Scope Statement

Vertical eddy diffusivity (VED) in the planetary boundary layer physical paramaterization has a significant impact on numerical forecasts of tropical cyclone structure and intensity. This study developed a modified VED scheme in the NCEP Hurricane WRF model. Results indicated the modified scheme has positive impact on numerical prediction of landfalling hurricanes.

Abstract

Word count: 221

Vertical eddy diffusivity (VED) in the planetary boundary layer (PBL) has a significant impact on forecasts of tropical cyclone (TC) structure and intensity. VED uncertainties in PBL parameterizations can be partly attributed to the model's inability to represent roll vortices (RV). In this study, RV effects on turbulent fluxes derived from a large eddy simulation (LES) by Li and Pu (2021) are added to the VED parameterization of the PBL scheme within the operational Hurricane Weather Research and Forecasting (HWRF) model. RV contribution to VED is parameterized through a coefficient and varies with the RV intensity and velocity scale. A modification over land has also been implemented. This modified VED parameterization is compared with the original wind-speed-dependent VED scheme in HWRF. Retrospective HWRF forecasts of Hurricanes Florence (2018) and Laura (2020) are analyzed to evaluate the impacts of the modified VED scheme on landfalling hurricane forecasts. Results show that the modified PBL scheme with the RV effect leads to an improvement in 10-m maximum wind speed forecasts of 14%-31%, with a neutral to positive improvement for track forecasts. Improved wind structure and precipitation forecasts against observations are also noted with the modified PBL scheme. Further diagnoses indicate that the revised PBL scheme enhances moist entropy in the boundary layer over land, leading to improved TC intensity prediction compared to the original scheme.

A Modified Vertical Eddy Diffusivity Parameterization in the

HWRF Model Based on Large Eddy Simulations and Its Impact

on the Prediction of Two Landfalling Hurricanes

12 Abstract

- 13 Vertical eddy diffusivity (VED) in the planetary boundary layer (PBL) has a significant impact on
- forecasts of tropical cyclone (TC) structure and intensity. VED uncertainties in PBL parameterizations
- can be partly attributed to the model's inability to represent roll vortices (RV). In this study, RV effects
- on turbulent fluxes derived from a large eddy simulation (LES) by Li and Pu (2021) are added to the
- VED parameterization of the PBL scheme within the operational Hurricane Weather Research and
- 17 VED parameterization of the FBE scheme within the operational fruitfeatic weather Research and
- 18 Forecasting (HWRF) model. RV contribution to VED is parameterized through a coefficient and varies
- 19 with the RV intensity and velocity scale. A modification over land has also been implemented. This
- 20 modified VED parameterization is compared with the original wind-speed-dependent VED scheme in
- 21 HWRF. Retrospective HWRF forecasts of Hurricanes Florence (2018) and Laura (2020) are analyzed
- 22 to evaluate the impacts of the modified VED scheme on landfalling hurricane forecasts.
- Results show that the modified PBL scheme with the RV effect leads to an improvement in 10-m
- 24 maximum wind speed forecasts of 14%-31%, with a neutral to positive improvement for track
- 25 forecasts. Improved wind structure and precipitation forecasts against observations are also noted with
- 26 the modified PBL scheme. Further diagnoses indicate that the revised PBL scheme enhances moist
- entropy in the boundary layer over land, leading to improved TC intensity prediction compared to the
- 28 original scheme.

Introduction 1

- 32 Accurate prediction of the track and intensity of tropical cyclones (TCs), especially landfalling TCs,
- 33 can significantly reduce the casualties and economic loss induced by these severe meteorological
- disasters. Vertical eddy diffusivity (VED) in the planetary boundary layer (PBL) scheme is a key 34
- parameter for simulating and forecasting TC intensity (e.g., Smith 1968; Ooyama 1969; Emanuel 1986, 35
- 1995; Braun and Tao 2000; Chen et al. 2007; Van Sang et al. 2008; Smith and Thomsen 2010; Zhang 36
- et al. 2011; Zhang and Pu 2017). Modification of VED based on aircraft observations over the ocean 37
- 38 significantly improved hurricane track and intensity forecasts (Zhang et al. 2011; Zhang and Drennan
- 2012; Tallapragada et al. 2014; Zhang et al. 2015, 2017). Improved VED parameterization can also 39
- potentially lead to improved TC track, intensity, and structure forecasts during landfalls (Zhang and 40
- 41 Pu 2017).

