(Received 29 July 2022; accepted 30 September 2022; published 31 October 2022)

The symmetry breaking of grand unified gauge groups in the early Universe often leaves behind relic topological defects such as cosmic strings, domain walls, or monopoles. For some symmetry breaking chains, hybrid defects can form where cosmic strings attach to domain walls or monopoles attach to strings. In general, such hybrid defects are unstable, with one defect “eating” the other via the conversion of its rest mass into the other’s kinetic energy and, subsequently, decaying via gravitational waves. In this work, we determine the gravitational wave spectrum from 1) the destruction of a cosmic string network by the nucleation of monopoles which cut up and “eat” the strings, 2) the collapse and decay of a monopole-string network by strings that eat the monopoles, 3) the destruction of a domain wall network by the nucleation of string-bounded holes on the wall that expand and eat the wall, and 4) the collapse and decay of a string-bounded wall network by walls that eat the strings. We call the gravitational wave signals produced from the eating of one topological defect by another “gravitational wave gastronomy.” We find that the four gravitational wave gastronomy signals considered yield unique spectra that can be used to narrow down the $SO(10)$ symmetry breaking chain to the Standard Model and the scales of symmetry breaking associated with the consumed topological defects. Moreover, the systems we consider are unlikely to have a residual monopole or domain wall problem.

I. INTRODUCTION

The Universe is transparent to gravitational waves, even at very early times. Therefore, the search for a cosmological gravitational wave background provides a new way of observing our early cosmic history. Furthermore, the Hubble scale H for cosmic inflation in the primordial universe could be as large as 5×10^{13} GeV [1] (for a review see [2]), implying the early Universe could have reached energies far beyond that of Earth based colliders. Therefore,

gravitational wave physics is a unique probe of extremely high scale physics.

A particularly promising class of sources for primordial gravitational waves arises from topological defects produced during certain types of transitions that spontaneously break a symmetry. Cosmic strings, domain walls, and textures all produce a gravitational wave power spectrum with an amplitude that monotonically increases with the scale of the symmetry breaking [3]. This implies that gravitational waves from topological defects are a unique probe of very high scale physics. We are coming into a golden age of gravitational wave cosmology, with new experiments using pulsar timing arrays [4–6], astrometry [7–9], space and ground based interferometry [10–16], all due to come online in the next few decades, and probing frequencies from the nanohertz to kilohertz range. Indeed, the North American Nanohertz Observatory for Gravitational Waves (NANOGrav) and parkers pulsar timing array (PPTA) might have already seen evidence of a primordial gravitational wave background [6, 17], which can be corroborated by future pulsar timing arrays and astrometry [9]. Information about the Universe at very early times and very high energy could be just over the horizon.

Of particular interest at the high scale is the possibility that the gauge groups in the Standard Model could unify to a single gauge group, perhaps through a series of intermediate steps (for a review see [18]). There are two remarkable hints that this might be the case: First, the gauge anomalies of the Standard Model miraculously cancel—a miracle that is necessary for the consistency of the theory and can be explained by an anomaly-free unified gauge group that has been spontaneously broken. Second, the gauge coupling constants in the Standard Model approximately unify at a scale of around 10^{15} GeV. On top of these hints, if $B - L$ local symmetry is embedded in a unified group, then the baryon asymmetry can be generated through leptogenesis when this $U(1)_{B-L}$ is spontaneously broken in the early Universe [19].

While elegant, these grand unified theories (GUTs) are notoriously difficult to test due to the high scales involved. Many symmetry breaking paths predict topological defects that are in conflict with present day cosmology unless their relic abundances are heavily diluted. For example, even a small flux of monopoles can destroy the magnetic fields of galaxies or potentially catalyze proton decays [20–23]. Moreover, domain walls, which dilute slowly with the expansion of the Universe, can come to dominate the energy density of the Universe which conflicts with the standard Λ cold dark matter (CDM) cosmology [24].

A solution to these problematic defects is for inflation to dilute their abundance [25, 26], which puts a qualitative constraint on the cosmological history of the Universe. Another possibility is for the problematic defects to be “eaten” by another defect, which is determined solely by the symmetry breaking. For example, for some symmetry

breaking chains, strings can be cut by the Schwinger nucleation of monopole-antimonopole pairs [27–29], which “eat” the string before annihilating themselves. Similarly, in other symmetry breaking chains, domain walls can be consumed by the Schwinger nucleation of strings on their surface or can be cut into pieces of string-bounded walls by a preexisting string network [30–32] and later decay via gravitational waves. We call the gravitational wave signatures from the “eating” of one defect by another “gravitational wave gastronomy.”

We, for the first time, derive the gravitational wave spectrum that arises from symmetry breaking paths that form walls bounded by strings. The case where the domain walls destroy a preexisting string network, and where the walls are consumed by string nucleation, generate distinct gravitational wave spectra. The former scenario is particularly interesting since it always occurs in chains that allow hybrid wall-bounded strings when inflation occurs prior to string formation.¹ The latter scenario arises when inflation occurs between string and wall formation scales. Moreover, string nucleation on the wall is a tunneling process exponentially sensitive to the degeneracy between the cube of the string tension μ^3 and square of the wall tension σ^2 and hence requires a coincidence of scales that is unnecessary in the first case. We also revisit the gravitational wave spectrum predicted from monopoles consuming strings [44–46] and derive, for the first time, the gravitational wave spectrum that arises from strings eating a preexisting monopole network. This case is, again, particularly interesting since it always occurs in chains that allow hybrid monopole-bounded strings when inflation occurs before monopole formation.²

Overall, we find that all types of hybrid defects generate distinguishable gravitational wave signals, implying that gravitational wave gastronomy is a remarkably promising method for learning information about the symmetry breaking chain that nature chose to follow. Such a program is, at the very least, complimentary to other probes of high scale physics, including searches for lepton number violation in neutrinoless double beta decay [48, 49], searches for non-Gaussianities in the cosmic microwave background [50–63], and searches for proton decay [64–71]. Finally, in the case where monopoles are produced alongside strings, the possibility was raised that the strings dilute slowly enough that they can be replenished after there is enough e foldings of inflation to dilute the monopoles. This results in

¹Domain walls bounded by strings can also appear in the breaking of an approximate $U(1)$ global symmetry, such as with axions. [33–43]. Unlike gauged defects, these global defects decay mostly via pseudogoldstone boson emission, not gravitational waves. This work focuses on gauged hybrid defects.

²During the writing of this manuscript, the power spectrum we predict was independently derived in Ref. [47], which confirms the results in this paper for the monopole eating strings gastronomy scenario of Sec. IV.

potentially observable burst [72] or stochastic signals [46,73–75]. We show explicit symmetry breaking chains that can accommodate this signal in Sec. VIII and discuss how both strings and domain walls can sometimes replenish after monopoles are diluted away to reform a scaling network.

The structure of this paper is as follows. In Sec. II we review the menu of topological defects that can be generated from symmetry breaking and give an overview of all possible symmetry breaking paths from the $SO(10)$ GUT group that can generate an observable gravitational wave signature. Finally, we make more general statements about all gauge groups by deriving a set of homotopy selection rules in order to argue that our menu of possible signals is complete and general. In Sec. III, we review upcoming prospects for gravitational wave detection, including possible ways of constraining or detecting high frequency signals. In Sec. IV we consider the gravitational wave spectrum of monopoles consuming strings via Schwinger nucleation and, in Sec. V, strings consuming a preexisting monopoles network. In Sec. VI we consider strings consuming domain walls via Schwinger nucleation and, in Sec. VII, domain walls consuming a preexisting string network. In Sec. VIII we briefly discuss topological defects that are washed out by inflation before summarizing our results and discussing how each gravitational wave signal from hybrid defects can be distinguished in Sec. IX. In Appendix A, we discuss that lower dimensional topological defects appear earlier than the associated higher dimensional defects in light of homotopy selection rules as we see in $SO(10)$ symmetry breaking chains. In Appendix B, we derive the action of a disk-shaped domain wall bounded by a circular cosmic string.

II. TOPOLOGICAL DEFECTS GENERATED FROM GRAND UNIFIED THEORIES

In this section, we review the menu of topological defects that can be produced by symmetry breaking chains. We then derive a set of topological selection rules and discuss four types of hybrid defects that commonly appear in $SO(10)$ GUTs.

A. Menu of topological defects in symmetry breaking paths

Let us begin by discussing the full set of defects that can occur in a symmetry breaking chain. As well as over-viewing the defects conceptually, we will discuss the connection between the scale of symmetry breaking and the physical quantities—the domain wall surface tension, the string tension, and the monopole mass. We will find there is substantial flexibility in surface tension of the domain wall and the monopole mass, up to naturalness concerns, and only a moderate amount of flexibility in the relationship of the string tension and the associated symmetry breaking scales.

Consider a gauge group G spontaneously breaking to H . In four dimensional spacetime, we have four possible topological defects that can arise during such a transition. Depending on the characteristics of the vacuum manifold $\mathcal{M} = G/H$, one can produce domain walls, cosmic strings, monopoles, and textures. The vacuum manifold is characterized by its homotopy class, that is, the equivalence class of the maps from an n -dimensional sphere S^n into $\mathcal{M}$, denoted as $\pi_n(\mathcal{M})$. We use the notation I for trivial homotopy groups. If $\mathcal{M}$ is disconnected, then $\pi_0(\mathcal{M}) \neq I$, and two dimensional topological defects (domain walls) are formed through the symmetry breaking. Similarly, $\pi_1(\mathcal{M}) \neq I$ predicts one dimensional defects (cosmic strings), $\pi_2(\mathcal{M}) \neq I$ predicts pointlike defects (monopoles), and $\pi_3(\mathcal{M}) \neq I$ predicts three-dimensional defects (textures).

Let us begin with a qualitative discussion of domain walls. A standard Mexican hat potential with a $\mathbb{Z}_2$ discrete symmetry,

$$V(\phi) = \frac{\lambda_\sigma}{4} (\phi^2 - v_\sigma^2)^2, \quad (1)$$

will have a vacuum manifold that satisfies $\pi_0(\mathcal{M}) \neq I$ and therefore admits domain walls. Consider a kink solution to the equation of motion between two degenerate vacua,

$$\phi(x) = v_\sigma \tanh \left(\sqrt{\frac{\lambda_\sigma}{2}} v_\sigma x \right). \quad (2)$$

The surface tension of the wall is

$$\sigma = \int_{-\infty}^{\infty} dx \left(\frac{1}{2} \left[\frac{\partial \phi(x)}{\partial x} \right]^2 + V(\phi(x)) \right) = \sqrt{\frac{8\lambda_\sigma}{9}} v_\sigma^3, \quad (3)$$

which, depending on the value of λ_σ , can, in principle, vary from an order of magnitude above v_σ^3 to arbitrarily small values (for a review see [76]). To avoid committing to a particular form of a potential, throughout this paper we will parametrize the flexibility of the relationship between the surface tension and the symmetry breaking scale as

$$\sigma = \epsilon v_\sigma^3. \quad (4)$$

Note that although ϵ , in principle, can be arbitrarily small, naturalness will require $\epsilon \gtrsim g^2/4\pi \gtrsim 10^{-3}$, with the lower limit arising from Coleman-Weinberg one-loop quantum corrections, where $g \sim 0.1$ is the grand unified gauge coupling associated with the $\mathbb{Z}_2$ symmetry above the scale v_σ .

Next let us consider the case where the first homotopy group of the vacuum manifold is nontrivial, that is when strings can form. Consider a scalar theory with a $U(1)$ gauge symmetry,

$$L = |D\phi|^2 + V(\phi) + \frac{1}{4} F^2, \quad (5)$$

where $D_\mu = \partial_\mu - ieA_\mu$ is the covariant derivative. Again, we use the same form of the potential

$$V = \frac{\lambda_\mu}{4} (|\phi|^2 - v_\mu^2)^2. \quad (6)$$

The classical equations of motion have the form

$$D^2\phi + \frac{\lambda_\mu}{2} (|\phi|^2 - v_\mu^2)\phi = 0, \quad (7)$$

$$\partial^\mu F_{\mu\nu} - ie(\phi^* D_\nu \phi - D_\nu \phi^* \phi) = 0, \quad (8)$$

and admit a nontrivial solution of the form

$$\phi(r) = f(r)v_\mu e^{i\theta}, \quad A_i = \frac{1}{er} A_\theta(r) \hat{\theta}_i, \quad (9)$$

where $A(\infty) = f(\infty) = 1$ and $A(0) = f(0) = 0$. The string tension can be found by substituting the string solution into the classical equations of motion into the Hamiltonian and integrating over the loop,

$$\mu = \int r dr d\phi \left[\left| \frac{\partial \phi}{\partial r} \right|^2 + \left| \frac{1}{4} \frac{d\phi}{d\theta} - iq A'_\theta \phi \right|^2 + V(\phi) + \frac{B'^2}{2} \right] \quad (10)$$

$$= 2\pi v^2 B \left(\frac{2\lambda}{e^2} \right), \quad (11)$$

where B' is the magnetic field related to the cosmic string. Note that $B(x)$ is a slowly varying function that is equal to 1 when $x = 1$ and [77]

$$B(x) \sim \begin{cases} 2.4/\ln(2/x) & x < 10^{-2} \\ 1.04x^{0.195} & 10^{-2} < x \ll 1 \end{cases} \quad (12)$$

for $x < 1$. Since $2\lambda_\mu/e^2$ can, in principle, take a large range of values, there are many orders of magnitude that the argument of B can take. However, as the function is so slowly varying, $\mu \sim v_\mu^2$ within an order of magnitude.

Finally, let us consider monopoles which exist in the case where the second homotopy group of the vacuum manifold is nontrivial. That is, the vacuum is topologically equivalent to a sphere. For a simple example, consider a model with an $SU(2)$ gauge symmetry,

$$\mathcal{L} = \frac{1}{2} D^\mu \phi D_\mu \phi - \frac{1}{4} B_{\mu\nu} B^{\mu\nu} - \frac{\lambda}{4} (\phi^2 - v_m^2)^2, \quad (13)$$

where ϕ is a real $SU(2)$ triplet. The 't Hooft-Polyakov monopole [78,79] has the behavior

$$\begin{aligned} \phi &= \hat{r} \frac{h(v_m er)}{er}, \\ W_a^i &= \epsilon_{aij} \hat{x}^j \frac{1 - f(v_m er)}{er}, \\ W_a^0 &= 0, \end{aligned} \quad (14)$$

where, using the shorthand $\xi = v_m er$ for the product of v_m with the gauge coupling constant e and radial coordinate r , the functions f and h are solutions to the equations [78,79]

$$\xi^2 \frac{d^2 f}{d\xi^2} = f(\xi)h(\xi)^2 + f(\xi)(f(\xi)^2 - 1), \quad (15)$$

$$\xi^2 \frac{d^2 h}{d\xi^2} = 2f(\xi)^2 h(\xi) + \frac{\lambda}{e^2} h(\xi)(h(\xi)^2 - \xi^2). \quad (16)$$

The boundary conditions satisfy $\lim_{\xi \rightarrow 0} f(\xi) - 1 = \lim_{\xi \rightarrow 0} h(\xi) \sim \mathcal{O}(\xi)$ and $\lim_{\xi \rightarrow \infty} f(\xi) = 0$, $\lim_{\xi \rightarrow \infty} h(\xi) \sim \xi$. The monopole mass again comes from solving the equations of motion and then calculating the static Hamiltonian,

$$\begin{aligned} E = m &= \frac{4\pi v_m}{e} \int_0^\infty \frac{d\xi}{\xi^2} \left[\xi^2 \left(\frac{df}{d\xi} \right)^2 + \frac{1}{2} \left(\xi \frac{dh}{d\xi} - h \right)^2 \right. \\ &\quad \left. + \frac{1}{2} (f^2 - 1)^2 + f^2 h^2 + \frac{\lambda}{4e^2} (h^2 - \xi^2)^2 \right]. \end{aligned} \quad (17)$$

It has the form

$$m = \frac{4\pi v_m}{e} f(\lambda/e^2). \quad (18)$$

The solution (17) has been calculated numerically for multiple values, and one finds that for $0.1 < \lambda/e^2 < 10^1$, $f(\lambda/e^2)$ is slowly varying the $\mathcal{O}(1)$ function [78].

In conclusion there is a reasonably tight relationship between the symmetry breaking scale and the string tension $\mu \sim v_\mu^2$. However, domain walls can have a significantly smaller surface tension than the cube of the symmetry breaking scale, and the monopole mass can be well above v_m . Even still, one should expect from naturalness considerations for all relevant quantities to be within a few orders of magnitude of the relevant powers of the symmetry breaking scale.

B. Hybrid defects in grand unified theories

In the previous subsection, we considered the various types of topological defects that can be generated during a single symmetry breaking $G \rightarrow H$. Now, with the table set, we consider how a sequence of multiple transitions,

$$G \rightarrow H \rightarrow K, \quad (19)$$

can give rise to hybrid topological defects composed of two different dimensional defects. For these hybrid defects, the bulk topological defect converts its rest mass to the kinetic energy of the boundary defect, leading to the appearance of one defect consuming the other. The relativistic motion of these defects leads to gravitational wave emission and eventual decay of the composite defect.

Consider first the case when the vacuum manifold H/K is not simply connected but the full vacuum manifold G/K

is. Then $\pi_1(H/K) \neq I$ and strings form at the transition $H \rightarrow K$. However, these strings are topologically unstable since in the full theory $\pi_1(G/K) = I$, which does not permit stable strings below K . The topological instability of strings manifests itself by the nucleation of magnetic monopole pairs that cut and eat the string [28,29] (see Fig. 2). A set of homotopy selection rules proven in Appendix A show that the monopoles that nucleate on the string boundaries must always arise from the earlier phase transition $G \rightarrow H$ so that $\pi_2(G/H) \neq I$ and $v_m \geq v_\mu$. The gastronomy scenario of monopoles nucleating and eating a string network is discussed in Sec. IV.

The requirement that $G \rightarrow H$ generates monopoles that can attach to strings implies that if inflation occurs before monopole formation, then a significant number of monopoles can already be in the horizon at the time of string formation. In this scenario, the magnetic field lines between monopole and antimonopole pairs squeeze into flux tubes (strings) after $H \rightarrow K$ (see Fig. 5) and hence strings bounded by monopoles form right at the string formation scale v_μ [27–29]. The gastronomy scenario of strings attaching to and eating a preexisting monopole network is discussed in Sec. V.

Similarly, consider now the case when the vacuum manifold H/K is disconnected but the full vacuum manifold G/K is connected. Then $\pi_0(H/K) \neq I$ and domain walls form at the transition $H \rightarrow K$. However, these domain walls are topologically unstable since in the full theory $\pi_0(G/K) = I$, which does not permit stable domain walls below K . The topological instability of walls manifests itself by the nucleation of string-bounded holes on the wall (see Fig. 8), which expand and eat the wall [31]. The same set of homotopy selection rules derived in Appendix A shows that the strings that nucleate on the wall must always arise from the earlier phase transition $G \rightarrow H$ so that $\pi_1(G/H) \neq I$ and $v_\mu \geq v_\sigma$. The gastronomy scenario of strings nucleating and eating a domain wall network is discussed in Sec. VI.

The requirement that $G \rightarrow H$ generates strings that can attach to walls implies that if inflation occurs before string formation, then a significant number of strings can already be in the horizon at the time of wall formation. In this scenario, the space between strings is filled with a wall after $H \rightarrow K$ (see Fig. 11), and hence walls bounded by strings form right at the wall formation scale v_σ [31,32]. The gastronomy scenario of walls attaching to and eating a preexisting string network is discussed in Sec. VII.

