Understanding spin and lattice excitations in a metallic magnetic ordered system forms the basis to unveil the magnetic and lattice exchange couplings and their interactions with itinerant electrons. Kagome lattice antiferromagnet FeGe is interesting because it displays a rare charge density wave (CDW) deep inside the antiferromagnetic ordered phase that interacts with the magnetic order. We use neutron scattering to study the evolution of spin and lattice excitations across the CDW transition T_{CDW} in FeGe. While spin excitations below ~ 100 meV can be well described by spin waves of a spin-1 Heisenberg Hamiltonian, spin excitations at higher energies are centered around the Brillouin zone boundary and extend up to ~ 180 meV consistent with quasiparticle excitations across spin-polarized electron-hole Fermi surfaces. Furthermore, c -axis spin wave dispersion and Fe-Ge optical phonon modes show a clear hardening below T_{CDW} due to spin-charge-lattice coupling but with no evidence of a phonon Kohn anomaly. By comparing our experimental results with density functional theory calculations in absolute units, we conclude that FeGe is a Hund's metal in the intermediate correlated regime where magnetism has contributions from both itinerant and localized electrons arising from spin polarized electronic bands near the Fermi level.

DOI: 10.1103/PhysRevLett.133.046502

In insulating magnets where unpaired electrons are localized on magnetic atomic sites, interactions of local spin moments are governed by the Heisenberg exchange couplings [1]. Magnons arising from spin vibrations about their equilibrium positions should be characterized by linearized spin wave theories that ignore all terms of order higher than quadratic and interactions with lattice vibrations [2,3]. For a magnetic ordered material with more than one magnetic ion per unit cell, we expect to observe acoustic and optical spin waves, just like acoustic and optical phonon modes are expected for a crystalline solid with more than one atom per unit cell [4]. For example, spin waves in an insulating kagome [5] and honeycomb [6] lattice ferromagnet have well-defined acoustic and optical modes as expected for a local moment Heisenberg magnet. A spin gap between the acoustic and optical spin waves at the Dirac points can give rise to protected topological magnon bands and edge modes [5,6].

For metallic magnets, magnetic order can arise from either localized moments similar to an insulating magnet or quasiparticle spin-flip excitations between the valence

(hole) and conduction (electron) bands at the Fermi level, dubbed a spin density wave (SDW) [7]. Spin excitations from these magnets can come from vibrations of localized moments [1] or electron-hole Fermi surface quasiparticle excitations of itinerant electrons [8–10], respectively. Since SDW order can coexist and intertwine with other orders such as charge density wave (CDW) [11] and superconductivity [12,13], a determination of the interplay between magnetic and other intertwined orders forms the basis to understand correlated electron materials.

Recently, the kagome lattice magnet FeGe was found to have a CDW order deep inside the magnetic ordered phase that couples with the ordered moment [Fig. 1(a)] [14–19]. With decreasing temperature, FeGe first exhibits collinear A-type antiferromagnetic (AFM) order at $T_N \approx 400$ K [Fig. 1(b)], forms a $2 \times 2 \times 2$ CDW order below $T_{\text{CDW}} \approx 110$ K with an enhanced ordered moment, and finally develops incommensurate AFM structure below $T_{\text{canting}} \approx 60$ K [Fig. 1(c)] [15–20]. The CDW order in as-grown samples can be suppressed or enhanced by different temperature annealing processes [21]. In previous angle resolved photoemission spectroscopy (ARPES) and inelastic neutron scattering (INS) experiments on as-grown FeGe, an electron-boson interaction induced kink around 30 meV,

*Contact author: pdai@rice.edu

seen in ARPES spectra, was identified as electron and optical phonon coupling [19]. From temperature dependent low-energy spin wave measurements, incommensurate spin fluctuations associated with incommensurate AFM static order show a kink at T_{CDW} and survive up to T_{N} [22]. Although these results suggest that incommensurate AFM order is actually a SDW phase instead of the double cone AFM structure [15,16], there is no determination of the spin-charge-lattice coupling across T_{CDW} [19]. Using first principle calculations, it was predicted that the nearest-neighbor magnetic exchange interactions are dominate and ferromagnetic (FM), incommensurate AFM order is due to lattice distortion-induced Dzyaloshinskii-Moriya (DM) interactions [23]. Furthermore, spin waves should be strongly dispersive in the kagome plane with an acoustic mode below about 100 meV and two optical modes extending up to 250 meV [23], similar to optical modes in an insulating kagome lattice magnet [5].