- 42 Near-surface vertical mixing impacts flux and entropy distributions that affect TC intensity through
- the energy balance argument (e.g., Zhu and Furst 2013; Doyle et al. 2014; Wing et al. 2019). Above 43
- 44 the surface layer, both the maximum value and vertical distribution of VED could affect the simulated
- track, intensity, and structure of TCs (Gopalakrishnan et al. 2013; Zhu et al. 2014; Bu et al. 2017; 45
- Gopalakrishnan et al. 2021; Kalina et al. 2021). Zhang and Rogers (2019) found that relatively low but 46
- 47 realistic values of VED in the Hurricane Weather Research and Forecasting (HWRF) model led to a
- 48 strong and deep forecasted hurricane vortex, which aligned faster in shear before and during rapid 49 intensification than large VED. Small VED also led to more symmetric distribution of deep convection
- and enhanced PBL inflow over the ocean before TC intensification. On the other hand, in landfalling 50
- 51 TCs, the underlying surface roughness increases from ocean to land, which affects the VED in the PBL
- 52 (Yu et al. 2008; Zhang et al. 2011; Zhang and Pu 2017; Zhang et al. 2017). Based on fast-response
- wind data collected during typhoons in 2010, Tang et al. (2018) found that VED is larger near the coast 53
- 54 when winds blow from land than from the ocean. Zhang and Pu (2017) and Zhang et al. (2017) found
- 55 that using different VED parameterizations over land and ocean in the PBL scheme resulted in more
- 56 realistic intensity forecasts of landfalling hurricanes by HWRF, especially during the wind decay stage
- 57 over land.
- 58 Furthermore, previous studies have found that roll vortices (RVs), a type of large turbulence eddy,
- 59 exist in the TC PBL (Wurman and Winslow 1998; Katsaros et al. 2000; Morrison et al. 2005; Huang
- et al. 2018). Numerical simulations by Foster (2005), Gao and Ginis (2016), and Gao et al. (2017) 60
- 61 showed that these large-scale eddies could generate strong and counter-gradient flux, in contrast to that
- predicted by the traditional down-gradient turbulence parameterizations in mesoscale numerical 62
- models. Aircraft observations in TCs confirmed that counter-gradient turbulent transfer exists, leading 63
- 64 to large VEDs near the top of the boundary layer in the eyewall and outer-core regions (Zhang and
- Drennan 2012; Zhao et al. 2020). Results from large eddy simulation (LES) are consistent with these 65
- 66 observations (Zhu 2008; Li et al. 2021). A laboratory study found that horizontal rolls could even
- 67 impact the intensification rate of TCs (Sukhanovskii and Popova, 2020). Therefore, the omission of
- RVs in the PBL scheme could potentially lead to relatively poor TC intensity forecasts (Ernst et al. 68
- 69 2019).
- 70 In light of the linkage between VED and RV in the PBL scheme within the Weather Research and
- 71 Forecasting (WRF) model, Li and Pu (2021) improved the Yonsei University (YSU) PBL scheme
- 72 (Hong et al. 2006; Hong 2010) by adding RV effects based on the LES of landfalling Hurricane Harvey
- 73 (2017). Numerical experiments indicated that the revised YSU scheme produced better hurricane track,
- 74 intensity, and quantitative precipitation forecasts (QPF). The positive impacts of including RV effects
- 75 in the WRF model motivate us to further evaluate these effects and implement the findings in other

models. Specifically, RV effects have not yet been included in the NCEP operational Hurricane WRF (HWRF) regional model. The hybrid Global Forecast System (GFS) PBL scheme in the current version of the HWRF model was previously modified based on observations (Bu et al. 2017; Wang et al. 2018; Zhang et al. 2020) with a wind-speed-dependent VED parameterization, but no RV effect was considered. Therefore, the purpose of this study is to improve the previous RV parameterization and implement it into the PBL scheme of the HWRF model. We also aim to evaluate the effects of the RV parameterization on hurricane prediction. We use the operational version of the HWRF model (version

parameterization on hurricane prediction. We use the operational version of the HWRF model (version 2020, referred to as H220 hereafter). Specifically, considering the high impact of landfalling hurricanes

on our society, our focus is on improving forecasts of landfalling storms.

The development of the RV parameterization in the HWRF model is described in Section 2. The forecast results and evaluations are discussed in Section 3. The influence of the modified PBL scheme with RV effect on the hurricane intensity and structure are examined in Section 4. A summary and concluding remarks are provided in Section 5.

2 Modifying the RV parameterization in the HWRF model

89

90

2.1 A brief description of the HWRF model and GFS PBL scheme

91 HWRF (Version 4) is a NOAA/NCEP regional operational hurricane models. It is composed of the 92 WRF (Weather Research and Forecasting) non-hydrostatic mesoscale model (NMM) on an E-grid 93 dynamic core (Janjić et al. 2010), the Message Passing Interface Princeton Ocean Model for Tropical Cyclones (MPIPOM-TC) (Yablonsky et al. 2015), the NCEP coupler, and the GSI data assimilation 94 platform (Kleist, et al. 2009; Wang 2010). The HWRF model domains are configured to have a parent 95 96 domain and two storm-following moving nested domains, with resolutions of ~13.5 km, ~4.5 km, and ~1.5 km, respectively. The atmospheric model in the HWRF system employs a suite of advanced 97 98 physics developed for TC applications, such as the Ferrier-Aligo microphysics scheme (Ferrier et al., 99 2002; Aligo et al., 2018), the simplified Arakawa-Schubert (SAS) deep convection scheme (Pan and Wu, 1995; Hong and Pan, 1998), the Geophysical Fluid Dynamics Laboratory (GFDL) longwave and 100 101 shortwave radiation schemes (Schwarzkopf and Fels, 1991; Lacis and Hansen, 1974), the GFDL 102 surface layer scheme (Sirutis and Miyakoda, 1990; Kurihara and Tuleya, 1974), the Noah land surface model (Ek et al. 2003), and the hybrid NCEP GFS or "GFS EDMF" PBL parameterization scheme 103 104 (Gopalakrishnan et al., 2013; Wang et al. 2018; Zhang et al. 2020; Kalina et al. 2021).

