## RESEARCH ARTICLE

10.1029/2022JA031081

### Key Points:

- Theory and global simulations of magnetopause surface waves' effects on the aurorae, ionosphere, and ground magnetic field are investigated
- We predict poleward-moving periodic aurora, convection vortices, and ground pulsations, with larger latitudinal scales than Alfvén modes
- Amplitudes of all signals peak near the projection of the inner/equatorward edge of the magnetopause rather than the open-closed boundary

**Abstract** Surface waves on Earth's magnetopause have a controlling effect upon global magnetospheric dynamics. Since spacecraft provide sparse in situ observation points, remote sensing these modes using ground-based instruments in the polar regions is desirable. However, many open conceptual questions on the expected signatures remain. Therefore, we provide predictions of key qualitative features expected in auroral, ionospheric, and ground magnetic observations through both magnetohydrodynamic theory and a global coupled magnetosphere-ionosphere simulation of a magnetopause surface eigenmode. These show monochromatic oscillatory field-aligned currents (FACs), due to both the surface mode and its non-resonant Alfvén coupling, are present throughout the magnetosphere. The currents peak in amplitude at the equatorward edge of the magnetopause boundary layer, not the open-closed boundary as previously thought. They also exhibit slow poleward phase motion rather than being purely evanescent. We suggest the upward FAC perturbations may result in periodic auroral brightenings. In the ionosphere, convection vortices circulate the poleward moving FAC structures. Finally, surface mode signals are predicted in the ground magnetic field, with ionospheric Hall currents rotating perturbations by approximately (but not exactly) 90° compared to the magnetosphere. Thus typical dayside magnetopause surface modes should be strongest in the East-West ground magnetic field component. Overall, all ground-based signatures of the magnetopause surface mode are predicted to have the same frequency across  $L$ -shells, amplitudes that maximize near the magnetopause's equatorward edge, and larger latitudinal scales than for field line resonance. Implications in terms of ionospheric Joule heating and geomagnetically induced currents are discussed.

**Plain Language Summary** Waves on the boundary of the magnetosphere, the magnetic shield established by the interplay of the solar wind with Earth's magnetic field, play a controlling role on energy flow into our space environment. While these waves can be observed as they pass over satellites in orbit, due to the small number of suitable satellites available it would be helpful to be able to detect these waves from the surface of the Earth with instruments that measure the northern/southern lights, motion of the top of our atmosphere, or magnetic field on the ground. However, we do not currently understand what the signs of these waves should look like in such instruments. In this paper we develop theory and use computer simulations of these boundary waves to predict key features one might expect to measure from the ground. Based on these predictions, we also discuss how the waves might contribute to the hazards of space weather.

## 1. Introduction

The interaction between the solar wind and Earth's magnetosphere results in a zoo of dynamical plasma waves. Those with wavelengths comparable to the size of the magnetosphere are well described by magnetohydrodynamics (MHD) and due to their corresponding frequencies, ~0.1–100 mHz (Jacobs et al., 1964), are known as ultra-low frequency (ULF) waves. ULF waves play important roles in space weather processes such as substorms (e.g., Kepko & Kivelson, 1999), wave-wave (e.g., Li et al., 2011) and wave-particle (e.g., Turner et al., 2012) interactions, magnetosphere-ionosphere (MI) coupling (e.g., Keiling, 2009), and geomagnetically induced currents (e.g., Heyns et al., 2021). In addition to familiar Alfvén and fast/slow magnetosonic body MHD waves (those which may freely propagate through plasma volumes), sharp discontinuities separating regions with different physical

parameters, such as the magnetopause and plasmopause, allow for collective modes—surface waves (Chen & Hasegawa, 1974; Goedbloed, 1971; Kruskal & Schwarzschild, 1954). Surface modes lead to mass, momentum, and energy transport across the boundary, consequently manifesting a controlling effect on global magnetospheric wave dynamics (e.g., Kivelson & Chen, 1995). As with the body waves, theory behind surface waves has largely been developed in simplified box model magnetospheres, typically with homogeneous half-spaces. Within these the surface mode is inherently compressional, being described by two evanescent fast magnetosonic waves (one in each half-space such that perturbations decay with distance from the boundary) that are joined by boundary conditions which ensure pressure balance and continuity of normal displacement across the interface (Plaschke & Glassmeier, 2011; Pu & Kivelson, 1983). On each side the magnetosonic relation

$$k_n^2 = -k_\perp^2 - k_\parallel^2 + \frac{\omega^4}{\omega^2 v_A^2 + c_s^2 (\omega^2 - k_\parallel^2 v_A^2)} \quad (1)$$

holds, where  $n$  represents the direction normal to the discontinuity, and  $v_A$  and  $c_s$  are the Alfvén and sound speeds respectively (see Notation). Under incompressibility, the last term of Equation 1 may be neglected and the normal wavenumber is imaginary. In contrast, if this assumption is not valid or if waves are damped/unstable then  $k_n$  may be complex, exhibiting both evanescence and normal phase motion (M. O. Archer et al., 2021, hereafter A21; Pu & Kivelson, 1983). The dispersion relation for incompressible surface waves in a box model can be analytically solved. Applied to the magnetopause, for zero magnetic shear across boundary (equivalent to northward interplanetary magnetic field; IMF) and no background flows, it is (Plaschke & Glassmeier, 2011)

$$\omega = k_\parallel \sqrt{\frac{B_{msp}^2 + B_{msh}^2}{\mu_0(\rho_{msp} + \rho_{msh})}} \approx k_\parallel \frac{B_{msp}}{\sqrt{\mu_0 \rho_{msh}}} \quad (2)$$

where  $msp$  refers to the magnetosphere and  $msh$  the magnetosheath. The boundary conditions of closed magnetic field lines at the northern and southern ionospheres impose quantized wavelengths along the field (Chen & Hasegawa, 1974), forming an eigenmode of the system. On the dayside, where magnetosheath flows are smaller, this magnetopause surface eigenmode (MSE) is expected to occupy frequencies below 2 mHz (M. O. Archer & Plaschke, 2015; Plaschke et al., 2009). Such low eigenfrequencies are a result of the combination of magnetic fields and densities from both sides of the magnetopause, making it the lowest frequency magnetospheric normal mode and highly penetrating. However, in the flanks the faster magnetosheath velocities are expected to dictate the wave frequency (O. Kozyreva et al., 2019; Plaschke & Glassmeier, 2011), rather than the extent of the field lines, yielding shorter wavelengths and periods. In the absence of continuous driving or instabilities, surface modes on a boundary of finite thickness are strongly damped, with this thought to be primarily due to mode conversion to Alfvén waves and spatial phase mixing within the boundary layer rather than dissipation in the ionosphere or due to the presence of the ionosphere-Earth boundary (Chen & Hasegawa, 1974).

Magnetopause surface modes may be excited by several driving processes, either external or internal to the magnetosphere. External mechanisms include upstream (solar wind, foreshock, or magnetosheath) pressure variations, which may be either quasi-periodic (e.g., Sibeck et al., 1989) or impulsive (e.g., Shue et al., 2009), and the Kelvin-Helmholtz instability (KHI) due to velocity shears (e.g., Fairfield et al., 2000). Internal processes, such as the drift mirror instability, can generate compressional ULF waves within the low- and high-latitude magnetospheric boundary layer (Constantinescu et al., 2009; Nykyri et al., 2021), which may also lead to surface wave growth at the magnetopause. There has been much evidence of magnetopause surface waves from spacecraft observations, particularly in the magnetospheric flanks where KHI-generated waves are thought to be prevalent (e.g., Kavosi & Raeder, 2015; Southwood, 1968). However, only recently was MSE, as proposed by Chen and Hasegawa (1974), discovered through multi-spacecraft observations on the dayside magnetosphere following impulsive external driving (M. O. Archer et al., 2019).

Understanding the fundamental properties and potential impacts of magnetopause surface modes within a realistic magnetospheric environment has necessitated the use of global MHD simulations (e.g., S. G. Claudepierre et al., 2008; Hartinger et al., 2015, henceforth H15). These have revealed surface waves might lead the entire magnetosphere to oscillate at the surface mode frequency by coupling to body MHD waves such as Alfvénic field line resonance (FLR) or fast magnetosonic waveguide modes (WM; Merkin et al., 2013; A21). Confirming such a global system response is challenging with in situ spacecraft observations. For any particular event, only a few

observation points are available from current missions (e.g., Cluster, THEMIS, MMS). Statistical studies are also difficult due to the highly variable conditions present throughout geospace, which influence the properties of ULF waves (M. O. Archer & Plaschke, 2015; M. O. Archer et al., 2015). On the other hand, ground-based instruments such as all-sky imagers (e.g., Donovan et al., 2006; Rae et al., 2012), radar (e.g., Nishitani et al., 2019; Walker et al., 1979), and ground magnetometers (e.g., Gjerloev, 2009; Mathie et al., 1999) provide good coverage of the near-Earth signatures of ULF waves. While they offer the possibility of remote sensing the magnetopause surface mode, we need to understand how its energy couples through the intervening regions. The theory behind ionospheric and ground effects of ULF waves has focused on the Alfvén mode (e.g., Hughes & Southwood, 1974, 1976), whereas the surface mode is fundamentally compressional. Several open conceptual questions about the nature of surface modes in these regions remain. It is also difficult to confidently distinguish with ground-based instruments between surface waves, either on the magnetopause (Glassmeier, 1992; Glassmeier & Heppner, 1992; Kivelson & Southwood, 1991) or low latitude boundary layer (Lyatsky & Sibeck, 1997; Sibeck, 1990), and propagating body waves near these boundaries (Tamao, 1964a, 1964b; Araki & Nagano, 1988; Slinker et al., 1999), especially as surface waves may excite secondary body waves (Southwood, 1974; A21).

It is not clear whether magnetopause surface waves are expected to directly affect the ionosphere. Kivelson and Southwood (1988) consider the currents and boundary conditions associated with MHD waves in a box model. They argue surface waves affect the ionosphere only across the thin transition layer. This work was, however, applied to the plasmopause, avoiding the complication with the magnetopause that adjacent magnetosheath field lines do not terminate in the polar cap (O. Kozyreva et al., 2019). Other theoretical models have focused on closed field lines Earthward of the boundary, considering field-aligned current (FAC) generation due to coupling between the compressional and Alfvén modes in an inhomogeneous/curvilinear magnetosphere (Sibeck, 1990; Southwood & Kivelson, 1990, 1991). The models all predict FACs communicate (tailward traveling) magnetopause disturbances to the ionosphere, resulting in so-called traveling convection vortices (TCVs). These were first inferred from ground magnetometer observations (Friis-Christensen et al., 1988) and can also be observed directly through radar observations (e.g., Bristow et al., 1995). Discrete auroral emission might also result from precipitating electrons which carry these FACs (Greenwald & Walker, 1980). The models, however, do not make predictions about the magnetopause surface mode directly. In particular, they circumvent the question of how the ionosphere is affected by field lines within (and close to) the boundary layer. Furthermore, auroral brightenings and TCVs are expected for any magnetospheric process which results in FACs, for example, FLR (Greenwald & Walker, 1980), hence predictions of how to distinguish effects caused by surface waves and other mechanisms are required.

The direct ground magnetic field signatures of surface waves are also poorly understood, even during confirmed case studies from in situ spacecraft observations (M. O. Archer et al., 2019; He et al., 2020). Kivelson and Southwood (1988) suggest the surface mode may be screened from the ground due to the thin ionospheric region affected, similar to with small wavelength Alfvén modes (Hughes & Southwood, 1976). They conclude the magnetic signal on the ground might be similar to that in the magnetosphere, that is, not rotated by  $\sim 90^\circ$  as Alfvén waves are (Hughes, 1974; Hughes & Southwood, 1974). However, vortical ground magnetic signals are often observed by high-latitude magnetometer networks, being associated with TCVs (e.g., Glassmeier, 1992; Glassmeier & Heppner, 1992; Hwang et al., 2022). This potentially calls the theoretical prediction into question or signals intermediate Alfvén waves may be involved.

Finally, it is not clear where auroral, ionospheric, and ground magnetic signals of magnetopause surface waves should map to. Intuitively one might expect them around the open-closed boundary (OCB) of magnetic field lines. O. Kozyreva et al. (2019) suggest that short-lived quasi-periodic motions of the OCB in auroral keograms and ground magnetic oscillations near the OCB with large latitudinal scales and similar periodicities across *L*-shells might distinguish magnetopause surface modes from the Alfvén continuum, presenting potential case studies. However, Pc5-6 band (periods  $\sim 3$ –15 min) oscillations in ground magnetometer data have been shown to peak systematically equatorward of optical and ionospheric proxies for the cusp OCB by  $1$ – $3^\circ$  (O. Kozyreva et al., 2019; V. A. Pilipenko et al., 2017, 2018). In the absence of conjugate space-based observations, conclusions have been mixed over whether these results relate to MSE and what the implications are for its excitation efficiency.