In many GUT symmetry breaking chains to the Standard Model gauge group G_{SM} , these type of homotopy sequences occur and hybrid defects form. Indeed, both $\pi_1(SO(10)/G_{\text{SM}}) = I$ and $\pi_0(SO(10)/G_{\text{SM}}) = I$ so that “at least” one string or domain wall that forms during the intermediate breaking of $SO(10)$ down to G_{SM} must become part of a composite defect, which can lead to the gastronomy signals of Secs. IV–VII.

FIG. 1. A sample of $SO(10)$ symmetry breaking paths down to the Standard Model that produce hybrid defects. The color of the arrows denotes the type of topological defect produced; red corresponds to magnetic monopoles, blue to cosmic strings, and green to domain walls. A red (blue) glow on an arrow indicates that defect becomes part of a monopole-bounded string (string-bounded wall). For example, monopoles formed at a red arrow with red glow become attached to strings formed at a blue arrow with red glow. Likewise, strings formed at a blue arrow with blue glow become attached to domain walls formed at a green arrow with blue glow. Note that the lower dimensional (boundary) defect of a hybrid defect always arises from an earlier stage of symmetry breaking than the higher dimensional (bulk) defect as discussed in Appendix A. A dot on a red arrow indicates stable monopoles form at that stage of symmetry breaking and need to be inflated away. If other monopoles, strings, or domain walls exist at this time, then they will also be inflated away. However, inflated defects can later destabilize the bulk defects and generate gravitational waves via nucleation of monopoles on strings (red glow) or string holes on walls (blue glow).

To see how ubiquitous hybrid topological defects are, we depict in Fig. 1 a sample of possible cosmic histories of $SO(10)$ breaking and the topological defects produced at each stage. The color of the arrows in Fig. 1 denotes which type of defect is produced at each stage of breaking, with strings in blue, walls in green, and monopoles in red. The chains which produce monopoles that become attached to strings are shown by the glowing red paths, while the chains which produce strings that become attached to walls are shown by the glowing blue paths. The meaning of each gauge group abbreviation is as follows:

$$\begin{aligned}
 51 &= SU(5) \times U(1)_X / \mathbb{Z}_5, \\
 5_F1 &= SU(5)_{\text{flipped}} \times U(1)_{\text{flipped}} / \mathbb{Z}_5, \\
 422 &= SU(4)_c \times SU(2)_L \times SU(2)_R / \mathbb{Z}_2, \\
 3221 &= SU(3)_c \times SU(2)_L \times SU(2)_R \times U(1)_{B-L} / \mathbb{Z}_6, \\
 3211 &= SU(3)_c \times SU(2)_L \times U(1)_Y \times U(1)_X / \mathbb{Z}_6, \\
 321 &= SU(3)_c \times SU(2)_L \times U(1)_Y / \mathbb{Z}_6.
 \end{aligned} \tag{20}$$

D refers to D parity, a discrete charge conjugation symmetry [30,31], Z_2 refers to matter parity, and $G_{\text{SM}} = 321$.

Note that the sequence for forming strings bounded by monopoles in Fig. 1 is typically realized by the two-stage sequence [80]

$$G \xrightarrow{\text{monopoles}} H \times U(1) \xrightarrow{\text{strings}} H, \quad (21)$$

with $\pi_1(G/H) = I$. Monopoles form in the first transition when G breaks to a subgroup containing a $U(1)$ and strings form and connect to the monopoles when this “same” $U(1)$ is later broken. Likewise, walls bounded by strings are typically realized in the two-stage sequence [80]

$$G \xrightarrow{\text{strings}} H \times Z_2 \xrightarrow{\text{walls}} H, \quad (22)$$

with $\pi_0(G/H) = I$. Strings form in the first transition when G breaks to a subgroup containing a discrete symmetry [since $\pi_1(G/(H \times Z_2)) \supseteq \pi_0(H \times Z_2) \neq I$]. The walls form and connect to the strings when the same discrete symmetry associated with the strings is broken.

As indicated in Fig. 1, many symmetry breaking paths from $SO(10)$ to the Standard Model yield hybrid defects. An example chain that produces all hybrid defects discussed in this paper is $SO(10) \rightarrow 5_F1 \rightarrow 3211 \rightarrow 321Z_2 \rightarrow 321$, which we now go over as a concrete example of the different types of gastronomy signals discussed in this paper.

In the first breaking, $SO(10) \rightarrow 5_F1$ generates monopoles which must be inflated away. The second breaking, $5_F1 \rightarrow 3211$, also generates monopoles, but these lighter monopoles can get connected by the strings formed at the third breaking, $3211 \rightarrow 321Z_2$. Thus, this sequence can produce gravitational wave gastronomy signals discussed in Secs. IV and V, with each section corresponding to when inflation occurs relative to monopole and string formation. Specifically, if inflation dilutes both heavy and light monopoles before the strings form, then the string network evolves as a pure string network until light monopoles nucleate and eat the string network (Sec. IV). Note that for the nucleation to occur within cosmological timescales, the relative hierarchy between the second and third symmetry breaking chains cannot be too large. However, if inflation occurs before the formation of the light monopoles, then the light monopoles connect to strings at the string formation scale and eat the monopole network (Sec. V).

At the third breaking, in addition to the previous strings, Z_2 strings appear and get filled by the domain wall formed at the fourth breaking, $321 \times Z_2 \rightarrow 321$. This sequence can produce gravitational wave gastronomy signals discussed in Secs. VI and VII, with each section corresponding to when inflation occurs relative to string and wall formation. If inflation dilutes the Z_2 strings before the walls form, then the wall network evolves as a pure wall network until Z_2 strings nucleate and eat the wall (Sec. VI). For the wall to nucleate strings before dominating the energy density of the Universe requires a relatively small hierarchy between the third and fourth symmetry breaking scales. However, if

inflation occurs before the Z_2 strings form, then the strings get filled by the domain walls, and the walls proceed to eat the string network (Sec. VII). In this gastronomy scenario, no degeneracy between scales is necessary.

III. GRAVITATIONAL WAVE DETECTORS

Topological defects leave a variety of gravitational wave signals that are, in many cases, detectable by proposed experiments. This means that gravitational wave detectors have a unique opportunity to probe the cosmological history of symmetry breaking. In the nHz to μ Hz range, pulsar timing arrays including European Pulsar Timing Array, PPTA, NANOGrav and square kilometre array (SKA) [4,5,81,82] and astrometry, including Gaia and Theia [8,9,83–85], can reach impressive sensitivity over the next few years. Spaced based interferometry experiments including Laser Interferometer Space Antenna (LISA) [86] (Tianqin [87,88] and Taiji [89] also cover similar regions), DECi-hertz Interferometer Gravitational wave Observatory (DECIGO) [16], and the Big Bang Observer (BBO) [90], all will probe mHz to Hz frequencies. Atom interferometry experiments including AEDGE [91], AION [92] and MAGIS [93] will probe a similar range. Finally, ground based experiments including aLIGO and aVIRGO [10,94–96], KAGRA [97], the Cosmic Explorer (CE) [15], and the Einstein Telescope [13] are, in principle, sensitive to the frequencies up to around a kHz.

Many topological defects leave quite broad spectra, which can lead to a boost in the naive sensitivity of a detector [98]. The integrated sensitivity of a detector to a specific signal is given by the signal-to-noise ratio

$$\text{SNR} = \sqrt{T \int_{f_{\min}}^{f_{\max}} df \left[\frac{h^2 \Omega_{\text{GW}}(f)}{h^2 \Omega_{\text{sens}}(f)} \right]^2}, \quad (23)$$

where T is the observation time of the detector, and $\Omega_{\text{sens}}(f)$ is the sensitivity to a monochromatic gravitational wave spectrum. To register a detection, the SNR must be above 1 as indicated by the sensitivity curves of [99], which we use throughout this work. In some cases the defects are only visible at frequencies higher than the reach of the above experiments. This can occur either in the case of strings consuming a preexisting monopole network or walls consuming a preexisting string network. Unfortunately, the strongest projected sensitivity at present for frequencies above a few kHz is the bound arising from constraints on the expansion of the Universe during big bang nucleosynthesis and recombination [100]. The current constraint on the expansion rate of the Universe is generally expressed in terms of the departure from the Standard Model prediction of the effective number of relativistic degrees of freedom,

$$\Delta N_{\text{eff}} = \frac{8}{7} \left(\frac{11}{4} \right)^{4/3} \frac{\Omega_{\text{GW}}^0}{\Omega_\gamma} \quad (24)$$

where

$$\Omega_{\text{GW}}^0 = \int \frac{df}{f} \Omega_{\text{GW}}(f). \quad (25)$$

Note that ΔN_{eff} constraints on the total energy density of gravitational waves can provide powerful bounds on defects, which only leave a high frequency, but large amplitude, gravitational wave spectrum. Current constraints on $\Delta N_{\text{eff}} < 0.284$ arise from the Planck 2018 dataset using TT, TE, EE + lowE + lensing [101]. This is expected to improve significantly to $\Delta N_{\text{eff}} < 0.03$ as a conservative estimate of the sensitivity of next generation experiments [102]. A hypothetical experiment limited only by the cosmic variance limit was found to be sensitive to changes to the number of relativistic degrees of freedom as small as [103]

$$\Delta N_{\text{eff}}^{\text{CVL}} < 3.1 \times 10^{-6}, \quad (26)$$

which is, in principle, sensitive to gravitational wave spectra at arbitrary frequency with an amplitude as small as $\mathcal{O}(10^{-12})$. Beyond cosmological limits, there are promising proposals using interferometers [104–108] (10^3 – 10^7 Hz), levitated sensors [109] (10^3 – 10^4 Hz), and magnetic conversion [110] (10^9 – 10^{10} Hz), which may probe high frequency gravitational wave cosmology as summarized in Ref. [100].

We now turn to calculating the gravitational wave gastronomy signal for strings bounded by monopoles and walls bounded by strings.

IV. MONOPOLES EATING STRINGS

In this section, we consider the gastronomy signal of monopoles nucleating on strings. As shown in Sec. II, if they are related by the same $U(1)$, then monopoles form first, (in the initial phase transition that leaves an unbroken $U(1)$ symmetry), and connect to strings in the second phase transition (when the $U(1)$ is broken). When inflation occurs after the formation of monopoles but before strings, the monopole abundance is heavily diluted by the time the strings form. The absence of monopoles initially prevents the formation of monopole-bounded strings at the second stage of symmetry breaking and the strings initially evolve as a normal string network. Nevertheless, the strings can later become bounded by monopoles by the Schwinger nucleation of monopole-antimonopole pairs, which cuts the string into pieces bounded by monopoles as shown in Fig. 2. Conversion of string rest mass into monopole kinetic energy leads to relativistic oscillations of the monopoles before the system decays via gravitational radiation and monopole annihilation [47,111,112].

Monopoles can only nucleate if it is energetically possible. The energy cost of producing a monopole-antimonopole pair is $2m$, where m is the mass of each

FIG. 2. Top: free energy diagram for a pair of monopoles nucleating on a string vs their nucleation separation l . For $l > l_{\text{tp}}$, the free energy of the system turns negative, and it becomes energetically possible to nucleate a pair of monopoles in place of a string segment of length l_{tp} . Bottom: illustration of the nucleation process. For strings with length $l > l_{\text{tp}}$ a string segment of length l_{tp} is eaten and replaced with a monopole-antimonopole pair, which forms the boundaries of the cut string piece.

monopole, and the energy gained from reducing a string segment of length l is μl , where μ is the string tension. The free energy of the monopole-string system is then

$$E = 2m - \mu l. \quad (27)$$

The energy balance between monopole creation and string length reduction leads to a critical string length l_{tp} , above which it is energetically favorable for the string to form a gap of length l_{tp} , separating two monopole endpoints as shown in Fig. 2. Note that $E < 0$ gives this turning point length

$$l_{\text{tp}} = \frac{2m}{\mu}. \quad (28)$$

The probability for the monopoles to tunnel through the classically forbidden region out to radius l_{tp} can be estimated from the WKB approximation. The nucleation rate per unit string length is

$$\Gamma_m \propto \mu e^{-S_E}, \quad (29)$$

where

$$S_E = \int_0^{l_{\text{tp}}} dl \sqrt{2mE} \propto \frac{m^2}{\mu}. \quad (30)$$

More precisely, the tunneling rate per unit string length can be estimated from the bounce action formalism [31,113] and is found to be [112]

$$\Gamma_m = \frac{\mu}{2\pi} \exp(-\pi\kappa_m), \quad (31)$$

where $\kappa_m = m^2/\mu$. As we saw in Sec. II, typically $m \sim v_m$ and $\mu \sim v_\mu^2$ with little flexibility. Therefore, the exponential sensitivity of the decay rate (31) implies that if the hierarchy between the monopole and string breaking energy scales is large, then $\kappa_m \gg 1$ and the string is stable against monopole nucleation on time scales greater than the age of the Universe. If this occurs, the gravitational wave spectrum is identical to the standard stochastic string spectrum, and no gastronomy signal is observable. Consequently, monopole nucleation typically requires a moderate coincidence of string and monopole scales, $v_m \sim v_\mu$, so that κ is not extremely large.

The remaining ingredients needed to determine the gravitational wave power spectrum for a stochastic background of metastable strings is the string number density spectrum as a function of the loop size and time, as well as the gravitational power spectrum for an individual string. Here, we use the number density of string loops, formed by the intercommutation of long (“infinite”) strings in the superhorizon string network, as derived by the velocity-dependent one-scale model [114–117]. After their formation, the infinite string network quickly approaches a scaling regime, with approximately $\mathcal{O}(1)$ long strings per horizon with curvature radius $R \approx t$ for all time t prior to nucleation. In the one-scale model, the typical curvature radius and separation between infinite strings is the same scale R so that the energy density of the infinite string network is

$$\rho_\infty \approx \frac{\mu R}{R^3} \approx \frac{\mu}{t^2}. \quad (32)$$

Prior to monopole nucleation, string loops break off from the infinite string network as intercommutation byproducts, with roughly one new loop formed every Hubble time. Loops that form at time t_k typically are of length $l_k \approx \alpha t_k$, where $\alpha \approx 0.1$ is found in simulations [118,119]. If the probability of a long string intersection produces a string loop that is $p \sim 1$, and the number of string intersections per Hubble volume in a time interval dt is $dN_{\text{int}} \sim dt/t$ [120], then the rate of loop formation per volume at time t_k is of the form

$$\frac{dn}{dt_k} \sim p \frac{\rho_\infty}{\mu l_k} \frac{dN_{\text{int}}}{dt_k} = \frac{p}{\alpha t_k^4}. \quad (33)$$

Indeed, the loop number density production rate as calculated from the one-scale model and calibrated from simulations is [46,121,122]

$$\frac{dn}{dt_k} = \left(\frac{\mathcal{F} C_{\text{eff}}(t_k)}{\alpha t_k^4} \frac{a(t_k)^3}{a(t)^3} \right). \quad (34)$$

Here, $\mathcal{F}$ and C_{eff} are roughly constants refined from the one-scale model and simulations. Note that $C_{\text{eff}} \approx 5.4$ is the loop formation efficiency in a radiation dominated era [46,123,124], and $\mathcal{F} \approx 0.1$ is the fraction of energy ultimately transferred by the infinite string network into loops of size l_k [119].

Since the loops are inside the horizon, they oscillate with roughly constant amplitude and hence redshift $\propto 1/a^3$, as shown by the rightmost term of Eq. (34), before decaying via gravitational radiation emission. Because the length of new string loops increases linearly with time, the nucleation probability of monopoles also grows with time, eventually cutting off loop production if κ_m is sufficiently small. This results in a maximum string size

$$\ell_{\text{max}} \approx \frac{1}{t \Gamma_m} \approx \sqrt{\frac{\alpha}{\Gamma_m}}, \quad (35)$$

which is generally much greater than l_{tp} .

The total power emitted in gravitational waves by string loops prior to nucleation or by the relativistic monopoles postnucleation can be estimated from the quadrupole formula, $P_{\text{GW}} \approx \frac{G}{45} \sum_{i,j} \langle \ddot{Q}_{ij} \ddot{Q}_{ij} \rangle \sim G(\mu l_k \dot{l}_k \omega^3)^2 \propto G\mu^2$. The power emitted by the string loops or monopole-bounded strings should be comparable since the kinetic energy of the relativistic monopoles originates from rest mass of the string. Indeed, more precise numerical computations and calibrations with simulations find the total power emitted [3,118,125],

$$P_{\text{GW}} = \Gamma G\mu^2, \quad (36)$$

where $\Gamma \approx 50$ for string loops prior to nucleation, and $\Gamma \approx 4 \ln \gamma_0^2$ for relativistic monopoles bounded to strings postnucleation [112]. Here, $\gamma_0 \approx 1 + \mu l/2m$ is the monopole Lorentz factor arising from the conversion of string rest mass energy to monopole kinetic energy.

The power emitted by gravitational waves reduces the string length, evolving in time as

$$l = \alpha t_k - \Gamma G\mu(t - t_k), \quad (37)$$

giving a loop lifetime of order $\alpha t_k / \Gamma G\mu$. The string length and harmonic number n is set by the emission frequency, $f' = n/T = 2n/l$, where $T = l/2$ is the period of any string loop [80,126]. The frequency observed today arises from redshift of f' with the expansion of the Universe,

$$f = \frac{2n}{l} \frac{a(t_0)}{a(t)}, \quad (38)$$

where t_0 is the present time.

The number density spectrum of string loops then follows from Eqs. (31), (34), and (37),

$$\begin{aligned} \mathcal{N}(l, t)_{\text{Schwinger}} &\equiv \frac{dn}{dl}(l, t) \approx \frac{dn}{dt_k} \frac{dt_k}{dl} e^{-\Gamma_m l(t-t_k)} \\ &= \frac{\mathcal{F}C_{\text{eff}}(t_k)}{t_k^4 \alpha(\alpha + \Gamma G \mu)} \left(\frac{a(t_k)}{a(t)} \right)^3 e^{-\Gamma_m l(t-t_k)}. \end{aligned} \quad (39)$$

The exponential factor on the right side of (39) is the monopole nucleation probability, which effectively cuts off loop production and destroys loops with lengths large enough to nucleate with significant probability. For $\Gamma_m l(t-t_k) \ll 1$, the probability of nucleation is negligible, and the string network evolves like a standard stable string network.³ Note that this cutoff is time dependent,

$$\Gamma_m l(t-t_k) = \Gamma_m \frac{2n}{f} \frac{a(t)}{a(t_0)} (t-t_k). \quad (40)$$

Although the number density of string loops decreases when nucleation occurs, as manifested by the exponential drop in the loop number density of Eq. (39), the number density of string-bounded monopoles increases. Since $l_{\text{max}} \gg l_{\text{tp}}$, a loop that nucleates monopoles will continue to nucleate and fragment into many monopole-bounded strings, each with asymptotic size of order $l \sim l_{\text{tp}} \ll l_{\text{max}}$. While the total energy density in these pieces is comparable to the original energy density of the parent string loop, the net energy density eventually deposited into gravitational waves is much less. This is because the lifetime of the string-bounded monopoles, $\sim \mu l_{\text{tp}} / \Gamma G \mu^2$, is much smaller than the parent loop because their power emitted in gravitational waves is similar to pure loops, while their mass is much smaller. The net energy density that is transferred into gravitational waves is, to a good approximation, the energy density of the defect at the time of decay. Since these pieces decay quickly and do not redshift $\propto a^3$ for as long as pure string loops, their relative energy density compared to the background at their time of decay is much less than for pure string loops. Consequently, the net energy density that goes into gravitational radiation by monopole-bounded string pieces compared to string loops is small, and we do not consider their contribution to the spectrum.