The "GFS" or "GFS EDMF" PBL scheme is essentially a first-order nonlocal scheme that originated from the traditional NCEP Medium-Range Forecast (MRF) scheme (Troen and Mahrt 1986; Hong and Pan 1996; Han and Bretherton 2019). In the latest operational version of the HWRF model (as of the end of 2020), a wind-speed-dependent VED of momentum (Km) modification has been applied in the GFS EDMF PBL scheme since 2015 (Bu et al. 2017; Wang et al. 2018):

$$K_m = \alpha k w_s h (1 - \frac{h}{PBLH})^2$$
 (1)

where k=0.4 is the Von Kármán constant; w_s represents the mixed-layer velocity scale, and PBLH represents the height of the planetary boundary layer (PBL). The coefficient α is computed based on the diagnosed eddy diffusivity of momentum K_m at a single level (h=500 m) based on observations (Zhang et al. 2011) and then applied through the entire PBL within that model column for grid points over the ocean.

$$\alpha = \frac{WS_{500}}{0.5K_{m500}} \tag{2}$$

where WS denotes the wind speed and the subscript 500 stands for the variable collection height of

118 500 m.

119

2.2 RV parameterization

- 120 In Li and Pu (2021), the large eddy simulation (LES) of landfalling Hurricane Harvey (2017) was used
- to parameterize RV and its effect was added to the YSU PBL scheme in the WRF model. Figure 1
- shows the azimuthally averaged Km (shading) from the simulations with the WRF YSU PBL scheme
- 123 (Figure 1a) and LES (Figure 1b), and their difference (Figure 1c) at 17 UTC 25 August 2017 for
- Hurricane Harvey. The simulations indicated that RV always contributed to VED at distances less than
- 125 100 km from the hurricane center. The RV intensity, $I_w = w' \cdot w'$, is shown as a contour line to
- distinguish the RV's contribution. Figure 1 also indicated that Km from the YSU scheme was weak,
- with a maximum of less than 90 m²s⁻¹, while the area with solid RV (intensity over 0.5 m²s⁻²) always
- had larger Km in the LES, with a maximum of over 210 m²s⁻¹. This large Km implies a strong vertical
- mixing effect led by the RV at 100-3000 m in LES. Therefore, based on the significant relationship
- between the large Km and RV intensity shown in Figure 1, Li and Pu (2021) regard the VED difference
- between the simulation with WRF and WRF-LES as the contribution from RV to the total VED. The
- 151 between the simulation with with and with -EES as the contribution from KV to the total VED. The
- RV intensity was first related to the horizontal divergence in the PBL and then used to quantify the
- VED contribution from RV.
- Li and Pu (2023) found that the inflow transports the rolls in the entire storm boundary layer and
- accumulates near the eyewall to support the intense rolls there. Specifically, in Li and Pu (2021), RV
- intensity, $I_w = w' \cdot w'$, is linked to horizontal convergence (negative divergence) where w' is the
- vertical component of the RV turbulence. Based on dimensional analysis, the maximum $I_{\rm w}$ ($I_{\rm wm}$) is
- proportional to the square of the mean horizontal divergence (div) in a vertical column of the PBL
- below 400 height:

$$I_{wm} = a \cdot div^2 \tag{3}$$

- The coefficient a is 1.97 based on LES data following Li and Pu (2021). Note that below 400 m altitude,
- divergence is mostly negative, indicating convergence in the PBL.
- To generate the vertical profile of I_w , the height of I_{wm} (H_m) is represented by the height of the minimum
- wind shear (du/dz). Then, with H_m and I_{wm} , I_w normalized by I_{wm} (g) in each vertical column is described
- by an adjusted gamma distribution function f as follows:

$$f(h) = \left(\frac{h}{100}\right)^{H_m/300} \cdot e^{-h/300} \tag{4}$$

$$(\mathbf{h}) = \frac{f(\mathbf{h})}{\max(f(\mathbf{h}))} \tag{5}$$

where h is the height above the ground and g(h) is the normalized I_w profile distribution function.

Finally, the $I_{\rm w}$ profile in a single column is derived:

$$I_{w}(h) = I_{wm} \cdot g(h) \tag{6}$$

As in the setup of the YSU PBL scheme, Li and Pu (2021) used a velocity scale $w_{\rm sr}$ for RV to

determine the RV-induced VED of momentum, that is, K_{mr} , in the form of:

$$K_{mr} = w_{sr} \cdot h(1 - \frac{h}{H_t})^2 \tag{7}$$

- where H_t is the height of the top of RV, which is assumed to be above H_m , and $I_w = 0.05 I_{wm}$. A height
- of 3000 m is used as the H_t maximum. According to the dimensional analysis, w_{sr} is proportional to
- the square root of I_w . A linear fitting method is applied as follows:

$$\mathbf{w}_{\mathrm{sr}} = \mathbf{b} \cdot (\mathbf{I}_{\mathrm{w}})^{1/2} \tag{8}$$

