

## CLIMATOLOGY

# A woody biomass burial

## Ancient, buried wood points to a possible low-cost method to store carbon

By Yuan Yao

1 Limiting climate change requires achieving net  
 2 zero carbon dioxide emissions. Although sub-  
 3 stantial reductions in fossil fuel emissions are  
 4 essential, they are insufficient for achieving the  
 5 international goal of limiting global warming to  
 6 1.5 or 2°C above preindustrial levels. These tar-  
 7 gets, established by the Paris Agreement, aim to  
 8 avoid severe impacts of climate change by  
 9 keeping the global average temperature in-  
 10 crease within these limits. (1). Achieving net-  
 11 zero necessitates approaches that remove car-  
 12 bon dioxide from the atmosphere, known as  
 13 carbon dioxide removal (CDR) (2). Engineering  
 14 CDR methods, such as direct air capture, are  
 15 expensive and energy-intensive. Nature-based  
 16 CDR, such as reforestation and afforestation,  
 17 are cheaper but face land use competition,  
 18 scalability issues, and carbon leakage risks (3).  
 19 On page XXX of this issue, Zeng et al.(4) de-  
 20 scribe a hybrid nature-engineering CDR  
 21 method that is inspired by a 3775-year-old  
 22 wood log buried belowground, which could  
 23 contribute to meeting the 1.5 °C warming  
 24 threshold.

25 Forests are central to climate change dis-  
 26 cussions because of their critical role as a dom-  
 27 inant land carbon sink in natural carbon cycles  
 28 (5). They sequester carbon from the atmos-  
 29 phere through photosynthesis. This carbon is  
 30 stored in wood with ~50% carbon content that  
 31 varies by species (6). The carbon is released  
 32 back to the atmosphere through burning (for-  
 33 est fires or prescribed burning for fire risk man-  
 34 agement) or decomposition of woody biomass.  
 35 Globally,  $10.9 \pm 3.2$  Gt (billion tonnes) of carbon  
 36 could be emitted from deadwood per year,  
 37 higher than anthropogenic carbon emissions  
 38 from fossil fuels (7). If an approach can extend  
 39 the duration of carbon storage in wood to hun-  
 40 dreds of years or longer and prevent the re-  
 41 lease of carbon back into the atmosphere, it  
 42 would naturally be an effective CDR approach.

43 Zeng et al. describe a pathway to make  
 44 deadwood carbon storage a reality. The au-  
 45 thors present a CDR approach involving the  
 46 burial of sustainably sourced wood in an under-  
 47 ground engineered structure called as “wood  
 48 vault” to prevent wood decomposition. This

49 method is based on their discovery of an an-  
 50 cient Eastern red cedar wood log in Saint-Pie,  
 51 Quebec, Canada, 50 km east of Montreal. The  
 52 log was found two meters underground and  
 53 surrounded by clay soil. Carbon-14 analysis in-  
 54 dicates that it is  $3775 \pm 35$  years old. Scanning  
 55 electron microscopy revealed that the late-  
 56 wood portion (the wood produced late in the  
 57 growing season) is well preserved.

58 How much carbon was lost from this wood  
 59 log over time has direct implications for the vi-  
 60 ability of wood burial for durable carbon stor-  
 61 age. It is difficult to estimate carbon loss by  
 62 comparing ancient wood with a perfectly pre-  
 63 served wood sample from the original tree that  
 64 lived thousands of years ago. To address this,  
 65 Zeng et al. cut one end of the ancient wood log  
 66 and a modern wood sample from the same  
 67 species and compared their physical properties  
 68 and chemical compositions. They found that  
 69 although the density of the ancient wood is  
 70 lower than that of the modern sample, the ten-  
 71 sile strength and main chemical compositions  
 72 were similar. Holocellulose, which includes cel-  
 73 lulose and hemicellulose, and lignin are the  
 74 main chemical components of wood carbon  
 75 (8). Holocellulose loss is a common indicator for  
 76 analyzing minor wood decay (9). Based on the  
 77 loss of holocellulose, the authors estimated the  
 78 carbon loss in the ancient sample to be up to  
 79 5%. This provides evidence for preserving car-  
 80 bon in wood through burial with low carbon re-  
 81 emission risk.