The gravitational wave energy density spectrum generated from a network of metastable cosmic strings, including dilution and redshifting due to the expansion history of the Universe, is

$$\frac{d\rho_{\text{GW}}(t)}{df} = \int_{t_{\text{scf}}}^t dt' \frac{a(t')^4}{a(t)^4} \int dl \frac{dn(l, t')}{dl} \frac{dP(l, t')}{df'} \frac{df'}{df} \quad (41)$$

³Using a Heaviside function $\theta(\Gamma_m l(t-t_k) - 1)$ or $\theta(\Gamma_m l t - 1)$ to cut off the loop production gives a nearly identical spectrum.

$$\frac{df'}{df} = \frac{a(t)}{a(t')} \quad \frac{dn}{dl}(l, t') = \mathcal{N}(l, t')_{\text{Schwinger}} \quad (42)$$

$$\frac{dP(l, t')}{df'} = \Gamma G \mu^2 l g\left(f \frac{a(t)}{a(t')} l\right), \quad (43)$$

where t' is the emission time, $f' = a(t)/a(t')f$ is the emission frequency, and f is the redshifted frequency observed at time t . The normalized power spectrum for a discrete spectrum is [80,122]

$$g(x) = \sum_n \mathcal{P}_n \delta(x - 2n), \quad (44)$$

which ensures the emission frequency is $f' = 2n/l$. Note that $\mathcal{P}_n = n^{-q}/\zeta(q)$ is the fractional power radiated by the n th mode of an oscillating string loop, where the power spectral index q is found to be $4/3$ for string loops containing cusps [127,128]. Equations (41)–(44) allow the stochastic gravitational wave spectrum from metastable strings to be written as

$$\Omega_{\text{GW}}(f) \equiv \frac{f}{\rho_c} \frac{d\rho_{\text{GW}}}{df} \quad (45)$$

$$\begin{aligned} &= \frac{8\pi}{3H_0^2} (G\mu)^2 \sum_{n=1}^{\infty} \frac{2n}{f} \int_{t_{\text{form}}}^{t_0} dt \left(\frac{a(t)}{a(t_0)} \right)^5 \\ &\times \mathcal{N}_{\text{Schwinger}}\left(l = \frac{2n}{f} \frac{a(t)}{a(t_0)}, t\right) \mathcal{P}_n. \end{aligned} \quad (46)$$

We numerically compute the gravitational wave spectrum, Eq. (46), over a range of string tensions μ and monopole masses m . Figure 3 shows a benchmark plot of the gravitational wave spectrum from cosmic strings consumed by monopoles for fixed $G\mu = 1 \times 10^{-8}$ and a variety of $\kappa_m = m^2/\mu$. In computing the spectrum, we sum up 10^4 normal modes and solve for the evolution of the scale factor from the Friedmann equations in a Λ CDM cosmology. The colored contours in Fig. 3 show the effect of the nucleation rate parameter κ_m on the spectrum, with larger κ_m corresponding to a longer lived string network. In the limit $\sqrt{\kappa_m} \gtrsim 9$, the nucleation rate is so weak that the string network is stable on cosmological time scales, reducing to the standard stochastic string spectrum as shown by the black contour. Larger loops, corresponding to lower frequencies and later times of formation, vanish because of Schwinger production of monopole-antimonopole pairs, and hence the gravitational wave spectrum is suppressed at low frequencies, scaling as an f^2 power law in the infrared. The slope is easily distinguishable from other signals such as strings without monopole pair production and strings consumed by domain walls, as discussed in Secs. VI and VII. Importantly, from Fig. 3, we see that it is possible to detect the f^2 slope in the low

FIG. 3. Representative spectra of gravitational waves emitted by cosmic strings that are eaten by the nucleation of monopoles for fixed $G\mu = 1 \times 10^{-8}$. Each colored contour corresponds to a different value of $\kappa_m = m^2/\mu$, which parametrizes the ratio between monopole and string symmetry breaking scales and sets the nucleation time of the monopoles on the string. Since nucleation is an exponentially suppressed process, the metastable string network is typically cosmologically long-lived and behaves as a pure string network before nucleation. At high frequencies, $\Omega_{\text{GW}} \propto f^0$ like a pure string network, while after nucleation, Ω_{GW} decays as f^2 . The black contour shows the pure string spectrum without monopoles. For $\kappa \geq 9$, the nucleation timescale of monopoles is greater than the age of the Universe, and the metastable string network is indistinguishable from the pure string spectrum. The dotted-yellow and blue boxes highlight the potential signals of NANOGraV [81] and PPTA [17], respectively.

frequency region of the power spectrum through many gravitational wave detectors, including NANOGraV, PPTA, SKA, Theia, LISA, DECIGO, BBO, and CE.

Figure 4 shows the parameter space in the $G\mu - \sqrt{\kappa_m}$ plane, where the f^2 decaying slope can be detected and distinguished from the standard string spectrum. For a given $(G\mu, \sqrt{\kappa_m})$, we register a detection of the monopole nucleation gastronomy in a similar manner to the “turning-point” recipe of [46]: First, $\Omega_{\text{GW}} h^2$ must exceed the threshold of detection for a given experiment. Second, to actually distinguish between the monopole-nucleation gastronomy spectrum and the standard string spectrum, we require that their percent relative difference be greater than a certain threshold within the frequency domain of the experiment. Following [46], we take this threshold at a conservative 10%. Figure 4 demonstrates that a wide range of μ and κ_m can be probed. String symmetry breaking scales $v_\mu \equiv \sqrt{\mu}$ between 10^9 GeV and 10^{16} GeV and κ_m between 30–80 can be detected by current and near future gravitational wave detectors. Interestingly, the yellow and blue dashed boxes show the particular μ and $\sqrt{\kappa_m}$ that generate a spectrum that passes through the recent NANOGraV (yellow) [81] and PPTA (blue) [17] signals.

Last, note that the benchmark spectra of Fig. 3 are similar to the spectra found in a previous paper [44], but the slope

FIG. 4. The parameter region in the $G\mu - \sqrt{\kappa_m}$ plane, where the gravitational wave spectrum from cosmic strings eaten by the nucleation of monopoles can be detected. For a given $(G\mu, \sqrt{\kappa_m})$, a detection is registered when Ω_{GW} is greater than the sensitivity curve of the given detector “and” the relative difference in spectra between cosmic strings eaten by monopoles and a pure string spectrum with the same $G\mu$ is greater than 10%. The latter condition ensures the two signals are sufficiently distinguishable and the detection of the infrared f^2 slope shown, for example, in Fig. 3 can be achieved. The yellow and blue dashed lines highlight the potential signals by NANOGraV and PPTA, respectively, as in Fig. 3.

in the low frequency region is not $f^{3/2}$, as found in [44], but f^2 . The difference comes from the authors of [44] using a fixed time at which loop production ceases, corresponding to when the average length of the string loop network $\langle l \rangle = l_{\text{max}}$. However, the average length of string loops in the loop network is dominated by the smallest loops, even though there exists much larger loops up to $l \approx at$ in the network at any given time. We take into account the nucleation rate on individual loop basis. This is necessary due to the shorter nucleation lifetime of longer strings than shorter strings because the probability of pair production of monopoles on a string is proportional to the length of the string. Our results agree with the more recent work of [47].

V. STRINGS EATING MONOPOLES

In this section, we consider the case where strings attach to, and consume, a preexisting monopole network. The symmetry breaking chains that allow this are the same as in Sec. IV, with the difference between the two scenarios arising from when inflation occurs relative to monopole formation. For the monopole nucleation gastronomy of Sec. IV, inflation occurs after monopole formation but before string formation. For strings attaching to a preexisting monopole network, as considered in this section,

FIG. 5. Illustration of monopoles connecting to strings below the string formation scale v_μ . At v_μ , the magnetic field of the monopoles squeezes into flux tubes (strings) with the typical string length l set by the monopole density at v_μ .

inflation occurs before monopole and string formation. In this scenario, the monopole network is not diluted by inflation, and at temperatures below the string symmetry breaking scale v_μ , the magnetic field of the monopoles squeezes into flux tubes (cosmic strings) connecting each monopole and antimonopole pair [28,120]. Note that since this is not a tunneling process, there does not have to be a coincidence of scales between v_m and v_μ as in the case of monopoles nucleating on strings as discussed in Sec. IV. Moreover, since “every” monopole and antimonopole get connected to a string, which eventually shrinks and causes the monopoles to annihilate, the monopole problem is absent in such symmetry breaking chains. As shown in Fig. 1, an example chain where this gastronomy scenario occurs is $3221 \rightarrow 3211 \rightarrow 321$. The first breaking produces monopoles, and the second breaking connects the monopoles to strings. Since there are no stable monopoles or domain walls that are also generated in this breaking pattern, inflation need not occur after the monopoles form when 3221 breaks to 3211 .

The scenario where strings attach to a preexisting monopole network has been considered before [28,80,129,130], but only with an initial monopole abundance of roughly one monopole per horizon at formation as computed originally by Kibble [131], and with the conclusion that there is no gravitational wave amplitude.⁴ Here, we redo the calculation with the enhanced abundance of monopoles using the Kibble-Zurek mechanism [132] and take into account monopole-antimonopole freeze-out that can occur between monopole and string formation [133]. We find that after string formation, monopole-antimonopole pairs annihilate in generally less than a Hubble time with the typical monopole velocities being nonrelativistic, often leading to no gravitational wave spectrum. However, for some monopole masses m and string scales v_μ , the monopole-bounded strings can be relativistic and emit a pulse of gravitational waves before decaying if friction is not severe. Moreover, the greater number density of monopoles predicted in the Kibble-Zurek mechanism compared to Kibble’s original estimate gives rise to significantly enhanced gravitational wave amplitude.

We begin with the Kibble-Zurek mechanism, where the initial number density of monopoles is set by the

⁴The case where monopoles are only partially inflated away so that eventually monopoles reenter the horizon was considered in [111,130]. We do not consider that scenario.

correlation length ξ_m of the Higgs field associated with the monopole symmetry breaking scale v_m . For a Landau-Ginzburg free energy near the critical temperature T_c of the phase transition of the form

$$V(\phi) = (T - T_c)m\phi^2 + \frac{1}{4}\lambda\phi^4, \quad (47)$$

the initial number density of monopoles is approximately [134]

$$n_m(T_c) = \frac{1}{\xi_m^3} \approx \frac{\lambda}{2} HT_c^2, \quad (48)$$

where H is the Hubble scale. Note that the monopole formation density calculated by Zurek, (48), is roughly a factor of $(M_{\text{Pl}}/T_c)^2 \approx (M_{\text{Pl}}/v_m)^2 \gg 1$ greater than the original estimate by Kibble. Note that $M_{\text{Pl}} = 1/\sqrt{G}$ is the Planck mass.

After formation, the monopole-antimonopole pairs annihilate, with a freeze-out abundance [133]

$$\frac{n_m(T)}{T^3} = \left[\frac{T_c^3}{n_m(T_c)} + \frac{h^2 CM_{\text{Pl}}}{\beta_m m} \left(\frac{m}{T} - \frac{m}{T_c} \right) \right]^{-1}, \quad (49)$$

where $C = (8\pi^3 g_*/90)^{-1/2}$, and

$$\beta_m \simeq \frac{2\pi}{9} \sum_i b_i \left(\frac{he_i}{4\pi} \right)^2 \ln \Lambda \quad (50)$$

counts the particles of charge e_i in the background plasma that the monopole scatters off of. The magnetic coupling is $h = 2\pi/e$, where e is the $U(1)$ gauge coupling constant, $\Lambda \sim 1/(g_* e^4/16\pi^2)$ is the ratio of maximum to minimum scattering angles of charged particles in the plasma, and $b_i = 1/2$ for fermions and 1 for bosons [80,135], with $e \sim 0.3$ and a comparable number of electromagnetic degrees of freedom as in the Standard Model, $\beta_m \sim 20$. For $T \ll v_m$, Eq. (49) asymptotes to a frozen-out abundance $n_m/T^3 \simeq \beta_m \text{Max}(T, T_*)/h^2 CM_p$, where $T_* = (4\pi/h^2)^2 m/\beta_m^2$ is approximately the temperature when the monopole mean free path becomes longer than the monopole-antimonopole capture distance [133].

Below the scale v_μ , the magnetic fields of the monopoles squeeze into flux tubes, with the string length set by the typical separation distance between monopoles,

$$l \approx \frac{1}{n_m(T = v_\mu)^{1/3}}. \quad (51)$$

Equation (51) is valid when the correlation length of the string Higgs field $\xi_\mu \geq l$ [80]. If $\xi_\mu < l$, then the monopole-bounded strings are straight on scales smaller than ξ_μ and Brownian on greater scales, which gives the strings a length longer than (51). For an initial abundance of strings set by the

Kibble-Zurek mechanism, $\xi_\mu/l(T = v_\mu) \approx (2\beta_m/\lambda_\mu h^2)^{1/3}$, which coincidentally, is usually of order or just marginally less than unity. Nevertheless, since the string correlation length grows quickly with time $\propto t^{5/4}$ [80,131], the string-bounded monopole becomes straightened out within roughly a Hubble time of string formation and ends up with a length close to Eq. (51). For $T_c = v_m \lesssim 10^{17}$ GeV, l is far below the horizon scale. Consequently, l is not conformally stretched by Hubble expansion and only can decrease with time by energy losses from friction and gravitational waves.

Because the string rest mass is converted to monopole kinetic energy, the initial string length (51) determines whether or not the monopoles can potentially move relativistically. Relativistic monopoles can emit a brief pulse of gravitational radiation before annihilating, while nonrelativistic monopoles will generally not. Energy conservation implies the maximum speed of the two monopoles on each string is roughly

$$v_{\max} \approx \sqrt{1 - \left(1 + \frac{\mu l}{2m}\right)^{-2}} \sim \text{Min}\left\{\sqrt{\frac{\mu l}{m}}, 1\right\}. \quad (52)$$

The density plot of Fig. 6 shows the parameter space in the $v_\mu - v_m$ plane, where $v_{\max} \sim 1$ (in red) and the monopoles can reach relativistic speeds according to Eq. (52). Initially, however, monopole friction can prevent the monopoles from reaching $v_{\max}$. This is because the relative velocity of the monopoles induced by the string produces an electromagnetic frictional force on the monopoles scattering with the background plasma. The force of friction between the monopole and plasma is [29,80]

$$F_f \approx -\beta_m T^2 v e^{-Mr(T)} (1 + Mr(T)), \quad (53)$$

where v is the relative speed between monopole and the bulk plasma flow. We include the Yukawa exponential factor, $e^{-Mr(T)}$, to take into account the exchange of the now massive photon of mass $M \simeq ev_\mu/2$ at temperatures below v_μ . Note that $r(T) \simeq \sqrt{4\pi T/e^2 n_e}$ is the inverse plasma mass associated with the screened magnetic field of the monopole. To a good approximation then,

$$Mr(T) = \frac{v_\mu}{T} \sqrt{\frac{30}{\zeta(3)\pi g_{*e}}} \approx \frac{v_\mu}{T}, \quad (54)$$

where g_{*e} is the charged relativistic degrees of freedom in the thermal bath.

The balance between the string tension and friction is described by the equation of motion of each monopole,

$$m \frac{dv}{dt} \simeq \mu + F_f(T). \quad (55)$$

To an excellent approximation, the drag speed, or terminal velocity, of the monopoles satisfies the quasisteady state

FIG. 6. The $v_m - v_\mu$ parameter space, where monopoles attached to strings can be relativistic. In the dark blue region at large v_m , the monopoles are sufficiently heavy that the conversion of string rest mass to monopole kinetic energy cannot accelerate the monopoles to relativistic speeds, and any gravitational wave signal is heavily suppressed. In the red region, the monopoles are light enough that the string can accelerate them to relativistic speeds, neglecting friction. This region of parameter space can potentially generate a gravitational wave signal. The black contours show the typical maximum drag speed of the monopoles from friction with the thermal bath. For sufficiently large β_m , a model dependent friction parameter, the drag speed prevents the monopoles from reaching relativistic speeds, and the gravitational wave signal can be suppressed. In the light blue region, $v_\mu > v_m$, which is forbidden for composite monopole-bounded strings.

solution $dv/dt \simeq 0$, which gives the monopole drag speed as a function of temperature

$$v_{\text{drag}} = \frac{\mu}{\beta_m T^2 e^{-v_\mu/T} (1 + \frac{v_\mu}{T})}. \quad (56)$$

The frictional damping of the monopole motion ends when v_{drag} equals $v_{\max}$, which occurs roughly a Hubble time after formation because of the decrease in T . However, even in this brief period of damping, the friction force (53) causes the string-monopole system to lose energy at a rate

$$P_f \approx -\beta_m T^2 v^2 e^{-v_\mu/T} \left(1 + \frac{v_\mu}{T}\right), \quad (57)$$

which can be considerable even in a Hubble time. Above, $v = \max(v_{\text{drag}}, v_{\max})$. For example, near string formation when $T^2 \sim \mu$, the power lost to friction is roughly $\beta_m/\Gamma G \mu v^4 \gg 1$ greater than the power lost to gravitational radiation, $P_{\text{GW}} \approx \Gamma G \mu^2 v^6$. Note that for the monopole

nucleation gastronomy of Sec. IV, the monopole nucleation occurs at a far lower temperature than the string formation time, and hence $P_f \ll P_{\text{GW}}$ for that gastronomy scenario. In the gastronomy scenario of this section, where strings eat a preexisting monopole network, $P_f \gg P_{\text{GW}}$. Consequently, the power lost from friction determines the lifetime τ of the string-bounded monopoles, with

$$\tau \approx -\frac{E}{P_f} \Big|_{T \approx v_\mu} \approx \frac{\mu l}{\beta_m \mu v^2} \approx \begin{cases} \beta_m l & v = v_{\text{drag}} \\ \frac{m}{\beta_m \mu} & v = v_{\text{max}} \lesssim 1 \\ \frac{1}{\beta_m} & v = v_{\text{max}} \sim 1. \end{cases} \quad (58)$$

To more precisely determine the monopole-string lifetime, we integrate Eq. (57) to determine the energy of the string-monopole system as a function of time and find that for $\beta_m \gtrsim 3$, the energy in the monopole-string system is entirely dissipated by friction before v_{drag} reaches v_{max} and hence relativistic speeds. The contours of Fig. 6 show the typical highest speed of the monopoles before losing energy via friction. Since the energy of the system is entirely dissipated in around a Hubble time, the largest monopole speed is typically set by the drag speed when $T^2 \sim \mu$; that is, $v_{\text{drag}} \sim \beta_m^{-1}$ according to Eq. (56). Consequently, we see analytically that the terminal velocity of the monopoles is not relativistic unless $\beta_m \sim 1$. If the number of particles interacting with the monopole in the primordial thermal bath is comparable to the number of electrically charged particles in the Standard Model and with similar charge assignments, then $\beta_m \sim 20$ and thus the monopole-string system is never relativistic before decaying. In this scenario, the gravitational wave signal is heavily suppressed.