- where b, the linear coefficient, is equal to 0.08 in the PBL and 0.20 in the free atmosphere from Li and
- Pu (2021). Then, K_{mr} is determined through Equation (7) in the modified PBL scheme.
- Since the vertical eddy diffusivity of heat (K_{hr}) and moisture (K_{qr}) produced by RV is weak, a fixed
- ratio for K_{hr}/K_{mr} and K_{qr}/K_{mr} is set to the mean value of 4.79×10^{-2} in LES for the RV parameterization
- in Li and Pu (2021). Finally, RV-induced K_{mr}, K_{hr}, and K_{qr} are added to the original K_m, K_h, and K_q of
- the PBL scheme. Further details can be found in Li and Pu (2021).
- In the present study, we modify the RV parameterization of Li and Pu (2021) and apply it to the HWRF
- PBL scheme. The different horizontal grid spacings of WRF (coarse grid) and HWRF (fine grid) could
- lead to different values of coefficient b in Equation (8), so a sensitivity test based on the WRF-LES
- simulation results was conducted with different horizontal grid spacings. Figure 2 shows the variation
- of b with the horizontal grid spacing, suggesting that b is not sensitive to the horizontal grid resolution,
- with a variance of less than 10%. This result also confirms that b = 0.20 for the free atmosphere and b = 0.20
- = 0.08 for the PBL in equation (8) work best for the HWRF model with the horizontal grid spacing of
- $\sim 0.033^{\circ}$ for domain 2 and 0.011° for domain 3.

191

- 172 In the LES simulation of Hurricane Harvey (2017) by Li et al. (2021) and Li and Pu (2021), the LES
- domain covers only the hurricane inner-core region (within a radius of less than 150 km from the
- hurricane center). Figure 1 shows that RV always contributes to VED at distances less than 100 km
- from the hurricane center. Therefore, an inner-core distance limitation, namely, 100 km, should be
- added to the HWRF system to avoid the RV contribution through the RV parameterization outside the
- inner core. To ensure that this hurricane's inner-core region is covered by all three domains with their
- own grid spacings, distance limitations of 150 km for domain 1, 115 km for domain 2, and 101 km for
- domain 3 are used when modifying the HWRF PBL scheme to include the RV effect.

2.3 Improvement of RV parameterization over land

- From Equation (8), the relation of w_{sr} and I_w differs only in the PBL and free atmosphere. Since this
- study emphasizes landfalling hurricanes, the different underlying surfaces of the land and ocean should
- be considered since they could lead to different VED (Tang et al. 2018; Zhang et al. 2017) and thus
- different values of b in Equation (8). From Li and Pu (2021), coefficient b in Equation (8) is determined
- mainly by the hurricane simulation results over the ocean. Therefore, for the inland configuration,
- 186 coefficient b in Equation (8) needs to be adjusted. Figure 3 shows the fitting relationship of w_{sr} and
- the mean root of I_w for the TC inland case based on additional LES simulations. Results show that b =
- 188 0.04 in the PBL and b = 0.06 in the free atmosphere should be used over land; these values are
- of the rest and the rest and the rest at the second of the
- significantly different from the values of b over the ocean from Li and Pu (2021). This adjusted
- coefficient b in the RV parameterization over land is used in the modified HWRF PBL scheme.

3 HWRF experiments and forecast impacts

3.1 **Experiment configurations**

192

- Following the modification of the PBL scheme with the RV parameterization in the HWRF model as 193
- 194 described in the previous section, the impacts of the modified PBL scheme on TC forecasts are
- 195 examined with the operational HWRF model (version H220). Considering the tuning coefficient α in
- the PBL scheme as mentioned above, the following three experiments are configured. Note that two of 196
- 197 the experiments combine the α effect with RV parameterization in the PBL scheme.
- 198 1) Control: no change in the HWRF model, where K_m is parameterized using Eqs. (1) and (2).
- 199 2) RV-A- α : in the hurricane inner-core region, the first guess of K_m is modified by including the RV parameterizations (K_{mr}) first, and then it is adjusted by α to generate the final K_m as follows: 200

$$K_m = \alpha \left[k w_s h \left(1 - \frac{h}{PBLH} \right)^2 + K_{mr} \right]$$
 (9)

- Outside the inner-core region, there is no change from Control. 202
- 3) RV-C- α : in the hurricane inner-core region, when K_{mr} is not equal to zero, the first-guess K_m is 203 204 modified only by adding the above RV parameterizations without α adjustment, namely:

$$K_{m} = kw_{s}h(1 - \frac{h}{PBLH})^{2} + K_{mr}$$
 (10)