To resolve these open questions, we employ MHD theory and a global MI-coupling simulation of MSE. Since MSE are the lowest frequency normal mode of the magnetosphere, they allow us to better understand the direct

effects of surface waves on the dayside aurorae, ionosphere, and ground magnetic field without the complications of secondary coupled wave modes. We aim to detail the physical processes that lead to these signatures, yielding specific qualitative predictions that might enable crucial remote-sensing observations of magnetopause surface modes in the future.

## 2. Box Model Theory

We first consider a box model magnetosphere. These straighten the geomagnetic field lines into a uniform field bounded by northern and southern ionospheres (Radoski, 1971; Southwood, 1974). While this is an unrealistic simplification (e.g., O. Kozyreva et al., 2019), it is used here to gain initial qualitative insight.

### 2.1. Method

We use the same model setup as Plaschke and Glassmeier (2011), who derived the magnetospheric signatures of incompressible MSE. The model equilibrium consists of two uniform half-spaces, the magnetosheath and magnetosphere, separated by the magnetopause discontinuity at  $x = 0$ . The geomagnetic field is confined to  $x > 0$  and points in the  $z$ -direction. Thus close to the MI-interface,  $x$  is directed equatorward and  $y$  is westward. Plaschke and Glassmeier (2011) derived the currents associated with surface waves in a box model by finding solutions on closed field lines and requiring continuity of pressure and normal velocity across the boundary. They showed the currents are sinusoidal and contained within the infinitesimally thin boundary, that is, the last shell of closed field lines, which we refer to as magnetopause currents. These magnetopause currents have field-aligned components, particularly at the MI-interface. Fast magnetosonic waves are not expected to have FACs in infinite uniform media, only Alfvén waves lead to these, hence generally fast magnetosonic modes are not expected to couple to the ionosphere. The surface mode, however, is unique as a fast mode which supports FACs at the interface of two uniform half-spaces due to the nonuniformity at this location. A complementary view considers amplitudes of the different MHD modes through the divergence and curl of electric field perturbations  $\delta\mathbf{E}$  (Yoshikawa & Itonaga, 1996, 2000), where  $(\nabla \times \delta\mathbf{E})_{\parallel}$  gives the fast/compressional mode and  $\nabla \cdot \delta\mathbf{E}$  yields the Alfvén/shear mode. Applying this to the Plaschke and Glassmeier (2011) analytic solutions reveals that in the two uniform half-spaces the surface wave is purely compressional ( $\nabla \cdot \delta\mathbf{E} = 0$ ), whereas inside the boundary layer there are non-zero amplitudes for both shear and compressional modes (via Gauss' and Stokes' theorems respectively).

Plaschke and Glassmeier (2011) suggested the surface waves' FACs at the MI-interface might close in the ionosphere. We, therefore, extend their model to incorporate a finite conductivity thin-shell ionosphere using the electrostatic MI-coupling method (Goodman, 1995; Janhunen, 1998; Ridley et al., 2004; Wolf, 1975), valid since surface waves occupy such low frequencies (Lotko, 2004). This works by determining the disturbance ionospheric potential  $\delta\psi_{isp}$  through current continuity, which for the northern hemisphere is given by

$$\begin{aligned}\delta j_r &= \nabla_{\perp} \cdot (\boldsymbol{\Sigma} \cdot \nabla \delta\psi_{isp})_{\perp} \\ &= \nabla_{\perp} \cdot \left[ \begin{pmatrix} \Sigma_P & -\Sigma_H \\ \Sigma_H & \Sigma_P \end{pmatrix} \cdot \nabla \delta\psi_{isp} \right] \\ &= \Sigma_P \left( \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \right) \delta\psi_{isp}\end{aligned}\quad (3)$$

where  $\delta j_r$  are the vertical currents (pointing radially/upwards) at the MI-interface from Plaschke and Glassmeier (2011), and  $\boldsymbol{\Sigma}$  denotes the height-integrated conductivity tensor consisting of Pedersen ( $P$ ) and Hall ( $H$ ) conductances, both assumed to be uniform. Equation 3 is solved numerically using the 2D Laplacian's Green's function

$$\delta\psi_{isp}(x, y) = \iint dx' dy' \frac{\delta j_r(x', y')}{\Sigma_P} \frac{\ln\left(\sqrt{(x-x')^2 + (y-y')^2}\right)}{2\pi}\quad (4)$$

from which the ionospheric electric field and currents are determined. Finally, magnetic field perturbations at some location  $\mathbf{r}$  are calculated using the Biot-Savart law

$$\delta\mathbf{B}(\mathbf{r}) = \frac{\mu_0}{4\pi} \iiint d^3\mathbf{r}' \frac{\delta\mathbf{j}(\mathbf{r}') \times (\mathbf{r} - \mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|^3}\quad (5)$$

which can be computed for the magnetopause, Pedersen, and Hall current systems separately (Rastätter et al., 2014).

## 2.2. Results

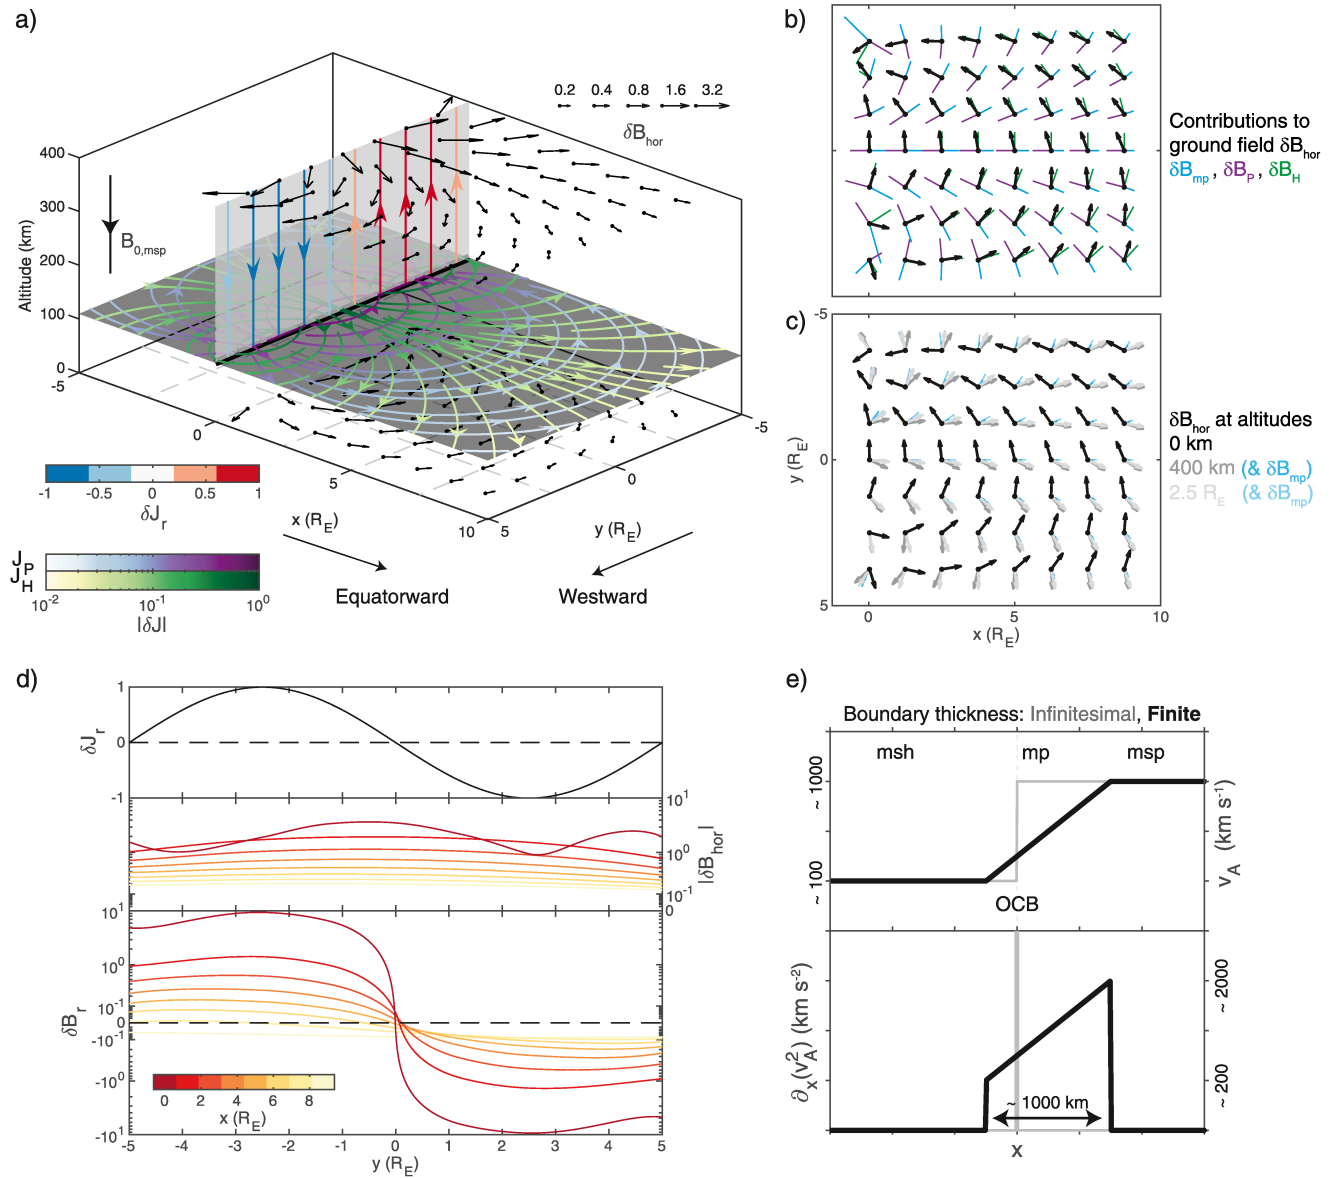

The model used typical dayside field line lengths of  $25 R_E$ , ionospheric conductances  $\Sigma_p = \Sigma_H = 5 \text{ S}$  valid for sunlit high-latitude regions, and zero magnetic shear across the magnetopause. We present results for one example surface mode, a localized perturbation with wavelength of  $2\pi/k_z = 50 R_E$  along the field (fundamental mode) and  $2\pi/k_y = 10 R_E$  azimuthally, based on previous simulation results (A21; M. O. Archer et al., 2022, hereafter A22). This is applied to a single time, shown in Figure 1a, since the entire pattern will propagate along  $y$ . The model size is twice the dimensions of that shown, to mitigate potential edge effects.

Figure 1a shows the Pedersen currents (purple) provide current closure in the East-West direction for the FACs. This is unlike in FLRs where closure is typically North-South (e.g., Greenwald & Walker, 1980). While the Pedersen currents are strongest along the OCB, due to the finite conductivity they spread out significantly across the ionosphere too. Their magnitudes fall off with distance from the OCB, but extend well beyond the  $1.56 R_E$  evanescent  $e$ -folding scale of the magnetospheric signatures, given by  $|k_x|^{-1} = (k_y^2 + k_z^2)^{-1/2}$ . Pedersen current patterns result in Hall current vortices (green) surrounding the FAC sources/sinks at the OCB. Their sense of rotation is clockwise for downward FACs and anticlockwise for upward FACs. Hall current magnitudes decrease with distance identically to the Pedersen currents, due to the conductivities used. Since ionospheric velocities are given by the  $\mathbf{E} \times \mathbf{B}$  drift, Pedersen currents result in TCVs colocated with the Hall current vortices but with the opposite sense of rotation. As the background magnetic field is uniform in this model, convection speeds also fall off similarly with distance from the OCB.

We now focus on the directions of the horizontal magnetic field perturbations, shown in Figure 1a as black arrows above and below the ionosphere. The ground magnetic signals exhibit a vortical pattern centered at the midpoint of the FACs. Figure 1b shows the relative contributions of different current systems (colors) to the overall horizontal field (black). This reveals the field points mainly in the direction of the Hall current contribution, with magnetopause and Pedersen current magnetic fields largely opposing one another. In the case of an infinite plane Alfvén wave (for vertical background field and uniform conductances) the ground magnetic field is entirely dictated by Hall currents with FAC and Pedersen contributions canceling (Hughes, 1974). However, we notice in Figure 1b that the total horizontal field is slightly misaligned from the Hall current contribution, due to magnetopause and Pedersen contributions no longer perfectly canceling. This occurs because, in the case of a surface wave, while the largest contributions to the ground field from the Hall and Pedersen currents still arise from above the ground station, the FACs into the ionosphere are confined to the OCB and thus are generally not directly overhead. This results in the misalignment growing with distance from the OCB, as well as very close to the OCB but on the outer edges of the localized FACs, as can be seen in Figure 1b.