Here we use INS to study the evolution of spin and lattice excitations of as-grown FeGe across T_{CDW} (see Supplemental Material for details [24], which includes [25–29]). While spin excitations below ~ 100 meV can be well described by a spin-1 ($S \approx 1$) local moment Heisenberg Hamiltonian, spin excitations at higher energies are centered around the Brillouin zone boundary and extend up to ~ 180 meV [Figs. 1(d)–1(f)], different from the predictions of the first principle calculations [23] and the local moment picture. Instead, the high energy spin waves are consistent with quasiparticle excitations between spin-polarized electron-hole Fermi surfaces, similar to spin excitations in the metallic antiferromagnets FeSn [30–32] and Fe_{0.89}Co_{0.11}Sn [33], van der Waals ferromagnet Fe_{2.72}GeTe₂ [34], weak itinerant ferromagnet MnSi [35,36], and heavy Fermion CePd₃ [37]. Furthermore, spin wave dispersions and Fe-Ge optical phonon modes show a clear hardening below T_{CDW} due to spin-charge-lattice coupling but with no evidence of a phonon Kohn anomaly. By comparing these results with density functional theory (DFT) calculations in absolute units, we conclude that FeGe has an intimate coupling between itinerant electrons and magnetism similar to iron pnictides [38], suggesting that it is a Hund's metal with intermediate electronic correlations [39,40]. Although the CDW order has been suggested to arise from the formation of Ge dimers along the c axis to save magnetic exchange energy [20,41], our observed strong spin-charge-lattice coupling, different from FeSn [30–32] and all other kagome lattice materials [42], should inspire future work to understand its microscopic origin.

We first examine energy (E) and momentum (\mathbf{Q}) dispersion of the in-plane spin excitations of FeGe in the A -type AFM ordered phase at 120 K. At low energy, spin-wave-like excitations stem from the Γ point at the zone center and gradually disperse to the zone boundary, first reaching the M points at $E = 90 \pm 10$ meV and then the K points at $E = 120 \pm 10$ meV, showing intensity

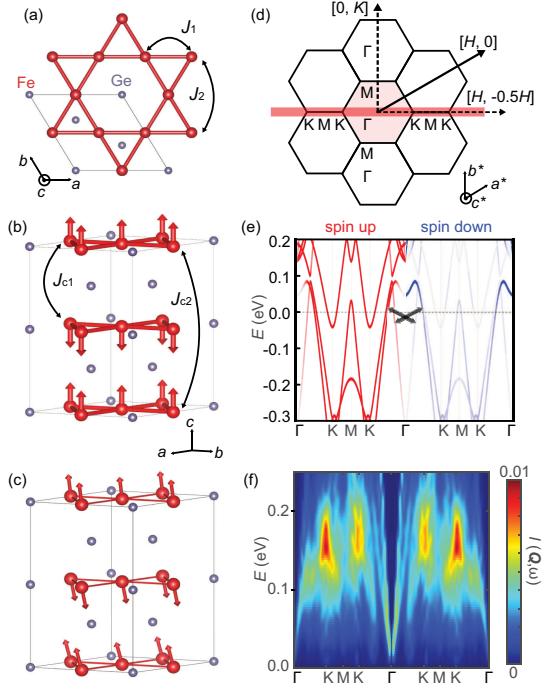

FIG. 1. (a) In-plane lattice structure of FeGe with red and gray denoting Fe and Ge atoms, respectively. Magnetic structure of FeGe at (b) $T > T_{\text{canting}}$ and (c) $T < T_{\text{canting}}$. (d) Reciprocal space of FeGe. The thick red line denotes the momentum path along the $[H, -0.5H, -1.5]$ direction. (e) DFT (with no spin orbit coupling) calculation. The red and blue bands represent spin up and down bands, respectively. Thick arrows indicate particle-hole (p - h) scattering. (f) Dynamic susceptibility calculated from p - h scattering of the set of bands in (e), where the energy axis has been renormalized by 1.7 [19].