- 206 Otherwise, when K_{mr} is equal to zero, the first-guess K_{m} is adjusted only by α as defined in the 207 current HWRF to generate the final K_m, as described in Eqs. (1-2). Outside the inner-core 208 region, there is no change from Control.
- 209 In the modified PBL scheme, α interacts with the added RV parameterization. In RV-A- α , the RV
- parameterization is added to the HWRF PBL while retaining the effect of coefficient α . In RV-C- α , 210
- 211 adding the RV parameterization is an option to replace coefficient α conditionally.
- 212 With the above configurations, HWRF forecasts are conducted for Hurricane Florence (2018), with
- 213 cycled forecasts (equivalent to the procedure of operational runs in 6 hourly analysis and forecast
- 214 cycles) from 18 UTC 13 to 18 UTC 14 September 2018, and for Hurricane Laura (2020), with cycled
- 215 forecasts from 00 UTC 25 to 00 UTC 27 August 2020. The forecast case is spun up at 00 UTC 13
- 216 September 2018 for Hurricane Florence, and at 06 UTC 24 August 2020 for Hurricane Laura with the
- 217 cycled run. A total of 14 cases, 5 for Florence and 9 for Laura, are analyzed to evaluate the impacts of
- 218 the revised PBL scheme on track, intensity, and structure forecasts compared to the original scheme.
- 219 To assess the quantitative precipitation forecasting (QPF), observations from NCEP stage IV
- 220 precipitation data (Lin and Mitchell, 2005) are used compute the threat score:

$$Threat score = \frac{correct}{forecast+observation-correct}$$
 (11)

- where *forecast* is the point number of the simulated QPF with special threshold precipitation, and 222
- observation is the point number of the QPF from the stage IV data. Correct is the point number of the 223
- 224 correct forecast that agrees with the observation.

225

Track, intensity, and precipitation forecasts

3.2.1 Hurricane Florence

226

227 Figure 4 shows the forecast tracks of Hurricane Florence from the three experiments at different 228 forecast times. The hurricane tracks of RV-A- α and RV-C- α are different from that of Control, with a slower-moving TC through the revised PBL scheme. Compared to the NHC best-track data, the 229 230 simulated storms in these three experiments move slightly faster after landfall. The storm in RV-C- α 231 is the slowest and is closest to the best track. Then, to quantify the forecast skill, the track and intensity errors are computed as shown in Figure 5. The track error of RV-C- α is smaller than that of Control, 232 with a mean error reduction of 6.02 km. The mean track error of RV-A- α is 65.13 km, which is slightly 233 234 larger than that of Control. For the maximum surface wind (MSW) error, RV-C- α also produces a mean 235 error of -4.42 kt, which is smaller than that of Control (-6.44 kt). RV-A- α produces an MSW error similar to that of Control, with a mean error of -6.21 kt. When the hurricane decays over land, the 236 237 MSW error of RV-C- α decreases with time and is smaller than those of the other two experiments. The most significant intensity forecast improvement is at 12 UTC 14 September 2018, at hurricane landfall. 238 239 For the minimum sea level pressure (MSLP) forecast, the improvement in RV-C- α is not consistent, in 240 that the MSLP error is smaller than that in Control in the first 24 h but larger at 30-66 h. Finally, the 241 mean MSLP error is -4.62 hPa for RV-C-α, close to the mean error of -4.02 hPa for Control. RV-A-α 242 has an MSLP error similar to that of Control, with a mean error of -4.03 hPa. Overall, RV-C- α produces 243 the best hurricane track and MSW forecasts against the best track from the NHC report. Note that the MSLP forecast reduction by RV-C-α compared to Control is smaller (15%) than the MSW forecast 244 245 improvement (> 31%).

Accurate precipitation forecasts near hurricane landfall time are essential for public warnings. The 12 246 247 h accumulated precipitation forecast, initialized at 06 UTC 14 September 2018, is compared with the NOAA Stage IV precipitation analysis (Lin and Mitchell, 2005) during Hurricane Florence's landfall 248 between 06 and 18 UTC 14 September 2018 (Figure 6). RV-C-α performs better than Control, which 249 250 underestimates the rainfall over the ocean. RV-C- α has an even larger precipitation maximum (160) 251 mm) than RV-A- α (120 mm) close to the hurricane eye and eyewall regions over the ocean. Overall, 252 RV-C- α provides the best rainfall forecast for Florence, consistent with the result of Li and Pu (2021). 253 To further examine the improvement in the precipitation of Florence, the mean threat score (TS) of the 254 OPF based on the NOAA Stage IV data for 12h, 24h, 36h, and 48h accumulated precipitation is 255 analyzed (figures not shown). The results show a strong increase in the mean TS for heavy rainfall (over 160 mm) in RV-C-α, with a TS increase of over 0.1 from Control. The increased mean TS 256 257 indicates that RV-C-α significantly improves the rainstorm forecast, which is important for public warnings. The slightly reduced (less than 0.04) or similar mean TS for the smaller rainfall (<160 mm) 258 reflects a similar QPF ability for RV-C- α and Control at these precipitation thresholds. RV-A- α shows 259 poor OPF with a gradually smaller mean TS than Control and RV-C-α. 260

3.2.2 Hurricane Laura

261

262 Figure 7 shows the forecast storm tracks from the three experiments at different forecast times for 263 Hurricane Laura. The storm tracks in these forecasts are all close to the NHC best track, with a maximum error of less than 100 km. Figure 8 shows the forecast track and intensity errors from these 264 265 experiments. Compared to Control, RV-C-α provides a comparable track forecast. The absolute track 266 error is 36.29 km for Control, 40.48 km for RV-A-α, and 37.04 km for RV-C-α. For the MSW error, RV-C- α again provides a smaller error, -10.51 knot, compared to the -12.16 knot from Control. The 267 268 MSW error reduction by RV-C-a, compared to Control, increases and then decreases with time. RV-269 A- α provides a slightly worse MSW forecast than the other two experiments, with a mean error of -13.34 knot. RV-C- α also provides a better MSLP forecast in the first 42h than Control, with the mean 270 271 error reducing in magnitude from -1.29 hPa (Control) to -0.83 hPa. Overall, RV-C-α performs the best,