If $\beta_m \sim 1$, however, which can occur in a dark sector with fewer charged particles in the thermal bath or with smaller $U(1)$ charges, then the monopoles reach the speed v_{max} before decaying via friction. In this case, the red region of Fig. 6 indicates where a gravitational wave signal can be efficiently emitted by the monopoles before annihilating. Unlike the monopole nucleation gastronomy of Sec. IV, v_μ does not need to be as nearly degenerate with v_m for gravitational waves to be produced. Moreover, since the lifetime of the string pieces is shorter than Hubble, the pulse of energy density emitted by relativistic monopoles in gravitational waves is well approximated by

$$\rho_{\text{GW,burst}} \approx n_m(v_\mu) P_{\text{GW}} \tau, \quad (59)$$

where $P_{\text{GW}} = \Gamma G \mu^2$ is the power emitted by oscillating monopoles connected to strings (36). The peak amplitude of the monopole gravitational wave burst is

$$\begin{aligned} \Omega_{\text{GW,burst}} &= \frac{\rho_{\text{GW,burst}}}{\rho_c(v_\mu)} \Omega_r \left(\frac{g_{*0}}{g_*(v_\mu)} \right)^{\frac{1}{3}} \\ &\approx \frac{30\pi^2}{g_*(v_\mu) \beta_m} \Gamma G \mu \left(\delta \frac{m}{M_{\text{Pl}}} \right)^{\frac{2}{3}}, \end{aligned} \quad (60)$$

where

$$\delta = \frac{1}{C \beta_m h^2} \left(\frac{4\pi}{h^2} \right)^2 \text{Max} \left\{ 1, \frac{v_\mu}{m} \left(\frac{\beta_m h^2}{4\pi} \right)^2 \right\}, \quad (61)$$

and $\rho_c(v_\mu)$ is the critical energy density of the Universe at string formation, which is assumed to be in a radiation dominated era. The “Max” argument of (61) characterizes the amount of monopole-antimonopole annihilation that occurs prior to string formation at $T = v_\mu$. For sufficiently small v_μ/m , the freeze-out annihilation completes before string formation, and the max function of (61) is saturated at its lowest value of 1. In this conservative scenario, $\delta \approx 10^{-4} \beta_m^{-1} (e/0.5)^4$.

Similarly, the peak frequency is

$$f_{\text{burst}} \sim \frac{1}{l} \frac{a(t_\mu)}{a(t_0)} \approx 10^8 \text{ Hz} \left(\frac{v_m}{1014 \text{ GeV}} \frac{\delta}{10^{-4}} \frac{106.75}{g_*(v_\mu)} \right)^{\frac{1}{3}}, \quad (62)$$

where $a(v_\mu)$ and $a(t_0)$ are the scale factors at string formation and today, respectively. Note that redoing the analysis of this section, but with Kibble’s original estimate for the number density of monopoles, yields a gravitational wave spectrum that is roughly $(v_m/M_{\text{Pl}})^{4/3} \ll 1$ suppressed compared to Eq. (60).

With the qualitative features of the monopole burst spectrum understood, we can turn to a numerical computation of Ω_{GW} in the case where $\beta_m \sim 1$. The gravitational wave energy density spectrum is

$$\frac{d\rho_{\text{GW}}(t)}{df} = \int^t dt' \frac{a(t')^4}{a(t)^4} \int dl \frac{dn(l, t')}{dl} \frac{dP_l(l, t')}{df'} \frac{df'}{df}, \quad (63)$$

$$\frac{df'}{df} = \frac{a(t)}{a(t')}, \quad \frac{dn}{dl}(l, t') = \frac{dn}{dt_k} \frac{dt_k}{dl}, \quad (64)$$

$$\frac{dP_l(l, t')}{df'} = \Gamma G \mu^2 l g \left(f \frac{a(t)}{a(t')} l \right), \quad (65)$$

where primed coordinates refer to emission and unprimed refer to the present so that gravitational waves emitted from the monopoles at time t' with frequency f' will be observed today with frequency $f = f' a(t')/a(t)$. Note that t_k is the formation time of monopole-bounded strings of length $l(t_k)$,

$$\frac{dn}{dt_k} \simeq n_m(t_k) \delta(t_k - t_\mu) \left(\frac{a(t_k)}{a(t)} \right)^3 \quad (66)$$

is the string-bounded monopole production rate, which is localized in time to the string formation time, $t_\mu \simeq CM_{\text{Pl}}/v_\mu^2$. See that dt_k/dl is found by noting that the energy lost by relativistic monopoles separated by a string of length l is

$$\frac{dE}{dt} = \frac{d}{dt}(\mu l + 2m) \approx -\beta_m v^2 \mu. \quad (67)$$

In the red region of Fig. 6, where a gravitational wave signal can be generated, $\mu l \gg 2m$ (otherwise the monopoles would not be relativistic). As a result, monopole-bounded strings that form at time t_k with initial size $l(t_k)$ decrease in length according to

$$l(t) \simeq l(t_k) - \beta_m v^2 (t - t_k), \quad (68)$$

so that

$$\frac{dt_k}{dl} \simeq \frac{1}{\beta_m v^2} \approx 1. \quad (69)$$

The normalized power spectrum for a discrete spectrum is

$$g(x) = \sum_n \mathcal{P}_n \delta(x - n\xi) \quad \xi \equiv \frac{l}{T} \quad (70)$$

and ensures the emission frequency of the n th harmonic is $f' = n/T$, where T is the oscillation period of the monopoles. For pure string loops, $T = l/2$ [$\xi = 2$, reducing to Eq. (44)], whereas for monopoles connected to strings, $T = 2m/\mu + l \simeq l$ [111,112] ($\xi \approx 1$). Note that $\mathcal{P}_n \approx n^{-1}$ is found [111,112] for harmonics up to $n \approx \gamma_0^2$, where $\gamma_0 \simeq (1 + \mu l/2m)$ is the Lorentz factor of the monopoles. For $n > \gamma_0^2$, $\mathcal{P}_n \propto n^{-2}$. Note that $\Gamma \approx 4 \ln \gamma_0^2$.

Integrating the energy density spectrum (63) and normalizing by the present day critical density, $\rho_c = 3H_0^2/8\pi G$ yields the present day gravitational wave spectrum from monopoles eaten by strings

$$\Omega_{\text{GW}} = \sum_n \frac{8\pi(G\mu)^2}{3H_0^2} \left(\frac{a(t_\mu - l^*)}{a(t_0)} \right)^5 \left(\frac{a(t_\mu)}{a(t_\mu - l^*)} \right)^3 \times \Gamma \mathcal{P}_n \frac{\xi n}{f} \frac{n_m(t_\mu)}{\beta_m v^2}, \quad (71)$$

where

$$l_* = \frac{\frac{\xi n}{f} \frac{a(t_\mu)}{a(t_0)} - n_m(t_\mu)^{-\frac{1}{3}}}{\beta_m v^2}. \quad (72)$$

The contours of Fig. 7 show $\Omega_{\text{GW}} h^2$ for range of a v_μ and v_m , where monopoles can oscillate relativistically before decaying via friction, assuming $\beta_m v^2 \sim 1$. For frequencies much lower than the inverse string length, we take the

FIG. 7. Representative spectra of gravitational waves emitted by monopoles that are eaten by strings. Each colored contour corresponds to a different value of symmetry breaking scales (v_m, v_μ) . In all cases, we fix β_m and the monopole speed v near unity. The dominant energy loss by the monopoles is from friction, which causes the monopole-bounded string to decay within a Hubble time. The emission of gravitational waves thus occurs in a “burst” and is peaked at high frequencies corresponding to the monopole-antimonopole separation distance when $T \approx v_\mu$. At high frequencies, $\Omega_{\text{GW}} \propto f^{-1}$, while at low frequencies $\Omega_{\text{GW}} \propto f^3$ by causality. The frequency dependence near the peak of the spectrum interpolates scales as $\Omega_{\text{GW}} \propto \ln f$.

causality limited spectrum f^3 [136]. Figure 7 shows that the spectral shape goes as f^{-1} at high frequencies, plateaus logarithmically for a brief period, and decays as f^3 at low frequencies. The duration of the logarithmic plateau corresponds to the number of modes where $\mathcal{P}_n \propto 1/n$, which is set by γ_0 and hence v_{max} . As suggested by the estimate f_{burst} , the frequency at which the spectrum decays typically occurs at very high frequencies because the separation length of the monopoles is small when eaten by strings at $T \simeq v_\mu$. Consequently, to observe the monopole burst gastronomy signal, future gravitational wave detectors near megahertz frequencies are needed.

Finally, we comment that string loops or open strings without monopoles also form at the string symmetry breaking scale v_μ . For $\xi_s \sim l$, as is generally the case, both simulations and free-energy arguments [80,137,138] suggest that these pure strings are clustered around the monopole separation scale l , with the distribution of strings of length greater than l exponentially suppressed and only making a subdominant $\lesssim 10\%$ of all strings [138]. Essentially, it becomes exponentially unlikely for a string with length greater than l to not terminate on two monopoles.

Like the monopole string segments, the dominant energy loss mechanism for these loops is friction with the plasma. Here, the friction is mainly due to Aharonov-Bohm scattering, which exerts a force

$$F_{\text{AB}} \simeq -\beta_s T^3 v l, \quad (73)$$

where

$$\beta_s \simeq \frac{2\zeta(3)}{\pi^2} \sum_i a_i \sin^2(\pi\nu_i) \quad (74)$$

counts the particles in the background plasma that experience a phase change, $2\pi\nu_i = e_i\Phi$, when moving around the string of magnetic flux Φ , thereby scattering off the string via the Aharonov-Bohm mechanism [80,139]. Note that $a_i = 3/4$ for fermions and 1 for bosons. v is the relative perpendicular motion of the string with respect to the plasma.

Just like the monopoles, the frictional force on the strings initially prevents the string loops, which are subhorizon, from freely oscillating relativistically [140]. Balancing the string curvature tension μ and friction force gives the string drag speed as a function of temperature

$$v_{\text{drag}} \approx \frac{\mu}{\beta_s T^3 l}. \quad (75)$$

For $T^2 \sim \mu$, $\beta_s \geq 1$, and for string lengths of order, the monopole separation distance (51), the string drag velocity is initially nonrelativistic for all $v_\mu, v_m \lesssim 10^{17}$ GeV. The frictional damping of the string motion causes the string loops to be conformally stretched, $l(t) \propto a(t)$, until v_{drag} becomes relativistic, or equivalently, their conformally stretched size drops below the friction scale $L_f \approx \mu l / |F_{\text{AB}}|$ (see Sec. VII E for a further discussion). This occurs at time $t_f \approx t_0 \max(\beta_s l_0 v_\mu, 1)$ and final string size $l_f \approx l_0 \max((\beta_s l_0 v_\mu)^{1/2}, 1)$, where $l_0 = l(T = v_\mu)$ is the typical monopole separation at string formation. However, even after this brief period of damping, the Aharonov-Bohm friction force (73) still causes the string to lose energy at a rate $\mu dl/dt = -P_{\text{AB}}$, where

$$P_{\text{AB}} = -\beta_s T^3 v^2 l, \quad (76)$$

with $v \sim 1$. The power lost via Aharonov-Bohm friction causes the string length to exponentially decrease in size. These small loops will then completely and quickly decay via gravitational radiation that, depending on the fraction of strings in loops, can generate a comparable Ω_{GW} to the monopole burst spectrum of Fig. 7. Unlike the monopole bursts, the ultraviolet frequency dependence of the string burst spectrum will scale approximately as f^{1-q} , where $q = 4/3$ is the power spectral index of string loops with cusps. This is because for $\mathcal{P}_n \propto n^{-q}$, the contribution of higher harmonics, and hence higher frequencies, becomes more important for smaller q , as discussed in [46,124,141].

VI. STRINGS EATING DOMAIN WALLS

In this section, we consider the case of strings nucleating on domain walls. As discussed in Sec. II, if they are related

FIG. 8. Top: free energy diagram for a circular string-bounded hole nucleating on a domain wall vs the string nucleation radius R . For $R > R_{\text{tp}}$, the free energy of the system turns negative, and it becomes energetically possible to nucleate a string in place of a wall element of area πR_{tp}^2 . Bottom: illustration of the nucleation process. For walls with radii $R > R_{\text{tp}}$ a piece of wall with area πR_{tp}^2 is eaten and replaced with a string, which forms the boundary of the punctured hole.

by the same discrete symmetry, then strings form first (in the initial phase transition that leaves an unbroken discrete symmetry) and connect to domain walls in the second phase transition (when the discrete symmetry is broken). When inflation occurs after the formation of strings but before domain walls, the string abundance is heavily diluted by the time the walls form. The absence of strings initially prevents the formation of string-bounded walls at the second stage of symmetry breaking, and the walls initially evolve as a normal wall network. Nevertheless, the walls can become bounded by strings later by the Schwinger nucleation of string holes as shown in Fig. 8. Conversion of wall rest mass into string kinetic energy causes the string to rapidly expand and eat the wall, causing the wall network to decay.

Strings can only nucleate on the wall if it is energetically possible. The energy cost of producing a circular string loop is μl , where $l = 2\pi R$ is the length of the string, and the energy gained from destroying the interior wall is σA , where $A = \pi R^2$ is the area of the eaten wall. The free energy of the string-wall system is then

$$E = \mu 2\pi R - \sigma \pi R^2. \quad (77)$$

The balance between string creation and domain wall destruction leads to a critical string radius R_{tp} , above which it is energetically favorable for the string to nucleate and

continue expanding and consuming the wall as shown in Fig. 8. Note that $E < 0$ gives this turning point radius

$$R_{\text{tp}} = 2R_c \quad R_c \equiv \frac{\mu}{\sigma}. \quad (78)$$

The probability for the string to tunnel through the classically forbidden region out to radius R_{tp} can be estimated from the WKB approximation. The nucleation rate per unit area is

$$\Gamma_s \propto \sigma e^{-S_E}, \quad (79)$$

where

$$S_E = \int_0^{R_{\text{tp}}} dr \sqrt{\mu r E} \propto \frac{\mu^3}{\sigma^2}. \quad (80)$$

More precisely, the tunneling rate can be estimated from the bounce action formalism and is found to be [31,113]

$$\Gamma_s \sim \sigma \exp\left(-\frac{16\pi}{3}\kappa_s\right), \quad (81)$$

where $\kappa_s = \mu^3/\sigma^2$. As a result, the string nucleation rate on the domain wall is typically exponentially suppressed, and the domain wall can be cosmologically long-lived if μ^3 and σ^2 are disparate, similar to the string and monopole scales in Sec. IV. For the coincidence of scales $\mu^3 \sim \sigma^2$, the domain wall network is metastable and may decay before dominating the energy density of the Universe.

In terms of the symmetry breaking scale, Eqs. (3) and (11) suggest

$$\kappa_s = \frac{9\pi^3}{\lambda_\sigma} \left(B\left(\frac{2\lambda}{e^2}\right)\right)^3 \left(\frac{v_\mu}{v_\sigma}\right)^6 \quad (82)$$

for the fiducial models of Sec. II. Since the homotopy selection rules require $v_\mu \geq v_\sigma$, nucleation of strings within cosmological timescales requires $B(2\lambda/e^2) \ll 1$, which can occur for $\lambda \ll e^2$.

Before decaying via string nucleation, the evolution of the metastable domain wall network is that of a pure domain wall network. The dynamics of a pure domain wall is well described by the wall Nambu-Goto action [80]

$$S = -\sigma \int d^3\zeta \sqrt{\gamma}, \quad (83)$$

where $d^3\zeta$ is the infinitesimal world volume swept out by the domain wall of tension σ , $\gamma \equiv |\det(\gamma_{ab})|$ is the determinant of the induced metric on the wall with $\gamma_{ab} = g_{\mu\nu} \frac{\partial X^\mu}{\partial \zeta^a} \frac{\partial X^\nu}{\partial \zeta^b}$. Note that $X^\mu(\zeta^a)$ are the spacetime coordinates of the wall with ζ^a ($a = 1, 2, 3$) parametrizing the wall hypersurface, and $g_{\mu\nu} = a^2(\eta)(d\eta^2 - d\mathbf{x}^2)$ is the

Friedmann-Robertson-Walker metric in conformal gauge. For large roughly planar walls with a typical curvature radius R , the Euler-Lagrange equation of motion of (83) is [142,143]

$$\frac{dv_w}{dt} = (1 - v_w^2) \left(\frac{k_w}{R} - 3Hv_w \right), \quad (84)$$

where v_w is the average wall velocity perpendicular to the wall surface, H is Hubble, and k_w is an $\mathcal{O}(1)$ velocity-dependent function that parametrizes the effect of the wall curvature on the wall dynamics. Conservation of energy implies

$$\frac{d\rho_w}{dt} + H(1 + 3v_w^2)\rho_w = -\frac{c_w v_w}{R}\rho_w, \quad (85)$$

which is coupled to Eq. (84) via the “one-scale” ansatz,

$$\rho_w \equiv \frac{\sigma R^2}{R^3} = \frac{\sigma}{R}. \quad (86)$$

Equation (86) states that the typical curvature and separation between infinite walls is the same scale R . c_w is an $\mathcal{O}(1)$ constant parametrizing the chopping efficiency of the infinite wall network into enclosed domain walls.⁵ Note that Eq. (85) does not include gravitational wave losses, which are small as long as the walls do not dominate the Universe.

Generally, the tunneling rate is sufficiently suppressed so that the domain walls reach the steady-state solution of Eqs. (84)–(86) before decaying, which is the scaling regime such that $R/t \sim 1$ [143]. In the scaling regime, the energy lost by the infinite wall network from self-intercommutation balances with the energy gained from conformal stretching by Hubble expansion so that the network maintains roughly one domain wall per horizon, similar to the scaling regime of the infinite string network in Sec. IV. As a result, the energy density in the domain wall network before decay evolves with time as

$$\rho_w = \mathcal{A} \frac{\sigma t^2}{t^3} = \mathcal{A} \frac{\sigma}{t}, \quad (87)$$

where $\mathcal{A}$ is found to be $\mathcal{O}(1)$ from simulations [145]. For domain walls that are not highly relativistic, the total power emitted as gravitational radiation for a wall of mass M_w and curvature radius R follows from the quadrupole formula [120],

⁵These enclosed walls, known as “vacuum bags,” are analogous to string loops forming from the intercommutation of a infinite string network. However, unlike string loops, which can be long-lived, the vacuum bags collapse under their own tension and decay quickly. This is because the wall velocity becomes highly relativistic during collapse causing length contraction of the wall thickness and hence efficient particle emission of the scalar field associated with the wall [144].

$$P_{\text{GW}} \approx \frac{G}{45} \sum_{i,j} \langle \ddot{Q}_{ij} \ddot{Q}_{ij} \rangle \sim G(M_w R^2 \omega^3)^2 = \mathcal{B} G \sigma M_w. \quad (88)$$

In the last equation, we take the typical oscillation frequency ω and curvature R^{-1} to be comparable. Numerical simulations of domain walls in the scaling regime confirm Eq. (88) with $\mathcal{B} \approx \mathcal{O}(1)$ [145–147].