Figure 1a shows that the horizontal field perturbations above and below the ionosphere are rotated from one another, seemingly by right angles. While an exactly  $90^\circ$  rotation would be expected for a plane Alfvén wave here (Hughes, 1974; Hughes & Southwood, 1974), Kivelson and Southwood (1988) suggested that no rotation in the field might occur sufficiently far from a surface wave. We find this not to be the case for up to the  $\sim 6 e$ -folding lengths shown. Panel c compares the directions of the ground field (black) to those at two altitudes above the ionosphere (grays). From these it is clear this rotation is not  $90^\circ$  and that the rotation angle also depends on altitude. This is because ionospheric Pedersen and Hall currents contribute to the magnetic field above the ionosphere, as evidenced by the blue lines which show only the field due to magnetopause currents (less sensitive to altitude). The difference between the gray and blue arrows grow with distance from the OCB, for similar reasons as to which current systems are closest. Such an effect would be less prominent with a plane Alfvén wave since FACs permeate space above the ionosphere. Above the ionosphere, the direction of the magnetic field due to only magnetopause currents are much closer to  $90^\circ$  different from the ground than the total field. The discrepancy from a right angle is exactly that due to the non-cancellation of magnetopause and Pedersen currents on the ground shown in panel b. This discrepancy will vary quantitatively with ionospheric conductivity and surface mode wavelength.

We now consider both horizontal and vertical components of the ground magnetic field. The horizontal field magnitudes shown in Figure 1d clearly show an overall decreasing trend with distance from the OCB (colors).

**Figure 1.** Results from box model theory at the northern ionosphere. (a) Streamlines of the perturbation magnetopause (red/blue), Pedersen (purple) and Hall (green) currents. Horizontal magnetic perturbations on the ground and above the ionosphere are shown as black arrows. (b) Directions and relative magnitudes of the current system contributions to the horizontal ground magnetic field (colors) normalized by the total horizontal perturbation (black) at each position. (c) Horizontal directions of the total magnetic perturbations on the ground (black) and above the ionosphere (gray). Contribution from magnetopause currents for the latter are shown in blue. (d) Magnetopause current variation with azimuth (top) along with the horizontal (middle) and vertical (bottom) ground magnetic perturbations at different equatorward distances (colors). (e) Comparison of Alfvén speed profiles and associated current coupling for an infinitesimally thin (gray) and finite thickness (black) magnetopause.

The vertical component has the same sense as the FACs into the ionosphere, that is, reversing direction at  $y = 0$ . The vertical component's magnitude also decreases with distance from the OCB. Close to the OCB the vertical component has root mean squared (RMS) values up to  $\sim 3$  times larger than the horizontal component. However, its RMS drops off much more quickly with distance, with them becoming equal at  $x \sim 0.45 R_E$  ( $k_x x \sim 0.3$ ), hence is largely negligible at further distances. The horizontal and total magnetic field magnitudes on the ground have RMS values  $1.2\text{--}2\times$  and  $1\text{--}1.7\times$  those of the incident/reflected waves, that is, only including the magnetopause currents (when all current systems are considered above the ionosphere the ratios become  $\sim 0.6\times$ ). Thus despite infinitesimal latitudinal width of FACs, the ionosphere might not screen the surface mode from the ground as suggested by Kivelson and Southwood (1988). The ionospheric screening effect goes as  $\exp(-kh_{isp})$ , where  $h_{isp}$  is the ionospheric altitude, meaning that the small latitudinal wavenumbers are not suppressed. While

in the  $y$ -direction there is only one wavenumber  $k_y$  present, in the  $x$ -direction the delta function in the current has equal Fourier amplitudes at all wavenumbers, thus small total wavenumbers  $k = \sqrt{k_x^2 + k_y^2}$  in this superposition may be transmitted to the ground. This highlights the need when applying the Hughes and Southwood (1976) formulas for non-plane waves to use Fourier (or spherical harmonic) decomposition, rather than simply measures of spatial amplitude extent (cf. Ozeke et al., 2009).

Finally, we quantify the extent to which each current system controls the total ground magnetic field through computing the Coefficient of Determination (see Appendix A). Since the pattern propagates, integration in time is equivalent to spatially along  $y$ . This is performed at each distance  $x$  away from the OCB. On average the Hall currents explain 92% of the variance in the ground field across all components (further statistics are given in Table S1 in Supporting Information S1), hence they still exhibit overwhelming control within the model.

We find that changing wavelengths and ionospheric conductivities in this model lead to qualitatively similar results, but leave a full parameterization to future work. However, we briefly discuss the likely effect of introducing a finite boundary thickness, which will change the surface magnetopause currents used into volume currents. Figure 1e considers a linear Alfvén speed variation between the two half-spaces (black) as in Chen and Hasegawa (1974), comparing this to the infinitesimal boundary used thus far (gray). Southwood and Kivelson (1990) note that in an azimuthally-uniform box model, FAC sources in a cold plasma are proportional to the product of: (a) the gradient in squared Alfvén speed; and (b) azimuthal derivative of the compressional magnetic field signal. The figure shows while in the infinitesimal case term (a) is non-zero coincident with the OCB, for a finite thickness boundary term (a) instead peaks at the inner edge of the magnetopause layer due to the high magnetospheric Alfvén speed. This is no longer coincident with the OCB, which will be located somewhere within the boundary. Considering term (b), outside of the boundary layer the surface mode's compressions must decay exponentially with distance from the magnetopause within the two half-spaces. The sign of the compressions must also reverse within the boundary layer itself. These two facts necessitate that term (b) exhibit peaks near the boundary layer edges (see also Figure 1 of A22). Combining both terms suggests surface mode FACs are largest near the inner edge of the magnetopause. This conclusion holds within a box model for more complicated transitions or if thermal effects are included (Itonaga et al., 2000).

### 3. Global Simulation

We now employ a global coupled MI simulation to better understand magnetopause surface modes' potential auroral, ionospheric, and ground magnetic signatures within a more representative environment.

#### 3.1. Overview

The Space Weather Modeling Framework (SWMF; Tóth et al., 2005, 2012) is used on NASA's Community Coordinated Modeling Center (CCMC). This includes BATS-R-US (Block-Adaptive-Tree-Solarwind-Roe-Upwind-Scheme; Powell et al., 1999) global MHD magnetosphere, which is run at high-resolution ( $1/8$ – $1/16$   $R_E$  in the regions considered), coupled to an electrostatic thin-shell ionosphere (Ridley et al., 2004), where the same uniform conductances as in Section 2 are used. The run, which was previously presented by A21 and A22 (based on H15), simulates the magnetospheric response to an idealized solar wind pressure pulse under northward IMF. Full setup details are in Table S2 in Supporting Information S1.

Here we summarize salient results from the BATS-R-US simulation. H15 showed, following an initial transient response, the pulse excites damped monochromatic compressional waves near-globally with 1.8 mHz frequency. Amplitudes of these waves decay with distance from the magnetopause, with a phase reversal across the boundary. The authors concluded these oscillations could only be explained by MSE. A21 found that across most of the dayside, magnetopause displacements showed little azimuthal phase variation. Indeed, the surface waves are stationary between 09 and 15 hr Magnetic Local Time (MLT), despite non-negligible magnetosheath flows being present. They demonstrated this is achieved by the time-averaged Poynting flux inside the magnetosphere surprisingly pointing toward the subsolar point, balancing advection by the magnetosheath flow such that the total wave energy flux is zero. Outside of this region, waves are seeded tailward at the dayside natural frequency and grow due to KHI. A22 reported the magnetospheric velocity polarization's handedness in the stationary region (Earthward of the surface mode's turning point) was also reversed from that typically expected, which was found

only in the tailward propagating regions. While associated magnetic field polarizations can be reversed by the field geometry near the cusp, Earthward of each field line's apex both polarizations are the same. A consequence of these results is MSE must have spatially varying wavenumbers. Across the dayside the system response is large-scale ( $k_{\perp} \ll k_{\parallel}$ ) and thus insensitive to the flow. Since fluctuations seeded downtail from the dayside have fixed frequency in Earth's frame, in the flanks this results in the Doppler effect (i.e.,  $\omega' = |\omega - \mathbf{k} \cdot \mathbf{v}_{msh}| \approx k_{\perp} v_{msh}$  due to the significant flow velocities) imposing shorter wavelengths along the magnetopause of  $\sim 10 R_E$ . Normal to the magnetopause, phase fronts inside the dayside magnetosphere slowly propagate toward the boundary ( $\ll v_A$ ). The authors argued this results from the magnetosonic dispersion relation (Equation 1) when both compressibility and damping of the surface wave are taken into account. Finally, the surface mode is shown to couple to MHD body waves where their eigenfrequencies match: waveguides were found along the equatorial terminator ( $x_{GSM} = 0$ ) and outer nightside flanks; FLRs were identified on the equatorial terminator Earthward of the magnetopause and in the magnetotail (A21; A22).

As in those previous studies, in this paper we focus on the MSE response (times  $t > 15$  min) neglecting the directly-driven transient activity. Perturbations (represented by  $\delta$ 's) from equilibrium (represented by subscript 0's) are extracted by subtracting 40 min LOESS (locally estimated scatterplot smoothing; Cleveland, 1979) filtered data, where outliers were neglected. This removed long-term trends well during the period of interest, with spurious values occurring only before the arrival of the pulse. For the ionosphere and ground, coordinates employ Northward and Eastward horizontal components as well as the vertical/radial direction. In the magnetosphere, an equivalent field-aligned system is used. The field-aligned direction  $\hat{\mathbf{B}}_0$  is the 90 min time-average of the LOESS-filtered magnetic field. Other directions are obtained as perpendicular projections of the local spherical polar unit vectors ( $\hat{\theta}$  for colatitude and  $\hat{\phi}$  for azimuth). Specifically, the perpendicular Northward direction is  $\hat{\mathcal{N}}_{\perp} = -(\hat{\theta} - [\hat{\mathbf{B}}_0 \cdot \hat{\theta}] \hat{\mathbf{B}}_0) / |\hat{\theta} - [\hat{\mathbf{B}}_0 \cdot \hat{\theta}] \hat{\mathbf{B}}_0|$  and perpendicular Eastward is  $\hat{\mathcal{E}}_{\perp} = (\hat{\phi} - [\hat{\mathbf{B}}_0 \cdot \hat{\phi}] \hat{\mathbf{B}}_0) / |\hat{\phi} - [\hat{\mathbf{B}}_0 \cdot \hat{\phi}] \hat{\mathbf{B}}_0|$ . All Fourier analysis is computed between  $t = 15$ –90 min and limited to frequencies 1.0–2.1 mHz, with results being integrated over this band.