modulation across zone boundaries [Figs. 1(d) and 2(a)]. Figure 2(b) shows the spin excitation dispersion along the high-symmetry direction $[H, -0.5H, -1.5]$ with $L = [-3, 0]$ as defined in Fig. 1(d) taken with an incident neutron energy of $E_i = 300$ meV. We take systematic constant energy cuts from $E_i = 45, 100$, and 300 meV data at temperatures across T_{CDW} and T_{canting} , and fit them with two Gaussians with a linear background. After averaging between the left and right, we obtain the spin wave dispersions at different temperatures, and find no significant change across T_{CDW} and T_{canting} from 120 K to 8 K [Fig. 2(c)].

To understand magnetic excitations using a local moment picture, we consider the Heisenberg Hamiltonian

$$H_0 = \sum_{\langle i,j \rangle} J_{ij} \mathbf{S}_i \cdot \mathbf{S}_j + \sum_i D_z (S_{z_i})^2.$$

Here, J_{ij} represents the magnetic exchange interaction between the i th and j th Fe atoms, \mathbf{S}_i and \mathbf{S}_j are the local spins at the i th and j th sites, respectively, and D_z is the single-ion anisotropy. For in-plane dispersions, we use J_1 and J_2 as the nearest and next-nearest-neighbor couplings,

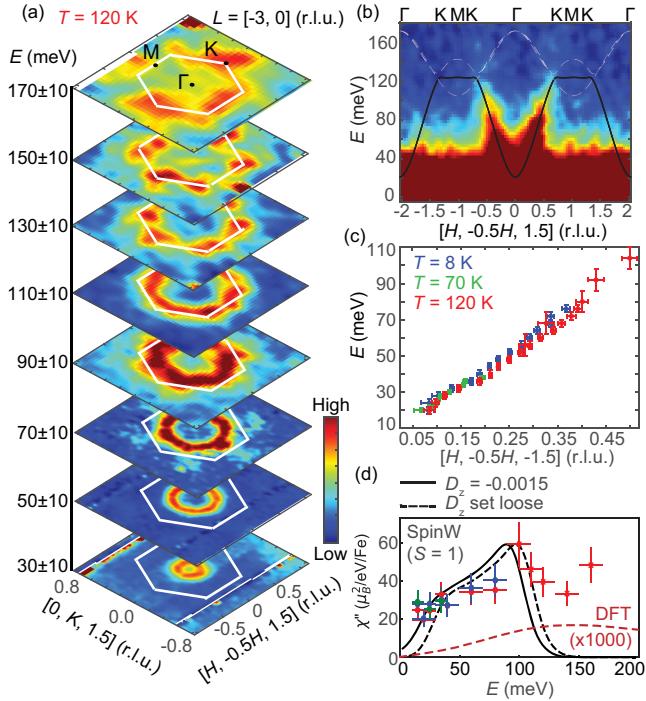

FIG. 2. (a) Constant energy slices at $E = 30 \pm 10, 50 \pm 10, 70 \pm 10, 90 \pm 10, 110 \pm 10, 130 \pm 10, 150 \pm 10, 170 \pm 10$ meV. The white lines are Brillouin zone boundaries, and high symmetry points are labeled with black points. (b) In-plane magnetic excitation along the $[H, -0.5H, -1.5]$ direction. The black solid lines and gray dashed lines indicate simulated acoustic and optical spin wave branches, respectively, using a Heisenberg model (SpinW) [43]. Data in (a) and (b) are taken at 120 K. (c) Spin wave dispersions extracted by Gaussian fitting with a linear background of the symmetrized spectra along the $[H, -0.5H, -1.5]$ direction. The vertical error bars indicate the energy integration range. Horizontal error bars are from fitting. Integration along the orthogonal in-plane direction is $[-0.1, 0.1]$. (d) Integrated magnetic intensity in the first in-plane Brillouin zone and averaged between $L = [-2.5, -0.5]$. The black line indicates the calculated spin wave intensity in absolute units assuming $S = 1$ in the SpinW + Horace program [43]. Red, green, and blue symbols represent 120 K, 70 K, and 8 K data, respectively [44]. The red-dashed line is the DFT estimated spin susceptibility from the two electronic bands in Figs. 1(f) and 1(e).

respectively [Fig. 1(a)]. The c -axis nearest and next-nearest-neighbor couplings J_{c1} and J_{c2} [Fig. 1(b)] are determined in Ref. [22]. We can simulate spin wave dispersions using the above Heisenberg Hamiltonian and compare with experiments.