In the scaling regime and prior to nucleation, the energy density rate lost into gravitational waves by the domain walls at time t is then

$$\frac{d\rho_w^{(\text{GW})}}{dt} = -n_w P_{\text{GW}} \simeq -\mathcal{A} \mathcal{B} \frac{G\sigma^2}{t}. \quad (89)$$

In writing the right-hand side of (89), we use $\rho_w \simeq n_w M_w$ and insert Eq. (87). The energy density injected into gravitational waves is subsequently diluted with the expansion of the Universe. The total energy density ρ_{GW} in the gravitational wave background is thus described by the Boltzmann equation,

$$\frac{d\rho_{\text{GW}}}{dt} + 4H\rho_{\text{GW}} = \mathcal{A} \mathcal{B} \frac{G\sigma^2}{t} \theta(t_\Gamma - t) - x \frac{d\rho_{\text{DW}}}{dt} \theta(t - t_\Gamma), \quad (90)$$

where $x \in [0, 1]$ is an efficiency parameter characterizing the fraction of the energy density of the wall transferred into gravitational waves after strings begin nucleating and eating the wall, which occurs at time

$$t_\Gamma \sim \frac{1}{\sigma A} e^{S_E} \sim \frac{1}{\sigma^{1/3}} \exp \frac{16\pi\kappa_s}{9}. \quad (91)$$

Here, we take the wall area A at time t_Γ to be $\sim t_\Gamma^2$ in accordance with the scaling regime. When the strings begin nucleating at t_Γ , they quickly expand from an initial radius $R_{\text{ip}} = 2R_c$, according to

$$R_s(t) = \sqrt{4R_c^2 + (t - t_\Gamma)^2}, \quad (92)$$

as shown in Appendix B for circular string-bounded holes. Consequently, the strings rapidly accelerate to near the speed of light as they eat the wall. The increase in string kinetic energy arises from the devoured wall mass. Thus, shortly after t_Γ , most of the energy density of the wall is transferred to strings and string kinetic energy. Numerical simulations outside the scope of this work are required to accurately determine the gravitational waves emitted from the typical relativistic collisions of the string-bounded holes, which mark the end of the domain wall network and hence the determination of x . As a result, we conservatively take $x = 0$ when computing the resulting gravitational wave spectrum. Nevertheless, we can estimate the potential effect of nonzero x by taking the sudden decay approximation for the wall. That is, assuming the

destruction of the wall following nucleation occurs shortly after t_Γ , we may take $d\rho_{\text{DW}}/dt \approx -\rho_{\text{DW}}\delta(t - t_\Gamma)$.

The solution to (90), during an era with scale factor expansion $a(t) \propto t^\nu$, is then

$$\rho_{\text{GW}}(t) = \begin{cases} \mathcal{A} \mathcal{B} \frac{G\sigma^2}{4\nu} \left(1 - \left(\frac{t_{\text{scl}}}{t}\right)^{4\nu}\right) & t \leq t_\Gamma \\ \left(\rho_{\text{GW}}(t_\Gamma) + x \mathcal{A} \frac{\sigma}{t_\Gamma}\right) \left(\frac{a(t_\Gamma)}{a(t)}\right)^4 & t > t_\Gamma. \end{cases} \quad (93)$$

Equation (93) demonstrates that the gravitational wave energy density background quickly asymptotes to a constant value after reaching scaling at time t_{scl} and to a maximum at the nucleation time t_Γ . We thus expect a peak in the gravitational wave amplitude of approximately

$$\Omega_{\text{GW,max}} \approx \frac{\rho_{\text{GW}}(t_\Gamma)}{\rho_c(t_\Gamma)} \left(\frac{g_{*0}}{g_*(t_\Gamma)}\right)^{\frac{1}{3}} \quad (94)$$

$$= \frac{16\pi}{3} [(G\sigma t_\Gamma)^2 + 2x G\sigma t_\Gamma] \Omega_r \left(\frac{g_{*0}}{g_*(t_\Gamma)}\right)^{\frac{1}{3}}, \quad (95)$$

where we take $t_\Gamma > t_{\text{scl}}$, $\mathcal{A} = \mathcal{B} = 1$, and a radiation dominated background at the time of decay with $\nu = \frac{1}{2}$. Note that $\Omega_r = 9.038 \times 10^{-5}$ is the critical energy in radiation today [101].

The first term in the second line of (94), the contribution to the peak amplitude from gravitational waves emitted prior to nucleation, agrees well with the numerical results of [145] if t_Γ maps to the decay time of unstable walls in the authors' simulations. Note that in [145], the domain walls are global domain walls and are unstable due to a vacuum pressure difference arising from the insertion of a Z_2 breaking term in the domain wall potential. In this work, we consider gauged domain walls in which such a discrete breaking term is forbidden.

The second term in (94), the contribution to the peak amplitude from gravitational waves emitted after nucleation, has not been considered in numerical simulations. The postnucleation contribution dominates the prenucleation contribution if $x \gtrsim G\sigma t_\Gamma$, which may be important for short-lived walls. The complex dynamics of string collisions during the nucleation phase motivates further numerical simulations.

The frequency dependence on the gravitational wave amplitude may be extracted from numerical simulations of domain walls in the scaling regime. The form of the spectrum was found in [145] to scale as

$$\Omega_{\text{GW}}(f) = \frac{f}{\rho_c} \frac{d\rho_{\text{GW}}(t_0, f)}{df} \approx \Omega_{\text{GW,max}} \begin{cases} \left(\frac{f}{f_{\text{peak}}}\right)^{-1} & f > f_{\text{peak}} \\ \left(\frac{f}{f_{\text{peak}}}\right)^3 & f \leq f_{\text{peak}}, \end{cases} \quad (96)$$

FIG. 9. Representative spectra of gravitational waves emitted by domain walls that are eaten by nucleation of strings for fixed $\sigma^{1/3} = 10^{12}$ GeV. Each colored contour corresponds to a different value of $\kappa_s = \mu^3/\sigma^2$, which parametrizes the ratio between string and wall symmetry breaking scales and sets the nucleation time of the strings on the wall. Since nucleation is an exponentially suppressed process, the metastable wall network is typically cosmologically long-lived and behaves as a pure wall network before nucleation. At high frequencies, Ω_{GW} scales as f^{-1} , while after nucleation Ω_{GW} decays as f^3 by causality [145]. For sufficiently large κ_s , the domain wall network is long-lived enough to dominate the energy density of the Universe at decay and emits enough gravitational radiation to violate measurements of ΔN_{eff} , as shown by the red region. Consequently, κ_s must be close to unity so that walls decay by string nucleation before wall domination.

where

$$f_{\text{peak}} \sim \frac{1}{t_\Gamma} \frac{a(t_\Gamma)}{a(t_0)} \quad (97)$$

is the fundamental mode of oscillation at the time of decay. The infrared f^3 dependence for $f < f_{\text{peak}}$ arises from causality arguments for an instantly decaying source [136].

Figure 9 shows a benchmark plot of the gravitational wave spectrum from domain walls consumed by string nucleation for fixed $\sigma = (10^{12} \text{ GeV})^3$ and a variety of $\kappa_s = \mu^3/\sigma^2$. In computing the spectrum, we evaluate (96), in the conservative limit of $x = 0$. The corresponding dots above each triangular vertex shows the potential peak of the spectrum in the $x \rightarrow 1$ limit, which corresponds to the assumption that all of the wall energy at nucleation goes into gravitational waves. For sufficiently large κ_s , the domain wall energy density grows relative to the background and can come to dominate the critical density of the Universe at the time of decay. This can lead to gravitational radiation producing too large ΔN_{eff} , (24), as shown by the red region. For relatively long-lived walls nucleating prior to wall domination, it is possible for many gravitational wave detectors to observe the $\Omega_{\text{GW,peak}}$ and the characteristic f^{-1} ultraviolet slope and f^3 infrared slope.

FIG. 10. The parameter region in the $v_\sigma - \kappa_s$ plane, where the gravitational wave spectrum from domain walls eaten by the nucleation of strings can be detected. We take the fiducial value $\epsilon = 1$ so that $\sigma = v_\sigma^3$. For a given (v_σ, κ_s) , a detection is registered when Ω_{GW} is greater than the sensitivity curve of the given detector. In the red region, the energy density emitted by walls into gravitational radiation is large enough to be excluded by ΔN_{eff} bounds. Deep in the red region, κ_s is sufficiently large that the walls are so long-lived that they dominate the energy density of the Universe.

Figure 10, shows the detector reach of Ω_{GW} in the $v_\sigma - \kappa_s$ plane. Here we take $\epsilon = 1$ so that $v_\sigma = \sigma^{1/3}$. Since the triangular shaped spectrum from a domain wall eaten by strings is sufficiently different compared to a flat stochastic string background, we register a detection of the string nucleation gastronomy as long as $\Omega_{\text{GW}} h^2$ exceeds the threshold of detection for a given experiment. Figure 10 demonstrates that a wide range of σ and κ_s can be probed. Note that most detection occurs when the walls decay shortly before coming to dominate the Universe as shown by the diagonal red ΔN_{eff} region. In general, wall

FIG. 11. Illustration of strings connecting to walls below the wall formation scale v_σ . The walls fill in the area between strings because winding the Higgs field ϕ , responsible for the symmetry breaking at v_σ , around a string necessarily generates a discontinuity in ϕ [148, 149]. As a result, a structure must abruptly change ϕ back to ensure the continuity of ϕ . This structure is the domain wall.

symmetry breaking scales v_σ between 1 and 10^{13} GeV and κ_s between 4–15 can be detected by current and near future gravitational wave detectors.

In addition, while the infrared (f^{-3}) and ultraviolet (f^{-1}) wall spectrum is similar to the monopole burst spectrum of Sec. V, there is a logarithmic plateau at the peak of the monopole burst spectrum that is absent for the walls and hence can be used to distinguish both gastronomy signals. Moreover, in first-order phase transitions, where the bulk of the energy goes into the scalar shells, the envelope approximation predicts a similar spectrum (f^3 in the infrared, f^{-1} in the ultraviolet) [150]. However, more sophisticated analyses of this type of phase transition appear to predict an UV spectrum that scales as $f^{-1.5}$ [151], making it unlikely that a wall or monopole network eaten by strings can be mimicked by a first-order phase transition.

VII. DOMAIN WALLS EATING STRINGS

In this section, we consider the gastronomy case where domain walls attach to, and consume, a preexisting string network. The symmetry breaking chains that allow this are the same as in the previous section, with the difference between the two scenarios arising from when inflation occurs relative to string formation. For the string nucleation gastronomy of Sec. VI, inflation occurs after string formation but before wall formation. For walls attaching to a preexisting string network, as considered in this section, inflation occurs before string and wall formation. In this scenario, the string network is not diluted by inflation, and at temperatures below the wall symmetry breaking scale v_σ , walls fill in the space between strings. Note that since the attachment of walls to a preexisting string network is not a nucleation process, there does not have to be a coincidence of scales between v_μ and v_σ as in the case of strings nucleating on walls, as discussed in Sec. VI.

The outline of this section is as follows: First, we derive the equation of motion for the string boundary of a circular wall and quantitatively show how the wall tension dominates the string dynamics when the radius R of the hybrid defect is greater than $R_c \equiv \mu/\sigma$ and how the string dynamics reduce to pure string loop motion for $R \ll R_c$. We then run a velocity one-scale model on an infinite string-wall network and show how the walls pull their attached strings into the horizon when the curvature radius of the hybrid network grows above R_c . Once inside the horizon, the domain wall bounded string pieces oscillate and emit gravitational radiation, which we compute numerically. We find that power emitted in gravitational wave asymptotes to the pure string limit $P_{\text{GW}} \propto G\mu^2$, for pieces of string-bounded walls with radii $R \ll R_c$, and to the expected power emitted by domain walls from the quadrupole approximation $P_{\text{GW}} \propto G\sigma^2 R^2$, for $R \gg R_c$. We use the numerically computed gravitational wave power to derive the energy density evolution and the gravitational

wave spectrum of a network of circular string-bounded wall pieces. We discuss the features of this gastronomy signal and its experimental detectability with current and future gravitational wave detectors. Last, we discuss how model dependent effects, such as friction on the string or wall, can affect the spectrum.

A. The string-wall equation of motion

Let us begin with the total action of a wall bounded by a string with wall tension σ and string tension μ ,

$$S = -\sigma \int d^3\zeta \sqrt{\gamma} - \mu \int d^2\zeta \sqrt{\Upsilon}. \quad (98)$$

The parameters of the wall action (left term) are the same as in Eq. (83). For the string action (right term), $d^2\zeta$ is the infinitesimal world sheet swept out by the string, $\Upsilon \equiv |\det(\Upsilon_{ab})|$ is the determinant of the induced metric on the string, and $\Upsilon_{ab} = g_{\mu\nu} \frac{\partial Y^\mu}{\partial \zeta^a} \frac{\partial Y^\nu}{\partial \zeta^b}$, where $Y^\mu(\zeta^0, \zeta^1)$, are the spacetime coordinates of the string which is fixed to lie at on the boundary of the wall.

Assuming the wall velocities are not ultrarelativistic, and the string boundary on the wall is approximately circular, one can derive the Lagrangian for the string boundary of the wall to be

$$L = -2\pi\mu |\mathbf{r}_s(\eta)| a^2(\eta) \sqrt{1 - \left(\frac{d\mathbf{r}_s}{d\eta}\right)^2} - \sigma\pi \mathbf{r}_s(\eta)^2 a^3(\eta), \quad (99)$$

where $\mathbf{r}_s$ is the comoving position vector of the string boundary, η is conformal time, and a the scale factor of the Universe. See Appendix B for details, including a justification of the assumptions. The Lagrangian (99) generates the following Euler-Lagrange equation of motion:

$$\frac{d^2\mathbf{r}_s}{d\eta^2} = -\frac{\sigma}{\mu} \left(1 - \left(\frac{d\mathbf{r}_s}{d\eta}\right)^2\right)^{3/2} a(\eta) \hat{\mathbf{r}}_s - \left(1 - \left(\frac{d\mathbf{r}_s}{d\eta}\right)^2\right) \left(\frac{\hat{\mathbf{r}}_s}{|\mathbf{r}_s|} + 2\mathcal{H} \frac{d\mathbf{r}_s}{d\eta}\right), \quad (100)$$

where $\mathcal{H} = d \ln a / d\eta = Ha$ is the conformal Hubble rate.

In the limit that the physical size of the wall, $\mathbf{R}_s = \mathbf{r}_s a$, is much smaller than the critical radius, $R_c \equiv \mu/\sigma$, the equation of motion for the string-bounded wall reduces to the standard result of a pure circular string loop [80,140]. However, for $|\mathbf{R}_s| \geq R_c$, the domain wall tension dominates the string tension, and the string motion becomes more relativistic. This can also be simply understood by noting that a wall-bounded string of curvature radius R experiences a wall tension force $F \sim \sigma R$ and a string tension force $F \sim \mu$, which become comparable at $R = R_c$ [32,120].

FIG. 12. Evolution of a circular string radius $\mathbf{R}_s$ as a function of time in the flat spacetime limit (i.e., subhorizon strings) when the string is the boundary of domain wall (solid) and when it is a pure string loop (dashed). The colored contours show the evolution for a variety of different string sizes. When the string is small, compared to $R_c = \mu/\sigma$, the string dominates the dynamics and circular string-bounded walls oscillate similarly to pure string loops of the same size. However, when the string size becomes of order or greater than R_c , the wall dominates the dynamics of the string and causes the string to oscillate highly relativistically compared to pure string loops of the same size. This can be seen by the increase of the period-averaged velocity squared $\langle v^2 \rangle$, which increases from approximately 0.5 in the pure string loop limit to more relativistic values as the size of the string-bounded wall grows above R_c .

Figure 12 shows the numerical solution of Eq. (100) for the string boundary as a function of the initial string size in the flat spacetime limit, ($a \rightarrow 1, \eta \rightarrow t$), or equivalently, after the loops have entered the horizon. For $|\mathbf{R}_s| \ll R_c$, the evolution of $\mathbf{R}_s$ for the string-bounded wall is identical to the pure string loop motion (dashed lines) [140]. For string-bounded walls with $|\mathbf{R}_s| \gtrsim R_c$, the evolution deviates from the pure string loop, with the domain wall accelerating its string boundary to highly relativistic speeds for most of its oscillation period. The highly relativistic string boundaries are responsible for the gravitational wave emission of string-bounded walls as discussed later in this section.

B. Collapse of the infinite string-wall network

For subhorizon loops, $|\mathbf{R}_s| \lesssim t$, the Hubble term in Eq. (100) is subdominant compared to the string curvature term, and hence the motion of the domain wall bounded

string loops approaches the flat spacetime limit. However, for superhorizon or infinite strings, the effect of the expansion of the Universe is critical. To understand the evolution and collapse of the infinite string-wall network, we implement a one-scale model [114–116] by rewriting Eq. (100) in terms of the rms comoving velocity, $v_s \equiv -\sqrt{\langle \mathbf{v}_s \cdot \mathbf{v}_s \rangle} = -\sqrt{\langle d\mathbf{r}/d\eta \cdot d\mathbf{r}/d\eta \rangle}$ of the typical long string,

$$\frac{dv_s}{dt} = (1 - v_s^2) \frac{k(R, v_s)}{R} - 2Hv_\infty, \quad (101)$$

where

$$k(v_s, R) = \frac{\langle (1 - \mathbf{v}_s^2 + \frac{R}{R_c} (1 - \mathbf{v}_s^2)^{3/2}) \mathbf{v}_s \cdot \hat{\mathbf{r}}_s \rangle}{v_s (1 - v_s^2)} \quad (102)$$

is the wall-modified curvature parameter. Similarly, the energy density of the infinite network ρ_∞ can be decomposed into infinite string $\rho_s = \beta \rho_\infty$ and wall $\rho_w = (1 - \beta) \rho_\infty$ contributions. That is, $0 \leq \beta \leq 1$ parametrizes the relative energy density between strings and walls with the entire energy density in strings when $\beta = 1$ and the entire energy density in walls when $\beta = 0$.⁶ The energy density evolution of the infinite string-wall network is then

$$\frac{d\rho_\infty}{dt} + 3H(1 + w)\rho_\infty = -\frac{cv_\infty}{R}\rho_\infty, \quad (103)$$

where c is a chopping efficiency parameter, and

$$w = \frac{2}{3}(1 + v_s^2)\beta + \left(\frac{1}{3} + v_w^2\right)(1 - \beta) - 1 \quad (104)$$

is the equation of state of the infinite wall-string network [153,154], with v_s and v_w the average string and wall speeds, respectively. Note the wall speed is unimportant to the wall-string evolution for the following reason: For $R \lesssim R_c$, the strings dominate the energy density and $\beta \simeq 1$. For $R \gtrsim R_c$, the energy density is initially mostly in the walls but is quickly converted to string kinetic energy with v_s and then β quickly becoming approximately 1. Thus, for any R , we expect the wall contribution in Eq. (104) (second term) to be subdominant to the string contribution (first term) and set $\beta \simeq 1$ for all time, which eliminates v_w from the wall-string dynamics.

The chopping efficiency c of the infinite network into loops is expected to be an $\mathcal{O}(1)$ number [120].

⁶A similar analysis for a string-monopole network with $Z_{N \geq 3}$ strings was considered in [152]. In [152], monopoles are connected to multiple strings, which allows the monopole-string “web” to be long-lived and reach a steady-state scaling regime.