### 3.2. Validity

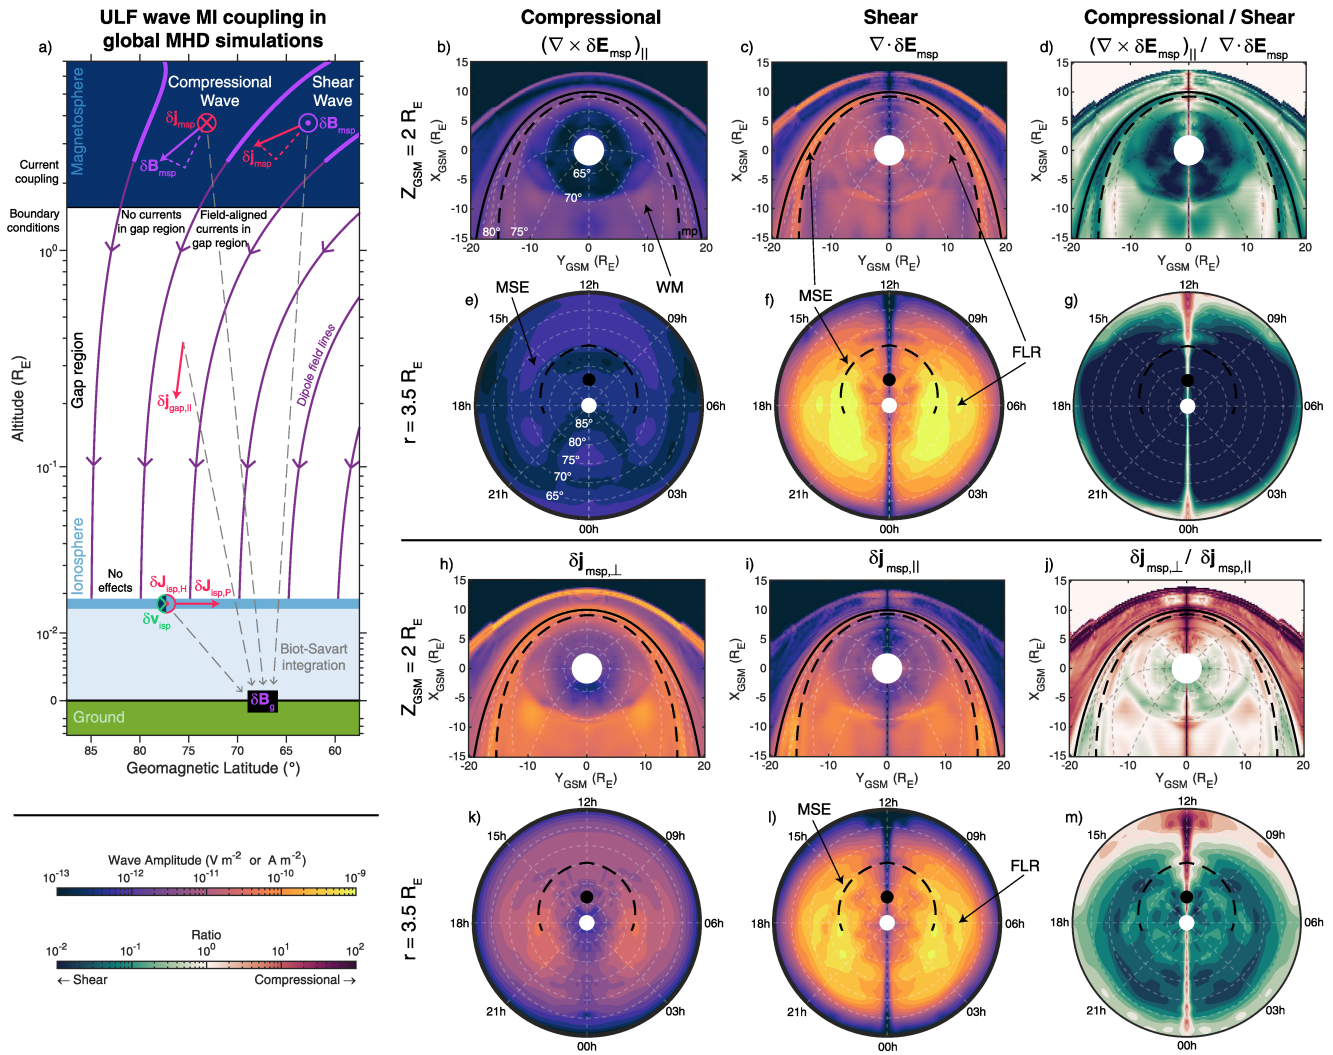

We must assess the validity of using this simulation to qualitatively predict auroral, ionospheric, and ground magnetic signatures of magnetopause surface modes. We do not aim for fully quantitative predictions due to known limitations of current global MHD codes, such as numerical diffusion and current sheet smearing which underestimate ULF wave effects (S. Claudepierre et al., 2009; H15). Thus only trends in wave patterns should be interpreted, rather than absolute amplitudes of signatures.

Global MHD models are not able to simulate down to ionospheric altitudes, for example, since high Alfvén speeds slow down computations, thus magnetospheric boundary conditions are imposed on the plasma and fields further out ( $r = 2.5 R_E$  here). This leaves a gap region between the magnetosphere inner boundary and the thin-shell ionosphere (110 km altitude) which is not simulated, as depicted in Figure 2a. MI-coupling occurs a few grid cells radial of the magnetosphere inner boundary ( $r = 3 R_E$ ), where FACs are mapped and scaled through the gap region to the ionosphere along dipole field lines (Ridley et al., 2004). This means equatorward of  $\pm 55^\circ$  magnetic latitudes there are no gap region FACs, hence we limit all analysis to poleward of  $60^\circ$ . The ionosphere model solves for the electric potential via current continuity with a given conductance pattern, similarly to Section 2, which yields ionospheric electric fields, currents, and velocities. The potential is mapped back to the magnetospheric inner boundary, setting the electric field and velocity there also.

As highlighted by Kivelson and Southwood (1988) and indicated in Figure 2a, compressional and shear MHD waves will affect the ionosphere differently due to their different currents. Shear modes exhibit FACs, hence coupling between the magnetosphere and ionosphere will occur, which in simulations will be performed by the current mapping. In contrast, compressional modes have only perpendicular currents and so no current is expected to flow between the magnetosphere and ionosphere. Purely compressional waves result in no significant ionospheric effects, which will be true in simulations also. Therefore, the ionospheric response to incident ULF waves should be reliable.

Potential issues, however, arise when considering ground magnetic field calculations. These are computed by Biot-Savart integration of all current systems: ionospheric Pedersen and Hall currents; those throughout the

**Figure 2.** (a) Illustration of magnetosphere–ionosphere coupling within global magnetohydrodynamics simulations applied to compressional and shear ultra-low frequency waves. (b–m) Simulation Fourier maps taken from the  $z_{GSM} = 2 R_E$  near-equatorial plane (b–d, h–j) and at  $r = 3.5 R_E$  near the simulation MI interface (e–g, k–m), the latter have been projected onto the ground. These show amplitudes of compressional (b, e) and shear (c, f) waves and associated currents perpendicular (h, k) and parallel (i, l) to the background magnetic field. Ratios are also shown (d, g, j, m). Solid black lines indicate the open–closed field line boundary whereas dashed lines indicate the magnetopause inner edge. Arrows highlight regions due to magnetopause surface eigenmode (MSE), waveguide mode (WM), and field line resonance (FLR).

magnetosphere domain; and gap region FACs (Rastätter et al., 2014; Yu et al., 2010). Because the MI-interface in simulations is much further away than in reality, perpendicular currents at this interface will make much smaller contributions than they would otherwise due to the increased distance. FACs, on the other hand, are unaffected as they can traverse the gap region. This is illustrated in Figure 2a and could affect both types of MHD waves, though likely more acutely for compressional modes.

We first investigate the amplitudes of compressional and shear modes via the curl and divergence of the electric field perturbations as before. Due to available model outputs on the CCMC, these are calculated via

$$(\nabla \times \delta \mathbf{E})_{\parallel} = -\frac{\partial}{\partial t} \delta B_{\parallel} = i\omega \delta B_{\parallel} \quad (6)$$

for the compressional mode, and

$$\nabla \cdot \delta \mathbf{E} = \delta[\nabla \cdot (\mathbf{B} \times \mathbf{v})] = \delta[\mu_0 \mathbf{j} \cdot \mathbf{v} - \mathbf{B} \cdot \boldsymbol{\Omega}] \quad (7)$$

for the shear mode, where  $\Omega = \nabla \times \mathbf{v}$  is the vorticity. Figures 2b–2d shows Fourier wave amplitudes, along with their ratio, for a near-equatorial plane ( $z_{GSM} = 2 R_E$ ). At the magnetopause, the OCB is shown as the black solid line and the magnetopause inner edge as the dashed line, which has been manually identified based on the background current, Alfvén speed, and velocity polarization (A22) and fitted to a polynomial with local time. The large (e.g.,  $\sim 1.5 R_E$  at noon) boundary width in the simulation is a consequence of MHD being unable to resolve small gyroradius scales that dictate the 400–1,000 km thickness of the real magnetopause (Berchem & Russell, 1982). Panel b demonstrates compressional mode amplitudes are generally largest near the magnetopause and decay slowly across the magnetosphere with distance from the boundary. Panel c shows shear wave amplitudes exhibit strong peaks inside the boundary layer, consistent with Plaschke and Glassmeier (2011), both at the inner edge and OCB. Away from these peaks, the amplitude falls off much more quickly than in the compressional mode. However, shear amplitudes remain larger than compressional ones almost throughout the equatorial magnetosphere, as indicated by the ratios in panel d. Since dayside FLR frequencies in the simulation are much larger than the observed waves (A22), we conclude the large shear amplitudes are due to non-resonant coupling between the compressional and shear modes. This occurs due to the inhomogeneous Alfvén speed and curvilinear magnetic geometry present (e.g., Radoski, 1971), resulting in a single wave that has mixed properties of both. The same quantities are also shown at  $r = 3.5 R_E$ , near the simulation MI-interface, in Figures 2e–2g, where these have been projected along dipole field lines to the northern hemisphere ground. The OCB is found to occupy a small area around the displayed black dot, indicating a mostly closed magnetosphere as has been seen in extended northward IMF simulations previously (Song et al., 2000; Zhang et al., 2009). The magnetopause inner edge maps to latitudes equatorward of the OCB. Compressional mode amplitudes (panel e) are significantly weaker near the MI-interface, in agreement with the expected standing structure (Plaschke & Glassmeier, 2011). They appear constrained to regions equatorward of the magnetopause inner edge and mostly to the dayside. Shear mode amplitudes (panel f) exhibit strong ridges on both flanks which are well-aligned with the inner/equatorward edge of the magnetopause, along which the amplitudes grow with MLT away from noon. Isolated peaks also occur equatorward of the inner edge on the terminator, corresponding to the FLRs identified by A21. Notably no clear peak occurs at the OCB. At  $r = 3.5 R_E$  the ratio of the shear to compressional mode amplitudes are even greater than at  $z_{GSM} = 2 R_E$  (panel g), indicating again the mixed properties of the wave.

The dominance of shear wave amplitudes over compressive suggests simulation results should be reliable. However, it is currents which are more crucial. Therefore, panels h–m display Fourier amplitudes for the perpendicular and parallel currents (and their ratios) at the same locations. Reassuringly the two components have similar patterns to the two wave modes. In particular, at  $r = 3.5 R_E$  FACs peak along the magnetopause inner/equatorward edge and at the discrete FLRs. No such peaks are present at the OCB, despite these occurring out in the magnetosphere. While at  $z_{GSM} = 2 R_E$  perpendicular and parallel currents are generally of similar magnitude, at the MI-interface FACs dominate poleward of  $\sim 65^\circ$ – $70^\circ$  latitudes (though the current ratio is not as large as that for mode amplitudes). Consequently, as perpendicular currents are small compared to FACs where MI-coupling is performed, Biot-Savart integration will be reliable in estimating ground magnetic field signals at high latitudes.

### 3.3. Optical Aurora

FACs associated with FLR can result in periodic optical auroral forms (Greenwald & Walker, 1980; Milan et al., 2001; Samson et al., 1996). Upward FACs at the ionosphere are carried by precipitating electrons that may, if sufficiently energetic, cause auroral emission, whereas regions of downward FACs appear relatively darker. Given we have demonstrated surface modes also exhibit FACs, it is worth exploring their potential auroral signatures.

As shown in panels i and l of Figure 2, oscillatory FACs associated with the surface mode peak at the inner edge of the magnetopause rather than the OCB. This is difficult to intuit theoretically within a realistic magnetosphere (Itonaga et al., 2000; Southwood & Kivelson, 1991), especially since the simplifying assumption of wave scales being smaller than changes in background conditions cannot be made (A22). Nonetheless, the result is in agreement with the box model prediction of Section 2. Movie S1 (left) shows perpendicular velocity perturbations near the magnetospheric equator. While near the subsolar point motion is largely normal to the boundary, away from the Sun-Earth line vortical structure emerges near the magnetopause, particularly at the flanks. The clearest structures have vortex cores Earthward of the OCB, corresponding to the inner surface mode (Lee et al., 1981; A22). These are associated with significant field-aligned vorticity, though this quantity is prevalent throughout

the magnetosphere (middle). In a uniform plasma only Alfvén waves exhibit parallel vorticity, hence this results from non-resonant coupling between the compressional and shear modes. On the dayside magnetosphere, the vorticity's phase structure has shorter normal scales ( $\sim 6 R_E$ ) than transverse ones (the entire morning/afternoon sector). There is also slow ( $\ll v_A$ ) phase motion toward the boundary. Since all signals' amplitudes decay with distance from the magnetopause inner edge, the vorticity appears to grow as its phase fronts travel toward the boundary. These features are very similar to those reported in A21 for the compressional magnetic field, explained as the result of surface wave damping. We also note these boundary normal wavelengths are much larger than those expected for FLR, since the large gradients in FLR frequencies (A22) suggest scales  $< 1 R_E$  (Southwood & Allan, 1987). In contrast to the dayside, tailward of approximately the terminator, transverse wavelengths shorten to  $\sim 10 R_E$  and phase motion appears predominantly tailward. Vorticity magnitudes in the flanks are significantly larger than on the dayside due to KHI-amplification and the shorter scales. We note that coupling of MSE to body modes, such as waveguides or FLR, has been shown to occur in these regions (A21), hence results in the nightside magnetosphere are generally a superposition of wave modes (including surface waves). Finally, FAC patterns (right) are very similar to the vorticity, as expected theoretically by Southwood and Kivelson (1991). Thus, magnetopause surface modes may exhibit FACs not just within the boundary, as in simple box models, but throughout the magnetosphere.