- with a 14% reduction in the MSW forecast error and a 36% reduction in the MSLP forecast error 272
- compared to Control and best track. Furthermore, the track error increment is less than 2% for RV-C-273
- 274
- 275 The 12h accumulated precipitation forecasts, initialized at 18 UTC 25 August 2020, for Hurricane
- 276 Laura from 00 to 12 UTC 27 August 2020 are compared with the NCEP Stage IV precipitation analysis
- (Figure 9). RV-C- α reduces the overestimated rainfall over the ocean in Control and RV-A- α . Control 277
- 278 strongly overestimates the rainfall, especially near the coastline, with a maximum of ~280 mm
- 279 compared to observations, while RV-A- α reduces this overestimation to some degree and RV-C- α
- 280 significantly reduces the precipitation forecast error with a precipitation maximum of ~160 mm.
- As with Florence, the mean threat score (TS) of the QPF of Laura against the NOAA Stage IV data for 281
- 282 12h, 24h, and 36h accumulated precipitation is analyzed (Figure not shown). Because of the relatively
- weak precipitation from Laura, the mean TS is small and often less than 0.4 for threshold precipitation 283
- 284 over 80 mm. For precipitation less than 80 mm, the revised PBL scheme in RV-A-α and RV-C-α
- provides a neutral impact on the QPF, with mean TS reduction and increment both less than 0.04 285
- against Control. The revised HWRF PBL scheme improves the 24h and 36h QPF. Due to its quick 286
- decay and relatively weak rainfall, the improvement from RV-C- α is somewhat weaker for Laura than 287
- for Florence. 288

311

Inner-core horizontal and vertical winds

- 290 To evaluate whether the modified PBL scheme improved the hurricane inner-core representation, we
- 291 compared the HWRF wind fields with available NOAA airborne Doppler radar observations. Figure
- 10 shows the winds at 1500 m from the three experiments, initialized at 18 UTC 26 August 2020, and 292
- 293 NOAA radar for Hurricane Laura at 00 UTC 27 August 2020 during landfall. Compared to the radar
- 294 data, Control overestimates the inner-core winds with a larger area of strong winds (over 50 ms⁻¹). RV-
- A- α only slightly reduces the high winds in the northern portion of the inner-core region. RV-C- α 295
- reproduces an asymmetric pattern similar to the radar observations and has a small high wind (over 50 296
- 297 ms⁻¹) area around the eyewall.
- Vertical wind profiles at 00 UTC 27 August 2020 from the NOAA P3 Doppler radar along the flight 298
- 299 line (black line in Figure 10) are used to evaluate the forecasts of Hurricane Laura, initialized at 18
- UTC 26 August 2020, shown in Figure 11. From the western portion of Laura, RV-C- α provides a high 300
- 301 wind (>55 ms⁻¹) region closer to the radar observations, with high wind extending just to 7 km. Control
- and RV-A- α have too large an area with high wind (>55 ms⁻¹), extending to nearly 10 km. Compared 302
- 303 to the eastern observations, RV-C- α provides a vertical structure similar to the radar data, with a
- 304 separate high wind at ~7 km and a small area with over 55 ms⁻¹ wind below 2 km altitude. Overall,
- 305 RV-C- α shows a better wind speed pattern both in east and west parts of hurricane with most shrinking
- area of strong winds. Control and RV-A- α still have stronger low-level and high-level wind. 306
- 307 The above results indicate that adding the RV effect into the HWRF PBL scheme can improve the
- 308 representation of hurricane inner-core wind profiles. The result here is quantitatively consistent with
- the findings of Zhang et al. (2015), who adjusted the VED to obtain better wind structure forecasts of 309
- TCs over the ocean, although they did not include the RV effect. 310

4 Influence of RV parameterization on the evolution of hurricane inner core

- The evolution of the hurricane inner-core structure is essential for hurricane track and intensity 312
- 313 changes. In this section, we further examine the effects of the modified PBL scheme on the evolution