For definiteness, we take the pure string result $c \approx 0.23$ inferred from simulations [116]. Last, the “momentum parameter” k is an $\mathcal{O}(1)$ number, which parametrizes the effect of the string curvature and wall tension on the infinite string dynamics and vanishes when v_∞ matches the rms velocity v_0 of the string loops in flat space [116]. Note that $v_0 = 1/\sqrt{2}$ for any pure string loop [80] but is an increasing function of R/R_c for string-bounded walls, as shown graphically by Fig. 12. As a result, we approximate $k(v, R)$ by the pure string momentum parameter [116],

$$k(v_s, R) \approx \frac{2\sqrt{2}}{\pi} (1 - v_s^2) (1 + 2\sqrt{2}v_s^3) \frac{v_0(R)^6 - v_s^6}{v_0(R)^6 + v_s^6}, \quad (105)$$

but with v_0 now the R/R_c dependent rms velocity of the string-bounded walls as computed numerically from Eq. (100). In the pure string limit, $R_c \rightarrow \infty$, Eqs. (101)–(105) reduce to the standard one-scale model.

The two equations, (101) and (103), are coupled via the one-scale ansatz,

$$\rho_\infty \equiv \frac{\mu R + \sigma R^2 \theta(t - t_{\text{DW}})}{R^3} = \frac{\mu}{R^2} \left(1 + \frac{R}{R_c} \theta(t - t_{\text{DW}}) \right), \quad (106)$$

where $t_{\text{DW}} \approx M_{\text{Pl}} C / v_\sigma^2$ is the wall formation time. The ansatz (106) amounts to assuming the typical curvature and separation between infinite string-bounded walls is the same scale R . Note that while ρ_∞ is the total rest mass energy density of the combined string-wall network, the allocation of the total energy density is shared among the two defects.

We evaluate the coupled system of equations (101)–(105) in time up until the one-scale ansatz breaks down. This occurs when the curvature radius R of the infinite strings approaches R_c , at which point the wall tension dominates the string tension, and the walls pull the infinite strings with curvature radius R effectively into string-bounded domain walls of radius R . At this point, we evaluate Eq. (100) with the initial conditions taken from the one-scale solution and piecewise connect the two solutions so that each solution is valid in their respective regimes.

For a given string tension μ and wall tension σ , two general collapse scenarios arise. One, when the walls form before $R \sim R_c$ and the other when they form after, as represented by the top and bottom panels of Fig. 13, respectively. If the wall formation time $t_{\text{DW}} < R_c$, then the walls gradually come to dominate the infinite string dynamics with v_s and R rising slightly before $t = R_c$, as shown by the orange and blue curves, respectively. Here, we define the right-axis v_{rms} as the rms velocity for the infinite strings v_s prior to network collapse, and to the rms velocity of the wall-bounded string pieces v_0 , after network

FIG. 13. Evolution of the infinite string-wall network. The blue curve shows the curvature radius of the string-bounded walls over time, R/t , while the orange curve shows the string rms velocity v_{rms} . Top: representative case where $t_{\text{DW}} < R_c$ so that walls form before dominating the string dynamics. For $t < R_c$, we numerically compute the modified one-scale model equations. The string-wall network reaches a scaling regime where R maintains a constant fraction of the horizon. As t approaches R_c , the walls begin dominating the dynamics, and the strings move more relativistically. At $t = R_c$, infinite string-bounded walls with curvature radius R behave like wall-bounded strings of curvature radius R . We approximate this transition by piecewise connecting the one-scale model solution to the numerical solution of the Euler-Lagrange equation of motion for a circular string-bounded wall. For $t > R_c$, the infinite network collapses, and the pieces oscillate at constant physical size before decaying via gravitational waves. Bottom: same as the top but representative of the case where $t_{\text{DW}} > R_c$ so that walls form already dominating the string dynamics. In this scenario, v_{rms} of the infinite wall network abruptly increases at wall formation. We transition from the one-scale to the Euler-Lagrange solution, when v_{rms} of the infinite strings approximately reaches v_{rms} of a string-bounded wall piece of the same curvature radius.

collapse.⁷ In this scenario, we define the network collapse time as $t_* = R_c$ from which point on we evaluate Eq. (100)

⁷For the one-scale model, the energy density “decreases” as R “increases.” R increases slightly before $t = t_*$ because ρ_∞ redshifts faster. This is because the equation of state of the wall-string network briefly behaves more like radiation due to the sudden increase in v_s caused by the walls.

to determine the dynamics of the string system. If the wall formation time $t_{\text{DW}} > R_c$, then the walls dominate the strings upon formation, and v_s increases abruptly as shown in the bottom panel of Fig. 13. In this scenario, we define the network collapse time as the time when v_s approximately matches v_0 as determined from Eq. (100), from which point on we evaluate Eq. (100) to determine the dynamics of the system. Since the collapse proceeds shortly after domain wall formation, the collapse time of the infinite network is effectively at $t_* = t_{\text{DW}}$.

In summary, we take the time of collapse of the infinite string-wall network, and hence the end of loop production, to be

$$t_* \equiv \text{Max}(R_c, t_{\text{DW}}), \quad (107)$$

as first proposed by [130]. More realistic simulations beyond our one-scale analysis and piecewise approximations are required to more precisely determine t_* . Nevertheless, the sudden increase in v_s and R around t_* , according to the one-scale analysis or comparing each term in the string equation of motion to determine at what time each term dominates, as done in Sec. VII E, when we consider friction indicates that the walls begin dominating the infinite string dynamics near a time of order Eq. (107). Moreover, the gravitational wave spectrum from wall-bounded strings is fairly weakly dependent on the precise value of t_* and knowing t_* to within a factor of a few is sufficient to accurately compute the gravitational wave spectrum as discussed later in this section.

C. Gravitational wave emission from string-bounded walls

When a string-bounded domain wall piece enters the horizon, it oscillates at constant amplitude, as shown by the dotted green curves of Fig. 13, since they are subhorizon and do not experience the conformal expansion with the horizon. As they oscillate, the loops emit gravitational waves with a total power [126]

$$P_{\text{GW}} = \sum_n \int d\Omega \frac{dP_n}{d\Omega} \quad (108)$$

$$\frac{dP_n}{d\Omega} = \frac{G\omega_n^2}{\pi} \left[T^{\mu\nu*}(\mathbf{k}, \omega_n) T_{\mu\nu}(\mathbf{k}, \omega_n) - \frac{1}{2} |T_\mu^\mu(\mathbf{k}, \omega_n)|^2 \right], \quad (109)$$

where $\omega_n = |\mathbf{k}| = 2\pi n/T$ is the frequency of the n th harmonic of the string-bounded wall oscillating with period T . The stress tensor of the string-wall system is

$$T^{\mu\nu}(\mathbf{k}, \omega_n) = \frac{1}{T} \int_0^T dt e^{i\omega_n t} \int d^3\mathbf{x} e^{-i\mathbf{k}\cdot\mathbf{x}} T^{\mu\nu}(\mathbf{x}, t) \quad (110)$$

FIG. 14. Top: the gravitational power P_{GW} emitted by string-bounded walls as a function of R/R_c . The orange contour shows the power in the first harmonic P_1 , while the blue contour shows the total power. For $R \ll R_c$, the string dominates the dynamics, and we recover the pure string loop limit, namely $P_{\text{GW}}/G\mu^2 = \Gamma_s$, where $\Gamma_s \approx 50$ is a constant and is independent of string size. For $R \gg R_c$, the wall dominates the dynamics, and we recover the pure domain wall limit, namely $P_{\text{GW}} \approx G\sigma M_{\text{DW}}$. Bottom: the power spectral index as a function of R/R_c , defined by $P_n \propto n^{-q}$. In the pure string limit, $q \rightarrow 1$ and in the pure wall limit, $q \rightarrow 3/2$.

$$T^{\mu\nu}(\mathbf{x}, t) = \int_{\text{string}} \mu |\mathbf{R}_s| d\theta \gamma \frac{dY^\mu}{dt} \frac{dY^\nu}{dt} \delta^3(\mathbf{x} - \mathbf{R}_s(t)), \quad (111)$$

where $dY/dt = (1, \mathbf{V}_s)$, $\gamma = (1 - \mathbf{V}_s \cdot \mathbf{V}_s)^{-1/2}$, and $\mathbf{V}_s = d\mathbf{R}_s/dt$ is the physical velocity of the string.

We calculate the gravitational wave power of the string-wall system by numerically computing Eqs. (108)–(110) for circular string-bounded walls, using the numerically computed time evolution of $\mathbf{R}_s$ from the Euler-Lagrange equation of motion (100). The orange contour of Fig. 14 shows the ratio of the gravitational wave power in the first harmonic P_1 to $G\mu^2$ as a function of R/R_c , where R is the string oscillation radius. For $R \ll R_c$, the string dominates the dynamics, and the power is independent of loop size, in agreement with the pure string case. However, for $R \gg R_c$, the domain wall dominates the dynamics, and the power deviates from the pure string case, increasing quadratically with R/R_c . Since $R_c \equiv \mu/\sigma$, this is equivalent to $P_{\text{GW}} \propto G\sigma^2 R^2 \propto G\sigma M_{\text{DW}}$, in agreement with the quadrupole formula expectation for gravitational wave emission from domain walls.

The bottom panel of Fig. 14 shows the power spectral index q as a function of R/R_c , where q is defined by the index $P_n \propto n^{-q}$. We numerically determine q by examining the asymptotic dependence of P_n for n up to ~ 300 . In the string dominated regime ($R \ll R_c$), $q \simeq 1$ which agrees with the pure string result of a “perfectly circular” string loop [155]. In the domain wall dominated regime ($R \gg R_c$), we find $q \simeq 3/2$.

Note the mild (logarithmic) divergence in the total power for $R \ll R_c$ is an artifact of perfectly circular loops [128,155] and more realistic loops, which will not be perfectly circular but have cusps, will moderate the divergence such that $P_n \propto n^{-4/3}$ for large n . Although realistic loops are not perfectly circular, nearly all loop configurations emit similar total power in gravitational waves [80,128,156], including nearly circular, but not completely symmetric loops. Indeed, numerical calculations of nearly circular pure string loops have P_1 nearly identical to our numerical result in the $R \ll R_c$ limit but have finite total power similar to most string loop geometries, $P_{\text{tot}} \approx (50\text{--}100)G\mu^2$ [128]. As a result, to match with a realistic ensemble of loops, which are not perfectly circular and contain cusps, we cut off the artificial logarithmic divergence in the $R \ll R_c$ regime by normalizing P_{tot} to the typical string loop such that $P_{\text{tot}}/G\mu^2 \equiv \Gamma_s \simeq 50$. For $R > R_c$ when $q < 1$, we take the total power $P_{\text{tot}} \simeq P_1/\zeta(q)$, which is the total power for $P_n = P_1 n^{-q}$. For convenience in computing the gravitational wave spectrum in the following subsection, we define the function $\Gamma(R) \equiv P_{\text{GW}}(R)/G\mu^2$ for string-bounded walls, where $\Gamma(R)$ is now a function of R/R_c . The blue contour of Fig. 14 shows $\Gamma(R)$ as a function of R/R_c . For $R/R_c \ll 1$, $\Gamma \rightarrow \Gamma_s$, while for $R/R_c \gg 1$, $\Gamma \rightarrow 3.7(R/R_c)^2$. Note the power in the large R/R_c regime is equivalent to $P_{\text{GW}} \simeq 1.2G\sigma M_{\text{DW}}$ for a circular string-bounded wall, which agrees well with the numerical power inferred from simulations of domain walls in a scaling regime [145].

D. Gravitational wave spectrum from string-bounded walls

Now that the gravitational wave power emitted by a string-bounded domain wall is known, we may calculate the gravitational wave spectrum from a network of circular string-bounded walls. First, we analytically estimate the expected amplitude and frequency of the spectrum to gain intuition before computing it numerically.

Consider first a pure string loop without walls that forms at time t_k with initial length $l_k = \alpha t_k$, where $\alpha \simeq 0.1$ is the typical fixed ratio between loop formation length and horizon size found in simulations [118,119]. Once inside the horizon, these loops oscillate, and their energy density redshifts $\propto a^{-3}$ because their energy $E = \mu l$ is constant in the flat space limit. The loops emit gravitational radiation with power $P_{\text{GW}} = \Gamma_s G\mu^2$, where $\Gamma_s \simeq 50$, and eventually decay from gravitational radiation at time

$$t_\Gamma \approx \frac{\mu l_k}{\Gamma_s G\mu^2} \quad (\text{Pure string loop lifetime}). \quad (112)$$

When the pure string loops form and decay in a radiation dominated era, their energy density at decay is

$$\rho(t_\Gamma) \approx \mu l_k n(t_k) \left(\frac{t_k}{t_\Gamma} \right)^{3/2} \quad \left(\begin{array}{c} \text{Pure string} \\ \text{decay density} \end{array} \right), \quad (113)$$

where $n(t_k) \approx \frac{1}{3} \frac{\mathcal{F} C_{\text{eff}}}{\alpha t_k^3}$ is the initial number density of loops of size l_k that break off from the infinite string network in a scaling regime [46,121,122]. As found by simulations, $\mathcal{F} \approx 0.1$ [119] is the fraction of energy ultimately transferred by the infinite string network into loops of size l_k , and $C_{\text{eff}} \approx 5.4$ is the loop formation efficiency in a radiation dominated era [46,123,124].

As a result, the gravitational wave amplitude arising from these pure string loops is approximately

$$\begin{aligned} \Omega_{\text{GW}}^{(\text{str})} &\approx \frac{\rho(t_\Gamma)}{\rho_c(t_\Gamma)} \Omega_r \left(\frac{g_{*0}}{g_*(t_\Gamma)} \right)^{\frac{1}{3}} \\ &= \frac{32\pi}{9} \mathcal{F} C_{\text{eff}} \sqrt{\frac{\alpha G\mu}{\Gamma_s}} \Omega_r \left(\frac{g_{*0}}{g_*(t_\Gamma)} \right)^{\frac{1}{3}} \quad \left(\begin{array}{c} \text{Pure string} \\ \text{amplitude} \end{array} \right), \end{aligned} \quad (114)$$

where $\rho_c(t_\Gamma)$ is the critical energy density of the Universe at t_Γ .

Until $t = t_*$, the strings dominate the dynamics of any string-bounded walls, and the spectrum must be approximately that of a pure string spectrum with Ω_{GW} given approximately by Eq. (114), independent of frequency. Now, consider a near circular string-bounded wall that forms at time $t_k = t_*$ with initial circumference $l_k = \alpha t_k$. If $l_k \lesssim 2\pi R_c$, then the power emitted and total mass of the system is effectively identical to the pure string case so that the Ω_{GW} is again the same as Eq. (114). However, if $l_k \gtrsim 2\pi R_c$, then the power emitted and mass of the system is dominated by the wall contribution of the wall-string piece. In this case, the wall bounded string decays from gravitational radiation at time

$$t_\Gamma \approx \frac{\sigma l_k^2 / 4\pi}{\Gamma(l_k) G\mu^2} \approx \frac{1}{G\sigma} \quad \left(\begin{array}{c} \text{String-bounded} \\ \text{wall lifetime} \end{array} \right). \quad (115)$$

When the wall bounded strings form and decay in a radiation dominated era, their energy density at decay is

$$\rho(t_\Gamma) \approx \frac{\sigma l_k^2}{4\pi} n(t_k) \left(\frac{t_k}{t_\Gamma} \right)^{3/2} \quad \left(\begin{array}{c} \text{String-bounded} \\ \text{wall decay density} \end{array} \right), \quad (116)$$

where $n(t_k) \approx \frac{1}{3} \frac{\mathcal{F} C_{\text{eff}}}{\alpha t_k^3}$ follows from the infinite string-wall network being in the scaling regime with $\mathcal{F}$ and C_{eff}

expected to be similar to the pure string values right before the infinite network collapses at t_* .

As a result, the gravitational wave amplitude arising from these string-bounded wall pieces is approximately

$$\begin{aligned}\Omega_{\text{GW}} &\approx \frac{\rho(t_\Gamma)}{\rho_c(t_\Gamma)} \Omega_r \left(\frac{g_{*0}}{g_*(t_\Gamma)} \right)^{1/3} \\ &= \frac{8}{9} \mathcal{F} C_{\text{eff}} \alpha \sqrt{G \sigma t_k} \Omega_r \left(\frac{g_{*0}}{g_*(t_\Gamma)} \right)^{1/3} \quad \left(\begin{array}{l} \text{String-bounded} \\ \text{wall amplitude} \end{array} \right).\end{aligned}\quad (117)$$

The largest amplitude of (117) occurs at the latest formation time t_k , which is t_* , the collapse time of the infinite network. Consequently, a ‘‘bump’’ relative to the flat string amplitude occurs if

$$\frac{\Omega_{\text{GW}}}{\Omega_{\text{GW}}^{(\text{str})}} \approx \frac{1}{4\pi} \sqrt{\frac{\Gamma_s \alpha t_*}{R_c}} \approx 0.2 \left(\frac{\alpha}{0.1} \right)^{1/2} \left(\frac{\Gamma_s}{50} \right)^{1/2} \left(\frac{t_*}{R_c} \right)^{1/2} \quad (118)$$

is greater than 1 and at a frequency

$$f_{\text{peak}} \sim \frac{1}{l_k} \frac{a(t_\Gamma)}{a(t_0)} \quad (119)$$

since the walls remain the same size once inside the horizon and dominantly emit at the frequency of the harmonic, $f_{\text{emit}} \sim l_k^{-1}$. Here, $l_k \approx \alpha t_*$.

The estimation of Eq. (118) indicates that if $t_* \gg R_c$, then Ω_{GW} features a bump relative to the flat string spectrum before decaying. Qualitatively, in this limit, the walls are large enough and hence massive enough to live much longer than the pure string loops of the same size. As a result, their energy density before decaying from gravitational radiation is enhanced relative to shorter-lived pure string loops. For $t_* \approx R_c$, the spectrum does not feature an enhancement over the pure string spectrum because the string-bounded walls are small in size and decay quickly. Nevertheless, as we will show numerically, the spectrum still decays as f^3 , which can still be distinguished from the f^2 decay signal from monopoles eating strings as discussed in Sec. V. As a result, for any t_* , we expect a unique gravitational wave gastronomy signature from gauge groups that produce string-bounded walls.

Figure 15 shows the parameter space in the $v_\mu - v_\sigma$ plane where we can expect certain gravitational wave signatures from cosmic gastronomy. Here, $v_\mu \equiv \mu^{1/2}$ and $v_\sigma \equiv (\sigma/\epsilon)^{1/3}$, where $\epsilon \lesssim 1$ is, parameterizes the coupling constant of the scalar field, which breaks the discrete symmetry associated with the domain wall.

With the qualitative features of the spectrum understood, we turn to a numerical computation of Ω_{GW} .

FIG. 15. The $v_\sigma - v_\mu$ parameter space where wall-bounded strings can generate a gravitational wave signal. In the green region, the largest string-bounded walls at the network collapse time t_* have a lifetime comparable to pure string loops of the same size. The energy density they deposit into gravitational waves when they decay is comparable to pure string loops, and hence they do not produce a bump in Ω_{GW} relative to the flat pure string spectrum at high frequencies. In the yellow region, the largest string-bounded walls at the network collapse time t_* are sufficiently large that their lifetime is long compared to a pure string loop of the same size. The energy density they deposit into gravitational waves when they decay is greater than pure string loops, and a bump in Ω_{GW} can be observed relative to the flat string spectrum. In the blue region, $v_\mu < v_\sigma$, which is forbidden for composite string-bounded walls. The black contours show the approximate frequency f_* , where Ω_{GW} decays from the pure string spectrum. The top and bottom panels show the same regions for $\epsilon \equiv \sigma/v_\sigma^3 = 1$ and 10^{-2} , respectively.