Based on these results near the equatorial plane, we expect that FAC structures at the MI-interface due to the surface mode consist of large-scale (compared to those of Alfvén waves) poleward moving forms on the dayside. Indeed, this can be seen in Movie S2 (left) which shows the ionospheric FAC input. On the dayside, FAC latitudinal wavelengths are  $\sim 10^\circ$  ( $\sim 1,000$  km in the ionosphere), larger than expected for FLRs in this region ( $< 1^\circ$  or 100 km). The structures propagate polewards at  $1.4^\circ \text{ min}^{-1}$  (or equivalently  $2.6 \text{ km s}^{-1}$ ), growing in amplitude with their phase motion until they peak at the projection of the magnetopause inner/equatorward edge (as demonstrated in Figure 2i). The azimuthal extent of these waves is likely a function of the driver, hence solar wind excited surface waves like in the simulation should exhibit more extended FACs than those due to most foreshock transients (Sibeck et al., 1999) or magnetosheath jets (M. O. Archer et al., 2019). In the simulation, we find that outside of the 09–15 hr MLT stationary region FAC structures propagate principally toward the tail, forming periodic structure along the projection of the boundary's inner/equatorward edge. While on the dayside structures appear azimuthally stationary, like the surface waves in the magnetosphere, the tailward propagating behavior of the eigenmode outside the stationary region causes the FACs to bifurcate at the boundary between the two regimes during their poleward phase motion. This results in more complex structure than simply a (spherical) harmonic wave.

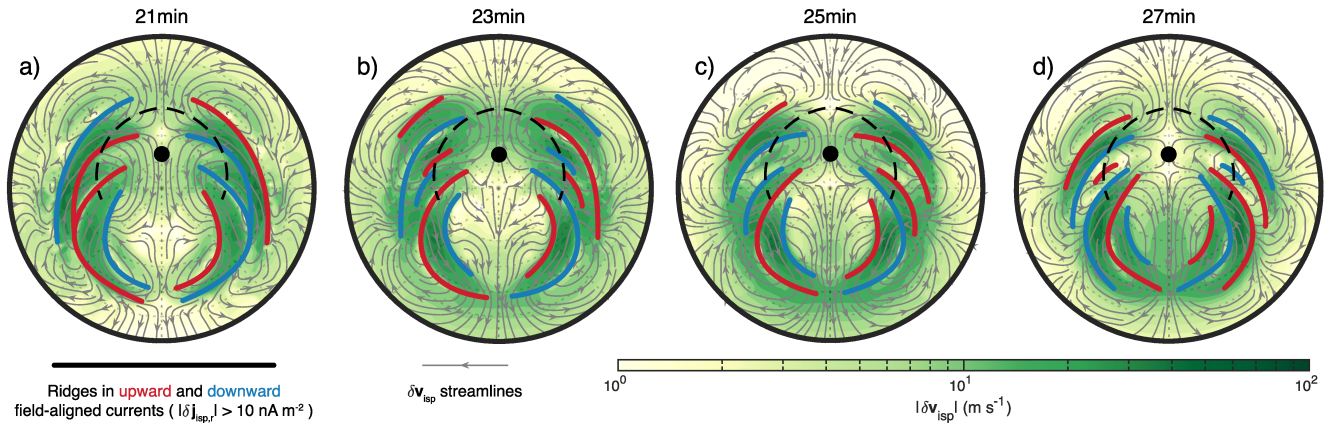

We conclude that magnetopause surface modes might have optical auroral signatures somewhat similar to FLRs. These consist of periodic brightenings with latitudinal arc widths of  $\sim 5^\circ$  that propagate polewards at slow speeds of  $\sim 1\text{--}2^\circ \text{ min}^{-1}$  ( $\sim 2\text{--}4 \text{ km s}^{-1}$ ). The intensity of these periodic aurorae should amplify with their phase motion, peaking not at the OCB as had been thought before (O. Kozyreva et al., 2019), but equatorward of it at the projection of the magnetopause inner edge. In our simulation the OCB and magnetopause inner/equatorward edge are highly separated, about  $\sim 7^\circ$  in latitude at noon. However, this is merely due to the large magnetopause thickness. We estimate realistic separations between the OCB and magnetopause inner/equatorward edge to be  $\sim 1\text{--}2^\circ$  for the driving conditions considered. This is based on the latitudinal difference in the simulation of traced footpoint locations from field lines separated by the boundary widths reported by Berchem and Russell (1982). Thus dayside auroral brightenings associated with surface modes, when visible due to the time of day/season, might consist of poleward moving arcs that intensify toward and peak a few degrees equatorward of an OCB proxy. Further into the flanks, auroral brightenings may form clear periodic structure along the projection of the boundary inner/equatorward edge, which will principally propagate azimuthally. KHI will likely make these auroral features generally stronger on the flanks. The auroral signatures of surface modes might be distinguished from FLR by their higher latitude location, lower frequency, and larger latitudinal extent. However, we make no claims here on the character, color, or taxonomy of such potential auroral signatures, since these cannot be easily predicted by MHD simulations. It also remains to be seen whether these auroral signals can be extracted from background emissions under different activity levels.

### 3.4. Ionospheric Convection

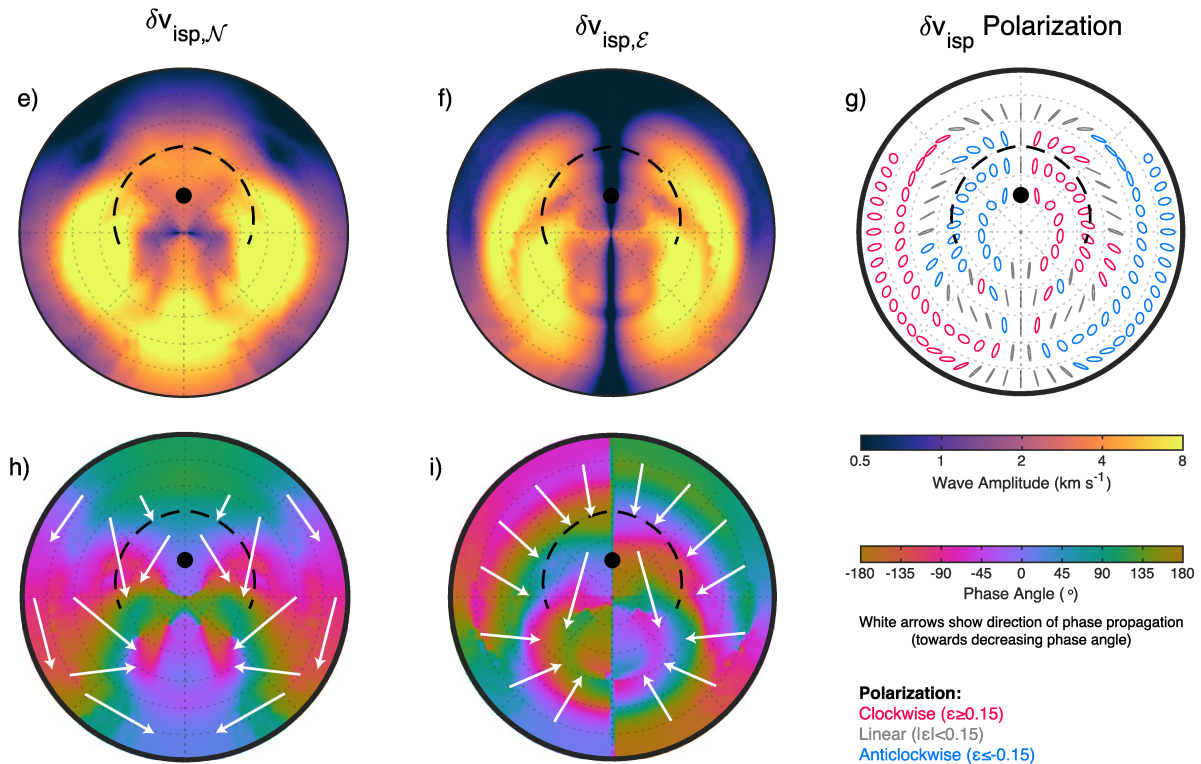

Perturbation convection patterns are shown in Figures 3a–3d as streamline snapshots over approximately half a cycle, and in Movie S2 as animated quivers. These reveal on the dayside large-scale convection vortices are present, which circulate the FAC maxima (bold lines in Figures 3a–3d). Vortices are clockwise for upward currents

### Snapshots of ionospheric convection

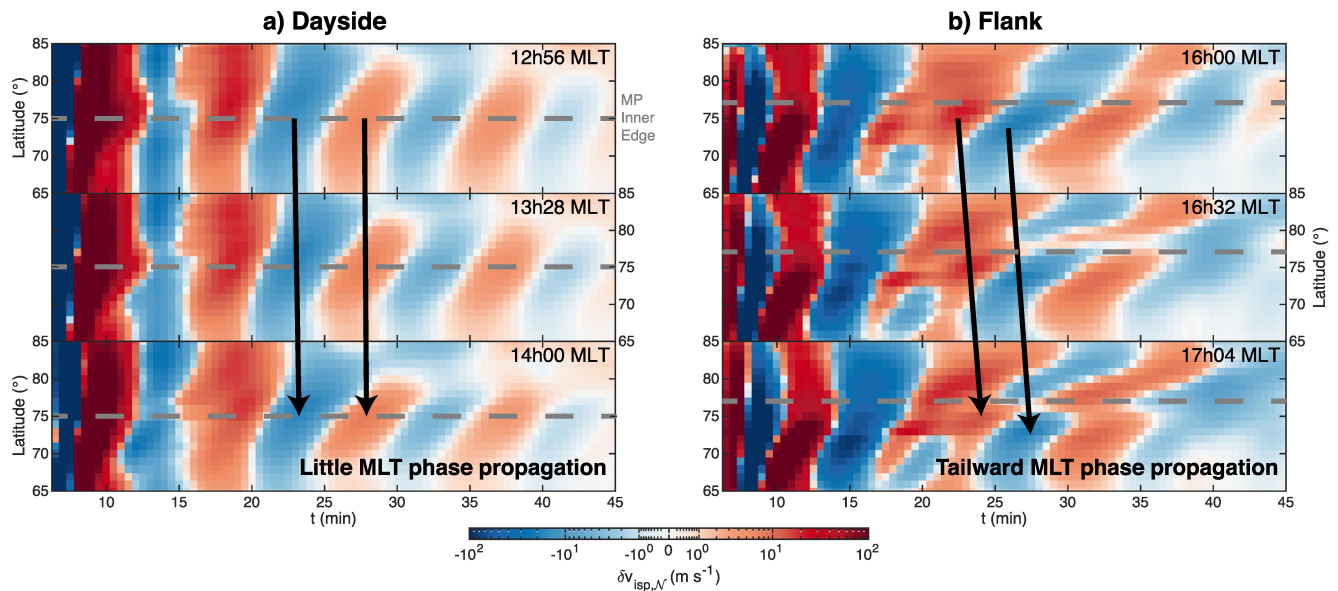

### Fourier analysis of ionospheric convection

**Figure 3.** (a–d) Snapshots of ionospheric convection over half an magnetopause surface eigenmode cycle, displaying the velocity magnitude (green) and streamlines (gray). Field-aligned current ridges are also indicated. (e–i) Fourier maps, in a similar format to Figure 2e, of the ionospheric velocity showing perturbation amplitudes (e, f) and phases (h, i) for the North-South (e, h) and East-West (f, i) components. Polarization ellipses are displayed in panel (g), colored by the sense of rotation.

and anticlockwise for downward, in agreement with Section 2. Interestingly, the vortex cores are located at  $\sim 09$  and  $\sim 15$  hr MLT, that is, the transition between stationary and propagating magnetopause surface waves. Like the FACs, dayside vortices have shorter latitudinal scales than longitudinal. At the lower latitudes considered though, vortices appear more spread out in the equatorward direction. This is likely because successive FAC structures become weaker toward the equator, making the ionospheric response more like in the box model. Since dayside FAC structures move polewards and grow in strength toward the magnetopause inner/equatorward edge, the convection vortices travel polewards and exhibit increases in speed up to this point also. Thus poleward-moving sequences of TCVs on the dayside may be a clear ionospheric signature of MSE. These are unlike typically

**Figure 4.** Examples of potential ionospheric Doppler radar observations. Simulation equivalents of range-time plots for adjacent beam directions (local times) are shown for the (a) dayside and (b) flank. The projection of the magnetopause inner edge is also indicated (gray dashed).

reported isolated/pairs of TCVs associated with the direct impacts of solar wind/foreshock pressure pulses or flux transfer events, which exhibit only tailward motion (Friis-Christensen et al., 1988; Sibeck, 1990), suggesting this phase motion could be a potential diagnostic for identifying MSE in ground-based data.