In previous low-energy INS experiments, the dispersion of spin excitations along the L direction was found to have a band top around $E \approx 24$ meV and a small $D_z \approx -0.015$ meV [22]. To better fit the high-energy in-plane spin excitation data, the anisotropic term was set loose in the fitting process due to the large L integration range with $E_i = 300$ meV. The solid black lines in Fig. 2(b) represent the acoustic spin-wave branches that are in agreement with

TABLE I. The first row gives magnetic exchange coupling constants obtained from the Heisenberg Hamiltonian simulation. The solid and dashed lines in Fig. 2(b) show the resulting spin wave dispersions. The second row shows exchange parameters predicted from the first principle calculations [23].

Model	J_1	J_2	J_{c1}	J_{c2}	D_z (meV)
Heisenberg	-16.4	-7.2	11.3	0	-0.015
First principle	-41.97	5.49	8.44	-2.04	0

the data below ~ 100 meV, with magnetic exchange couplings in Table I. However, two distinctions between the data and the simulation cannot be explained by the Heisenberg model. First, the optical branches predicted by the Heisenberg model and DFT calculations [23] are absent in the data [Fig. 2(b)]. Second, when approaching the Brillouin zone boundary at K (Dirac points) and M points [Figs. 2(b) and 2(c)], the magnetic excitations continue to rise and form a convex shape, instead of bending over to a concave shape as predicted by the simulation. As a consequence, there is no spin gap at the Dirac points and we do not expect spin excitations of FeGe to have protected topological magnon bands and edge modes [5,6]. Figure 2(d) compares the integrated local dynamic spin susceptibility in the first Brillouin zone at 8 K, 70 K, and 120 K with $L = [0.5, 2.5]$, normalized by acoustic phonons near a nuclear Bragg peak to the absolute unit [28], with calculated results from the Heisenberg model assuming $S = 1$. The susceptibility shows a broad peak around 100 meV, and decays rapidly for energies above 100 meV [Fig. 2(d)]. Although DFT calculations of the hole-electron quasiparticle excitations [Figs. 1(e) and 1(f)] correctly predicted the high energy spin excitations, the absolute magnetic scattering estimated from the DFT is much smaller than the observation [Fig. 2(d)], similar to iron pnictides [45].

Since spin excitations above 120 meV in FeGe are rodlike at both the M [Fig. 3(a)] and the K points [Fig. 3(b)], they are similar to metallic antiferromagnets FeSn [30–33], ferromagnets $\text{Fe}_{2.72}\text{GeTe}_2$ [34], MnSi [35,36], and heavy Fermion CePd_3 [37]. To further investigate the behavior of this rodlike dispersion, we plot the constant energy slices in multiple Brillouin zones [Figs. 3(c)–3(f)]. The magnetic excitations are concentrated at the Brillouin zone boundary [Figs. 3(c)–3(e)], clearly different from that of MnSi where the rodlike dispersions reside inside Brillouin zone boundaries [35,36]. Spin excitations gradually vanish around $E = 200$ meV [Fig. 3(f)], different from expectations of a local moment Heisenberg Hamiltonian and the DFT calculations [23]. These results are similar to high-energy spin excitations of FeSn, which also has A-type AFM but without CDW order [30,31]. The wave vector dependences of these excitations are clearly different from cluster spin excitations associated with localized spins in insulating frustrated pyrochlore [46] and

