_2$  [7].

#### 4. Conclusion

The reduction kinetics study of Ir-added  $\text{Fe}_2\text{O}_3/\text{ZrO}_2$  was carried out in 20%  $\text{H}_2$  in 500-575  $^{\circ}\text{C}$  by MS. The desired starting iron oxide,  $\text{Fe}_3\text{O}_4$ , was obtained by controlling the ratio of  $\text{H}_2\text{O}$  and  $\text{H}_2$  concentration. The reduction kinetics of  $\text{Fe}_3\text{O}_4$  to Fe was modeled by Johnson-Mehl-Avrami (JMA) theory. The obtained rate constant of Ir-added  $\text{Fe}_2\text{O}_3/\text{ZrO}_2$  is one order magnitude higher than  $\text{Fe}_2\text{O}_3/\text{ZrO}_2$ . The increased rate constant was found to result from the high pre-exponential factor (A), not the activation energy. The variations in  $E_a$  follows three steps involving the change in nucleation and growth.