Figures 3e and 3f shows Fourier amplitudes of the two ionospheric velocity components. Around noon signals are mostly North-South, like the radial motions exhibited in the magnetosphere in this sector (A21; A22). Amplitudes peak at the magnetopause inner/equatorward edge, just like the FACs. However, the amplitude of the East-West component increases significantly away from noon toward the flanks. This is most evident in panel g, which displays polarization ellipses derived from the Fourier transforms (as outlined in A22). Away from noon the ellipses' orientations rotate away from the North-South direction and the magnitude of their ellipticity increases. Ionospheric velocity polarizations show consistent handedness with those out in the equatorial magnetosphere (A22), in particular a reversal is present either side of the transition between stationary and propagating surface waves. Panels h, i indicate phases and propagation directions for the velocity components, which are quite different from one another. There is little phase variation in the North-South component on the dayside, with only slight poleward phase motion in the stationary region. This reflects the large-scale periodic North-South motion associated with the surface waves that is clear from Movie S2. In contrast, the East-West component exhibits much larger gradients in phase latitudinally across the dayside. These differences are due to a combination of the vortices' larger longitudinal scales compared to latitudinal along with the poleward motion of these vortices. Azimuthal phase variation is introduced in the tailward propagating regime for both velocity components, though is clearest in the North-South direction.

The finite ionospheric conductivity causes significant spreading out of patterns caused by localized FACs. Therefore, in the above we have focused on the dayside as we know an FLR is also present at lower latitudes on the terminator. Figures 3e and 3f shows that at the terminator two amplitude peaks on each flank are present in both components. One of these is near the magnetopause inner boundary corresponding to the surface mode, whereas the lower latitude peak is due to the FLR. There is clearly significant spreading longitudinally of the FLR-related amplitude structures by  $\pm 3$  hr, meaning that ionospheric convection patterns in general consist of a complex superposition of those due to the surface mode and its coupled FLR(s). Only within  $\pm 3$  hr of noon is the ionospheric response be dominated by the surface mode.

Figure 4 shows potential ionospheric Doppler radar observations, emulating typical range-time plots. These show the time variation of the North-South velocity perturbations with latitude for nearby local times. Figure 4a corresponds to the dayside, which clearly shows in each panel periodic oscillations in the ionospheric velocity that exhibit poleward phase motion and peak in amplitude near the projection of the magnetopause inner boundary (gray dashed line). Comparing the panels indicates there is little phase propagation in MLT since the surface

waves are stationary, again unlike typical tailward TCVs. Figure 4b corresponds to the flanks, highlighting the increased complexity of the signal away from noon. Nonetheless, some similar features to the dayside are seen. While the amplitude does maximize near the magnetopause inner boundary due to the surface mode, a secondary amplitude maximum is present at lower latitude associated with the terminator FLR. All of these patterns in the flank exhibit tailward phase propagation when comparing panels.

### 3.5. Ground Magnetic Field

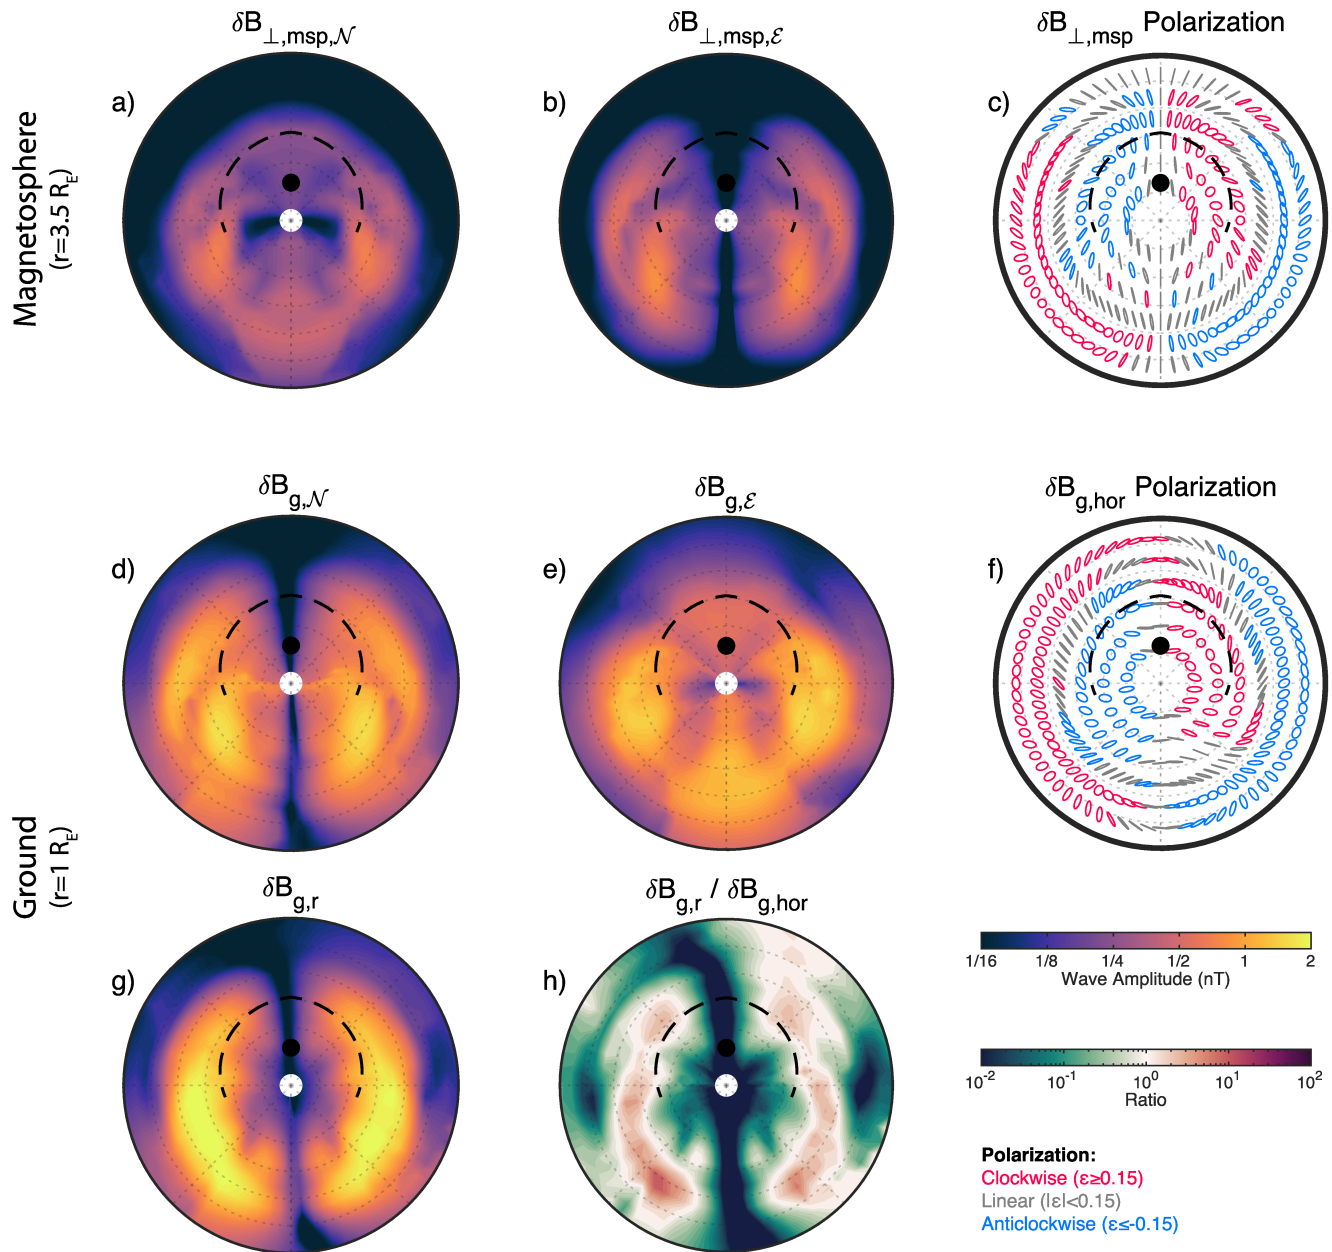

Ground magnetic field perturbations were computed using the CalcDeltaB post-processing tool (Rastätter et al., 2014), performed in SM coordinates due to the idealized model setup. We compare these to the magnetic field signals near the MI-interface. Both are shown in Movie S3.

Figures 5a–5c show the wave amplitudes and polarizations in the magnetosphere near the MI-interface. On the dayside perturbations are predominantly North-South oriented and maximize at the magnetopause inner/equatorward edge. In contrast, as shown in panels d–f, on the ground the magnetic field is mostly in the East-West direction. The movie shows these East-West signals are coherent across most of the dayside, converging/diverging from the ionospheric vortex cores at ~09 and ~15 hr MLT. This is unlike toroidal mode Alfvén waves, some of the most intensively studied ULF waves, which are aligned mostly North-South on the ground. The Fourier amplitude maps at the MSE frequency in Figure 5 for the ground horizontal components resemble those in the magnetosphere for the other component, that is, that at right angles. Ground signals are of significantly greater amplitude than in the magnetosphere. While this is similar to the box model, in the simulation this will partly be due to the scaling of FACs across the gap region with  $B_0$ . Ground magnetic field amplitudes also appear more extended than above the ionosphere. This is due to the spreading of currents in the ionosphere by the finite conductance, as discussed previously, as well as spatial integration of these ionospheric currents (Plaschke et al., 2009). The handedness of wave polarizations above and below the ionosphere are largely the same. Notable differences occur at the lowest latitudes shown, where the ground magnetic field is less reliable. Generally we see the ground magnetic field has greater ellipticity than in the magnetosphere, likely due to finite ionospheric conductance spreading out the currents' vortical patterns.

The time-averaged rotation angle from the magnetosphere to the ground was calculated for each point using the Fourier method outlined in Appendix B. Over the region depicted, this had a mean and standard deviation of  $89^\circ \pm 21^\circ$ . Note the magnetic field near the MI-interface does not include contributions from ionospheric Pederesen and Hall currents, hence is associated with the incident/reflected waves only. We find in agreement with the box model that the ionosphere rotates surface wave magnetic fields by close to  $90^\circ$ , though significant spread in this angle occurs. Unlike in Section 2, however, we found no systematic spatial ordering of the rotation angle. This may be because in the simulation FACs are not confined to within the boundary and move poleward. We again compute the Coefficient of Determination at each point to quantify the contribution of different current systems to the total ground magnetic field. Here this is done using Fourier methods, as outlined in Appendix A. As in the box model, it is Hall currents which dominate the ground field, hence why the rotation angle is close to  $90^\circ$ . However, on average Hall currents explain only 43% of the variance across all components—much smaller than in the simple box model. Tabel S1 demonstrates, however, that the other current systems (excluding Hall) and their combinations are not significant predictors of the ground field. Therefore, the total variance on the ground must be a complex superposition of many current systems, including most notably Hall currents.

Movie S3 also shows the vertical component of the ground magnetic field. Qualitatively this somewhat resembles the FACs, in line with predictions from the box model. However, Figure 5g shows toward the flanks, unlike the FACs, the vertical field amplitudes peak at lower latitudes than the magnetopause inner/equatorward boundary. At the terminator the peak corresponds well with the FLRs. Therefore, it appears that the FLR is dominating the vertical field perturbations on the ground, relative to surface mode, across a wide local time range. Vertical field amplitudes are generally greater than the horizontal ones only in the vicinity of their peaks. Close to noon, however, the vertical field is weak and only becomes significant at ~09 and ~15 hr MLT, the locations of dayside ionospheric vortex cores. Thus, like with the ionosphere, only in the vicinity of noon are the ground magnetic perturbations solely due to the surface mode.