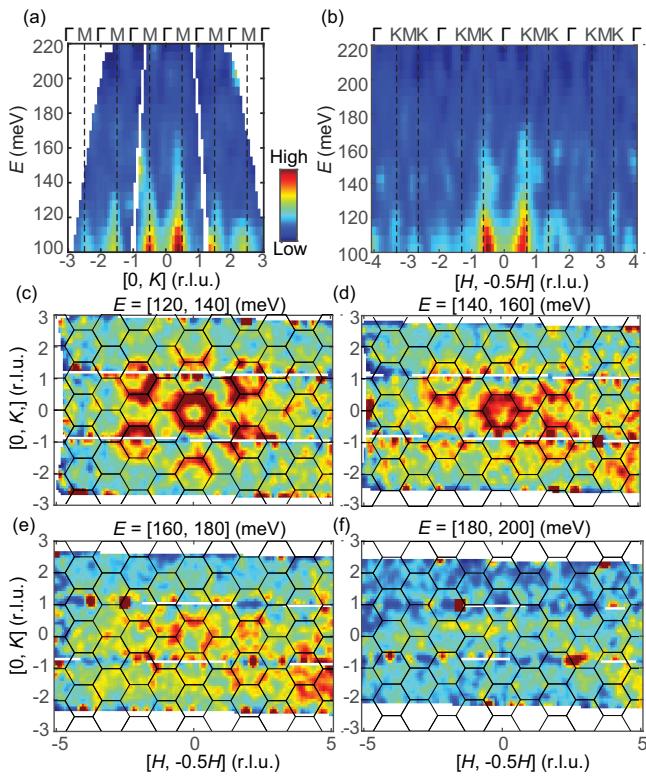

FIG. 3. High energy magnetic excitations along (a) $[0, K]$ with $[H, -0.5H] = [-0.1, 0.1]$ and (b) $[H, -0.5H]$ with $K = [-0.1, 0.1]$, $L = [-4, 0]$ (r.l.u.) measured with $E_i = 300$ meV. The dashed lines indicate the M points in (a) and K points in (b). Constant energy slices at (c) $E = 130 \pm 10$, (d) 150 ± 10 , (e) 170 ± 10 meV, and (f) 190 ± 10 meV. The solid black lines mark the Brillouin zone boundaries. Data are taken at 120 K.

triangular lattice antiferromagnets [47], as well as in high energy spin excitations in metallic kagome lattice ferrimagnet TbMn_6Sn_6 [48,49].

Figures 4(a)–4(c) show the out-of-plane spin wave excitations at different temperatures across T_{CDW} and T_{canting} . The fitted spin wave dispersions are shown in Fig. 4(d). By extracting the band top E_{top} at $L = -1.25$ for each temperature, we find that spin waves harden by around 11.6% from 120 K to 70 K across T_{CDW} , but remain unchanged across T_{canting} . The temperature dependence of the spin wave energy measured at $L = 1.25$ and $L = 1.35$ near the zone boundary using a triple-axis spectrometer shows a clear hardening of spin wave dispersion around 2 meV below T_{CDW} [Fig. 4(e)]. This hardening of spin waves coincides with an increase of around $0.1 \mu_B/\text{Fe}$ in the static magnetic moment, from around $1.5 \mu_B/\text{Fe}$ to $1.6 \mu_B/\text{Fe}$ across T_{CDW} [17]. The behavior is not as prominent for the in-plane dispersion because of its steeper dispersion [24]. Therefore, the hardening of spin wave dispersion below T_{CDW} arises from the CDW order induced moment increase and spin waves from the A-type AFM order mostly conform to a local moment Hamiltonian below about 100 meV.