82 The preservation conditions of the ancient  
 83 wood log are crucial to replicate for achieving  
 84 long-term carbon storage. Zeng et al. at-  
 85 tributed the well-preserved ancient wood  
 86 mainly to the clay soil characteristics that cre-  
 87 ated an environment lacking oxygen. Oxygen,  
 88 moisture, and temperature are the main fac-  
 89 tors contributing to wood decomposition. The  
 90 latter two factors are not limited at the Mon-  
 91 treal site where the ancient wood log was dis-  
 92 covered. The site has low-permeability clay soil,  
 93 as well as waterlogged and stagnant soil condi-  
 94 tions, creating an oxygen-depleting environ-  
 95 ment. Fungi and insects, the main decompos-  
 96 ers, cannot survive in this environment.  
 97 Anaerobic bacteria can, but they cannot break  
 98 down lignin, the most stable biomass compo-  
 99 nent that protects cellulose structure (10).  
 100 Thus, coarse woody biomass, such as a whole  
 101 log with its original structure maintained, will  
 102 be better for wood preservation than fine

103 woody biomass. Based on these findings, the  
 104 Zeng et al. suggest that burying clean, coarse  
 105 woody biomass in a chamber capped by low-  
 106 permeability clay soil—a “wood vault”—would  
 107 replicate oxygen-depleting conditions.

108 An exciting aspect of the Zeng et al. study is  
 109 the potential for wood burial as a low-cost,  
 110 highly scalable CDR. Zeng et al. estimated a CDR  
 111 cost of \$100-200 per tonne. Scaling up and op-  
 112 timizing the process over the next one to two  
 113 decades would potentially lower the cost to  
 114 \$30-100/tonne. The cost of future individual  
 115 wood burial projects can vary substantially, de-  
 116 pending on wood sourcing and transportation  
 117 distances. Considering these variations, wood  
 118 burial can be cost-competitive compared to en-  
 119 gineering approaches such as direct air capture  
 120 (\$125-335 per tonne of carbon dioxide) (11) or  
 121 other hybrid nature-engineering methods such as  
 122 bioenergy combined with carbon capture and  
 123 storage (\$15-400 per tonne)(12). The latter in-  
 124 volves using biomass (organic matter such as  
 125 plants) to generate energy, while capturing and  
 126 storing the resulting carbon dioxide under-  
 127 ground. Wood burial has an advantage in using  
 128 underutilized wood residues, such as urban  
 129 tree wastes and forest residues from com-  
 130 mercial thinning. It can be integrated into sustain-  
 131 able forest management, especially in areas with  
 132 overstocked forest residue and increasing fire  
 133 risks due to climate change. Zeng et al. esti-  
 134 mated the global potential of wood burial to be  
 135 as large as 10 GtCO<sub>2</sub> per year, on the basis of  
 136 potentially available coarse woody biomass.  
 137 This CDR potential per year is the largest in  
 138 South America (3.3 GtCO<sub>2</sub>) and Africa (2.1  
 139 GtCO<sub>2</sub>), followed by the Maritime Continent  
 140 (1.0 GtCO<sub>2</sub>), United States (0.51 GtCO<sub>2</sub>), and  
 141 China (0.51 GtCO<sub>2</sub>), which would compensate  
 142 for 9-300% of fossil fuel emissions from these  
 143 countries.

144 To accelerate wood burial as a CDR path-  
 145 way, more knowledge is needed to guide pro-  
 146 jects in locations with environmental condi-  
 147 tions different from the Montreal site and for  
 148 various wood sources or other biomass types,  
 149 such as agricultural biomass (10). Effective  
 150 monitoring, reporting, and verification of CDR  
 151 impacts is essential. Many such protocols have  
 152 been developed for carbon markets and poli-  
 153 cies, but only 1 protocol is available for biomass  
 154 burial (12). Some protocols use life cycle assess-  
 155 ment to assess the net carbon negativity of a  
 156 CDR project. The initial estimates from Zeng et  
 157 al. suggest that wood burial could be a low-cost  
 158 and scalable CDR approach.

1 al. pinpoint several greenhouse gas emission  
2 sources, such as biomass transportation and  
3 vault construction. However, a full life cycle as-  
4 sessment is needed to quantify the net emis-  
5 sions and environmental impacts across eco-  
6 systems, supply chains, and engineered wood  
7 vaults, as well as to understand how these im-  
8 pacts vary by location and wood sources. Spe-  
9 cifically, these assessments should include the  
10 potential environmental impacts of all energy  
11 and materials used in a wood vault project and  
12 consider the competition with alternative  
13 wood uses, such as bioenergy, pulp and paper,  
14 and durable wood products. These under-  
15 standings will be critical to develop biomass  
16 burial projects on a global scale.