The energy lost by oscillating circular loops of length $l = 2\pi R$ is

$$\frac{dE}{dt} = \frac{d}{dt} \left(\mu l + \frac{\sigma l^2}{4\pi} \right) = -\Gamma(l) G \mu^2. \quad (120)$$

As a result, loops that form at time t_k with initial size $l_k = \alpha t_k$ slowly decrease in size according to

$$G \mu(t - t_k) = \int_l^{\alpha t_k} dl' \frac{1 + \frac{l'}{2\pi R_c}}{\Gamma(l')}. \quad (121)$$

As before, the stochastic gravitational wave energy density spectrum is

$$\frac{d\rho_{\text{GW}}(t)}{df} = \int_{t_{\text{sc}}}^t dt' \frac{a(t')^4}{a(t)^4} \int dl \frac{dn(l, t')}{dl} \frac{dP(l, t')}{df'} \frac{df'}{df} \quad (122)$$

$$\frac{df'}{df} = \frac{a(t)}{a(t')} \quad \frac{dn}{dl}(l, t') = \frac{dn}{dt_k} \frac{dt_k}{dl} \quad (123)$$

$$\frac{dP(l, t')}{df'} = \Gamma(l) G \mu^2 l g \left(f \frac{a(t)}{a(t')} l \right), \quad (124)$$

where

$$\frac{dn}{dt_k} = \left(\frac{\mathcal{F} C_{\text{eff}}(t_k)}{\alpha t_k^4} \frac{a(t_k)^3}{a(t')^3} \right) \theta(t_* - t_k) \quad (125)$$

is the loop number density production rate, which follows from roughly one loop of size αt_k breaking off from the infinite wall-string network every Hubble time and then redshifting $\propto a^{-3}$. Note the Heaviside function $\theta(t_* - t_k)$ ensures the gravitational wave spectrum only includes contributions from loops produced at times before t_* . That is, we set the time at which loop production ends to the time at which the infinite string-wall network collapses as computed in Sec. VII B. Also note that the collapse time of the infinite wall network at t_* is not the same as the time at which the last wall-string loops of size αt_* decay. These subhorizon wall-string loops are long-lived, shrinking and decaying from gravitational wave emission as expressed in Eq. (121). In general, loop lifetime is taken into account on a loop-by-loop basis for all times, giving rise, for example, to a distribution of loop lengths arising from the different loop production times,

$$\frac{dt_k}{dl} = \frac{1 + \frac{l}{2\pi R_c}}{\Gamma(l) G \mu} \left(1 + \frac{\alpha(1 + \frac{\alpha t_k}{2\pi R_c})}{\Gamma(\alpha t_k) G \mu} \right)^{-1}, \quad (126)$$

which follows from differentiating Eq. (121) with respect to t_k . Lastly,

$$g(x) = \sum_n \mathcal{P}_n \delta(x - \xi n) \quad \xi \equiv \frac{l}{T} \quad (127)$$

is the normalized power spectrum for a discrete spectrum, where $2 \leq \xi \leq \pi$ with $\xi = 2$ corresponding to the pure string limit ($l \ll 2\pi R_c$) and $\xi = \pi$ corresponding to the ultra-relativistic limit ($l \gg 2\pi R_c$). As discussed in the previous subsection, we take $\mathcal{P}_n = n^{-q}/\zeta(q)$ with $q = 4/3$ to match on to more realistic noncircular strings with cusps. Above, primed coordinates refer to emission and unprimed refer to the present so that gravitational waves emitted from the string-bounded wall at time t' with frequency f' will be observed today with frequency $f = f' a(t')/a(t)$. Lastly, t_k is solved numerically from Eq. (121).

Integrating the energy density spectrum, (122) over loop length l and normalizing by the present day energy density, $\rho_c = 3H_0^2/8\pi G$ yields the present day gravitational wave spectrum from domain wall bounded strings,

$$\Omega_{\text{GW}} = \sum_n \frac{8\pi(G\mu)^2}{3H_0^2} \int_{t_{\text{sc}}}^{t_0} dt' \frac{a(t')^5}{a(t_0)^5} \left(\frac{\mathcal{F} C_{\text{eff}}(t_k)}{\alpha t_k^4} \frac{a(t_k)^3}{a(t')^3} \right) \times \mathcal{P}_n \frac{\xi n}{f} \left(1 + \frac{\xi n}{2\pi R_c f a(t_0)} \right) \frac{\Gamma(\alpha t_k) \theta(t_* - t_k)}{\Gamma(\alpha t_k) G \mu + \alpha(1 + \frac{\alpha t_k}{2\pi R_c})}. \quad (128)$$

Figure 16 shows a benchmark plot of the gravitational wave spectrum from cosmic strings consumed by domain walls for fixed $v_\mu \equiv \sqrt{\mu} = 10^{12}$ GeV and a variety of $v_\sigma \equiv (\sigma/\epsilon)^{1/3}$, where we take $\epsilon = 1$. In computing the spectrum, we sum up 10^4 normal modes and solve for the evolution of the scale factor in a Λ CDM cosmology. The colored contours in Fig. 16 show the effect of t_* on the spectrum, while the black contour shows the pure string spectrum, equivalent to the limit $t_* \rightarrow \infty$. When $v_\sigma \ll v_\mu$, the walls form before dominating the strings, and the network collapses at $t_* = R_c$, with the largest wall bounded strings approximately of size αR_c . These wall bounded string pieces decay approximately with the same lifetime as pure strings of the same size, implying the spectrum is not enhanced over the pure string spectrum before decay. The smaller R_c is, the longer the string network evolves as a pure string network, which is why the f^3 decaying spectrum in Fig. 16 occurs at lower frequencies the lower v_σ is. Conversely, when $v_\sigma \sim v_\mu$, as shown, for instance, by the brown $v_\sigma = 10^{11}$ GeV contour, the walls form already dominating the strings. The network collapses at $t_* = t_{\text{DW}} \gg R_c$ with the largest string-bounded walls approximately of size αt_{DW} . These string-bounded wall pieces decay much later than pure string loops of the same size, causing the spectrum to be enhanced over the pure string spectrum before decay, as shown by the bump near 10^{11} Hz. Because v_σ must be near v_μ in this scenario, the frequency of the bump generally occurs at very high

FIG. 16. Representative spectra of gravitational waves emitted by strings that are eaten by domain walls for fixed $\sqrt{\mu} = 10^{12}$ GeV. Each colored contour corresponds to a different value of the wall symmetry breaking scales v_σ . Prior to wall domination at t_* , the wall-string network behaves similarly to a pure string network and $\Omega_{\text{GW}} \propto f^0$ at high frequencies. After the network collapses and the largest string-bounded walls decay, Ω_{GW} drops as f^3 at low frequencies. For $t_{\text{DW}} < R_c$, the largest wall-bounded string pieces at decay do not live longer compared to pure string loops of the same size and hence do not deposit significantly more energy density into gravitational waves compared to pure string loops. There is no bump in Ω_{GW} in this case. For $t_{\text{DW}} \gg R_c$, the largest wall-bounded string pieces at decay have size $R \gg R_c$ and are long-lived compared to pure string loops of the same size. These pieces deposit significant energy into gravitational waves at decay and generate a bump in Ω_{GW} , as shown by the $v_\sigma = 10^{11}$ GeV contour.

frequencies, as shown, for instance, by the yellow region of Fig. 15.

Finally, note that the spectrum is identical to the monopole nucleation spectrum of Sec. IV at high frequencies, namely a pure string spectrum, but at low frequencies, the two gastronomy spectra are distinguishable by the slope of their infrared tails, which goes as f^3 and f^2 , respectively.

E. Frictional losses and chopping

Until now, we have ignored the effect of string friction and wall friction on the gastronomy signal from walls eating strings. In this subsection, we investigate how friction can affect the evolution of the wall-string network and hence the gastronomy signal.

First, we consider friction on the strings due to the Aharonov-Bohm force, Eq. (73). It can be shown [80,139,157] that the effect of this frictional force on the string equation of motion, (100) is to replace $\mathcal{H} \rightarrow \mathcal{H} + a(t)/L_f$, where $L_f = \mu/\beta_s T^3$ is known as friction length, which is effectively the reciprocal of the friction force per unit string mass. There are then four relevant scales (forces per unit mass) in the string equation of motion, with each dominating at a different stage in the evolution of the wall-string network:

- (a) $2Hv$ (Hubble)
- (b) $\frac{\beta_s T^3 v}{\mu}$ (String Friction)
- (c) $\frac{1}{R}$ (String Tension)
- (d) $\frac{\sigma}{\mu} = \frac{1}{R_c}$ (Wall Tension).

Consider first the network evolution when $R < R_c$, which is the pure string limit. In this case, strings will be damped by friction until the Hubble (a) and friction terms (b) are equal. For a radiation-dominated era, this occurs at time

$$t_f = \frac{M_{\text{Pl}}^3 \beta_s^2 C^3}{8\mu^2}, \quad (129)$$

where $C = (8\pi^3 g_*/90)^{-1/2}$ as before. After t_f , the Hubble (a) and string curvature (c) terms dominate; the strings oscillate freely and the network reaches the standard scaling regime. If $R_c > t_f$, then the walls do not dominate the string network until after the strings reach scaling, and the results of this section are unchanged. The condition for the wall to dominate the string dynamics only after t_f then occurs when

$$\frac{R_c}{t_{\text{DW}}} \geq \frac{\beta_s^{2/3}}{\epsilon} \quad (130)$$

is satisfied. For nearly all (μ, σ) with $t_* = R_c$, $R_c \gg t_{\text{DW}}$, and hence Eq. (130) is easily satisfied, and the gastronomy signal discussed in the previous subsection remains unchanged.

However, for $t_* = t_{\text{DW}}$, $R_c < t_{\text{DW}}$, and Eq. (130) is generally not satisfied. In this case, the walls dominate the string dynamics during the initial string friction era. In this scenario, the two largest terms in the string equation of motion around the time of domain wall formation are the string friction term (b) and the wall tension term (d). Balancing the two terms gives the string terminal velocity

$$v = \frac{\sigma}{\beta_s T^3} \simeq \frac{\epsilon}{\beta_s} \left(\frac{t}{t_{\text{DW}}} \right)^{3/2}, \quad (131)$$

valid until v becomes relativistic. Friction prevents the string-wall system from initially collapsing since the friction scale of the system,⁸

$$R_f \sim vt = t \left(\frac{t}{t_{\text{DW}}} \right)^{3/2} \frac{\epsilon}{\beta_s}, \quad (132)$$

can be smaller than R . Specifically, perturbations on the string larger than R_f remain stuck by friction, while those smaller than R have been smoothed out by friction and can move freely. The wall-bounded strings cease expanding conformally when R_f equals the string radius, $R = R(t_{\text{DW}})(t/t_{\text{DW}})^{1/2}$, which occurs at radius

⁸We find a more rigorous derivation of the evolution of the string curvature from the Euler-Lagrange equation of motion gives the same scaling. Also note the different scaling compared to pure strings when the string curvature and friction balance, which gives $R \propto t^{5/4}$, known as the Kibble regime [131,149].

$$R \approx R(t_{\text{DW}}) \times \text{Max} \left(1, \left(\frac{R(t_{\text{DW}})\beta_s}{t_{\text{DW}}\epsilon} \right)^{1/4} \right). \quad (133)$$

Unless $\epsilon \ll 1$ or $\beta_s \gg 1$, Eq. (133) occurs at or very close to the string curvature radius at wall formation, $R(t_{\text{DW}})$, since $R(t_{\text{DW}})/t_{\text{DW}} < 1$ in the friction regime. Thus, when $t_* = t_{\text{DW}}$, the strings oscillate highly relativistically nearly immediately after wall formation, even with string friction. Nevertheless, there are still frictional energy losses after the strings move freely shortly after t_{DW} . The power lost to Aharonov-Bohm friction for these pieces is given by Eq. (76). Since the energy of the wall-bounded string piece is dominated by walls in this case, $E \sim \sigma R^2$, Eq. (76) can be integrated to obtain the string-wall size vs time,

$$R(t) \approx R(t_{\text{DW}}) - \frac{\beta_s C^{3/2}}{\sigma G^{3/4}} (t_{\text{DW}}^{-1/2} - t^{-1/2}), \quad (134)$$

where we take $v \sim 1$. For $t > t_{\text{DW}}$, the curvature radius quickly decreases to its asymptotic size,

$$R_{\text{final}} \simeq R(t_{\text{DW}}) \left(1 - \frac{\beta_s}{\epsilon} \frac{t_{\text{DW}}}{R(t_{\text{DW}})} \right). \quad (135)$$

If the term in parenthesis remains of $\mathcal{O}(1)$, then the wall-bounded string pieces do not appreciably shrink due to friction and will decay via gravitational radiation. In such a scenario, the domain wall induced bump in Ω_{GW} right before decay, a feature of the $t_* = t_{\text{DW}}$ regime, still occurs but without the flat f^0 part of the spectrum to the right because the string network is frozen prior to t_{DW} and does not significantly emit gravitational waves. According to Eq. (135), the condition for the wall-bounded string pieces to remain long-lived is then

$$R(t_{\text{DW}}) \gtrsim \frac{\beta_s}{\epsilon} t_{\text{DW}}. \quad (136)$$

In the friction regime, it is generally the case that $R(t_{\text{DW}}) \ll t_{\text{DW}}$, in contrast to the frictionless scaling regime when $R \sim t$ at wall formation.⁹ As a result, if $t_* = t_{\text{DW}} < t_f$, then the wall-string system decays quickly

⁹If the number of strings in the horizon at string formation time t_μ is sufficiently dilute such that $(G\mu/\beta_s^2 C^2)^{1/4} \lesssim R(t_\mu)/t_\mu \lesssim 1$ [114,158], the strings are stretched with the scale factor $R(t)/t_\mu = \xi(t/t_\mu)^{1/2}$, where $\xi \equiv R(t_\mu)/t_\mu$. Since the horizon grows with t , the abundance of strings in the horizon increases with time. For sufficiently large string densities within the horizon, whether initially at t_μ or after increasing in the stretching regime, the curvature radius of strings enters the Kibble regime with $R(t)/t_\mu \sim (G\mu/\beta_s^2 C^2)^{1/4} (t/t_\mu)^{5/4}$, independent of whether the strings start in the stretching regime or Kibble regime. Only at the very beginning of the stretching regime, if $\xi_0 \sim 1$, or at the end of the Kibble regime does $R \sim t$, (the latter of which anyway marks the end of the friction era) can Eq. (136) be satisfied and a gastronomy signal be observed.

to friction unless $\beta_s \ll 1$. If $\beta_s \sim 1$ at wall formation, then the friction dominates and the wall-string system decays via friction in around a Hubble time, and the gastronomy signal is suppressed. This may eliminate the bump feature that occurs in $t_* = t_{\text{DW}}$ cosmologies, as shown, for example, by the rightmost contour of Fig. 16. Nevertheless, there can still be an appreciable gravitational wave pulse from walls bounded by strings in this scenario. This is because the number of string-bounded walls in the horizon in the friction era can be significant, giving rise to a brief, but significant pulse of gravitational waves similar to the monopole burst of Sec. V. Moreover, the gastronomy signal for walls eating strings for the case of $t_* = R_c$ is still observable and distinguishable from other gastronomy signals even without its bump due to its f^3 infrared spectrum.

In addition, after the string friction era, there can be friction on the walls from scattering with the bulk motion of the plasma [32,131]. Like string friction, wall friction is model dependent and gives rise to a temperature dependent retarding force [32,80],

$$F_w \sim -\beta_w T^4 v R^2, \quad (137)$$

where v is the velocity of the wall relative to the plasma, R the wall curvature radius, and

$$\beta_w \sim \sum_i w_i \frac{30\zeta(3)}{\pi^4} \quad (138)$$

characterizes the number of relativistic particles that scatter with the scalar field composing the wall, and where $w_i = 1$ for bosons and $6/7$ for fermions. If there are no particles with mass $m \ll T$ in the bath that strongly scatter with the scalar field of the wall, then $\beta_w = 0$, and the following discussion is inapplicable. Likewise, if the only particles that strongly scatter with the wall are of order v_μ , such as scalar field of the wall itself, β_w quickly becomes exponentially suppressed and the following discussion is inapplicable. If there exists such particles and $\beta_w \gtrsim 1$, then the balance of the friction force (137), with the wall tension force $F \sim \sigma R$, gives the terminal velocity of the walls,

$$v \sim \frac{4G\sigma t^2}{\beta_w c^2 R}, \quad (139)$$

in a radiation dominated era. We now follow the discussion of [32] but further generalize the authors' results to the case when $t_* = t_{\text{DW}}$, which was not considered previously. The wall friction scale is

$$R_f \sim vt \approx \sqrt{\frac{4G\sigma t^3}{\beta_w c^2}}, \quad (140)$$

whereas the string curvature of the infinite string-wall network scales as $R \sim t$ in the scaling regime. Perturbations

on the wall larger than R_f remain stuck by friction, while those smaller than R have been smoothed out by friction and can move freely. At $t = t_*$, the wall dominates the string dynamics, and normally, this would cause the walls to pull the strings into the horizon and oscillate at constant amplitude as discussed in Sec. VII B. However, the $R > R_f$ periphery of the wall and hence string boundary (which goes along for the ride) is conformally stretched until R_f equals the string radius, $R = R(t_*)(t/t_*)^{1/2}$, which occurs at time t_1 and curvature radius

$$t_1 \sim \frac{t_*}{\delta} \quad R(t_1) \sim \frac{t_*}{\sqrt{\delta}}, \quad (141)$$

where

$$\delta = \sqrt{\frac{G\sigma t_*}{\beta_w C^2}}, \quad (142)$$

valid for $t_* = R_c$ or $t_* = t_{\text{DW}}$. At time t_1 , the wall-bounded string pieces cease being conformally stretched and oscillate at constant size. Nevertheless, the walls lose energy via friction. The power lost to friction by the walls is

$$P_f = F_w v \sim -\frac{\beta_w c^2}{G t^2} R(t_1)^2 v^2, \quad (143)$$

where $v = \delta^{1/2}(t/t_1)^2$ for $t > t_1$ using Eqs. (139) and (141). The integral of (143) gives the energy of the system as a function of time,

$$E(t) = E(t_1) - \frac{1}{3} E(t_1) \left(\frac{t^3}{t_1^3} - 1 \right), \quad (144)$$

where $E(t_1) \sim \sigma R(t_1)^2 = G\sigma^2 t_1^3 / \beta_w C^2$ is the initial energy of the wall at t_1 . Equation (144) demonstrates that the walls lose most of their energy in a Hubble time after t_1 . The energy loss causes the size of the string-bounded walls to shrink until they become relativistic, which occurs at $t_2 \sim t_1$, and, according to (139), at $R(t_2) \sim t_*$. At this point, Eq. (144) is invalid, and we must return to Eq. (143) to describe the power lost to friction by the relativistic wall-string piece. If $t_* = R_c$, then the time at which the walls become relativistic coincides with the moment the strings return to dominating the dynamics of the shrinking wall-bounded string piece, that is, $R \approx R_c$ when v becomes 1. If $t_* = t_{\text{DW}}$, then $R > R_c$ when v becomes 1, and the walls still dominate the dynamics. However, it is easy to see that if the wall still dominates the dynamics for $v \sim 1$, then the curvature radius exponentially drops in time so that even for the case $t_* = t_{\text{DW}}$, the wall-bounded string pieces will shrink to R_c at $t \sim t_1$.