Figure 6 shows stacked time-series of a latitudinal chain of virtual ground magnetometers located close to noon, where effects of the FLR are small. These demonstrate poleward phase motion of the ground magnetic field in all three components, unlike ground magnetometer observations of typical isolated/pairs of TCVs which show predominantly tailward motion (e.g., Friis-Christensen et al., 1988). Like with the ionospheric velocity though, this phase motion is slightly different for all three components. The amplitude variation (blue lines) is quite

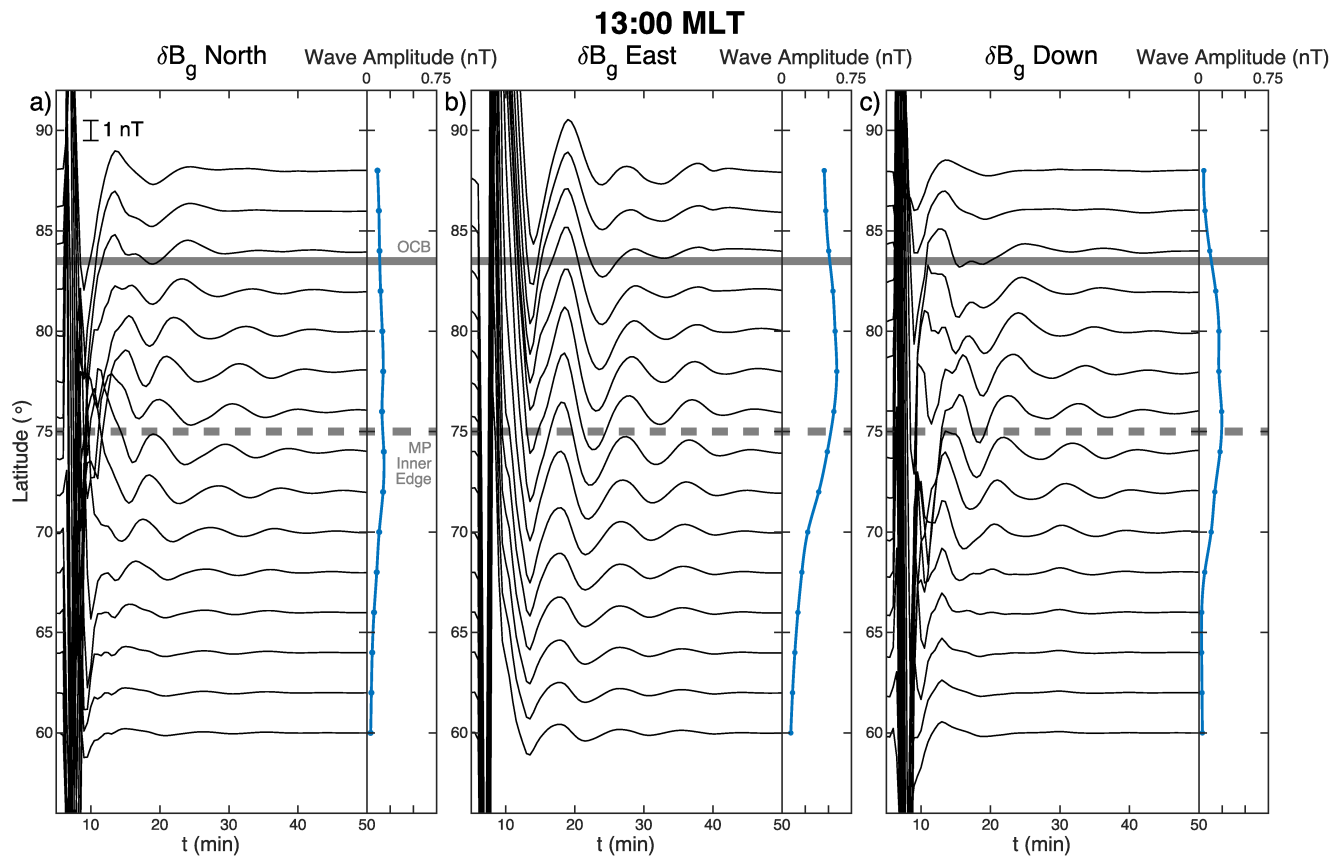

**Figure 5.** Comparison of magnetic perturbations (a–c) near the magnetosphere–ionosphere interface, and (d–h) on the ground. Fourier amplitudes (a, b, d, e, g) and polarization ellipses (c, f) are displayed. Finally, the ratio of vertical to horizontal ground perturbations is shown (g). Formats are similar to Figures 3e–3g.

broad for all three components. While the vertical component appears to peak at the magnetopause inner/equatorward edge, the East-West component's maximum appears shifted slightly poleward of this location and the North-South component has a rather flat peak. Nonetheless, all three maxima are clearly closer to the magnetopause inner/equatorward edge than the OCB within the simulation. We suggest that all these features could be used as diagnostics for identifying surface modes in ground magnetometer networks.

## 4. Discussion

### 4.1. Limitations

In both aspects of this study we have employed uniform ionospheric conductances. This was to understand the surface mode's ground-based signatures in the simplest case. Improved empirical conductance maps typically

**Figure 6.** Examples of potential latitudinal ground magnetometer chain observations. Magnetic field perturbations in the (a) North-South, (b) East-West, and (c) vertical components are shown as stacked time-series (black) as well as Fourier amplitudes (blue). Gray lines depict projections of the open-closed boundary (solid) and magnetopause inner edge (dashed).

include effects of solar illumination and/or auroral oval conductance contributions (Ridley et al., 2004). The former exhibit relatively small variations over scales much larger than surface mode wavelengths, hence likely have little effect on the predictions. In contrast, auroral oval Hall conductances can be significantly larger than those outside this region. While these could result in stronger currents within the auroral oval, and thus stronger ground magnetic signals, the sense of FAC closure would likely remain. Hartinger et al. (2017) performed simulations comparing ground field perturbations from a solar wind pressure increase under different conductance models. They found qualitatively similar results for the uniform and solar conductance patterns, but somewhat different amplitude profiles with the auroral pattern.

So far we have treated the ground as a perfect insulator, in line with most past global modeling and observational work (e.g., Samsanov et al., 2015; Tanaka et al., 2020). While some other ULF wave studies have considered the ground to be a perfect conductor (e.g., Hughes, 1974; Hughes & Southwood, 1974; Waters & Sciffer, 2008), neither regime realistically includes contributions from induced telluric currents in the ground. To estimate their likely effect we apply the Complex Image Method (Boteler & Pirjola, 1998; Pirjola & Viljanen, 1998). This places an image current, with the same strength as that in the overhead ionosphere, at a depth of  $h_{\text{isp}} + 2p$  for complex skin depth  $p$ . Here we take this skin depth to be

$$p = \frac{1}{\sqrt{i\omega\mu_0\sigma}} \quad (8)$$

where  $\sigma$  is the ground conductivity. One can assume a uniform conductivity that is able to capture the spatial variations in the field/currents through a plane wave (Pirjola et al., 2009). For wavelengths  $>200$  km and periods  $<1$  min, valid for MSE, this yields values of  $\sim 1\text{--}2$  mS  $\text{m}^{-1}$ , in line with ground conductivities for rocky or city areas (Cebik W4RNL, 2001). These values along with the simulation MSE frequency result in skin depths

of magnitude 190–270 km, much greater than the ionospheric altitude. Given that in both the box model and simulation the ground magnetic field was mostly dictated by Hall currents with large scale sizes, we estimate the ground magnetic fields from telluric currents by assuming an infinite line current in the ionosphere (Boteler & Pirjola, 1998). This predicts horizontal ground magnetic field perturbations are amplified by 18%–24% and vertical fields reduced by 3%–6% due to the induced ground currents. Phase changes are negligible ( $<7^\circ$ ). These are relatively small contributions due to the low 1.8 mHz frequency of the surface mode, since lower frequencies are less effective at inducing telluric currents for a given amplitude. In contrast, higher frequency ULF waves of 10–100 mHz are predicted to change the horizontal field by 40%–70%. We also note that near oceans, the high  $5 \text{ S m}^{-1}$  conductivity of salt water likely renders all ULF waves' ground signatures greatly affected ( $>90\%$ ). Future studies could more comprehensively investigate the importance of telluric currents to ground magnetometer signals of surface and other ULF waves.

Our brief evaluation of these limitations suggests the use of a wide range of latitudes when examining potential observations to these predictions, where overall trends likely persist. On smaller scales, local effects due to varying conditions in the ionosphere and the ground may be more important, which could form the basis of future work.

#### 4.2. Comparison to Previous Observations

Auroral brightenings, ionospheric convection vortices, and ground pulsations are expected from FACs in general. However, mapping observations from the ground out to space is difficult when trying to distinguish surface waves from nearby body waves. We thus limit comparative discussion to studies that could better constrain ground-based observations.

Previous conjugate observations have linked aurorae to surface waves. He et al. (2020) suggested sawtooth aurorae, large-scale undulations along the equatorward edge of the diffuse aurora, may be the optical atmospheric manifestation of plasmopause surface waves. During a geomagnetic storm, they showed 1.4 mHz plasmopause surface waves (i.e., with similar frequencies to MSE) in the afternoon-dusk correlated with sawtooth auroral patterns near the footprints of the plasmopause field lines, with wavelengths and propagation speeds of both being in agreement. The authors suggested the modulation of hot plasma by the plasmopause surface mode may have led to particle precipitation, and thus diffuse aurora. Similarly, Horvath and Lovell (2021) presented two case studies of KHI-waves on the flank magnetopause during geomagnetic storms, which appeared to excite surface waves on/near the plasmopause in the hot zone of the outer plasmasphere. During these events, correlated complicated sub-auroral plasma flows and large auroral undulations were observed at low Earth orbit. The authors conclude magnetopause surface modes couple, in complex ways, to the inner magnetosphere and auroral zones. Finally, the ground-based study of O. Kozyreva et al. (2019) used observations of the equatorward edge of the red cusp aurora as an optical proxy for the OCB following southward IMF turnings. They noted quasi-periodic motion of this boundary in three events, which they interpreted as evidence for MSE. While these studies demonstrate a connection between magnetopause/plasmopause surface waves and aurorae, the latter's generation mechanism remains unclear. Further work should determine whether surface waves' FACs directly result in periodic aurorae or merely perturb existing auroral current systems.

M. O. Archer et al. (2019) first showed MSE signatures may be present in dayside ground magnetometer data, though unfortunately data was low resolution and had poor spatial coverage which limited conclusions. O. Kozyreva et al. (2019) presented data from a near-noon latitudinal chain following impulsive external driving. Short-lived oscillations in the North-South component were found to peak  $\sim 1^\circ$ – $2^\circ$  equatorward of the optical OCB proxy. While the authors attributed this to experimental uncertainty, it is unclear why this would result in a systematic effect. The offset agrees with our estimates for the inner/equatorward edge of the magnetopause boundary layer, thus could instead be consistent with our results. They also noted poleward phase motion and large  $\sim 8^\circ$ – $10^\circ$  latitudinal scales, both like in our simulation. He et al. (2020) demonstrated ground magnetic pulsations associated with plasmopause surface waves in the afternoon-dusk sector. A latitudinal magnetometer chain showed clear poleward phase motion, as in the simulation. However, the authors suggest the plasmopause surface wave may have coupled to an FLR outside the plasmasphere due to the amplitude and phase structure observed, potentially complicating these observations. Finally, Hwang et al. (2022) presented two case studies of KHI-waves and their ground effects. Vortical horizontal field perturbations were observed at high latitudes, corresponding to bead-like FACs elongated in the east-west direction like those seen in the simulation flanks.

There are some interesting similarities and differences between these magnetopause surface mode results and the classic Sudden Commencement (SC) or, more generally, TCV response of the magnetosphere. These models are generally used to interpret ground-based observations following impulsive solar wind driving, for example, interplanetary shocks or solar wind pressure pulses, hence warrant further discussion. The Araki (1994) model of SC predicts bipolar variations of the geomagnetic field at polar latitudes due to a global ionospheric twin vortex resulting from pairs of FACs on each of the morning and afternoon sectors. These are similar but larger in scale than typical TCVs. Our simulation results are broadly consistent with this model during the transient period (see Movie S2 and Figure 6). The Araki (1994) model, however, does not predict the subsequent periodic oscillations following this transient, which are associated with MSE. This is because it only considers the intensification of magnetopause currents and FACs related to a single ripple on the magnetopause, hence not a surface wave or eigenmode. This is also true of similar TCVs models (e.g., Sibeck, 1990). MHD wave propagation during SC is typically linked to the Tamao (1964a, 1964b) path or cavity/waveguide theory (Kivelson et al., 1984; Kivelson & Southwood, 1985), where compressional waves couple to FLRs at the location their (eigen)frequencies match. Thus the possible contributions of magnetopause surface waves has not been considered in past SC observations or modeling (see the review of Fujita, 2019). SC can often be followed by long  $\geq 10$  min period waves (e.g., Matsushita, 1962), however, these are rarely discussed. It is therefore possible that ground-based evidence of MSE could be prevalent in past SC observations, with the subsequent pulsations either being neglected or misidentified as cavity/WMs and FLR, which are generally not expected to occupy such low frequencies on the dayside (M. O. Archer et al., 2015).