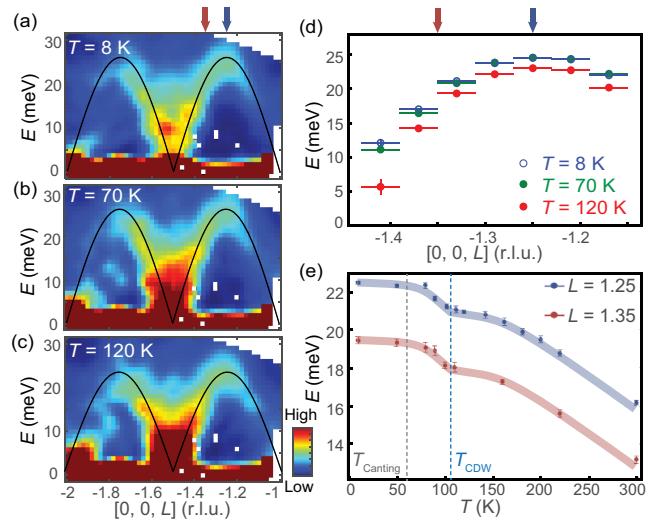

FIG. 4. Temperature dependent spin excitations along the c axis (L direction) at (a) 8 K, (b) 70 K, and (c) 120 K measured with $E_i = 45$ meV. (d) Spin wave dispersions determined by fitting constant momentum cuts taken from (a)–(c) with the Lorentzian on a constant background. Red and blue arrows in (a) and (d) mark $L = 1.35$ and $L = 1.25$, respectively. (e) Temperature dependent spin wave energy at $L = 1.35$ (blue dots) and 1.25 (red dots), obtained from IN8. Gray and blue dashed lines mark T_{canting} and T_{CDW} respectively. Thick blue and red lines are guides to the eye.

After mapping out the spin excitation evolution across T_{CDW} and T_{canting} , we investigate the temperature dependence of the in-plane phonon spectra [Figs. 5(a)–5(j)] [24]. In previous Raman and neutron Larmor diffraction measurements, the crystal structure is found to change from hexagonal to monoclinic with a small in-plane lattice distortion, but becomes more symmetric below T_{CDW} [50]. However, much is unclear on the dynamic spin-lattice-charge interactions across the CDW transition. Figure 5(a) shows the overall phonon spectra where optical phonon 1 (OP1) and optical phonon 2 (OP2) are marked. They agree well with the DFT calculated spectra shown in solid black lines. For both OP1 and OP2, the entire phonon dispersion hardens about 1 meV at all measured wave vectors on cooling from 300 K to 10 K [Figs. 5(b)–5(d)], distinct from previous work on the acoustic phonon mode where no phonon energy shift is observed at M points [20]. To further determine if the phonon hardening is coupled with CDW order, we plot the temperature dependence of phonon energy at high symmetry Γ and M points for OP1 and OP2 [Figs. 5(e)–5(g)]. There is almost no shift in phonon dispersion below around 80 K, and CDW order is clearly coupled with phonon hardening at M points for OP1 and OP2 modes [Figs. 5(f) and 5(g)]. Since OP1 is the optical A_{2u} mode involving out of plane Fe-Ge vibrational modes and OP2 is Fe out of plane vibrational mode, the results suggest a strong coupling of these modes with the CDW order associated with the Ge c -axis dimerization