- of hurricane inner-core structure, especially for the period near landfall. We will show Hurricane
- Florence case as an example. Specifically, we analyze the forecasts initialized at 06 UTC 14 September
- 316 2018, when Florence is close to land.
- Figure 12 shows the evolution of azimuthally averaged surface wind speed from Control (Figure 12a),
- RV-A- α (Figure 12b), and RV-C- α (Figure 12c) during the 60h forecast. The maximum azimuthally
- averaged surface wind in RV-C- α is higher than that in Control and RV-A- α . The radius of MSW is
- smaller in RV-C- α in the first 12h than in the other two experiments. After 24h, the azimuthally
- 321 averaged surface wind speed in RV-C- α maintains a maximum wind of greater than 34 ms⁻¹. After this
- time, the maximum winds decay more slowly with time in RV-C- α than in the other two experiments.
- Through the intensity forecast analysis in Figure 5b, the simulated hurricane in Control and RV-A- α
- decays more quickly than the best track. The evolution of maximum wind here supports a much better
- intensity forecast of RV-C- α compared to Control (c.f., Figure 5).
- To further examine the reason why RV-C- α leads to a better intensity forecast, Figure 13 shows the
- 327 azimuthally averaged momentum VED from Control (Figure 13a), RV-A-α (Figure 13b), and RV-C-
- 328 α (Figure 13c) at the 12h, 24h, and 36h forecast times. The maximum azimuthally averaged VED in
- RV-C- α is higher than that in Control and RV-A- α at the 24h and 36h forecasts. Previous studies have
- indicated that RV can enhance the vertical mixing effect near the TC eyewall region (Zhu 2008; Zhang
- and Drennan 2012; Zhao et al. 2020; Li et al. 2021), thus influencing hurricane intensity and evolution.
- Therefore, the larger VED in RV-C- α implies a larger vertical mixing effect on the wind speed. With
- the decay of the hurricane, the hurricane eye enlarges, and the RV effects extend from the hurricane
- center to its vicinity. Consequently, RV-C- α results in a largest VED within a radius of 100-150 km at
- the 36h forecast among all three experiments.
- Figure 14 shows the azimuthally averaged wind speed from the three experiments at the 12h, 24h, and
- 337 36h forecast times. The maximum azimuthally averaged wind speed, which is typically located at 850-
- 900 hPa, is the same in Control as in RV-A- α , with a value of 42 ms⁻¹ at 12h, 33 ms⁻¹ at 24h, and 30
- 339 ms⁻¹ at 36h, respectively. In contrast, RV-C-α provides stronger azimuthally averaged wind speeds,
- with a maximum of 42 ms⁻¹ at 12h, 36 ms⁻¹ at 24h, and 33 ms⁻¹ at 36h, respectively. The larger VED
- 341 (as shown in Figure 13g-i) indicates that adding the RV parameterization in RV-C-α causes a stronger
- mixing of high wind downward from levels above 900 hPa to the boundary layer that acts to increase
- the surface wind speed (near the 1000 hPa level) by offsetting the surface friction effect, and maintain
- 344 the hurricane intensity over land (as shown in Figure 3c).
- 345 Although the above analysis indicates that the higher surface wind is associated with the vertical
- mixing in RV-C- α , the reason for the stronger high-level (above 900 hPa) winds in RV-C- α still needs
- to be clarified. According to Persing and Montgomery (2003) and Montgomery et al. (2006), the high-
- entropy air in a hurricane eye can lead to a stronger hurricane through eye-eyewall mixing. Therefore,
- the strong hurricane in the RV-C- α could be associated with the high-entropy air and eye-eyewall
- mixing process. To test this hypothesis, Figure 15 shows the equivalent potential temperature (θ_e)
- difference between RV-A- α and RV-C- α as well as Control at 12h, 24h, and 36h. There is a large area
- difference between KV-A-a and KV-C-a as wen as control at 12h, 24h, and 30h. There is a large area
- of positive θ_e difference (> 0.6 K) close to the storm center between RV-C- α and Control. This positive
- difference is generally smaller between RV-A- α and Control, indicating stronger eye-eyewall mixing
- with the RV effect. Wang and Xu (2010) found that higher entropy in the boundary layer inflow can
- 355 significantly enhance hurricane development through an energy budget argument. Since the RV effect
- in RV-C- α provides stronger mixing near the surface (Figure 13 g-i), the increase in boundary layer
- entropy is associated with stronger mixing. This high-entropy air helps offset the downdrafts induced
- by low-entropy air into the boundary layer in sheared TCs and helps maintain convective activity in

- combination with the strong inflow. Overall, the RV effect enhances the simulated hurricane intensity
- and reduces the intensity forecast error in RV-C- α . Of note, the wind-speed-dependent VED in RV-A-
- 361 α offsets the RV contribution to VED, leading to a weaker storm compared to that in RV-C- α , but the
- RV effect still helps improve the intensity forecast in RV-A- α compared to Control.

5 Summary

363

- In this study, the parameterization of roll vortices (RV), a type of large turbulence eddy in the TC
- boundary layer, was added into the PBL scheme of the NCEP HWRF model. The RV parameterization
- scheme that was originally developed by Li and Pu (2021) based on WRF-LES runs was adjusted to
- 367 fit into the GFS PBL scheme within the HWRF model. Improvement was also made to the RV
- parametrization over land. Based on additional WRF-LES sensitivity experiments of landfalling storms
- beyond previous work, the coefficient that connects the RV intensity, velocity scale, and VED was
- 370 modified from 0.20 to 0.06 for the free atmosphere and from 0.08 to 0.04 for the PBL in HWRF, taking
- into account differences in both grid spacing and land versus ocean. The new VED parameterization
- 271 Into account differences in both grid spacing and land versus ocean. The new VED parameterization
- with the RV effect was compared with the original wind-speed-dependent VED parameterization in HWRF (Control) to evaluate their impacts on hurricane forecasts. Cycled HWRF forecasts are
- 27.4 TIWKI (Control) to evaluate their impacts on numerate forecasts. Cycled TIWKI forecasts are
- performed for Hurricanes Florence (2018) and Laura (2020), with a total of 14 cases during the analysis
- and forecast cycles of the two storms.
- Results showed a better surface MSW forecast with a 14%-31% improvement in the experiment with
- 377 the modified PBL scheme with the RV effect, compared with the original PBL scheme. The improved
- performance of the revised scheme on track and SLP forecasts were significant, with an increment of
- 379 -2% to 9% for track and -15% to 36% for SLP forecasts.
- Further diagnoses showed that the vertical turbulent mixing adjustment due to the RV effect in the
- revised scheme leads to a better wind structure forecast than the original scheme compared to NOAA
- 382 airborne Doppler radar observations. The RV effect also modulates the moisture structure by enhancing
- 383 θ_e in the boundary layer. The enhanced θ_e lead to a stronger storm during landfall in the HWRF forecast
- with the RV parameterization. The overall intensity forecast performance is better using the scheme
- with the RV effect according to the retrospective forecast. Overall, the modified PBL scheme with the
- 386 RV effect could potentially be applied in the HWRF model for real-time TC forecasts. More cases will
- be performed in future work.