But the shrinking can continue further. Once the string dominates the dynamics and $v \sim 1$, the integration of the

power loss, Eq. (143), gives the curvature radius of the wall-bounded string piece as

$$R(t) = \left[\frac{1}{R(t_2)} - \frac{\beta_w c^2}{G\mu} \left(\frac{1}{t} - \frac{1}{t_2} \right) \right]^{-1}, \quad (145)$$

which asymptotically shrinks to

$$R_{\text{final}} = \frac{G\mu t_2}{\beta_w c^2} = R_c \delta. \quad (146)$$

For $\beta_w \gtrsim 1$, $\delta \ll 1$ and the wall-bounded string pieces shrink far below R_c and subsequently decay quickly via gravitational radiation. In this scenario, the gastronomy signal is again suppressed, even for $t_* = R_c$, unlike the case for string friction. However, this is highly model dependent and requires relativistic particles in the thermal bath to scatter off the domain wall far past wall formation so that $\beta_w \gtrsim 1$ still at t_1 . If the only particles that scatter with the wall have mass compared to v_σ , then $\beta_w \ll 1$ by t_1 so that the wall friction becomes negligible, and the gastronomy discussion of the previous subsections are unchanged.

Last, we mention that it is possible that the wall-bounded string pieces can potentially lose energy from self-intercommutation when they oscillate, thereby chopping themselves into finer pieces. If this occurs, then the chopping is likely to stop becoming important once the pieces slice and dice themselves below $R < R_c$, at which point the strings dominate the dynamics, and the wall-bounded string pieces dynamically behave similar to pure string loops. If this occurs, it only effects the $t_* = t_{\text{DW}}$ parameter space where the wall-bounded string pieces can have curvature radii $R > R_c$. Moreover, the final number of chopped pieces of size R_c will be greater than the usual $t_* = R_c$ cosmology because the total energy in the wall-bounded string pieces postchopping is similar to prechopping due to energy conservation.¹⁰ Furthermore, for an asymptotic chopped radius of $R \sim R_c$, the lifetime of the chopped wall-bounded string pieces is comparable to larger pieces with $R > R_c$ because the gravitational wave power at this radius is approximately proportional to the wall mass so that the lifetime is the same for string-bounded walls for any size $R \gtrsim R_c$. Thus, because the total energy density and lifetime of the chopped pieces remains similar to the prechopped pieces, the bump in the spectrum for $t_* = t_{\text{DW}}$ cosmologies should stay roughly the same height, if there was no chopping, but may be shifted to slightly higher frequencies because the pieces are smaller than before.

¹⁰The total energy density of the system pre- and postchopping may be somewhat smaller if the chopped pieces inherit a large translation kinetic energy, which can be redshifted away by the expansion of the Universe.

VIII. TOPOLOGICAL DEFECTS WASHED OUT BY INFLATION

Inflation exponentially dilutes all topological defects. This is useful for removing monopoles, for which even small relic abundances are in tension with present-day cosmology. However, other topological defects, such as superhorizon strings and domain walls, dilute slower than the background radiation and hence can replenish even after enduring many e -folds of inflation. Examples of symmetry breaking chains in Fig. 1, where this can occur, are

$$SO(10) \rightarrow G_{\text{SM}} \times \mathbb{Z}_2$$

$$SO(10) \rightarrow 3221D$$

since these chains “simultaneously” produce stable monopoles and strings and thus require the strings to be diluted by inflation too.

Recent work [72] found that if a string network forms early in inflation, then the strings can replenish enough such that bursts emanating from ultrarelativistic cusps can give an observable signal at frequencies around pulsar timing arrays. However, there is a limit to how many e -fold strings can be diluted and still leave an observable signal.

Limits on monopole flux are most stringent for monopoles that catalyze baryon number violation. Such bounds on the flux Φ are at no stricter than [159]

$$\Phi \lesssim 10^{-28} \text{ cm}^{-2} \text{ sr}^{-1} \text{ sec}^{-1}, \quad (147)$$

which requires at least 30 e -foldings of inflation to dilute, whereas strings can replenish after many more e -foldings [72]—up to about 54.

Domain walls, in principle, can also replenish after being diluted by inflation. The evolution of a domain wall network can be estimated by taking a conservative initial number density to be H_I^3 (the Kibble or scaling limit) and the initial mass of a domain wall to be σ/H_I^2 , where H_I is the value of Hubble during inflation. After formation, the domain wall is stretched by N e -foldings, and the number density is diluted by a factor e^{-3N} . Due to the superhorizon size, the walls are conformally stretched with the evolution of the curvature radius R stretching with the scale factor until horizon reentry when $HR = 1$. After horizon reentry, that is when the domain wall size is the Hubble size, the domain walls reach a scaling regime and $\rho_{\text{DW}} \approx \sigma/R \propto 1/t$, which is slower than all other energy densities bar the vacuum contribution. In order to not dominate the energy density today and taking $H = 10^{13}$ GeV, domain walls require nearly 100 e -foldings. In principle, if a small amount of the energy budget today is from domain walls, then a larger fraction could occur during recombination, implying a larger expansion rate in the early Universe. We leave the phenomenology of such a possibility to future work.

IX. SUMMARY

In this work, we have studied the formation, evolution, decay, and gravitational wave gastronomy signatures of hybrid topological defects. These objects, composed of two different dimensional topological defects bounded to each other, come in two flavors: cosmic strings bounded by monopoles and domain walls bounded by cosmic strings. As shown in Fig. 1, these hybrid defects are common in many breaking chains from $SO(10)$ to the Standard Model. As a result, if the early Universe reached sufficiently high temperatures, then it is possible that hybrid defects were once part of our cosmic history.

The relativistic motion of defects, and especially during the “devouring” of one defect by the other, leads to interesting gravitational wave signatures. We revisited the gravitational wave spectrum of strings unstable toward monopole pair creation in Sec. IV and found a range of monopole and string symmetry breaking scales that are observable at near-future gravitational wave detectors, including within the recent NANOGrav and PPTA signal region. Similarly, we estimated the gravitational wave signal from domain walls unstable toward string holes nucleating on their surface in Sec. VI. In both nucleation cases, the gravitational wave spectrum prior to nucleation behaves as a pure string or wall network, respectively. The frequency dependence of the nucleation gastronomy scenarios are summarized in Table I.

Note that since nucleation is an exponentially suppressed process, the defect can be long-lived, therefore, the scale size of the topological defect at decay can be large and hence emit in low frequencies observable at near future gravitational wave detectors. Nevertheless, while nucleation gastronomy scenarios typically involve easier to detect lower frequency gravitational waves, the likelihood of a nucleation gastronomy may be challenging as it requires a near degeneracy in symmetry breaking scales of the bulk and boundary defects.

TABLE I. A summary of the different gastronomy signals and the characteristic fingerprints of their gravitational wave spectra at low (IR) and high (UV) frequencies. Since each gastronomy signal has a unique combination of the spectral index in the IR and UV, it is possible to map a gravitational wave spectrum to a given gastronomy scenario and hence a subset of GUT symmetry breaking chains.

Cosmic course	IR	UV
Monopoles eating string network (nucleation)	f^2	f^0
Strings eating monopole network (collapse)	f^3	$\ln f \rightarrow f^{-1}$
Strings eating domain wall network (nucleation)	f^3	f^{-1}
Domain walls eating string network (collapse)	f^3	f^0

Other types of cosmological scenarios with hybrid defects, such as a monopole network becoming connected to (and eaten by) strings and string loops becoming filled with (and eaten by) domain walls, do not require any fine-tuning of the symmetry breaking energy scales. We constructed analytic models for these hybrid defects and found that they predict gravitational waves typically at high frequencies of order 10^{1-10} Hz, which will be explored by interferometers in some parts of parameter space, but will typically need new experimental techniques to detect the signal. Unlike nucleation, the gravitational wave signals for these gastronomy scenarios are typically high frequency because the hybrid defects decay around the time of string or domain wall formation, respectively. This can occur in the early Universe when the defects are physically small. If future high frequency detectors can observe such a signal, then they may be able to see unique spectral features as shown in Table I or even a characteristic bump on top of a pure string spectrum when domain walls eat strings. To confirm our analytic models describing the hybrid defects in this paper, numerical simulations will be needed.

Because all four gastronomy spectra are distinguishable by their UV and IR frequency dependence, a measurement around the peak of Ω_{GW} can be used to determine the IR and UV spectral dependence. In some cases this only requires detecting the spectra over a relative small frequency domain. It may then be possible to infer which of the four types of cosmic courses generated Ω_{GW} . Knowledge of the gastronomy course thus elucidates the hybrid defect which created that signal. Consequently, knowing that a certain hybrid defect existed in the early Universe can be used to narrow down the subset of GUT symmetry chains that produce that hybrid defect. Moreover, the amplitude and frequency dependence Ω_{GW} can be used to infer the scales of symmetry breaking associated with “both” the boundary and bulk defects. Thus, gravitational wave gastronomy has the ingredients to infer many fundamental properties of nature.

APPENDIX A: HOMOTOPY SELECTION RULES

As can be seen from Fig. 1, all hybrid defects from the breaking of $SO(10)$ involve a symmetry breaking chain where the homotopy group of the first symmetry breaking step has a higher group number n than the succeeding one, e.g., for monopole-bounded strings, the monopoles form prior to strings. In order to show that the feature is a generic feature of any symmetry breaking group, we derive homotopy selection rules leading to hybrid defects.

For any groups $G \supset H \supset K$, there is a fiber bundle¹¹

$$H/K \rightarrow G/K \rightarrow G/H. \quad (\text{A1})$$

It leads to the exact sequence of homotopy groups,

$$\begin{aligned} \cdots \rightarrow \pi_n(H/K) \rightarrow \pi_n(G/K) \rightarrow \pi_n(G/H) \\ \rightarrow \pi_{n-1}(H/K) \rightarrow \pi_{n-1}(G/K) \rightarrow \pi_{n-1}(G/H) \rightarrow \cdots \end{aligned} \quad (\text{A2})$$

with each arrow indicating a homomorphism, whose image is equal to the kernel of the following homomorphism. For a topological defect of dimension k in three-dimensional space, its stability is guaranteed by π_{2-k} . If a defect is stable at one step of symmetry breaking, then we need a nontrivial $\pi_{2-k}(H/K)$ or $\pi_{2-k}(G/H)$, while if it is unstable in the whole theory, then we need $\pi_{2-k}(G/K) = I$. This tells us to study a part of the exact sequence, $(n = 2 - k)$,

$$I = \pi_n(G/K) \rightarrow \pi_n(G/H) \rightarrow \pi_{n-1}(H/K), \quad (\text{A3})$$

or

$$\pi_n(G/H) \rightarrow \pi_{n-1}(H/K) \rightarrow \pi_{n-1}(G/K) = I. \quad (\text{A4})$$

In the first case (A3), the image of the homomorphism between $\pi_n(G/K)$ and $\pi_n(G/H)$ is I . Thus, the kernel of the homomorphism between $\pi_n(G/H)$ and $\pi_{n-1}(H/K)$ is I , implying the homomorphism is injective and hence $\pi_n(G/H) \subseteq \pi_{n-1}(H/K)$. Therefore, any element of $\pi_n(G/H)$ at the first stage of symmetry breaking can be “undone” by an element of $\pi_{n-1}(G/K)$ at the second stage of symmetry breaking, and hence a k -dimensional defect formed at the first phase transition can be destabilized by a $(k + 1)$ -dimensional defect formed at the second phase transition. For example, a string can be filled with a wall, or monopoles can be connected by a string to destabilize the defect.

In the second case (A4), the kernel of the homomorphism between $\pi_{n-1}(H/K)$ and $\pi_{n-1}(G/K)$ is $\pi_{n-1}(H/K)$. Thus, the image of the homomorphism between $\pi_n(G/H)$ and $\pi_{n-1}(H/K)$ is $\pi_{n-1}(H/K)$ and hence $\pi_n(G/H) \supseteq \pi_{n-1}(H/K)$. Therefore, any element of $\pi_{n-1}(H/K)$ at the second stage of the symmetry breaking can be undone by an element of $\pi_n(G/H)$ at the first stage of symmetry breaking,

¹¹For a proof, see <https://ncatlab.org/nlab/show/principal+bundle>.

and hence a $(k + 1)$ -dimensional defect formed at the second phase transition can be destroyed by the production of a k -dimensional defect formed at the first transition. For example, a string can be cut by the nucleation of a monopole-antimonopole pair, or a domain wall can be punctured by the nucleation of a string-bounded hole.

In summary, the lower dimensional topological defect (boundary defect) of a hybrid defect forms earlier than the one-dimensional higher topological defect (bulk defect) that it attaches to.

APPENDIX B: ACTION OF A STRING-BOUNDED DOMAIN WALL

Here we derive the Lagrangian, (99), from Sec. VII. Since the world volumes of the string and wall are invariant under reparametrizations of the coordinates ζ , we choose a coordinate system on the wall and string such that $\zeta^0 = \eta$, $\zeta^1 = \theta$, $\zeta^2 = \rho$, where $0 \leq \theta < 2\pi$ parametrizes the polar direction in the plane of the wall, and $0 \leq \rho \leq \rho_{\text{string}}$ parametrizes the radial direction in the plane of the wall. ρ_{string} is the boundary of the wall located at the attached string, as shown in Fig. 17. In this basis, $X^\mu = (\eta, \mathbf{X})$, $Y^\mu = X^\mu|_{\rho_{\text{string}}}$, $(\partial_\rho \mathbf{X})^2 = 1$, and $\partial_\rho \mathbf{X} \cdot \partial_\theta \mathbf{X} = 0$.

The determinant of the induced metric on the wall may be written as

$$\gamma = a^6(\eta) \begin{vmatrix} 1 - (\partial_\eta \mathbf{X})^2 & -\partial_\eta \mathbf{X} \cdot \partial_\theta \mathbf{X} & -\partial_\eta \mathbf{X} \cdot \partial_\rho \mathbf{X} \\ -\partial_\eta \mathbf{X} \cdot \partial_\theta \mathbf{X} & -(\partial_\theta \mathbf{X})^2 & 0 \\ -\partial_\eta \mathbf{X} \cdot \partial_\rho \mathbf{X} & 0 & -1 \end{vmatrix} \quad (\text{B1})$$

$$= \frac{a^6(\eta)}{\gamma_{\perp,w}^2} (\partial_\theta \mathbf{X})^2, \quad (\text{B2})$$

FIG. 17. Coordinate parametrization of a wall-bounded string. The coordinates $\xi^1 = \rho$ and $\xi^2 = \theta$ are orthogonal and parametrize the radial and azimuthal directions in the plane of the wall, respectively. The string lies on the boundary of the wall at the coordinate ρ_{string} .

where we define $\gamma_{\perp,w} = (1 - v_{\perp,w}^2)^{-1/2}$ as the Lorentz factor for motion perpendicular to the wall. In going from Eqs. (B1) and (B2), we decompose the wall velocity into perpendicular and tangential motion, $\partial_\eta \mathbf{X} = v_{\perp,w} \hat{\theta} \times \hat{\rho} + \mathbf{v}_{\parallel}$, where $\mathbf{v}_{\parallel} = (\partial_\eta \mathbf{X} \cdot \partial_\rho \mathbf{X}) |\partial_\rho \mathbf{X}|^{-1} \hat{\rho} + (\partial_\eta \mathbf{X} \cdot \partial_\theta \mathbf{X}) |\partial_\theta \mathbf{X}|^{-1} \hat{\theta}$. As indicated by Eq. (B2), only the motion perpendicular to the wall is physical and any use of “ v_w ” in the text means $v_{\perp,w}$. Similarly, the determinant of the induced metric on the string world sheet is

$$\Upsilon = a^4(\eta) \begin{vmatrix} 1 - (\partial_\eta \mathbf{Y})^2 & -\partial_\eta \mathbf{Y} \cdot \partial_\theta \mathbf{Y} \\ -\partial_\eta \mathbf{Y} \cdot \partial_\theta \mathbf{Y} & -(\partial_\theta \mathbf{Y})^2 \end{vmatrix} \quad (\text{B3})$$

$$= \frac{a^4(\eta)}{\gamma_{\perp,s}^2} (\partial_\theta \mathbf{Y})^2, \quad (\text{B4})$$

where $\mathbf{Y} = \mathbf{X}(\theta, \rho_{\text{string}})$, and $\gamma_{\perp,s} = (1 - v_{\perp,s}^2)^{-1/2}$ is the Lorentz factor for motion perpendicular to the string, which will dominantly be in the tangent plane of the wall when the wall dominates the string dynamics. As a result of Eqs. (B2) and (B4), the combined action of the domain wall and string system (98) becomes

$$S = -\sigma \int d\eta \int_0^{2\pi} d\theta \left| \frac{d\mathbf{X}}{d\theta} \right| \int_0^{\rho_{\text{string}}} d\rho \frac{a^3(\eta)}{\gamma_{\perp,w}} - \mu \int d\eta \int_0^{2\pi} d\theta \left| \frac{d\mathbf{Y}}{d\theta} \right| \frac{a^2(\eta)}{\gamma_{\perp,s}}. \quad (\text{B5})$$

Because the eating of the wall by the string converts wall rest mass energy to string kinetic energy, we expect $\gamma_{\perp,s} > \gamma_{\perp,w} \sim 1$,¹² and for the string velocity $v_{\perp,s}$ to be directed in the tangent plane of the wall. As a result, we analyze Eq. (B5) in the limit $\gamma_{\perp,w} \rightarrow 1$, where the perpendicular wall velocity is small and subdominant compared to the string velocity. In addition, we take the string boundary to be a circular loop $\mathbf{Y} = \mathbf{r}_s$ of coordinate radius $\mathbf{r}_s$ [physical radius $\mathbf{R}_s = \mathbf{r}_s a(\eta)$], though we do not expect more realistic loops that are not perfectly circular to behave quantitatively different since the key relationship between wall mass and string radius, $M_{\text{DW}} \sim \sigma |\mathbf{R}_s|^2$, will still hold for more complicated loop geometries, and it is this energy which is transferred to the string as kinetic energy. Under

¹²Simulations of domain walls without strings, which do not transfer any mass energy into string kinetic energy, only have perpendicular rms velocities mildly relativistic, $v_{\perp,w} \sim 0.3$ [143], while pure string loops have intermediate rms velocities $v_{\perp,s} = \sqrt{2} \simeq .707$. Strings attached to walls become even more relativistic from the conversion of wall rest mass to string kinetic energy during the eating process (see Fig. 12), which makes this approximation better. Only for enclosed domain walls without strings, or vacuum bags, which collapse relativistically under their own tension, do we expect $v_{\perp,w}$ to be significant.

these assumptions, we obtain the Lagrangian for a domain wall disc with a circular string loop boundary in Eq. (99).

For a nucleated string hole, the string forms the inner boundaries of a domain wall, and the integration over the radial coordinate ρ in Eq. (B5) then begins at $\rho = \rho_{\text{string}}$ up to some arbitrary bulk ρ . The effect is thus a relative

minus sign in the Lagrangian Eq. (99) between the string and domain wall terms. In a nonexpanding universe, or for subhorizon times and distances, the solution to the Euler-Lagrange equation of motion is the relativistic rocket, of Eq. (B5), which is in agreement with results found in [80].