Overall, our simulation results appear consistent with the few previous reported observational signatures of magnetopause surface waves specifically. However, some aspects could not be tested with the data presented, motivating the need for both dedicated future observational studies and reanalysis of previously examined events in light of this work.

### 4.3. Implications

The results presented in this paper have potential consequences within the context of space weather, which we briefly comment on.

We have demonstrated magnetopause surface modes are predicted to result in ionospheric currents and electric fields. This offers the possibility that surface wave energy may be dissipated in the ionosphere, like it is for other ULF wave modes (e.g., Glassmeier et al., 1984). Joule heating rates are given by

$$\begin{aligned} \mathbf{j} \cdot \mathbf{E} &= \frac{1}{\Sigma_P} E^2 \\ &= \frac{1}{\Sigma_P} (E_0^2 + 2\mathbf{E}_0 \cdot \delta\mathbf{E} + \delta E^2) \end{aligned} \quad (9)$$

where the first term corresponds to the DC equilibrium heating rate and the subsequent terms are associated with pulsations. Recall a uniform Pedersen conductance of 5S was used, which is reasonable for sunlit high-latitude regions (cf. Ridley et al., 2004). In the simulation, we integrate these over the entire dayside ionosphere. While the DC rate is 3 GW, we find the maximum pulsation-related rate is 40 GW, occurring during the transient response. The peak dissipation rate during times of confirmed MSE ( $t > 15$  min) is also significant compared to the background at 0.4 GW (i.e., 13%). While the inclusion of the KHI-amplification of the surface waves and their coupling to FLRs on the nightside result in the global ionospheric dissipation rates being even greater during MSE times at 25% of the global DC rate, the ionospheric conductances in the nightside hemisphere are less realistic. Overall, these simulation results qualitatively suggest magnetopause surface modes may provide important contributions to ionospheric heating. Further work could quantitatively predict heating rates due to surface waves using a range of more representative wave amplitudes and ionospheric conditions, improving our understanding of their global significance under different driving regimes.

We also predict that magnetopause surface modes result in oscillatory magnetic fields at Earth's surface. This suggests they could be a source of geomagnetically induced currents driven by geoelectric fields (e.g., Belakhovsky et al., 2019; Heyns et al., 2021). While geoelectric fields are frequency-dependent with a higher frequency bias relative to the underlying disturbance geomagnetic field (e.g., Boteler & Pirjola, 1998; Pirjola & Viljanen, 1998), distinct Pc5-6 frequency ULF waves (1–7 mHz) can result in significant measured geoelectric

fields (Hartinger et al., 2020; Shi et al., 2022). Therefore, it may be possible that magnetopause surface waves, at either MSE or higher (e.g., intrinsic KHI) frequencies, could similarly result in strong geoelectric fields. Modeling this is beyond the scope of this study, as it is known the three-dimensional conductivity structure of Earth is important in accurate characterization of geoelectric fields (Bedrosian & Love, 2015). Therefore, further study is warranted in assessing whether magnetopause surface modes of more realistic amplitudes may be a source of geoelectric fields and thus geomagnetically induced currents (cf. Belakhovsky et al., 2019; Heyns et al., 2021; Yagova et al., 2021).

## 5. Conclusions

We have investigated magnetopause surface waves' direct effects on the aurorae, ionosphere, and ground magnetic field through both MHD theory and a global MI-coupling simulation. Our main conclusions are as follows.

1. Magnetopause surface modes have associated FACs into/out of the ionosphere, which for a finite thickness boundary maximize at the inner/equatorward edge of the magnetopause rather than the OCB. Non-resonant coupling between the compressional and Alfvén modes results in further monochromatic FACs throughout the magnetosphere, hence are unrelated to the Alfvén continuum. The amplitudes of these currents fall off with distance from the magnetopause.
2. The normal phase structure reported by A21 in the equatorial magnetosphere due to damping also manifests at the MI-interface as slow  $\sim 1^\circ\text{--}2^\circ \text{ min}^{-1}$  poleward moving FAC structures. With latitudinal wavelengths of  $\sim 10^\circ$  on the dayside, these are large-scale compared to expectations for FLR.
3. FACs associated with global MSE are weakest on the dayside, due to smaller boundary displacements and azimuthal scales that span the morning/afternoon sector. In the flanks, where the Doppler effect imposes shorter scales and wave perturbations are amplified through KHI, strong periodic FACs may be present along the magnetopause inner/equatorward edge.
4. We suggest upward FACs associated with surface modes may lead to periodic auroral brightenings that peak in intensity at the magnetopause inner/equatorward edge. On the dayside, these auroral forms move slowly poleward at  $\sim 1^\circ\text{--}2^\circ \text{ min}^{-1}$  ( $\sim 2\text{--}4 \text{ km s}^{-1}$ ) and occupy large  $\sim 5^\circ$  latitudinal bands compared to narrower FLR-related aurorae. Periodic longitudinal structure will reflect that out at the magnetopause.
5. Ionospheric convection vortices circulate the surface mode's FAC structures. Like the FACs, they are large-scale, poleward moving, and strongest at the magnetopause inner/equatorward edge. The finite conductivity causes ionospheric signals to be more spread out than the FACs.
6. Magnetopause surface modes can also cause ground magnetic field signals. These are largely caused by Hall current vortices, which rotate the magnetic field perturbations from above the ionosphere to the ground by almost  $90^\circ$  (though significant non-systematic spread in this rotation angle occurs). Therefore, ground signatures of MSE near noon are strongest in the East-West direction. Oscillations have the same frequency across  $L$ -shells, amplitudes peak near the magnetopause inner/equatorward edge, and latitudinal variations are large-scale.

These conclusions provide qualitative predictions for magnetopause surface modes which might be applied to interpreting high-latitude ground-based data.

Different plasma conditions throughout geospace are expected to slightly modify some of the features observed. Penetration of surface modes into the magnetosphere is governed by local normal wavenumbers (Equation 1). This is very weakly dependent on the Alfvén speed distribution for MSE, due to its such low frequencies compared to FLR, thus varying the simulation inner boundary density or including a ring current would have little effect. The inclusion of a plasmasphere (S. G. Claudepierre et al., 2016), however, might have a greater influence since it could lower the Alfvén continuum at the plasmopause to MSE-range frequencies. This would limit the surface mode's access to the inner magnetosphere and lead to coupling to plasmopause surface waves and/or FLR on the dayside, introducing an additional superposition of waves. Nonetheless, surface mode signatures in the outer magnetosphere would be little affected. Different Alfvén speed distributions would, however, change the eigenfrequencies of WMs and FLRs, hence where MSE may excite these secondary waves. The polar cap in the simulation presented is very small. While our results (both theoretically and in the simulation) suggest surface mode currents at the MI-interface maximize at the inner/equatorward edge of the magnetopause boundary rather than the OCB, whether the amount of open flux affects possible currents near the OCB should be explored in future work. We also note this simulation is North-South and dawn-dusk symmetric due to zero dipole tilt, whereas

interhemispheric (e.g., Engebretson et al., 2020; Xu et al., 2020) and dawn-dusk (e.g., Henry et al., 2017) asymmetries in geospace are of great interest in understanding solar wind—magnetosphere—ionosphere coupling. Overall, how magnetopause surface modes manifest in the magnetosphere, ionosphere, and on the ground under varying magnetospheric conditions should be ascertained through series of further simulations.

Finally, a further potential avenue for remote sensing magnetopause (or even plasmopause) surface modes could be ionospheric Total Electron Content (TEC) data derived from Global Navigation Satellite Systems. Recent work has shown that ULF waves may modulate TEC, yielding periodic oscillations of similar frequency (Belakhovsky et al., 2016; O. V. Kozyreva et al., 2020; V. Pilipenko et al., 2014; Watson et al., 2015; Zhai et al., 2021). While several mechanisms for this have been proposed, overall they remain poorly understood. Future work could use the predicted ionospheric electric fields associated with surface modes to drive height-resolved ionosphere and neutral atmosphere models (Ozturk et al., 2020). This would crucially unveil how the coupled ionosphere—thermosphere—mesosphere system reacts to boundary waves in our magnetosphere.

## Appendix A: Coefficient of Determination

The Coefficient of Determination,  $R^2$ , is the proportion of the variance in a dependent variable that is predictable from an independent variable, often used in statistical models to quantify how well outcomes are replicated. In the case that the variables are complex vector time-series, this is given by

$$R^2 = 1 - \frac{\int dt(\mathbf{y} - \mathbf{f}) \cdot (\mathbf{y} - \mathbf{f})^*}{\int dt \mathbf{y} \cdot \mathbf{y}^*} \quad (\text{A1})$$

where  $\mathbf{y}$  is the dependent variable and  $\mathbf{f}$  is its predicted/modeled value. It follows from Parseval's theorem that for oscillatory signals  $R^2$  can also be determined from the complex Fourier amplitudes (denoted by tildes here)

$$R^2 = 1 - \frac{\int df (\tilde{\mathbf{y}} \cdot \tilde{\mathbf{y}}^* - \tilde{\mathbf{y}} \cdot \tilde{\mathbf{f}}^* - \tilde{\mathbf{f}} \cdot \tilde{\mathbf{y}}^* + \tilde{\mathbf{f}} \cdot \tilde{\mathbf{f}}^*)}{\int df \tilde{\mathbf{y}} \cdot \tilde{\mathbf{y}}^*} \quad (\text{A2})$$

$R^2$  can be interpreted as the fraction of explained variance, with  $R^2 = 1$  corresponding to perfect prediction. Negative values are possible when the predictor performs worse than one which always predicts the mean value. In this paper we use  $R^2$  to indicate what proportion of the total ground magnetic field perturbations are determined by contributions from different current systems. This has the benefits over simply comparing the root-mean-squared magnitudes of contributions (e.g., Rastätter et al., 2014) since the vector directions are also included.

## Appendix B: Rotation Angle

The signed right-handed rotation angle from a vector  $\mathbf{b}$  to  $\mathbf{a}$  about some direction  $\hat{\mathbf{z}}$  may be expressed as

$$\Delta\theta = \text{atan2}([\mathbf{b} \times \mathbf{a}] \cdot \hat{\mathbf{z}}, \mathbf{b} \cdot \mathbf{a}) \quad (\text{B1})$$

In the case of oscillatory vectors, the time-average (angular brackets) of  $\Delta\theta$  can be arrived at by using the following properties of complex Fourier amplitudes

$$\begin{aligned} \langle \mathbf{b} \times \mathbf{a} \rangle &= \frac{1}{2} \text{Re}\{\tilde{\mathbf{b}} \times \tilde{\mathbf{a}}^*\} \\ \langle \mathbf{b} \cdot \mathbf{a} \rangle &= \frac{1}{2} \text{Re}\{\tilde{\mathbf{b}} \cdot \tilde{\mathbf{a}}^*\} \end{aligned} \quad (\text{B2})$$

and hence

$$\langle \Delta\theta \rangle = \text{atan2}(\text{Re}\{\tilde{\mathbf{b}} \times \tilde{\mathbf{a}}^*\} \cdot \hat{\mathbf{z}}, \text{Re}\{\tilde{\mathbf{b}} \cdot \tilde{\mathbf{a}}^*\}) \quad (\text{B3})$$

In this paper, we use this to calculate the rotation of the horizontal magnetic field components from above the ionosphere to below it. Thus the direction  $\hat{\mathbf{z}}$  is taken as the vertical/radial.

## Notation

<i>msh</i>	Magnetosheath
<i>mp</i>	Magnetopause

<i>m</i> <sub>sp</sub>	Magnetosphere
<i>i</i> <sub>sp</sub>	Ionosphere
<i>g</i>	Ground
<i>GSM</i>	Geocentric Solar Magnetospheric coordinates
<i>SM</i>	Solar Magnetic coordinates
<i>N</i>	Northward component