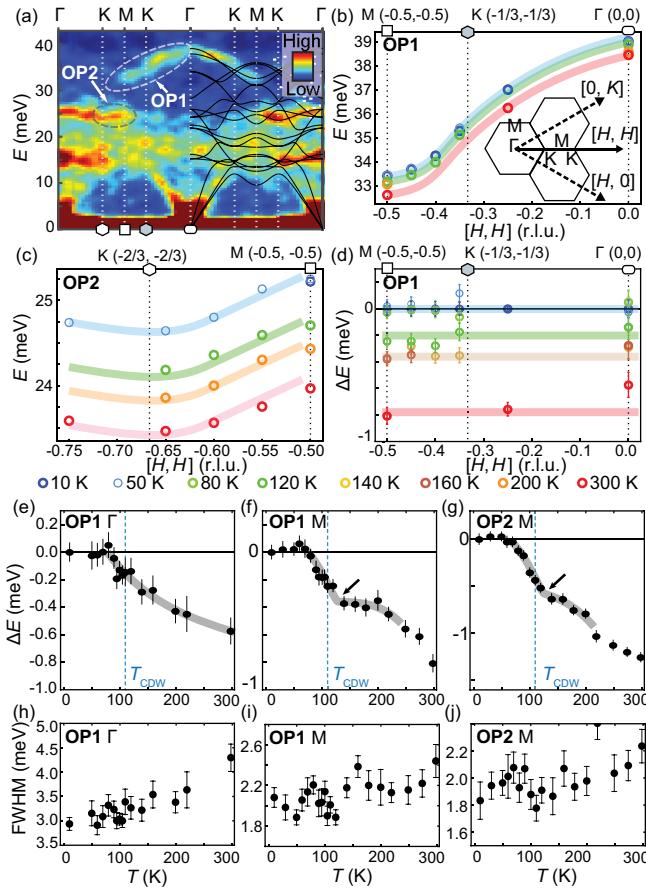

FIG. 5. (a) In-plane phonon dispersion at $L = [-3.1, -2.9]$ and 120 K. The solid black lines are DFT calculations. Two separate optical phonon branches are labeled as OP1 and OP2, corresponding to Fe-Ge A_{2u} and Fe out-of-plane vibrations, respectively. Phonon dispersions of (b) the OP1 and (c) OP2 at 10 K, 50 K, 80 K, 120 K, 140 K, 160 K, and 300 K. (d) Temperature dependence of the OP1 energy shift throughout the Brillouin zone at 10 K, 50 K, 80 K, 120 K, 140 K, 160 K, and 300 K. The phonon energy at the base temperature (10 K) is subtracted. Temperature dependence of the OP1 phonon mode at (e) Γ , (f) M points, and the OP2 phonon mode at M point. The thick colored lines in (b)–(d) and the gray lines in (e)–(g) are guides to the eye. Temperature dependence of phonon full width half maximum (FWHM) at the OP1 Γ (h), OP1 M (i), and OP2 M (j).

[20]. Note that the phonon full width half maximum (FWHM) at different wave vectors consistently decreases with decreasing temperature [Figs. 5(h)–5(j)], corresponding to a larger phonon lifetime at lower temperatures. For comparison, the acoustic zone boundary phonon lifetime was found to decrease at A point from 400 K to 200 K but not at M point from inelastic x-ray scattering experiments [20].

In previous work on FeGe [20], the CDW transition is suggested to arise from Ge c -axis dimerization, different from the usual Kohn anomaly in electron-phonon coupled CDW materials but similar to spin-lattice coupling in FeSi [51] and CuGeO₃ [52,53], to save magnetic exchange

energy [41]. These results are consistent with the DFT calculations [41,54,55] and subsequent experiments [56,57], suggesting that CDW order in FeGe arises from electron correlations instead of the usual electron-phonon interaction [58]. From our INS experiments summarized in Figs. 2–5, we find that high energy spin excitations of FeGe behave similarly to other itinerant magnets [30–37]. The lack of optical spin waves and rodlike spin excitations confined to the Brillouin zone boundary for energies above 100 meV (Fig. 3) are consistent with quasiparticle excitations from spin down to spin up bands across the Fermi level as shown in our DFT calculations [Figs. 1(e) and 1(f)], indicating that itinerant electrons play an important role in determining the high energy spin excitations. However, the magnitude of the magnetic scattering determined from DFT is much smaller than that of the observation [Figs. 1(f) and 2(d)]. For comparison, we note that high energy spin excitations in iron pnictides are consistent with a local moment picture while low-energy spin excitations are from the nesting of electron and hole Fermi surfaces and the DFT calculated spectral weight is also much smaller than the observation [38,45]. Since the DFT calculated electronic dispersions need to be renormalized by about 1.7 to account for those determined from ARPES experiments [19] similar to the values in iron pincite superconductors [59], we conclude that FeGe is a Hund's metal in the intermediate electron correlation regime. Similarly, while a pure local moment Heisenberg model with $S = 1$ can account for temperature dependent spin excitations above the anisotropy gap energy of ~ 1 meV [22], spin excitations above 100 meV appear to have an itinerant origin [Fig. 2(d)]. These results are consistent with recent theoretical calculations indicating that FeGe is slightly more electron correlated compared with FeSn [60], and the flattish electronic bands near the Fermi level responsible for correlated properties of FeGe arise from $(d_{xy}, d_{x^2-y^2})$ and (d_{xz}, d_{yz}) orbitals [61]. Therefore, FeGe is in the intermediate correlated regime where magnetism has contributions from both itinerant and localized electrons, and couples with CDW order to form a strong spin-charge-lattice coupled kagome metal, suggesting that FeGe is a rare case where the energy scales of spin, charge, lattice degrees of freedom are similar and their interactions give rise to the observed exotic properties different from its sister compound FeSn and all other known kagome lattice magnets [42].