- 594 Figure captions
- 595 **FIGURE 1**. Azimuthally averaged vertical eddy diffusivity of momentum (shading) from the WRF
- simulations with (A) YSU PBL scheme, (B) LES, and (C) their difference (K_{mr}) at 17 UTC 25 August
- 597 2017 for Hurricane Harvey. The black contour line stands for the RV's intensity at the same time.
- 598 **FIGURE 2**. Coefficient b in equation (8) as a function of horizontal grid spacing. The dashed line
- represents coefficient b from LES in Li and Pu (2021).
- FIGURE 3. Plot of w_{sr} as a funcion of the mean root of I_w over land. The least square best fit lines
- for free atmosphere (blue) and PBL (black) are also shown.
- FIGURE 4. Comparison of forecast track with the best-track data for Hurricane Florence at (A) 18
- 603 UTC 13, (B) 00 UTC 14, (C) 06 UTC 14, (D) 12 UTC 14, and (E) 18 UTC 14 September 2018.
- 604 Control, RV-A-\alpha, RV-C-\alpha, and best track are represented by the blue, red, green, and black lines,
- 605 respectively.
- 606 FIGURE 5. Mean forecast errors against the best-track data for Hurricane Florence (A) track, (B)
- maximum surface wind (MSW), and (C) minimum sea level pressure (SLP). The black lines in (A)
- and (C) denote the best-track MSW and minimum SLP, respectively. The dashed line in (A) denotes
- the landfall time.
- FIGURE 6. The 12h accumulated precipitation from (A) Stage IV, (B) Control, (C) RV-A- α , and (D)
- 611 RV-C-α during Hurricane Florence's landfall at 06-18 UTC 14 September 2018.
- FIGURE 7. Comparison of forecast track with the best-track data for Hurricane Laura at (A) 00 UTC
- 613 25, **(B)** 06 UTC 25, **(C)** 12 UTC 25, **(D)** 18 UTC 25, **(E)** 00 UTC 26, **(F)** 06 UTC 26, **(G)** 12 UTC 26,
- 614 **(H)** 18 UTC 26, and **(I)** 00 UTC 27 August 2020.
- 615 **FIGURE 8**. Same as Figure 5, except for Hurricane Laura.
- FIGURE 9. The 12h accumulated precipitation from (A) Stage IV, (B) Control, (C) RV-A- α , and (D)
- 617 RV-C-α during Hurricane Laura's landfall at 00-12 UTC 27 August 2020.
- 618 FIGURE 10. The 1500 m wind from (A) NOAA Doppler radar, (B) Control, (C) RV-A-α, and (D)
- 619 RV-C-α for Hurricane Laura near landfall time at 00 UTC 27 August 2020. The white contour line

- stands for wind over 50 ms⁻¹ for observations and simulations. The black line represents the cross-
- section in Figure 12.

- 622 FIGURE 11. Wind field of vertical cross section for Laura at 00 UTC 27 August 2020, from (A)
- NOAA P3 TDR radar, (**B**) Control, (**C**) RV-A- α , and (**D**) RV-C- α .
- 624 **FIGURE 12**. Evolution of azimuthally averaged surface maximum wind of Hurricane Florence
- 625 initialized at 06 UTC 14 September 2018, from (A) Control, (B) RV-A-α, and (C) RV-C-α. The radius
- of MSW is represented by the black line.
- 627 **FIGURE 13**. Azimuthally averaged momentum vertical eddy diffusivity (VED) of Hurricane Florence
- 628 initialized at 06 UTC 14 September 2018, from (A-C) Control, (D-F) RV-A- α , and (G-I) RV-C- α at
- 629 (A, D, and G) 12h, (B, E, and H) 24h, and (C, F, and I) 36h.
- 630 **FIGURE 14**. Same as Figure 13, except for azimuthally averaged wind speed of Hurricane Florence.
- 631 **FIGURE 15**. Difference in azimuthally averaged equivalent potential temperature of Hurricane
- Florence, initialized at 06 UTC 14 September 2018, between Control and (A-C) RV-A- α and (D-F)
- 633 RV-C- α at (**A** and **D**) 12h, (**B** and **E**) 24h, and (**C** and **F**) 36h.
